The appropriate use of the WBC differential is a serious concern for most hematology laboratories (Table 40.8). As with other laboratory tests, there should be different criteria for ordering differential WBCs for ambulatory patients as opposed to hospitalized patients. There is sufficient evidence to indicate that the differential WBC is not useful in the routine screening of ambulatory patients. Because the prevalence of hematologically manifested disease is low in this group of patients, significant clinical disease is typically not identified from the differential count unless it has also been suspected on other clinical grounds. Even when differential counts outside the normal range are identified in the ambulatory population, only rarely is a specific disease process diagnosed. Therefore, in the outpatient group, a differential WBC should be performed only in patients in whom the information may provide important diagnostic, prognostic, or therapeutic decisions.

In hospitalized patients, there are many clinical situations in which an abnormal differential count will correlate with a particular clinically important disease. Subsequent sections of this chapter outline the clinical situations associated with either cytopenias or cytoses of particular leukocyte components. As in the outpatient group, if no abnormality is suspected, a differential WBC will not be useful because of the low prevalence of disease in this particular group. If, however, an abnormality is suspected, then the differential WBC may provide some important information. For example, if there is a suspicion of a primary hematologic disorder, a differential count may be the primary means of making a specific diagnosis. Likewise, an unexpected leukocytosis or leukopenia found on a CBC may be more specifically elucidated if a leukocyte differential count is obtained. In patients with suspected infections or fevers, a differential count may be useful in documenting a neutrophilia if other data are inconclusive. It typically does not contribute diagnostic information if a leukocytosis has already been identified on a CBC, thus indicating a reactive process. Conversely, the differential WBC is seldom abnormal if the total WBC is normal, even if there is an ongoing infectious process. Thus, it should be recognized that a normal WBC and a differential WBC do not exclude the possibility of an infectious process.

A larger question that remains is the frequency at which to repeat a differential WBC in hospitalized patients. Repetitive testing may have diagnostic value if an infection has not shown improvement or if new symptoms evolve that are suspicious of either an infectious or hematologic disorder. Certainly, if management decisions are based on differential counts, for example, in a leukopenic or hematologic patient, then appropriate repetitive testing would be indicated. Overall, there has not been a consensus as to the appropriate testing interval for the differential count, but it would appear unlikely that daily differential counts in nonleukopenic patients would be indicated.

Platelet Count

A platelet count provides the starting point in the functional evaluation of the hemostatic system. An abnormality in the platelet count can lead to significant bleeding complications in a patient and may be indicative of a variety of underlying malignant or nonmalignant conditions. A diminished platelet count may be the result of either a marrow production problem or a peripheral destructive process. In cases in which megakaryopoiesis is decreased and platelet production diminished, evaluation of the bone marrow may reveal an infiltrative malignant process, whether metastatic or hematologic in nature. In addition, various drugs and some viral infections may lead to a reduction in platelet production. In patients receiving chemotherapeutic regimens, platelets are commonly diminished to very low levels. Peripheral destructive processes of platelets are common and are frequently entertained as part of a differential diagnosis. These are primarily immune-based thrombocytopenias but may occasionally involve splenic sequestration of platelets. Further discussion of the role of platelets in hemostasis is included in Section VIII of this book, Coagulation. This chapter does not deal with the platelet assays that are used to evaluate the bleeding patient. Rather, the laboratory's analysis of the total platelet count as obtained from hematology analyzers is described here.

EDTA is the preferred anticoagulant for platelet analysis and must be mixed thoroughly with the blood to avoid clotting and platelet clumping. If clotting does occur, a spuriously decreased platelet count may result. As discussed previously, in individuals with EDTA-dependent platelet agglutinin, citrate is the preferred alternative anticoagulant.

Today's automated hematology analyzers routinely obtain platelet counts over a wide range of values. However, manual hemacytometer counts are still essential in patients with low platelet counts, e.g., those patients with fewer than 50.0×10^9 platelets. Various red and white blood cells, platelet, and instrument artifacts may interfere with platelet counting. Newer instrumentation enhancements such as hydrodynamic focusing and pulse editing have helped to eliminate some of the crossover abnormalities seen in red cells and platelets. Some instruments,

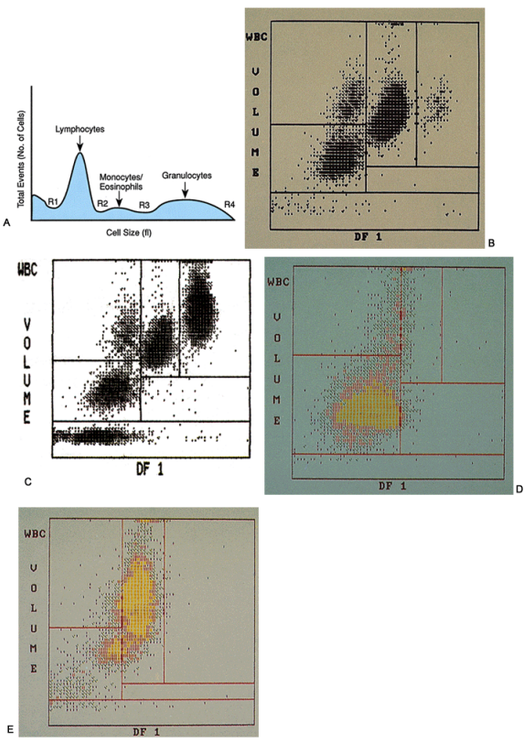

FIGURE 40.6. Blood cell histograms (Coulter STKS). **A:** Example of a white blood cell count (WBC) differential histogram based on volumetric studies. The various components of the WBC are shown on the graph. R1 to R4 correspond to flags generated by the instrument representing distribution abnormalities warranting manual observation. R1, nucleated red blood cells (RBCs), platelet clumps, large platelets, cryoglobulin, small lymphocytes, unlysed RBCs; R2, reactive lymphocytes, lymphoblasts, basophils, clotted sample; R3, eosinophilia, monocytosis, blasts, clotted sample; R4, granulocytosis. **B:** STKS—normal differential; **C:** STKS histogram—eosinophil (52%); **D:** STKS histogram—chronic lymphocytic leukemia; **E:** STKS histogram—acute myelogenous leukemia.

TABLE 40.8. INDICATIONS FOR ORDERING THE LEUKOCYTE DIFFERENTIAL COUNT

Indication	Usefulness
Ambulatory population	
General population (screening)	Not useful
Specific subgroups	Possibly useful (see below)
Hospital population	
No abnormality suspected	Not useful
Abnormality suspected	
Newly suspected infection or new fever	Useful in some patients
Suspicion of a primary hematologic disorder	Useful
Leukocytosis or leukopenia	Useful in some patients
Repeat tests	Useful in some patients at appropriate intervals

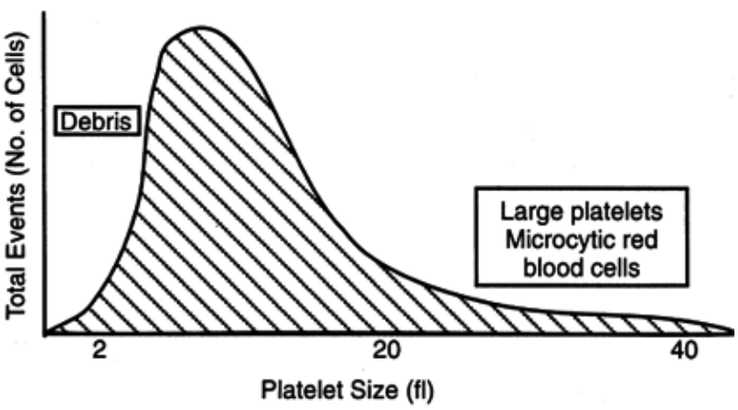

FIGURE 40.7. Platelet distribution histogram from 2 to 40 fl. The left portion of the curve may be contaminated with debris; the right portion may be contaminated with large platelets and microcytic red blood cells.

such as those manufactured by Coulter, count platelets within a particular size range, e.g., 2 to 20 fl, to eliminate any possible interference by red blood cells (Fig. 40.7). The instrument's computer then fits the results to a lognormal curve and extrapolates the curve to cover the normal range of platelet size of 0 to 70 fl.

Artifacts that can specifically interfere with platelet counting include red or white blood cell fragments/debris or electronic noise that can be found at the low end of platelet distribution. Interfering microcytic red blood cells or giant platelets may skew the distribution curve to the right. Platelet clumping is the most common cause of mistaken thrombocytopenia in the automated laboratory. Clumps of platelets will look to the instrument like large, single platelets or even white blood cells and will usually be excluded from the platelet distribution curve. In such cases, phase microscopy is necessary to obtain an accurate platelet count.

Some instruments will also calculate MPVs. The MPVs represent the mean volume (size) of platelets as determined by the platelet distribution histogram. Some studies indicated that the presence of large platelets, i.e., those with a high MPV, is suggestive of younger platelets that are found in peripheral destructive processes such as immune thrombocytopenias. The MPV may falsely increase or decrease with EDTA anticoagulation and therefore must be interpreted with caution. This inconsistency has limited its routine use. As discussed in the previous platelet section, the MPV will be unreliable if cytoplasmic fragments, electronic noise, giant platelets, or microcytic red blood cells artifactually interfere with platelet determination. Figure 40.8 demonstrates that the typical reference range of the MPV is inversely related to the platelet count. In other words, as the platelet count decreases, the MPV typically increases. The MPV is found to be high in patients with thrombocytopenia owing to idiopathic thrombocytopenic purpura (ITP) and other peripheral destructive processes, whereas patients with thrombocytopenia owing to marrow suppression typically have decreased MPV values (Table 40.9). Despite these possible uses, the clinical value of the MPV has not been clearly elucidated and must not be considered a gold standard in the evaluation of the thrombocytopenic patient.

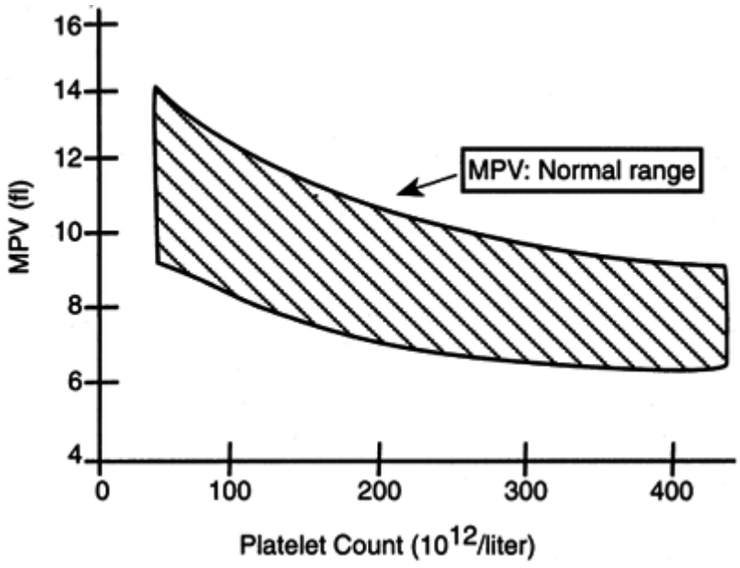

FIGURE 40.8. Mean platelet volume (MPV). The MPV varies inversely with total platelet count. Those samples having MPV values above the normal range for their total platelet count represent cases with adequate marrow production and, therefore, thrombocytopenia owing to peripheral destructive processes. Those samples with MPV values below the normal range for their total platelet count represent cases with probable marrow suppression and diminished platelet production.

TABLE 40.9. MEAN PLATELET VOLUME: CLINICAL CORRELATIONS

Low MPV	Normal to High MPV	High MPV
Marrow suppression	Hyperdestruction with marrow compensation	Hereditary disorders
Chemotherapy	Immune-related (ITP, drug-induced)	Bernard-Soulier syndrome
Megaloblastic anemia	Mechanical (consumptive coagulopathies, vasculitis)	May-Hegglin anomaly
Aplastic anemia		Miscellaneous
Marrow infiltration	Hemorrhage (major)	α-and ß-thalassemia trait (unknown cause)
Sepsis	Sepsis (without marrow suppression)	Myelodysplastic syndrome
Hypersplenism (variable)		Myeloproliferative disorders (in some cases)
Hereditary disorders Wiskott-Aldrich syndrome		

MPV, mean platelet volume.
Modified from Cornbleet PJ, Astanita R, Wolf PL. White blood cell and platelet disorders. In: Howanitz JH, Howanitz PJ, eds. Laboratory medicine—test selection and interpretation. New York: Churchill-Livingstone, 1991:553–618.

Reticulocyte Count

A reticulocyte can be broadly defined as an erythrocyte that still contains residual ribosomes and organelles but has ejected its nucleus from the previous orthochromatic erythroblast stage. Reticulocytes may take on various morphologic appearances depending on the amount of residual ribosomes and organelles, or reticulum (hence, the term reticulocyte). The definition of a reticulocyte from a technologist's perspective has classically been described as an erythrocyte containing a few (two or three) scattered dots. Although this may describe most of circulating reticulocytes, reticulocytes may rarely appear as diffusely granular cells. The life span of a reticulocyte has been estimated to be 3 to 4 days, but probably only 24 hours of the life span is spent in the peripheral circulation. Clinically, the reticulocyte percentage can be used as an indicator of erythropoiesis and is often utilized for evaluating patients with anemia. Although reticulocyte counts do not absolutely correlate with bone marrow erythroid activity,

the ease of obtaining and performing such a count has led to its common usage as a marker of red cell production. A normal or decreased reticulocyte count in moderate to marked anemia is strong evidence that the bone marrow is not responding in an appropriate fashion, as would be seen in iron, folate, or vitamin B_{12} deficiency, or as a result of a bone marrow infiltrative process. In contrast, an increased reticulocyte count generally reflects a rapid erythroid turnover, as would be seen in acute blood loss or acute or chronic hemolysis. In other words, the reticulocyte level can be used as a general indicator of bone marrow erythropoiesis and release.

Most current laboratory microscopic methods make the reticulocyte visible by precipitating the residual ribosomal RNA material with a dye such as new methylene blue or brilliant creosol blue; the precipitated RNA (or reticulum) will form small clumps that will stain with the dye and be visible as blue cytoplasmic dots or filaments (Fig. 40.9). Usually, a 1,000-erythrocyte count is performed manually through the microscope and the percentage of stained red blood cells derived. This manual determination of reticulocyte counts is a very imprecise method and open to subjective interpretation by the technologist. The imprecision and inaccuracy of reticulocyte counts have been well documented in several studies, with coefficients of variation ranging from 25% to more than 50%. These inaccuracies are probably related to (a) sampling error, (b) interobserver bias, (c) supervital staining of other cytoplasmic elements, such as nuclear debris, sidersomes, Heinz bodies, etc., and (d) variation in the quality of the smear and stain.

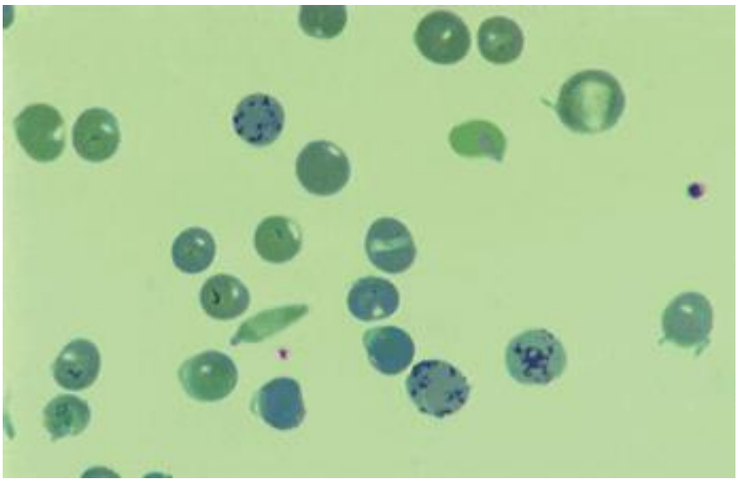

FIGURE 40.9. Peripheral blood smear with reticulocytes; staining is with new methylene blue dye. The blue granules represent precipitated, residual RNA.

Automated reticulocyte counting methods, such as image analysis and flow cytometry, have gained respectability and use in the clinical laboratories. Both these procedures remove much of the subjective interpretation involved in manual reticulocyte counting, allow evaluation of large numbers of red blood cells to avoid sampling error, and provide a standard and uniform analysis. Flow cytometric procedures depend on the binding of a suitable fluorescent dye to residual erythrocyte RNA. Although numerous dyes have been developed that accomplish RNA binding, not all have been successful in meeting the laboratory requirements for reticulocyte counting. To date, auramine O and thiazole orange are probably the two preferred fluorescent dyes for reticulocyte counting. Studies with both these fluorescent dyes have shown good to excellent correlation with results obtained from manual counts of cells and have consistently shown a tight reproducibility with duplicate samples. Flow cytometric detection methods offer many advantages over manual counting methods and will undoubtedly become the method of choice for reticulocyte analysis. Improved fluorescent dyes and increasing automation will continue to promote this transition.

Erythrocyte Sedimentation Rate

The ESR is one of the time-honored traditional tests in the hematology laboratory that has perhaps garnered too much importance in the clinical laboratory. In the laboratory, the ESR measures the distance a red blood cell falls in a vertical tube over a given period of time. The principle behind this process is the increased negative charge that the various inflammatory proteins (fibrinogen, α-, β-, and γ-globins) exact on the surrounding red blood cells. This promotes red blood cell separation and thus a more rapid fall of the red blood cell in the analysis tube. The resulting higher stack of measured red blood cells is interpreted as an elevated ESR.

Specimen collection and the anticoagulant used are crucial in the determination of the ESR. The Westergren method has become the standard procedure for determining the ESR (3). In this procedure, the blood specimen is anticoagulated with

sodium citrate and placed in a 30-cm glass tube with a 2.5-mm internal diameter. The modified Westergren procedure uses EDTA as the anticoagulant and may be the easiest method to use in the hematology laboratory because such samples can be used routinely for other hematologic parameters. The EDTA tube must be full and used within 2 hours if kept at room temperature; refrigerated samples may keep for as long as 12 hours if warmed before analysis.

The Wintrobe method has also historically been a popular method for ESR determination (4). The Wintrobe method also uses EDTA blood but requires only 1 mL of blood (as opposed to 2 mL with the Westergren procedure), uses a shorter but wider diameter tube than with the Westergren procedure, and may be preferred in the pediatric population because of the decreased amount of blood that is required.

Various factors, both clinical well as laboratory based, are known to disrupt the ESR. A slightly tilted ESR tube, high room temperature, or the use of heparin as an anticoagulant are all known to increase the ESR level. Conversely, a clotted blood sample, low room temperature, too short an ESR tube, or prolonged delay (longer than 2 hours if at room temperature) in analysis may all lead to a false decrease in ESR values. Clinical factors may also complicate the interpretation of the ESR. Anemia, hypercholesterolemia, chronic renal failure, as well as inflammatory disease may all produce an elevated ESR. Conversely, fragmented red blood cells (e.g., sickle cell anemia, burn patients), spherocytes, microcytic red blood cells, steroids, hypofibrinogenemia, and other miscellaneous entities may all lead to a decrease in the ESR value.

Clinically, an elevated ESR has been used as evidence for an inflammatory process. However, false-positive and false-negative results abound, and a wasteful hunt for a nonexistent underlying condition could result if only the ESR is relied on. The only consistent diagnostic use for the ESR, albeit begrudgingly, is in the diagnosis and monitoring of temporal arteritis and polymyalgia rheumatica. What then would constitute a valid indication for requesting an ESR? As with most laboratory tests, the ESR should not be used as a screening device in the healthy, asymptomatic population. No study has shown a significant contribution of an elevated ESR in detecting unsuspected disease in the asymptomatic patient. In the symptomatic patient, interpretation of ESR is complicated by the numerous factors that can lead to falsely elevated or falsely decreased values. Physicians often obtain an ESR in patients whose history and physical findings do not suggest any specific cause for their illness. Several studies showed that an ESR is not useful in those patients, such as in those for whom a diagnosis of a specific disease is not confirmed by other clinical data. In general, the ESR must be markedly elevated in such patients to be diagnostically useful, which is an exceedingly rare event in patients with no clear evidence of serious disease. A subsequent ESR several months later is the first step in evaluating an initial ESR elevation, rather than the physician instituting an extensive search for occult disease.

As previously indicated, the ESR is almost always increased in patients with temporal arteritis and polymyalgia rheumatica, and a normal ESR virtually excludes the diagnosis of temporal arteritis. The ESR may be useful in distinguishing inflammatory arthritic processes from other causes of joint symptoms, such as osteoarthritis. However, it is neither absolutely specific nor sensitive for rheumatoid arthritis and must be interpreted with great caution and obviously in conjunction with other clinical and laboratory findings. Some studies also suggested the role of ESR as an indicator of Hodgkin's disease, and other studies suggested a possible role as a marker for relapse of disease. Patients with a markedly elevated ESR greater than 100 mm/h usually have underlying malignancy, acute infection, or some type of connective tissue disease. However, unexplained elevations in the ESR less than this amount probably do not warrant evaluation and most do not have any associated disease process.

In summary, the ESR is a laboratory test that has remained essentially unchanged over its 75-year laboratory history. As such, its role in clinical diagnosis should be tempered with the reality that it is associated with numerous false-positive and false-negative results. A more judicial use of this screening test is definitely warranted.

BONE MARROW EXAMINATION

Part of "40 - Peripheral Blood and Bone Marrow: Morphology, Counts and Differentials, and Reactive Disorders"

Components

Examination of the bone marrow ideally consists of evaluating three major components (Table 40.10): (a) the peripheral blood, (b) the bone marrow aspirate smear, and (c) a bone marrow tissue section (trephine biopsy and/or aspirate clot). Not all three components may contribute to a diagnosis in a given case, but each may potentially provide important diagnostic information and must be a part of the total examination process. Examination of the peripheral blood includes reviewing the CBC, differential count, reticulocyte percentage, and blood smear morphology. The bone marrow aspirate provides useful information for various studies, including (a) morphology and cytochemical stains, (b) flow cytometric immunophenotyping, (c) cytogenetic analysis, (d) molecular biological studies, and (e) microbiological

studies, if needed. Bone marrow tissue sections provide important information regarding the overall cellular distribution and marrow architecture and may consist of either a decalcified trephine biopsy or a clotted aspirate specimen (Fig. 40.10). Miscellaneous laboratory studies are also essential in interpreting a bone marrow study. These may include studies to evaluate red cell problems such as iron studies, B_{12}/folate levels, hemoglobin electrophoresis, and Coombs' test; lactate dehydrogenase, serum/urine immunoelectrophoresis, microbiological or virologic culture results, and other pertinent laboratory tests that may also provide important laboratory data needed to evaluate properly a bone marrow study.

Indications for Bone Marrow Evaluation

Indications for examining a bone marrow are outlined in Table 40.11. The most common reason is for the evaluation of a known or suspected malignancy. A bone marrow study is definitely mandated if a hematologic malignancy is suspected. This suspicion may arise from either clinical or physical examination findings (e.g., splenomegaly or lymphadenopathy) or if abnormal or immature circulating cells are found in the peripheral blood smear. The bone marrow may also be involved in metastatic malignancies of nonhematopoietic origin. Evaluation of patients with either non-Hodgkin's lymphomas or Hodgkin's disease usually indicates that a bone marrow study be performed to adequately stage the patient for the presence of lymphoma. Bone marrow studies are also essential in monitoring the effect of therapy for patients with hematologic malignancies, as well as monitoring the effectiveness of bone marrow transplantation.

In nonspecialized institutions and practices, bone marrow studies are frequently required to evaluate patients with unexplained cytopenias. Patients who have unexplained thrombocytopenias or neutropenias can benefit by having a bone marrow

aspirate and biopsy performed to evaluate fully whether the cytopenia is a reflection of decreased marrow production or, by inference, increased peripheral destruction. Bone marrow studies for the evaluation of an anemia are not indicated as a primary procedure unless other clinical, peripheral blood morphology and biochemical studies failed to reveal the etiology of the anemia. Other indications for a bone marrow biopsy include obtaining tissue for culture in patients with fever of unknown origin.

Interpretation of Bone Marrow Studies

Bone marrow cellularity is best determined on the bone marrow tissue sections but can be estimated from the bone marrow aspirate smear. Marrow cellularity varies with age and is expressed as an estimate of the percentage of the bone marrow area occupied by cells to the total area of cells plus background elements and fat. The normal cellularity decreases with age and for a newborn is approximately 75% to 100%, 50% to 90% in the adolescent, 30% to 80% in the adult, and 20% to 50% in the elderly (older than age 65) (Fig. 40.11). Determination of cellularity is useful when evaluating patients with unexplained cytopenias; for example, increased cellularity in a patient with a cytopenia would suggest ineffective hematopoiesis (i.e., decreased cellular release) or increased peripheral destruction (Fig. 40.12). In contrast, decreased cellularity in an individual with a particular cytopenia would suggest a marrow production problem (Fig. 40.12).

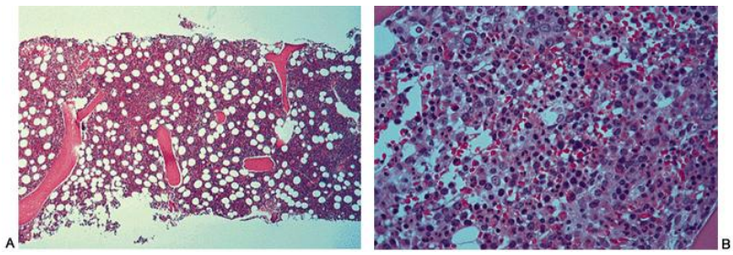

FIGURE 40.11. Bone marrow biopsy sections demonstrate normal cellularity. **A:** Approximately 40% to 50% cellularity in an otherwise healthy 60-year-old man; **B:** virtually 100% cellular marrow from a newborn boy.

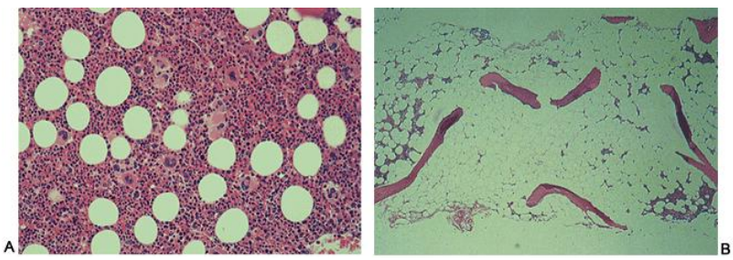

FIGURE 40.12. Bone marrow biopsy sections. **A:** Megakaryocytic hypercellularity from an individual with immune thrombocytopenia purpura; bone marrow from an individual with granulocytic hyperplasia owing to Kostmann syndrome. **B:** Markedly hypocellular bone marrow after chemotherapy in an individual with acute lymphoblastic leukemia.

The next step in evaluating bone marrow is determining the distribution of cells within the marrow. The adequacy of megakaryocyte production is easily estimated by evaluating either the marrow biopsy, aspirate clot sections, or an aspirate spicule. Typically, one to two megakaryocytes can be seen on a 40× or 50× objective field. The determination of increased or decreased numbers of megakaryocytes relative to the overall platelet count can suggest that a production or destruction problem may exist.

The next step in the evaluation of bone marrow is assessing myeloid and erythroid development both quantitatively and qualitatively. There should be a normal distribution of all cell types within each of the granulocytic and erythroid lines, indicating a normal maturational process. A 500-cell differential count of the bone marrow aspirate is useful in quantifying the

Culture (fever of unknown origin)

amount of granulocytic and erythroid precursors within the marrow (Table 40.12). This myeloid:erythroid ratio ranges from 2:1 to 4:1 in the adult and is useful in determining whether there are relative hyper- or hypoplasias. Again, this may provide useful information in evaluating a patient with a neutropenia or anemia. In addition to quantitative abnormalities, qualitative abnormalities of myeloid development must also be assessed. Dysplastic changes in erythroid or granulocytic cells is not an uncommon finding and must be looked for when evaluating a bone marrow aspirate.

TABLE 40.12. BONE MARROW DIFFERENTIAL CELL COUNTS: NORMAL VALUES

Bone Marrow Cells	Childhood (%)	Adult (%)
Normoblasts (total)	23.1	21.5 (14.2–30.4)
Pronormoblasts	0.5 (0.0–1.5)	0.6 (0.2–1.4)
Basophilic	1.7 (0.2–4.8)	2.0 (0.7–3.7)
Polychromatophilic	18.2 (4.8–34.0)	12.4 (12.2–24.2)
Orthochromatic	2.7 (0.0–7.8)	6.5 (2.0–22.7)
Granulocytes (total)	57.1	56.0 (45.1–66.5)
Myeloblasts	1.2 (0.0–3.2)	1.0 (0.5–1.8)
Promyelocytes	1.4 (0.0–4.0)	3.4 (2.6–4.6)
Myelocytes	18.3 (8.5–29.7)	11.9 (8.1–16.9)
Metamyelocytes	23.3 (14.0–34.2)	18.0 (9.8–25.3)
Bands	?	11.0 (8.5–20.8)
Segmented	12.9 (4.5–29.0)	10.7 (8.0–16.0)
Lymphocytes	16.0 (4.8–35.8)	15.8 (10.8–22.7)
Monocytes		1.8 (0.2–2.8)
Eosinophils	3.6 (1.0–9.0)	3.2 (1.2–6.2)
Basophils	0.06 (0.0–0.8)	<0.1 (0.0–0.2)
Plasma cells	0.4 (0.2–0.6)	1.8 (0.2–2.2)
M:E ratio	2.9 (1.2–5.2)	2.5 (1.2–5.0)

M : E, myeloid : erythroid.

Other cell types and lesions may be identified within the bone marrow and must be assessed including the presence or absence of granuloma, necrosis, lymphoma, metastatic neoplasia, bone marrow fibrosis, lipid storage disease, benign lymphoid aggregates, and bone abnormalities such as osteosclerosis and osteoporosis. Also, a Prussian blue iron stain of the bone marrow aspirate and/or tissue section can provide useful information concerning a patient's iron stores (Fig. 40.13). Iron stains of a bone marrow trephine biopsy must be interpreted with caution. A decalcification may cause a false-negative interpretation; evaluation of the clot section for iron stores is probably superior to the trephine biopsy. In addition to iron stores, iron stains of the bone marrow aspirate smear need to be evaluated for the presence or absence of sideroblasts and, in particular, ringed sidero-blasts (Fig. 40.13); detection of sideroblastic iron cannot be reliably assessed on tissue section stains.

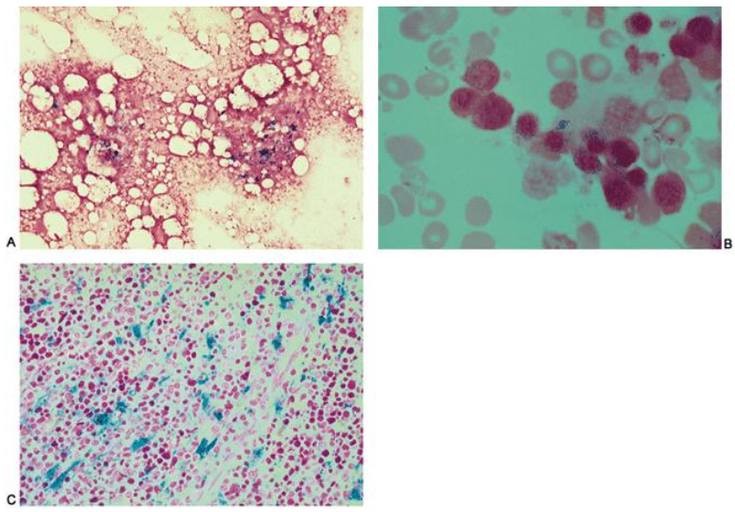

FIGURE 40.13. Iron stains of bone marrow. **A**, Bone marrow aspirate spicule shows iron stores; **B**, bone marrow aspirate smear shows sideroblastic iron (note the small green granules present in the cytoplasm); **C**, bone marrow aspirate clot section showing iron stores.

REACTIVE DISORDERS

Part of "40 - Peripheral Blood and Bone Marrow: Morphology, Counts and Differentials, and Reactive Disorders"

Disorders of white blood cells include both malignant and nonmalignant diseases. The nonmalignant disorders of white blood cells may consist of quantitative abnormalities leading to an increase or decrease of a particular WBC component, benign morphologic

changes that have little if any effect on cellular function, and true functional disorders of a white blood cell type that may lead to significant patient morbidity and mortality. Although the peripheral blood is obviously the easiest vehicle by which to evaluate these nonmalignant abnormalities, the effects of these changes are truly reflected in the tissues in which they circulate, e.g., lymph nodes, spleen, or any other organ.

Neutrophilia

Neutrophils play an important role in the inflammatory response and are the primary cells involved in phagocytosis of foreign organisms. The number of circulating neutrophils is determined by multiple factors, including the rate of bone marrow production, the speed at which cells leave the marrow and enter the peripheral circulation, and changes in vascular margination. Clinical findings associated with neutrophilia are listed in Table 40.13. The most commonly encountered reason for neutrophilia is an acute bacterial infection. Other frequent causes include an inflammatory response to necrotic tissue (e.g., tumor necrosis), drugs (e.g., corticosteroids), and acute hemorrhagic episodes.

Cyclic neutrophilia
Hereditary/miscellaneous Idiopathic neutrophilia

Morphologic changes in neutrophils associated with acute infection include a shift toward the release of immature granulocytes (i.e., shift to the left), toxic granulation, Döhle bodies, and cytoplasmic vacuolation (Fig. 40.14). The left shift seen in patients with an acute infection consists of primarily neutrophil bands and metamyelocytes and occasionally more immature granulocytic precursors, such as myelocytes and promyelocytes; blast forms are only rarely seen. The quantitative assessment of neutrophil bands is a time-honored test within the hematology laboratory as an indicator of an acute infection. However, there are many problems in accurately determining neutrophil band counts, which mandates that some caution is necessary when interpreting band counts in isolation. Clinicians frequently use elevated band counts as evidence of acute infection and frequently may look at sequential changes in band counts as evidence of response or nonresponse to antiinfection therapy. However, this is fraught with inaccuracies for several reasons. The first is the poorly defined normal range of neutrophil bands in the peripheral blood. As gleaned from several reference laboratories and textbooks, the upper limit of normal for band counts in peripheral blood can range from 0.5×10^9/L to 1.8×10^9/L. This variation between laboratories is much greater than with any other peripheral blood component, such as total neutrophils, lymphocytes, and eosinophils.

The next problem is the inability to define a band accurately. Some have defined a band as any cell not having a well-defined filament between lobes, whereas others have required that a thick filament be present before a neutrophil band is identified (Fig. 40.15). In other words, there is a spectrum of cell appearances between the metamyelocyte and segmented neutrophil that prevents the band from being well defined. This inability to define a band accurately has led to extreme variability between technologists performing differential counts. Every laboratory has known “high banders,” “intermediate banders,” and “low banders.” National comparison studies of neutrophil band identification have shown coefficients of variations of greater than 100% between laboratories performing band counts. This lack of reproducibility also emphasizes the inaccuracy of differential counts performed by counting only 100 or 200 cells. The classic 95% competence limit table by Rümke et al. (5) (Table 40.7) demonstrates that at least 1,000 cells must be classified to get a reasonably accurate differential count. Thus, the actual range of what the true count may be of a low-percentage cell such as a neutrophil band is quite wide and leads to significant inaccuracy (Table 40.7). Any sequential use of band counts to evaluate therapeutic response is therefore inaccurate and wrought with clinical witchcraft.

There is also a significant amount of biological variability that will affect band counts. For example, it is well known that neutrophil counts may increase or decrease by several thousand, remain the same, or be quite variable from morning to evening among individuals. Again, this variability limits the accuracy of using sequential band counts in a meaningful fashion. There are conflicting reports in the literature as to the utility of band

counts in predicting acute infection. Some studies have shown that a “bandemia” is significantly associated with proven infection, whereas others have shown no correlation of band count to fever, infection, or tissue inflammation. In general, total leukocyte count and total neutrophil count provide more meaningful and consistent information in predicting an acute infection than the presence or absence of neutrophil bands. It is likely that a band count, which is carefully enumerated using clearly defined uniform criteria, is a useful indicator of acute inflammation. However, routine band counts performed by a clinical laboratory with multiple technologists during a 7-day workweek have little value in the evaluation of acute infection and should not be considered a reliable test.

Toxic granulation is another classic sign of an infectious neutrophilia (Fig. 40.14). This is characterized by coarse cytoplasmic granules that represent prominent primary granules still present from a “rush” through the normal maturation sequences. Toxic granulation may be difficult to identify with certainty unless

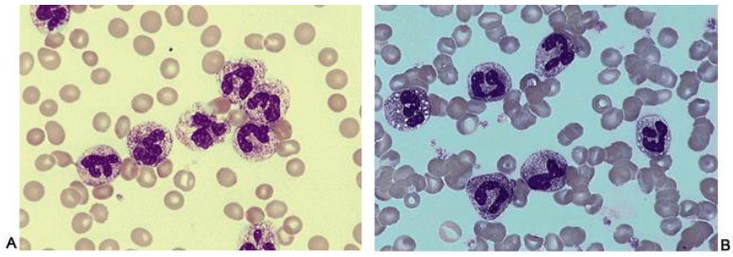

FIGURE 40.14. A, Toxic neutrophils with prominent azurophilic granules and cytoplasmic vacuolation; **B**, toxic neutrophils with cytoplasmic vacuolation.

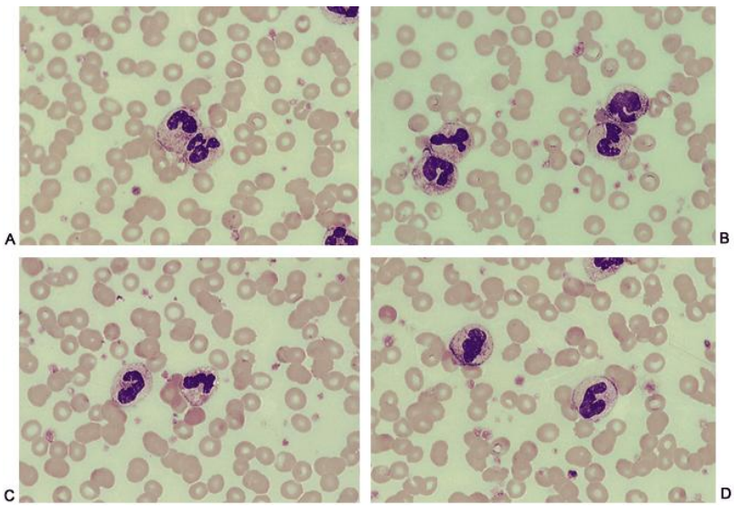

FIGURE 40.15. A–D: Examples of band neutrophils. Note the variation in nuclear appearance, complicating the exact definition of this cell type.

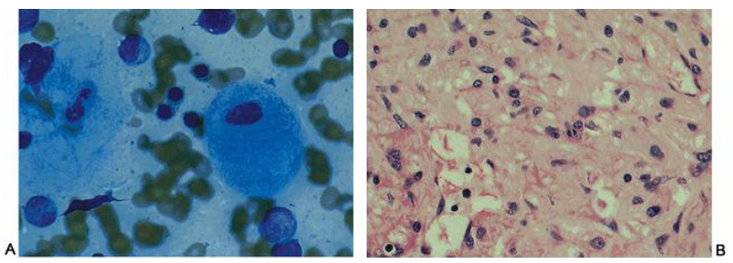

FIGURE 40.16. Gaucher's disease. **A**, Bone marrow aspirate shows macrophage with prominent blue cytoplasmic fibrils; **B**, bone marrow biopsy section shows classic accumulation of Gaucher cells having a fibular cytoplasm (tissue paper appearance).

appropriate peripheral blood smear staining is performed. A weak or faint Wright's stain may not accentuate toxic granulation; at the other extreme, laboratories not familiar with a Wright-Giemsa stain may have the tendency to overcall toxic granulation owing to the prominence of the granules seen with the Giemsa portion of the stain. Thus, laboratorians need to be familiar and confident with the stain that they are observing before diagnosing toxic granulation. Döhle bodies are a faint, pale blue cytoplasmic area near the periphery of a neutrophil that becomes prominent during an infectious episode (Fig. 40.14). These small bodies represent endoplasmic reticulum and are a very reliable sign of an infectious process. Again, Döhle bodies may be easily overlooked if appropriate staining is not performed. Cytoplasmic vacuolation is a less common feature of acute infection and is thought to represent cellular areas in which lysosomal ingredients have been released to engulf and destroy bacteria (Fig. 40.14). Cytoplasmic vacuolation caused by EDTA artifact can also occur and must be distinguished from vacuolation resulting from infectious process. The EDTA-associated vacuolation appears to be a result of the time spent in anticoagulant.

In most situations, the degree of neutrophilia in an acute infection seldom exceeds 50.0×10^9/L and is more typically in the 15.0 to 30.0×10^9/L range. In cases in which the neutrophilia exceeds 50.0×10^9/L, the term *leukemoid reaction* has been used. The obvious differential problem that arises in cases of leukemoid reaction is differentiation from chronic myelogenous leukemia (CML). Several features that will aid in the distinction of a leukemoid reaction from CML are listed in Table 40.14. Leukemoid reactions are typically characterized by morphologic signs of infections, such as a left shift, toxic granulation, Döhle bodies, and cytoplasmic vacuolation. The left shift in a leukemoid reaction is a gradation with greater prominence of segmented neutrophils, band forms, and metamyelocytes, whereas CML shows a prominence of both mature neutrophils and myelocytes. Leukemoid reactions lack dysplastic changes and basophilia and should only show rare blast forms at best. Laboratory tests that may be useful in this distinction include leukocyte alkaline phosphatase and cytogenetic karyotyping. The leukocyte alkaline phosphatase will be increased, and no Philadelphia chromosome will be found in a leukemoid reaction. Obviously, the clinical history and physical examination (e.g., presence or absence of splenomegaly) will also provide important diagnostic information.

Neutropenia

Neutropenia is defined as having counts less than 1.5 to 2.0×10^9/L. Neutropenia may result from either decreased marrow production or increased peripheral destruction of neutrophils. Causes of decreased neutrophil production in the bone marrow are vast and may include replacement of normal bone marrow elements by hematologic or metastatic malignancies, marrow fibrosis, or marrow necrosis. Chemotherapeutic or other toxic agents may also suppress normal marrow activity, including granulopoiesis; this group of toxins also includes alcohol and a variety of drugs and antibiotics (Table 40.15). Aplastic anemia, bone marrow irradiation, megaloblastic anemia (folate/vitamin

B_{12} deficiency), myelodysplastic syndromes, and congenital abnormalities of granulopoiesis may all be associated with neutropenia. The latter inherited disorders include Fanconi's anemia and familial benign and cyclic neutropenia (also known as Kostmann syndrome).

Increased destruction or utilization of neutrophils in the peripheral blood or tissue is common and may result from hypersplenism associated with several collagen vascular disorders, liver abnormalities, among others. Immune-mediated neutropenia owing to the presence of specific antineutrophil antibodies may also occur. Many viral infections, including human immunodeficiency virus (HIV), have been associated with neutropenia. Other particular causes of neutropenia are listed in Table 40.15. The neutropenia associated with viral disorders is thought to be the result of direct marrow damage by the infecting virus, which causes a disruption in normal myelopoiesis.

Usually in acute bacterial infection, significant neutrophilia will result. However, if the particular infection is overwhelming or if it occurs in an individual with borderline marrow reserves, the prolonged infection may deplete the marrow reserves and create more demand than what the marrow can respond to. This occurs primarily in the elderly, newborns, or any patient with an underlying myelosuppressive process. The resulting neutropenia will prevent an adequate response to the tissue infection and may lead to an overwhelming infection with subsequent death.

Monocytosis

Monocytosis is defined as an increase in peripheral blood monocytes greater than 0.8×10^9/L and is associated primarily with inflammatory and immune disorders. It is difficult to correlate monocytosis directly with specific disease states, as opposed to neutrophilia (Table 40.16). One of the classic associations of monocytosis is with tuberculosis infections. However, other infections such as subacute bacterial endocarditis, salmonellosis, listeriosis, syphilis, leprosy, and brucellosis can also be associated with a monocytosis. Monocytosis often appears during the recovery phase of an acute infection or after bone marrow suppression. This relative or absolute monocytosis heralds the marrow recovery and usually precedes the return of granulocytes. Monocytoses may also be associated with hematologic malignancies, such as myelodysplastic syndromes and some types of acute and chronic leukemia. Interestingly, as many as 25% of patients with Hodgkin's disease have been reported to have peripheral blood monocytosis. Monocytosis may also accompany many nonhematopoietic malignancies as well as some of the collagen vascular disorders. Thus, the finding of a patient with monocytosis is relatively nonspecific and can be associated with a variety of benign and malignant hematologic and nonhematologic disorders.

Corticosteroids Lipid storage disorders

The mononuclear phagocyte system is also the primary cell affected in several storage disorders. These storage disorders are generally hereditary abnormalities or deficiencies of enzymes that are necessary for lipid storage and processing. The macrophages become the most obvious morphologic abnormality in these disorders as they become packed full of lipid material that cannot be further digested. Hematologic abnormalities, such as cytopenias, may result from bone marrows that are replaced with accumulated macrophages. Splenomegaly and hypersplenism may also result. Table 40.17 lists some of the hereditary disorders associated with storage diseases and the accompanying blood and bone marrow findings.

TABLE 40.17. STORAGE DISORDERS/BLOOD AND BONE MARROW FINDINGS

Vacuolated lymphocyte	Foam cells	Niemann-Pick disease
Metachromatic inclusion	Metachromatic inclusion	Mucopolysaccharidosis Alder-Reilly anomaly

Gaucher's disease is a hereditary deficiency of glucocerebrosidase that results in an intracellular accumulation of the sphingoglycolipid glucocerebroside. Gaucher cells appear as enlarged macrophages within the bone marrow and are engorged with distinctive cytoplasmic fibriles that are meshed in an irregular pattern (Fig. 40.16). In bone marrow sections, Gaucher cells have been described as having a cytoplasmic appearance of wrinkled tissue paper. Pseudo-Gaucher cells have been commonly observed in patients with chronic myelogenous leukemia, representing increased glucocerebroside turnover from the massive leukocyte population in CML.

Pseudo-Gaucher cells have also been observed in patients with thalassemia and multiple myeloma. The pseudo-Gaucher cells of CML are thus different from true Gaucher cells in that they represent normally functioning macrophages overloaded with lipid byproducts, although they are morphologically very similar.

Niemann-Pick disease is a rare autosomal recessive disorder caused by deficiency of sphingomyelinase and results in accumulation of sphingomyelin in the mononuclear phagocytes. Numerous large, foamy macrophages are identified in the bone marrow of patients with Niemann-Pick disease (Fig. 40.17). These foamy cells are not specific for Niemann-Pick disease because such cells can be identified in other lipid disorders and various hematologic diseases.

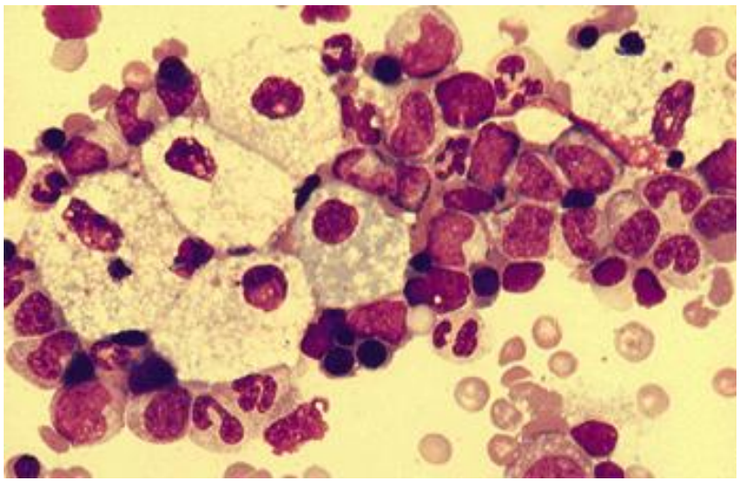

FIGURE 40.17. Niemann-Pick disease. Bone marrow aspirate smear shows large, foamy macrophages. These macrophages are not specific for Niemann-Pick disease and can be found in other diseases.

Eosinophilia

Eosinophils are primarily associated with anaphylactic responses and hypersensitivity reactions. Bacterial killing is not a major function of eosinophils, but eosinophils probably play a minimal role in antigen recognition. The cause of an eosinophilia in a patient can be quite difficult to determine. Benign eosinophilia is associated with a variety of drugs, parasitic infections, allergic reactions, and some collagen vascular diseases (Table 40.18). These must be differentiated from malignant disorders of eosinophils, such as hypereosinophilic syndrome.

Hypereosinophilic syndrome

Hypereosinophilic syndrome is a chronic myeloproliferative disorder characterized by a proliferation of mature eosinophils. The eosinophils frequently appear agranular and atypical. This disorder is characterized by splenomegaly, leukostatic problems and complications caused by the release of eosinophilic products in susceptible tissues (such as heart and brain).

Basophilia

Basophils are the least common of the peripheral blood cell components and typically number less than 0.1×10^9/L. CML is the most common and significant cause of basophilia. Benign

basophilia may be associated with hypersensitivity reactions, renal disease, myxedema, and some inflammatory responses. Other causes of basophilia are listed in Table 40.19.

Monocytopenia/Eosinopenia/Basopenia

The determination of monocytopenia, eosinopenia, and basopenia can be made only if large numbers of cells are directly counted (Table 40.20); manual counts of 100 or 200 total cells are inaccurate for these low numbers. Eosinopenia and basopenia have both been reported to occur in situations of acute stress or acute infection, with corticosteroids of exogenous source, or with Cushing's syndrome. Monocytopenia has also been reported to occur after treatment with corticosteroids. Monocytopenia is also a well-described phenomenon in hairy cell leukemia.

Reactive Lymphocytosis

Reactive lymphocytoses are polyclonal expansions of T and/or B lymphocytes. Table 40.21 lists some of the common causes associated with peripheral blood lymphocytoses. An acute viral infection is the classic disease associated with a lymphocytosis. These can include infectious mononucleosis (Epstein-Barr virus), cytomegalovirus, and a variety of other viral agents. It must be emphasized that an absolute lymphocyte count must be determined in the evaluation of a lymphocytosis, so that absolute lymphocytosis can be distinguished from relative lymphocytosis owing to absolute neutropenia. It must also be remembered that the normal range age of lymphocyte counts varies with age. Children younger than 4 years of age have a much higher absolute lymphocyte count than older children and adults (Table 40.4).

The morphologic hallmark of an acute viral infection is the so-called atypical or reactive lymphocyte (Fig. 40.18). This refers to lymphocytes that are transformed and are larger than the small lymphocyte with scant cytoplasm. These transformed lymphocytes have a slightly finer chromatin than a small lymphocyte and usually have a distinct nucleus and abundant cytoplasm. The cytoplasm may have a blue to plasmacytoid appearance. Occasional azurophilic granules (large granular lymphocytes) may also be identified. These reactive lymphocytes have also been called Downey cells. The atypical lymphocytes often comprise more than 20% of the total lymphocyte count. Some diseases, such as cytomegalovirus infection, hepatitis, and toxoplasmosis, are more commonly associated with a lymphocytosis than with an increase in plasmacytoid-appearing lymphocytes and plasma cells. The lymphocytosis associated with *Bordetella pertussis* may appear as deeply clefted cells that can mimic the clefted cells of a peripheralized, small cleaved cell lymphoma (Fig. 40.18). Obviously, a clinical history of lymphoma or lymphadenopathy and the patient's age will aid in this differential diagnosis. The lymphocytes in the so-called infectious lymphocytosis disorder are usually small, with scant cytoplasm. This vague disorder can be associated with WBCs greater than 100.0×10^9/L and is not associated with any known etiology.

Lymphopenia

Lymphopenia is defined as an absolute decrease in the lymphocyte count to less than 1.5×10^9/L in adults and less than 3.0 ×

10^9/L in children. This decrease in lymphocytes may be the result of decreased production or increased destruction or loss of peripheral lymphocytes. The decreased production of lymphocytes may be associated with a variety of inherited or acquired immunologic deficiencies. Rare disorders associated with abnormalities of the lymphatic system have also been associated with lymphopenias. Acquired immunodeficiency syndrome that is associated with HIV has become a frequent cause of lymphopenia because of the lymphocytotoxic effect of the HIV virus. Other abnormalities associated with lymphocytopenias include Hodgkin's disease, irradiation, chemotherapy, corticosteroids, Cushing's disease, and other diseases (Table 40.22).

Morphologic and Functional Leukocyte Disorders

Several qualitative disorders of neutrophils may be manifested as either morphologic or functional disorders (Table 40.23). Some of these abnormalities are little more than laboratory curiosities with little clinical impact on the patient, whereas other disorders are clinically quite significant and can lead to potentially life-threatening complications.

May-Hegglin Anomaly. The May-Hegglin anomaly is an uncommon autosomal dominant disorder characterized by large, abnormal Döhle bodies in neutrophils and monocytes, giant platelets, and a variable degree of thrombocytopenia (Fig.

40.19). Although the majority of patients with May-Hegglin anomaly are asymptomatic, some of these patients may have problems with abnormal bleeding from an unknown abnormality. Although it would be easy to surmise that a platelet defect is responsible for this abnormality, platelet function studies in the laboratory have not shown any abnormality. The Döhle bodies in May-Hegglin anomaly are quite prominent and are typically larger and bolder than the Döhle bodies associated with an acute infection. As with acute infections, the Döhle bodies in May-Hegglin anomaly consist of rough endoplasmic reticulum. The giant platelets measure anywhere from 4 to 8 μm in diameter and, when present with Döhle bodies, are diagnostic of the May-Hegglin anomaly.

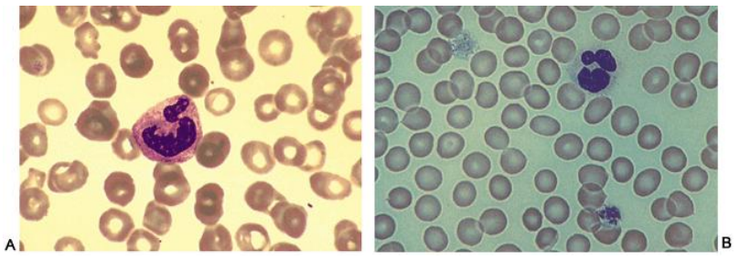

FIGURE 40.19. A, B: May-Hegglin anomaly shows large platelets and prominent Döhle bodies in the cytoplasm.

Pelger-Huët Anomaly. The Pelger-Huët anomaly is a benign autosomal dominant disorder characterized by the inability of the neutrophils to undergo proper segmentation. This results in a neutrophil that has a bilobed or dumbbell-shaped nucleus with coarsely clumped chromatin (Fig. 40.20). More than 75% of the neutrophils will show this bilobed segmentation. Patients who are homozygous for the Pelger-Huët anomaly are incredibly rare and have been reported to have neutrophils with a single, round nucleus without segmentation and with coarsely condensed chromatin. Both the homozygote and heterozygote states are associated with normal granulocytic function and are not thought to be associated with any clinical problems. Pseudo–Pelger-Huët neutrophils found in the myelodysplastic syndromes are morphologically identical to this hereditary type and are a characteristic finding in granulocytic dysplasia.

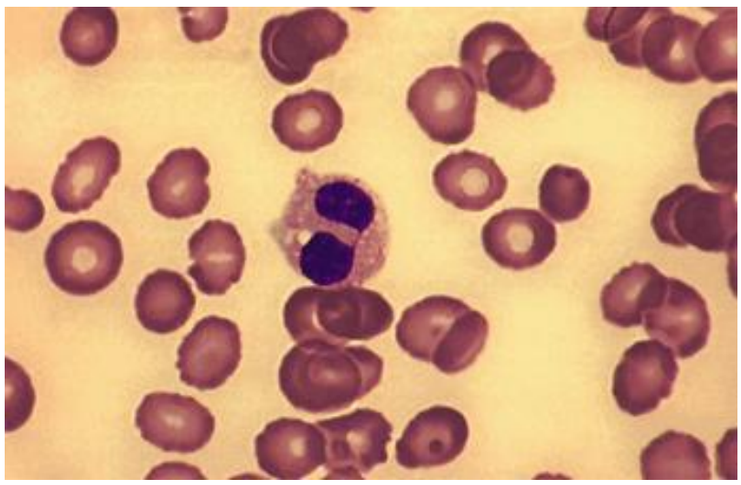

FIGURE 40.20. Pelger-Huët anomaly showing abnormal, bilobed segmentation of mature neutrophils.

Hereditary Hypersegmentation in Neutrophils. This rare autosomal dominant disorder results in giant neutrophils having five or more segments. Neutrophil precursor cells, such as the promyelocyte and myelocyte, also show nuclear indentation and segmentation. No oval macrocytes or other megaloblastic changes are seen. These neutrophils are reported to possess normal function.

Alder-Reilly Anomaly. This anomaly relates to the dense, large, azurophilic granules that can be found in neutrophils, eosinophils, basophils, and occasionally lymphocytes and monocytes from patients with a variety of metabolic disorders, including many of the mucopolysaccharidoses, such as Hurler's, Hunter's, or Maroteaux-Lamy syndromes (Fig. 40.21). This heavy granulation is easily confused with toxic granulation but is not associated with any infectious process and is a “permanent” feature of the circulating cells. In these syndromes, the neutrophils

become constipated with granular mucopolysaccharide deposits, which stain metachromatically with toluidine blue stains. This morphologic characteristic has also been reported to be found occasionally in otherwise healthy individuals.

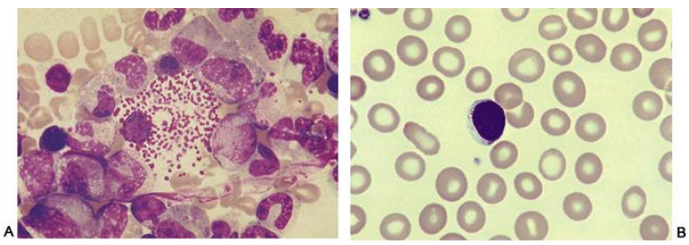

FIGURE 40.21. Alder-Reilly anomaly shows prominent cytoplasmic inclusions surrounded by a clear halo. **A**, Macrophage; **B**, lymphocyte.

Inclusions within the lymphocytes are less numerous than in the neutrophils or monocytes in patients with the Alder-Reilly anomaly. These basophilic inclusions are surrounded by a clear halo and stain metachromatically. The evaluation of the bone marrow will reveal these same inclusions in the mononuclear phagocytes, lymphocytes, and granulocytic cells.

Chédiak-Higashi Syndrome. The Chédiak-Higashi syndrome is a rare autosomal recessive disorder characterized by giant, cytoplasmic lysosomal inclusions in all types of circulating leukocytes (Fig. 40.22). The primary granules within neutrophils fuse into large cytoplasmic structures that are deficient in the enzymes required for normal neutrophil phagocytosis and chemotaxis. The granules found in Chédiak-Higashi syndrome are myeloperoxidase positive. Patients with Chédiak-Higashi syndrome also exhibit oculocutaneous albinism, recurrent infections, and an increased bleeding tendency. These patients are

Chronic Granulomatous Disease. Chronic granulomatous disease (CGD) is an X-linked (two thirds of cases) or autosomal recessive (one third of cases) disorder associated with a deficient functional ability of neutrophils to undergo an oxidative respiratory burst. This defect leads to an inability to succeed in the killing of bacterial organisms. Patients with CGD have recurrent and severe infections beginning early in life, typically with catalase-positive bacteria or fungi. The defect in at least the X-linked form is related to a deficiency in cytochrome b_{558}. There is also some association of CGD with the Macleod phenotype as well as Duchenne's muscular dystrophy in some patients. This relates to the close proximal location of the genes involved in these three disorders. The neutrophils and monocytes are morphologically unremarkable. Tests of phagocytic and chemotactic function are abnormal in patients with CGD. Specific tests that evaluate the oxidative metabolic pathway, such as the nitroblue tetrazolium dye test or oxidative burst analysis by flow cytometry, are used to evaluate the ability of the patient's neutrophils to undergo an intact oxidative burst and are used to confirm the diagnosis of CGD.

Myeloperoxidase Deficiency. Myeloperoxidase deficiency is a benign autosomal recessive trait associated with the absence of myeloperoxidase in neutrophils and monocytes. Paradoxically, eosinophilic myeloperoxidase is normal. Although neutrophils lack this enzyme, which mediates the oxidative burst, neutrophil function remains intact and is not associated with any significant clinical problems. Morphologically, the neutrophils and monocytes appear unremarkable. However, the myelo-peroxidase cytochemical stain will be negative in these pa-tients. Likewise, hematologic blood counters that rely on peroxidase cytochemical staining for determining differential counts will be unable to determine an accurate neutrophil count. Indeed, the majority of patients with this benign enzyme deficiency have been detected when evaluated on such hematologic analyzers.

Miscellaneous Defects. There are several other inherited or acquired defects that may interfere with any step of normal neutrophil function, including cellular adhesion to an endothelial surface, chemotaxis, opsonization, phagocytosis, degranulation, and the oxidative response. These may include specific defects such as CD11/CD18 (CR3) deficiency, specific neutrophil granule deficiency, lazy leukocyte syndrome, or various complement or immunoglobulin deficiencies. Several systemic diseases may also affect neutrophil function such as autoimmune diseases, chronic renal failure, diabetes, malnutrition, burns, and various malignancies.

SUMMARY

Part of "40 - Peripheral Blood and Bone Marrow: Morphology, Counts and Differentials, and Reactive Disorders"

This chapter outlined much of the foundation of clinical laboratory hematology. As in no other clinical laboratory, the hematologic evaluation of a patient specimen frequently requires a combination of morphologic features, instrument analysis, and clinical findings. A strong footing in morphologic skills is essential and the basis for understanding both basic hematopoiesis and clinical hematology. Modern hematology analyzers allow increasing automation within the laboratory and provide a wealth of information in a relatively rapid fashion. The frequency of hematologic abnormalities in both benign and malignant disease has underscored the importance of this field in clinical laboratory medicine. Important changes in the future will likely include increasing automation and robotics, computer-aided interpretation and control of specimen utilization, development of specific practice parameters related to the utilization of CBCs and differential counts, and the impact that modern therapeutic approaches, such as transplantation and cytokine/growth factors, will have on hematologic studies. The hematology laboratory is steeped in tradition, yet remains at the forefront of modern laboratory and clinical medicine.

ANEMIA

Part of "41 - Red Blood Cell Disorders"

It is helpful to consider the circulating red blood cell and its progenitors as a single functional unit, the erythron. Many of the diseases afflicting the erythron may then be seen to result from the same basic processes that affect other organ systems: genetic disorders, disorders of immunity, neoplasia, infectious diseases, nutritional disease, and environmental disorders. The result of the majority of these disease processes is anemia.

Anemia is defined as a reduction in total red cell mass. As total red cell mass is not easily measured, anemia is considered to be present if the hemoglobin concentration or the hematocrit is below the normal range. The range of normal values is subject to variables imposed by lifestyles, geographic altitude, age, and gender.

Clinical Manifestations of Anemia

Anemia itself is not a disease, but rather an objective sign of an underlying process. Hence, the clinical manifestations of anemia, which result from the diminished delivery of oxygen to the tissues, are often similar regardless of the etiology. The rate of onset, the degree of reduction in red cell and plasma volume, and the adequacy of circulatory and respiratory compensation influence the signs and symptoms of anemia.

Physiologic adjustments of the cardiovascular system in response to anemia include increases in cardiac output, heart rate, and stroke volume. This compensatory high-output state may result in palpitations, tinnitus, dizziness, or syncope. High-output cardiac failure may ensue with prolonged anemia, advanced age, or underlying heart disease.

As the red cell mass decreases, blood flow is redistributed to maintain adequate visceral and cerebral oxygenation. Shunting of blood flow away from the skin results in the characteristic pallor of anemia, which is best observed by inspection of the oral mucosa, conjunctivae, or nail beds. To further facilitate oxygen delivery to critical tissues, the concentration of red cell 2,3-diphosphoglycerate increases shortly after the onset of anemic hypoxia.

At rest, few changes in respiration are noticeable. Most patients, however, exhibit signs of dyspnea on exertion. Respiratory failure is typically a sign of cardiac decompensation and is usually accompanied by pulmonary edema. Transfusion, in an attempt to improve the oxygen-carrying capacity of the blood, is tempting in such cases but must be approached with extreme caution because the risk of precipitating volume overload and further cardiovascular compromise is imminent.

A Morphologic Approach to Anemia

Although anemia may first be suspected from a patient's presenting symptoms, the diagnosis is usually based on laboratory findings. The laboratory data provided by an automated hematology analyzer supply a framework upon which further investigation can be built. Utilizing red cell indices, a morphologic classification to anemia can be structured (Table 41.1). The red cell indices only describe the average red cell, however. Important clues may be missed if evaluation does not include examination of the peripheral blood smear. A balanced population of microcytic and macrocytic red cells may otherwise go unnoticed in a normal mean corpuscular volume (MCV). Shape changes in the erythrocytes (poikilocytes) often offer clues to a number of specific disease states. Rouleaux, agglutination, or evidence of increased erythrocyte regeneration are also important findings that may direct further investigation. A measure of anisocytosis, or variation in red cell size, is often offered as part of an automated hematology profile and is referred to as the red cell distribution width (RDW) or the red cell morphology index (RCMI). Adding this information may help further stratify the morphologic classification of anemias.

TABLE 41.1. MORPHOLOGIC CLASSIFICATION OF ANEMIA

Microcytic hypochromic anemias
Iron deficiency anemia
Anemia of chronic disease
Thalassemias
Sideroblastic anemia

Some hemoglobinopathies
Macrocytic anemias
Vitamin B_{12} deficiency
Folic acid deficiency
Aplastic anemia
Liver disease
Myelodysplastic syndromes
Some hemolytic anemias

A Pathophysiologic Approach to Anemia

In addition to the information provided by the automated hematology analyzer, the history and physical examination may also provide clues directing further study. The history and review of the prior medical and laboratory data should help to establish the onset and duration of the anemia. Attention to cardiovascular complaints will also provide similar information. Blood loss may be documented by a history of menorrhagia or melena. Dietary inadequacies, current medicinal use, or history of toxin exposure may be elicited in questioning. A family history may provide evidence of an inherited red cell abnormality. Systemic symptoms such as fever or weight loss might point toward neoplasia or infection.

The physical examination should document the signs of anemia.

Signs of hyperbilirubinemia, which may suggest increased red cell destruction, should be sought. Lymphadenopathy or hepatosplenomegaly may provide clues to an underlying infection, lymphoproliferative disorder, or myeloproliferative state. Changes detected in the neurologic examination may reflect not only nonspecific signs of global cerebral hypoxia but may also provide clues indicative of vitamin B_{12} deficiency or hypothyroidism.

The information obtained through the history and physical examination is helpful in understanding the physiologic mechanisms underlying a decreased red cell mass. A pathophysiologic approach to the anemias can be utilized as an alternative to the morphologic classification scheme provided by the initial laboratory data (Table 41.2). Subsequent discussion of the red cell disorders will follow such a pathophysiologic approach. It is important, however, to understand both classification schemes and how they relate, as evaluation of the anemic patient requires a thorough and careful history, physical examination, laboratory investigation, and examination of the peripheral blood smear.

POSTHEMORRHAGIC ANEMIA

Part of "41 - Red Blood Cell Disorders"

Acute Blood Loss

The clinical manifestations of acute blood loss are largely related to the loss of blood volume. Healthy individuals may tolerate a loss of as much as 20% of blood volume without clinical manifestations. The loss of larger quantities of blood results in cardiovascular distress; losses exceeding 50% of total blood volume typically result in death. The following discussion presumes a single episode of acute blood loss unattended by therapeutic intervention, an infrequent clinical scenario.

Immediately after acute blood loss, a proportional decline of plasma volume and red cell mass occurs, thus, the hemoglobin and hematocrit remain normal. In an attempt to maintain an adequate blood volume, albumin and fluid are shifted from the extravascular space to the vascular compartment. As this is a slow process, the maximum fall in hematocrit is reached approximately 3 days after blood loss when plasma volume is restored; before this time the extent of blood loss is underestimated by the hematocrit. The resulting anemia is initially normochromic and normocytic.

A compensatory increase in red cell production is stimulated by the release of erythropoietin. A lag phase of 3 to 5 days occurs as the erythrocytes mature in the marrow. Subsequently, evidence of increased erythrocyte regeneration is seen in the peripheral blood reflected by increased numbers of polychromatophilic macrocytes or by an increased reticulocyte count. Maximal reticulocytosis is evident approximately 10 days after blood loss; at this time, an increased MCV may be noted.

The platelet and leukocyte counts are also affected by acute blood loss. An early transient thrombocytopenia is typically followed within hours by a thrombocytosis that may reach $1{,}000 \times 10^9$/L. The leukocyte count may rise as high as 35×10^9/L, in part responding to an epinephrine-induced shift of the marginating granulocytes to the circulating granulocytic pool. Leukocytosis, which may be accompanied by a mild left shift in granulocytic maturation, occurs within several hours of blood loss and typically resolves within 2 to 4 days.

Such changes in the peripheral blood are readily recognizable as secondary to acute blood loss when hemorrhage is external. Acute blood loss into a body space or cavity, however, may initially go undetected clinically. In such instances, anemia, coupled with evidence of increased erythrocyte regeneration, might suggest a hemolytic anemia. Hyperbilirubinemia, typical of hemolytic anemias, may also be evident as internal blood loss leads to erythrocyte breakdown and heme metabolism. Other laboratory findings often seen in conjunction with hemolytic anemia, such as erythrocyte shape abnormalities, decreased serum haptoglobin, hemoglobinemia, hemoglobinuria, and hemosiderinuria are absent, however.

Chronic Blood Loss

The previously described changes of acute blood loss are lacking if the loss of blood occurs slowly over an extended period of time. Chronic blood loss results in anemia only when the rate of blood loss exceeds the regenerative capacity of the bone marrow or when the body's iron stores are depleted. In the latter circumstance, the resultant blood picture is one of iron deficiency.

IMPAIRED ERYTHROCYTE PRODUCTION

Part of "41 - Red Blood Cell Disorders"

The anemias discussed in this section each result from the bone marrow's inability to produce adequate numbers of functional

erythrocytes. This may arise from an inadequate number of erythroid precursors or from an insufficient quantity of substances essential for nuclear or cytoplasmic maturation. A deficiency of such factors vital to cell maturation often affects nonhematopoietic tissue as well; the following discussion, however, focuses only on the consequences to the hematopoietic system.

Disorders of Heme Synthesis

Cytoplasmic maturation is a reflection of hemoglobin synthesis. The normal biosynthesis of hemoglobin requires that iron, protoporphyrin, and globin are present in optimal amounts within the developing erythrocyte. Therefore, abnormalities in synthesis

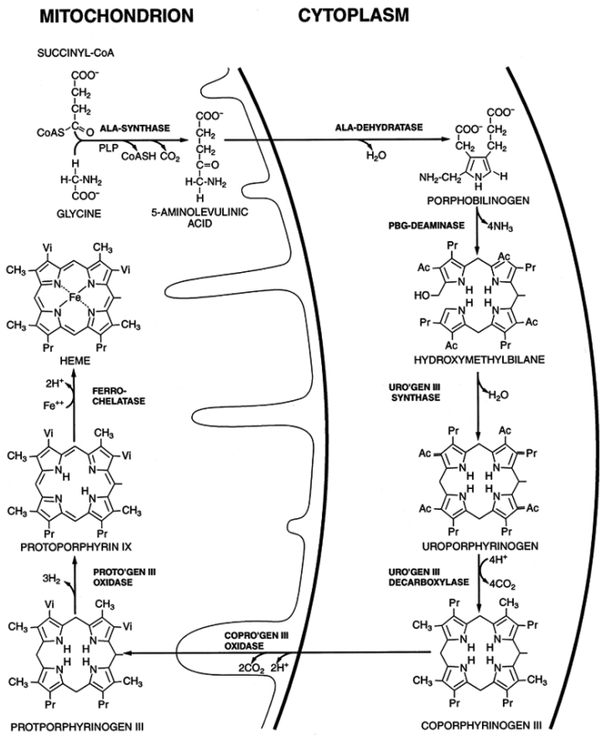

FIGURE 41.1. Heme biosynthesis. M, methyl (-CH_3); P, propionate (-CH_2 -CH_2 -COOH); V, vinyl (-CH=CH_2); ALA, (-aminolevulinic acid; PBG, porphobilinogen; Uro I synthase, uroporphyrinogen I synthase; Uro III cosyn, uroporphyrinogen III cosynthase; Urodecarb, uroporphyrinogen decarboxylase. Uro'gen, uroporphyrinogen; Copro'gen, coproporphyrinogen; Proto'gen, protoporphyrinogen. (From Wintrobe MM, et al. Erythropoiesis. In: *Clinical hematology*, 8th ed. Philadelphia: Lea & Febiger, 1981, with permission.)

or integration of any of these three constituents result in an anemia characterized by deficient hemoglobin synthesis, morphologically manifest as hypochromic erythrocytes. Because mitosis is terminated when a critical intracellular concentration of hemoglobin is reached, erythrocytes deficient in hemoglobin typically undergo an additional cell division, resulting in the production of small or microcytic red blood cells. Abnormalities of globin synthesis are discussed in Chapter 42, and, therefore, the following discussion is limited to abnormalities of heme synthesis (Fig. 41.1).

Under the influence of δ-aminolevulinic acid (ALA) synthetase and pyridoxal 5′-phosphate as a cofactor, succinyl coenzyme A (CoA) and glycine combine to form ALA. This initial step is the major rate-limiting step in heme synthesis, largely controlled as an inverse function of the intracellular concentration of heme. Two molecules of ALA then combine to form porphobilinogen, with subsequent condensation of four porphobilinogen molecules to form the tetrapyrrole ring structure of uroporphyrinogen. Uroporphyrinogen undergoes a number of changes, each under the influence of specific enzymes, eventually resulting in an oxidized molecule of protoporphyrin IX. The final step in heme synthesis occurs in the mitochondria as ferrous iron is incorporated into protoporphyrin IX.

Diminished heme synthesis will result from abnormalities at any point in this multistep pathway. Examples include pyridoxine deficiency, or the diminished conversion of pyridoxine to pyridoxal 5′-phosphate seen in alcoholics; the toxic effects of lead, which inhibits ALA dehydrase and inhibits iron delivery to protoporphyrin IX; and deficiencies of enzymes integral to the tetrapyrrole conversions of uroporphyrinogen that result in the rare, typically inherited group of disorders known as the porphyrias.

Normally, protoporphyrin IX is produced in slight relative excess to the amount of iron available for heme synthesis and can be measured clinically as free erythrocyte protoporphyrin (FEP). FEP is actually zinc protoporphyrin, a naturally fluorescent moiety. The action of heme synthetase is not specific for iron and zinc, the second most plentiful transitional metal within the erythrocyte, is readily incorporated into protoporphyrin IX when iron is unavailable. If incorporation of iron is reduced, owing to either an enzymatic block or a deficiency of available iron, an excess of protoporphyrin IX results (increased FEP). Increased FEP is perhaps the most sensitive laboratory indicator available for iron-deficient erythropoiesis.

Iron-Deficiency Anemia

If one excludes the clinically silent thalassemia syndromes, iron deficiency is the primary cause of anemia worldwide. To understand the multiple causes of iron deficiency and the consequent biochemical changes that are used clinically as aids in establishing a diagnosis of iron-deficiency anemia, one must first understand iron metabolism.

Iron Metabolism

Iron is supplied exogenously through the diet in two forms: heme iron and nonheme iron. Heme iron is derived from hemoglobin, myoglobin, or other heme proteins in foods of animal origin. Nonheme iron must be converted to or maintained in the ferrous state to facilitate absorption, a process enhanced by the acid environment of the stomach. Iron is absorbed primarily in the duodenum or upper jejunum by means of specific mucosal receptors. The absorption of iron is regulated at the level of the mucosal cell, and hence, the tight balance of iron is controlled (Fig. 41.2). Under normal circumstances, 5% to 10% of ingested iron is absorbed; in states of iron deficiency, absorption may increase severalfold. Exactly how this process occurs and how it is controlled remain unclear.

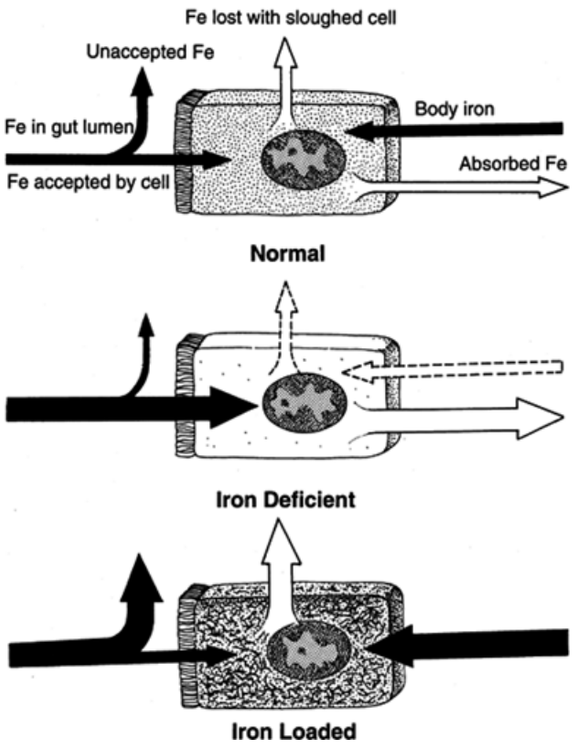

FIGURE 41.2. The concentration of iron within the intestinal mucosal cell likely parallels body iron stores and serves to regulate the amount of iron absorbed. Iron accepted into the mucosal cell may pass through the cell and enter the circulation, a fate that is promoted by decreased intracellular iron concentration. Alternatively, iron may be retained within the mucosal cell and subsequently lost from the body as the cell is sloughed with normal epithelial turnover. Increased intracellular iron promotes retention of iron as well as diminishing acceptance of iron into the cell. (Modified from Crosby WH. The control of iron balance by the intestinal mucosa. *Blood* 1963;22:441.)

Once absorbed, iron may be sequestered within the mucosal epithelial cell to be subsequently excreted with cell death, or it may pass through the cell to enter the circulation, where it is quickly complexed with the plasma carrier protein transferrin. The synthesis of transferrin, occurring principally in the liver, is regulated by feedback inhibition in inverse relation to the body's iron stores. Under normal circumstances, approximately one third of the binding sites of transferrin are saturated with iron.

Transferrin provides purposeful transport of iron by directing

the transferrin-iron complex to transferrin receptors located on the surface of all cells requiring iron. The critical role of transferrin in iron transport is evident by the rare congenital disorder atransferrinemia. The absence of transferrin in this disease results in severe transfusion-dependent anemia as well as hemosiderosis owing to random iron deposition throughout the body.

When bound to the surface of the developing red cell, the transferrin-iron complex is internalized by a process of pinocytosis. Iron is then liberated from transferrin with subsequent return of the intact transferrin molecule to the plasma, where it resumes its transport function.

The majority of the iron delivered to the developing erythrocyte is incorporated into heme. A small amount of residual nonheme iron is accounted for as ferritin. These small ferritin granules can be visualized with a Prussian blue stain of a bone marrow aspirate. Normally, one to five small randomly distributed Prussian blue–positive granules are seen in the cytoplasm of 20% to 60% of normoblasts; these nonheme iron-containing erythroblasts are referred to as sideroblasts (Fig. 41.3). The number of sideroblasts present reflects both the availability of iron and the incorporation of iron into heme. A good correlation exists between the number of sideroblasts and the percentage of saturation of transferrin, defined as serum iron × 100/total iron binding capacity or serum iron × 100/transferrin. These normal cytoplasmic ferritin deposits are removed by solubilization and extrusion of ferritin into the surrounding media, a process that requires active cellular oxidative metabolism.

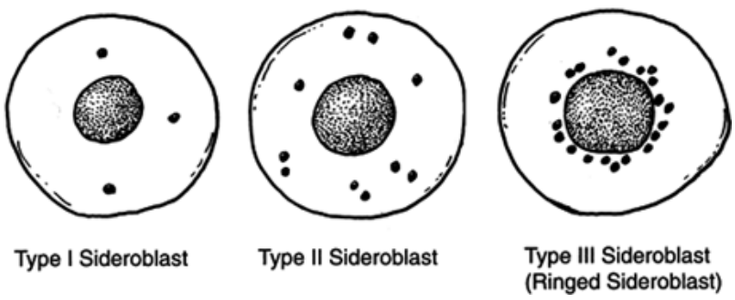

FIGURE 41.3. Small particles of nonheme iron may be seen in the cytoplasm of developing erythroblasts utilizing iron stains such as Prussian blue. Type I sideroblasts contain one to five small, randomly distributed iron particles and account for 20% to 60% of erythrocytes. Type II sideroblasts contain five or more coarse, randomly distributed iron granules and are often seen in states of excess reticuloendothelial iron and/or abnormal iron utilization. Type III sideroblasts, or ringed sideroblasts, are the morphologic hallmark of the sideroblastic anemias and are characterized by a ring or arc of iron encircling two thirds or more of the erythroblast nucleus.

Iron incorporated into heme remains in the erythrocyte throughout its life span. Erythroid senescence results in removal of the red cell from circulation, primarily by the splenic macrophages. Within the macrophage, hemoglobin is catabolized with ultimate liberation of iron, protoporphyrin, and globin. Iron is then stored in the reticuloendothelial system of the spleen, bone marrow, and liver. From these storage sites, iron is liberated to transferrin to be directed to a newly developing erythrocyte and to begin the iron cycle once again.

Iron is stored in two forms: hemosiderin and ferritin. Ferritin is well characterized and is the major physiologic storage form of iron. Hemosiderin, considered to represent an agglomerate of degraded ferritin and debris from lysosomal vacuoles, is distinguished from ferritin by its insolubility in water and its intense stainability with Prussian blue. The latter characteristic is employed in assessing iron stores in tissue sections or bone marrow aspirate smears.

Iron stores may also be assessed by quantitation of serum ferritin. Although ferritin is typically sequestered within the reticuloendothelial system, a trace amount normally leaks into the circulation. Serum ferritin generally correlates with the body's iron stores. A low serum ferritin is usually a valid indication of decreased iron stores. An elevated serum ferritin, however, does not necessarily indicate adequate or excess body iron stores because ferritin shows an acute phase response, which may persist for several days to weeks. Consequently, serum ferritin may not be a valid indication of iron stores when measured in the face of underlying inflammatory processes, neoplasia, or liver disease. Interestingly, immunohistochemical assessment of ferritin in bone marrow biopsy specimens has been reported to be a very sensitive tool in the evaluation of body iron stores.

Etiology

From the foregoing discussion, it is evident that iron is highly conserved by the body. How then does iron-deficiency anemia develop? In general, iron deficiency may arise either from an inadequate intake of iron or from a depletion of the body's iron stores. Dietary inadequacy is typically not a problem in the United States, except during periods of increased metabolic need. Rapid periods of growth, as found during the first year of life and early in adolescence, require additional dietary intake. Consequently, infants between the ages of 6 and 20 months are vulnerable, particularly those maintained solely on an unsupplemented milk diet. Increased demands for iron are also noted during pregnancy and lactation.

A decreased intake of iron may arise in the presence of an adequate diet if the body is incapable of absorbing iron. Malabsorption of iron may be seen with achlorhydria, after partial or total gastrectomy, or as a complication of diffuse enteritis (e.g., celiac disease). Pica, the ingestion of unusual substances, may be seen both as a cause and as a manifestation of iron deficiency. When habitually ingested, substances such as clay or starch can not only interfere with iron absorption but also serve as an iron-poor caloric substitute.

In the adult population of the United States, depletion of the body's iron stores through chronic blood loss is a much more common cause of iron-deficiency anemia than is an insufficient intake of iron. If an average diet is consumed, a steady loss of as little as 3 to 4 mL of blood per day can result in negative iron balance. Gastrointestinal bleeding is the most frequent cause of iron deficiency in men and postmenopausal women; menstrual blood loss must be considered first in premenopausal women. Common gastrointestinal disorders resulting in blood loss are presented in Table 41.3. Unusual causes of chronic blood loss include hemoglobinuria and pulmonary hemosiderosis.

Clinical Symptoms

Iron-deficiency anemia is typically insidious in onset and gradual in progression. Consequently, patients adapt well and medical attention is often delayed. Many patients present with signs and symptoms common to anemia. Others may present with symptoms related to the cause of the iron deficiency (e.g., ulcer disease), whereas in some patients, the anemia may be discovered incidentally.

Because iron is vital to the growth and development of all cells, it is not surprising that a deficiency of iron leads to manifestations beyond the hematopoietic system. The clinical changes appear as the body becomes incapable of replacing cells at a rate equivalent to cell loss or exfoliation. Abnormalities of the nails, tongue, and upper gastrointestinal tract are common. Brittle, breakable, or ridged fingernails may be seen, eventually becoming concave or spoon-shaped (koilonychia). Absence or flattening of the papillae of the tongue may be accompanied by soreness or burning. Angular stomatitis, characterized by fissures or ulcers at the corners of the mouth, may also be noted. Upper esophageal webs or strictures may develop; the combination of dysphasia, stomatitis, lingual abnormalities and hypochromic anemia is referred to as Paterson-Kelly or Plummer-Vinson syndrome.

Laboratory Findings

Serum Chemistry. The appearance of a microcytic hypochromic anemia is actually a finding late in the course of iron deficiency. Several laboratory changes reflective of the body's declining iron stores are observed before the appearance of microcytic hypochromic red cells. Decreased iron stores, reflected by decreased serum ferritin, are found early in the course of iron deficiency, as stored iron is liberated to transferrin to maintain adequate delivery of iron to the developing erythroblast. As iron stores are depleted, serum iron falls and a compensatory increase in transferrin synthesis begins. These two events result in decreased transferrin saturation; by definition, iron-deficient erythropoiesis is present when the transferrin saturation falls below 16%. Elevation of FEP becomes evident when insufficient iron is available for heme synthesis. As previously mentioned, although low serum ferritin is usually a very good indicator of decreased iron stores, elevated serum ferritin may not indicate adequate or excess body iron stores, particularly in the presence of underlying inflammatory processes and other disorders. Recently, a quantitative test measuring the soluble fragment of transferrin receptor in serum (sTfR) has become available. Elevated levels of sTfR are present in iron-deficient subjects, as well as in individuals with malignancies or conditions with ineffective hematopoiesis. Levels do not appear to be increased in anemia of chronic disease without iron deficiency. Although further studies are necessary, measurement of sTfR may prove to be useful in distinguishing iron deficiency from anemia of chronic disease.

Blood. Early in the course of iron deficiency, the anemia appears normocytic and normochromic. As heme synthesis is impaired, hypochromic erythrocytes become evident. Microcytosis usually develops in tandem. Consequently, the MCV, mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC) are typically proportionally reduced. Examination of the peripheral blood smear reveals an erythroid population heterogeneous in both size and shape, features that become quite striking in severe cases (Fig. 41.4). As iron deficiency becomes pronounced, many erythrocytes exhibit only a thin peripheral rim of hemoglobin. Poikilocytes that are often seen include ovalocytes, pencil cells, teardrop forms, fragments, and target cells.

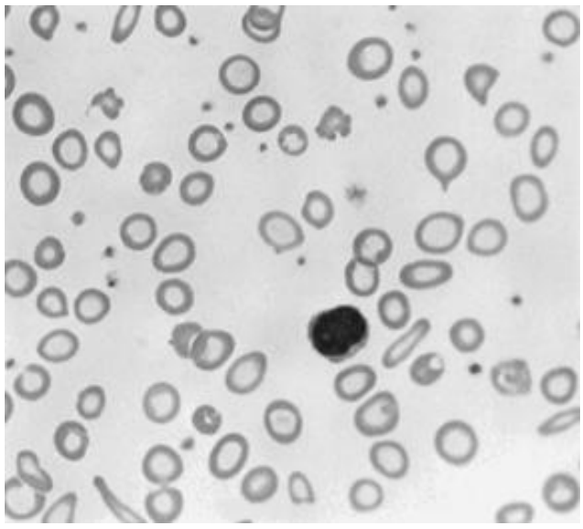

FIGURE 41.4. The peripheral blood smear in fully developed iron-deficiency anemia exhibits erythrocytes rich in central pallor. Although virtually all erythrocytes are microcytic, note the prominent variation in both size and shape, typical of iron-deficiency anemia.

The leukocyte count is typically normal, although slight granulocytopenia may be seen. The platelet count is often elevated, commonly as much as twice normal. Values reaching $1{,}000 \times 10^9$/L may rarely be seen, mimicking essential thrombocythemia.

Bone Marrow. The bone marrow often demonstrates mild erythroid hyperplasia. The developing erythroblasts appear small with scanty cytoplasm and exhibit frayed or ragged cell borders (Fig. 41.5). Nuclear budding or fragmentation may be noted. Periodic acid-Schiff-positive erythroblasts indicative of abnormal cytoplasmic maturation may also be seen. Many of these small abnormal erythroblasts die within the marrow, resulting in

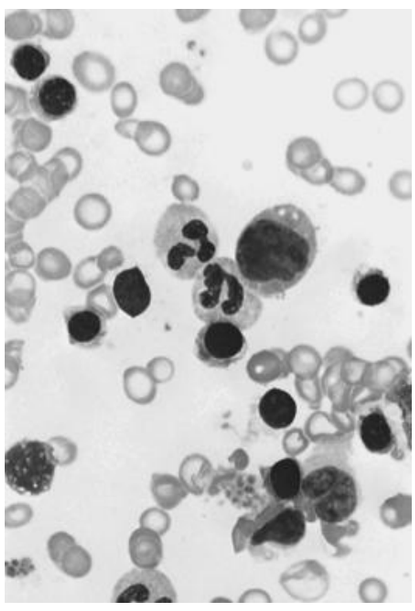

FIGURE 41.5. The developing erythroblasts in iron deficiency are small with scanty cytoplasm, often having a frayed, ragged, or moth-eaten appearance.

ineffective erythropoiesis. A Prussian blue stain demonstrates an absence of stainable iron. Sideroblasts are decreased or absent.

Therapy

It cannot be overemphasized that iron-deficiency anemia is not a disease but merely a sign of disease. Consequently, patients presenting with iron-deficiency anemia must be thoroughly evaluated to establish the cause of the deficiency. After the cause has been identified and appropriate therapy instituted, iron stores must be replenished. This is usually best accomplished by oral administration of ferrous iron salts, usually ferrous sulfate; although several oral iron preparations are available, cost is generally increased and substantial benefits compared with ferrous sulfate are often lacking. Parenteral administration of iron is infrequently necessary but may be indicated in unusual circumstances such as malabsorption, intolerance to or inability to complete a course of oral therapy, or a continued rapid rate of blood loss (so that oral therapy cannot compensate).

Signs of iron deficiency usually begin to abate within days of iron therapy. Hematologic response can be monitored with the reticulocyte count, which should reach a maximum 7 to 10 days after the institution of therapy. The reticulocyte count seldom exceeds 10% and slowly falls as the hemoglobin level rises. Normalization of the hemoglobin should be complete within 8 weeks, but continued iron therapy should be continued to replenish storage iron, generally 3 to 6 months.

Sideroblastic Anemia

Sideroblastic anemias are a group of disorders characterized by impaired utilization of iron resulting in diminished heme synthesis. The uptake of iron by the developing erythrocyte is partly controlled by the concentration of intracellular heme, which acts as a feedback inhibitor. The diminished heme synthesis resulting from impaired utilization of iron therefore results in a continued stimulus for iron absorption despite an adequate or increased level of intracellular iron. Excess iron is deposited in the mitochondria of the erythrocytes, the site of incorporation into protoporphyrin IX. The excessive deposition of iron is seen as rings or arcs around the nucleus of the erythroblast with a Prussian blue stain; these ringed sideroblasts are the morphologic hallmark of this group of disorders (Fig. 41.6). Ringed sideroblasts often succumb to the toxic effects of iron, leading to intramedullary destruction or ineffective erythropoiesis.

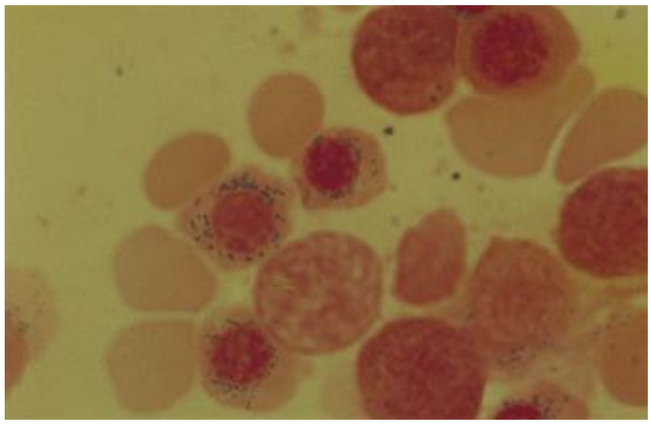

FIGURE 41.6. Ringed sideroblasts (Prussian blue stain). Numerous erythroblasts demonstrate deposition of granular iron nearly encircling the nucleus.

Diminished heme synthesis results in microcytic hypochromic erythrocytes. The degree of microcytosis and hypochromia varies among the different forms of sideroblastic anemia. Often, a dimorphic red cell population is present consisting of a distinct population of microcytic hypochromic erythrocytes among normocytic or even macrocytic red cells (Fig. 41.7).

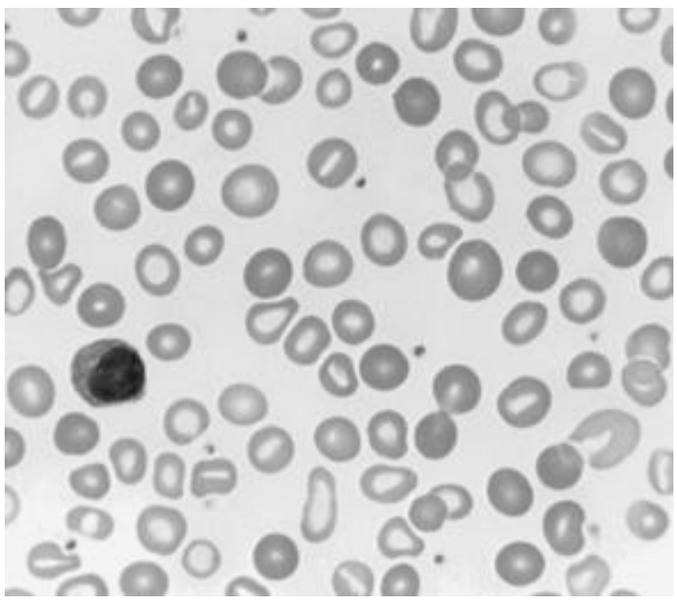

FIGURE 41.7. The peripheral blood smear of refractory anemia with ringed sideroblasts is characterized by a dimorphic red cell population. A distinct population of hypochromic, often microcytic erythrocytes can be found admixed with normochromic, normocytic, or macrocytic erythrocytes.

Iron absorption by the body continues despite the inability of the erythron to utilize iron properly in heme synthesis. Consequently, plasma (serum) iron rises, transferrin becomes saturated, and transferrin synthesis is suppressed. With time, the reticuloendothelial stores become overloaded, and iron is deposited in the parenchymal cells of various tissues. Excessive iron deposition in the heart, pancreas, or liver can result in organ dysfunction and sequelae analogous to the genetic disorder hemochromatosis.

These three features, ringed sideroblasts, a population of microcytic hypochromic erythrocytes, and hyperferremia, characterize the sideroblastic anemias. As a group, these disorders may be divided into hereditary and acquired forms.

Hereditary Sideroblastic Anemia

Hereditary forms of sideroblastic anemia are distinctly less common than acquired sideroblastic anemia. Most hereditary forms have been traced to an X-linked pattern of inheritance. Typically, it is only the male hemizygote who exhibits manifestations of the disease; rarely, female carriers may be moderately anemic.

The severity of the anemia is variable. Often severe microcytic hypochromic anemia is detected in infancy or early childhood, but mild forms of the disease may go undetected until early adulthood. The red cell population often exhibits marked anisopoikilocytosis, obscuring the classic dimorphic picture ascribed to sideroblastic anemia. Coarse basophilic stippling is present, and, when found in microcytic hypochromic cells, is a clue to the diagnosis. Ringed sideroblasts constitute 10% to 40% of erythroblasts and are typically seen only in late stages of erythroid development. Serum iron is high, and transferrin and reticuloendothelial stores are saturated. Over the course of years, parenchymal deposition may lead to cirrhosis, cardiomyopathy, and/or diabetes. Consequently, the removal of excess iron should be initiated. This may not only delay or prevent the damage of parenchymal iron deposition, but it may also improve the hematologic status of the patient by diminishing the toxic effects of excess iron on the erythron.

Variable defects of ALA synthetase have been implicated as the cause of X-linked sideroblastic anemia. Some forms respond to pharmacologic doses of pyridoxine; although not truly pyridoxine deficient, these patients possess ALA synthetase variants that either have an increased Michaelis constant (K_m) for pyridoxal 5′-phosphate or are unstable and abnormally sensitive to mitochondrial proteases. Clinical responses to pyridoxine are variable. Subtotal correction of the hemoglobin is common with persistence of microcytic hypochromic erythrocytes.

A few cases of hereditary sideroblastic anemias have been described that, although clinically indistinguishable from the X-linked variants, are indeterminate in their pattern of genetic transmission. An autosomal recessive pattern of inheritance has been suggested.

Acquired Sideroblastic Anemia

Acquired sideroblastic anemia is typically a disorder of adulthood, occurring as an idiopathic condition or as a secondary reversible phenomenon during administration of certain medicinal agents or after exposure to various myelotoxic chemicals (Table 41.4).

TABLE 41.4. DRUGS IMPLICATED IN SECONDARY SIDEROBLASTIC ANEMIA

Antituberculous agents
Isonicotinic acid hydrazine
Pyrazinamide
Cycloserine
Ethionamide
Chloramphenicol
Chemotherapeutic agents
Alkylating agents
Antimetabolites
Lead
Alcohol

The antituberculous drugs and alcohol interfere with pyridoxine metabolism or the conversion of pyridoxine to the active pyridoxine 5′-phosphate, respectively. Ringed sideroblasts may be transiently associated with the administration of chemotherapeutic drugs or may appear years after therapy as part of a secondary or therapy-related myelodysplastic syndrome or leukemia. Lead is toxic to the erythron in several ways, including inhibitory effects at multiple sites in the heme biosynthetic pathway. Regardless of the etiology, the number of ringed sideroblasts and the degree of anemia and microcytosis tend to be less prominent than in either the inherited or idiopathic forms of sideroblastic anemia.

Ringed sideroblasts have also been described in association with a variety of other hematologic and nonhematologic conditions, including myeloproliferative disorders, multiple myeloma, lymphomas, megaloblastic anemia, collagen vascular disorders and myxedema. In some circumstances, this finding may be secondary to the administration of therapeutic agents, as previously described.

Known causes of sideroblastic anemia must be excluded before rendering the diagnosis of idiopathic sideroblastic anemia, which falls within the diagnostic category of myelodysplastic syndromes as refractory anemia with ringed sideroblasts. The myelodysplastic syndromes, including refractory anemia with ringed sideroblasts, are discussed in Chapter 43.

Iron Overload

Iron is highly conserved by the body. Under normal circumstances, the 1 to 2 mg of iron lost daily through turnover of the upper gastrointestinal epithelium is balanced by absorption of ingested iron. Prolonged administration of iron or enhanced absorption of iron cannot be matched by increased iron excretion because there is not a physiologic pathway for iron excretion in humans. A gradual progressive buildup of iron eventually leads to accumulation outside the reticuloendothelial system, causing injury to parenchymal cells. It is postulated that the toxic effects of iron may be related to the formation of free radicals, causing lipid peroxidation, or to the liberation of lysosomal enzymes. The clinical manifestations of parenchymal damage are referred to as hemochromatosis. Organs principally involved include the liver (cirrhosis), the heart (cardiomyopathy or arrhythmias), and the pancreas (glucose intolerance). Additionally, later in the disease, patients may exhibit bronze pigmentation of the skin, resulting from a combination of iron deposition and increased

melanin. Arthritis, resembling rheumatoid arthritis, and manifestations of hypogonadism may also be present. Hemochromatosis has been divided into hereditary (primary) and secondary forms. Common causes of hereditary and secondary forms of hemochromatosis are shown in Table 41.5.

TABLE 41.5. HEREDITARY (PRIMARY) AND SECONDARY CAUSES OF HEMOCHROMATOSIS

Hereditary hemochromatosis
Genetic abnormalities involving *HFE* gene
C282Y homozygosity
C282Y/H63D compound heterozygosity
Non-*HFE* related
Juvenile hemochromatosis
Autosomal dominant hemochromatosis
Secondary hemochromatosis
Iron-loading anemias:
Thalassemia, sideroblastic anemia, chronic hemolytic anemias
Dietary or parenteral iron overload
Chronic liver disease
Dysmetabolic iron overload
Post-portacaval shunting

Hereditary Hemochromatosis

Increased body iron stores with primary parenchymal cell deposition of iron owing to inappropriate iron absorption is the hallmark of hereditary hemochromatosis (HHC). The diagnosis of HHC requires a high index of clinical suspicion and careful clinicopathologic correlation. HHC should be considered in any patient with unexplained hepatomegaly, abnormal skin pigmentation, cardiomyopathy, diabetes, arthritis, or hypogonadism. Previous criteria for the diagnosis of HHC have included stainable hepatic iron of grade 3 or 4 (of four grades), hepatic iron concentration greater than 80 μmol/g (dry weight), and hepatic iron index greater than 1.9. Clinical tests such as elevated serum ferritin or increased transferrin saturation are also currently used.

Recent advances in the understanding of HHC have enhanced the diagnostic capabilities in this disorder. Most patients with HHC carry a mutation involving the hemochromatosis gene (*HFE*) that encodes a novel nonclassic major histocompatibility complex (MHC) class I-like molecule. There are two common mutations involving the *HFE* gene. The more common mutation involves a point mutation at nucleotide 845 (G to A), resulting in a substitution of tyrosine for cysteine at amino acid 282 (referred to as C282Y mutation). The other mutation, in which a point mutation occurs at nucleotide 187 (C to G), results in a substitution of aspartate for histidine at amino acid 63 (H63D). The majority of the HHC patients (85% to 90%) have homozygosity for the C282Y mutation. Some recent studies reported mutations involving non-*HFE*–related genes. For example, the juvenile hemochromatosis locus has been mapped to chromosome 1q, which is genetically distinct from adult *HFE*-associated hemochromatosis.

HHC is a common inherited disorder, with a prevalence of one in 300 to 400 U.S. whites. As many as one in 10 white Americans have been estimated to carry at least one allele with the C282Y mutation. The prevalence in other ethnic populations appears to be lower. Although clinically significant iron overload usually develops in individuals who are homozygous for C282Y, the phenotype shows considerable variation, suggesting that other factors affect the overall expression of the disease. Occasional C282Y homozygotes do not have evidence of iron overload. Individuals heterozygous for the C282Y mutation may have increased serum iron indices and a small increase in hepatic iron concentration but usually do not develop progressive iron accumulation or significant liver disease in the absence of cofactors or additional mutations.

H63D homozygotes and compound heterozygotes (C282Y and H63D) patients have a higher risk of hemochromatosis compared with normal population.

HFE encodes for a 343 amino acid nonclassic MHC class I molecule. This protein contains a short cytoplasmic tail, a membrane-spanning domain, and three extracellular domains analogous to the α1, α2 and α3 domains of MHC class I molecules. The α1 and α2 domains form the ligand-binding cleft in the MHC class I molecules. The α3 domain is the most highly conserved within the class I molecules. This region interacts with $ß_2$-microglobulin, which appears to be essential for the correct cell surface presentation of the class I MHC molecules.

HFE is believed to play a general role in the cellular uptake of iron. The HFE–$ß_2$-microglobulin complex is expressed on the basolateral surface of the epithelial cells in the stomach, colon, and biliary tract, as well as on the sinusoidal lining cells of the liver. In the crypt cells of the small intestine, HFE has a unique subcellular localization in proximity to probable sites of iron absorption.

In HHC, there is an inappropriately high level of iron absorption, with increased transfer of iron from intestinal cells. Absorbed iron becomes tightly bound to transferrin in the bloodstream and enters cells after endocytosis of diferric transferrin bound to transferrin receptors on the cell surfaces. The internalized endosome becomes acidified and causes the release of iron from transferrin. It is believed that HFE interacts with the transferrin receptor and participates, along with transferrin, in the receptor-mediated endocytosis. The carboxy region of the α1 domain and the adjacent loop of HFE are the binding sites. The transferrin receptor is necessary for the assembly, transport and expression of the cell surface of HFE. This interaction likely decreases the number of transferrin binding sites, blocks the internalization of the transferrin receptor, decreases the affinity of the transferrin receptor for transferrin, and reduces the amount of iron taken by reducing the amount released from transferrin in the endosomes.

The C282Y disrupts the disulfide mutation bond in the α1 and α3 domains of HFE. This prevents the binding of $ß_2$-microglobulin, which is essential for the correct intracellular processing and transport of HFE to the plasma membrane. The mutant protein is retained in the endoplasmic reticulum and fails to undergo late Golgi processing. It is not expressed on the cell surface and is unable to participate in its normal function. The H63D mutation is located in the α1 domain and, unlike the C282Y mutation, does not interfere with $ß_2$-microglobulin binding. H63D HFE does not appear to have any significant difference from the wild type protein in its intracellular processing, transportation, and cell surface expression. The functional significance of this mutation is not clear. H63D HFE can form a complex with the transferrin receptor; however, it does not reduce

the affinity of HFE to transferrin to the same extent as wild type HFE.

Genotypic analysis (discussed in Chapter 11) of hemochromatosis is currently recommended for individuals with first-degree family members who have been identified with a mutation in the *HFE* gene, as well as in patients with evidence of iron overload, such as increased serum transferrin saturation, high serum ferritin levels, or excess iron staining on liver biopsy. Screening of the normal population by genetic analysis is not currently recommended. Transferrin saturation and unbound iron binding capacity are currently recommended for initial screening of individuals. Those individuals with normal values should be reassured and retested later if there is any clinical suspicion of hemochromatosis. *HFE* testing should include molecular analysis for both C282Y and H63D mutations as discussed in the molecular section.

Secondary Hemochromatosis

Secondary causes of iron overload principally result in deposition of iron within the reticuloendothelial system (also referred to as hemosiderosis). Damage to parenchymal tissues indistinguishable from inherited hemochromatosis, however, occurs with time as iron becomes deposited outside the saturated reticuloendothelial stores.

Increased intake of dietary iron may rarely result in iron overloading; more frequently, iron overloading is a complication of the anemias characterized by lifelong ineffective erythropoiesis. Examples include thalassemia major, inherited sideroblastic anemia, and some forms of congenital dyserythropoietic anemia. All display hyperabsorption of iron in response to an increased rate of erythropoiesis. A program of maintenance transfusion therapy may be necessary in these disorders, further complicating the picture of iron overload through the associated parenteral administration of iron in blood products.

Anemia of Chronic Disease

Anemia of chronic disease is the term used to describe the anemic state that is often seen in conjunction with a number of chronic nonhematologic disorders (Table 41.6). Considering the array of conditions with which anemia of chronic disease has been associated, it is not surprising to find that it follows closely behind iron deficiency as a cause of anemia.

TABLE 41.6. CONDITIONS ASSOCIATED WITH THE ANEMIA OF CHRONIC DISEASE

Chronic infections
Tuberculosis
Chronic fungal infections
Subacute bacterial endocarditis
Osteomyelitis
Pyelonephritis
Pelvic inflammatory disease
Chronic inflammatory disorders
Rheumatoid arthritis
Systemic lupus erythematosus
Sarcoidosis
Rheumatic fever
Neoplasms
Carcinoma
Malignant lymphoma

Beyond the descriptive association with chronic disease, anemia of chronic disease may also be characterized as anemia of impaired iron utilization. As such, it is defined by a reduction in both serum iron and serum transferrin. Hypoferremia typically outpaces the hypotransferrinemia, resulting in decreased transferrin saturation. These changes occur in the presence of adequate or increased iron stores, indicating sequestration of iron in the reticuloendothelial system.

Iron trapping is only one factor in the pathogenesis of anemia of chronic disease. Additionally, there is diminished erythrocyte survival time, which is further compounded by the inability of the bone marrow to compensate by increasing the rate of erythropoiesis. Each of these factors, in part, appears to be related to the sustained release of interleukin-1 (IL-1) found during chronic inflammation and neoplasia.

IL-1 triggers the release of lactoferrin, a glycoprotein found in the secondary granules of neutrophils, which competes with transferrin for the binding of iron. Unlike iron bound to transferrin, which is transported to tissues in need, lactoferrin-bound iron is delivered to the macrophage, where it is internalized and effectively trapped, preventing delivery to the developing erythron.

Decreased erythrocyte survival may, in part, be related to fever induced by IL-1 or to enhanced ingestion of erythrocytes by macrophages activated by IL-1. IL-1 activation of macrophages and T lymphocytes may also alter the microenvironment of the bone marrow, creating conditions unfavorable for a compensatory erythroid hyperplasia.

Clinical and Laboratory Features

Anemia of chronic disease typically develops within 1 to 2 months after the onset of a chronic illness and remains stable throughout the disease course. It is typically mild to moderate in severity, with the hematocrit ranging from 0.30 to 0.40. As such, the signs and symptoms of the underlying disease tend to overshadow the effects of the anemia.

The anemia is frequently normocytic and normochromic; however, microcytic hypochromic anemia may occasionally be encountered. Anisopoikilocytosis is usually minimal, in contrast to the findings in iron-deficiency and sideroblastic anemias. The reticulocyte count, when corrected for the degree of anemia, is normal or low. The bone marrow shows essentially normal numbers of erythroid precursors with no significant morphologic abnormalities. Iron stores appear adequate or increased in the marrow; however, the number of sideroblasts is decreased (less than 20%); this combination of findings is virtually diagnostic of anemia of chronic disease.

Anemia of chronic disease and iron-deficiency anemia have in common a diminished delivery of iron to the erythron; hence, both are characterized by decreased serum iron. The two disorders may be distinguished by quantitation of serum transferrin and ferritin. Transferrin is normal or decreased in anemia of chronic disease, in contrast to the elevated values found in iron deficiency. Transferrin saturation is typically decreased in both disorders; however, values are often less than 10% in iron deficiency, a level seldom reached in anemia of chronic disease. Ferritin

is normal or increased in anemia of chronic disease, reflecting adequate iron stores, whereas ferritin is decreased in iron deficiency. Caution must be exercised, however, in interpreting serum ferritin in the presence of inflammation or neoplasia because it is an acute phase reactant.

Summary: A Laboratory Approach to the Disorders of Heme Synthesis

The thalassemias, iron-deficiency anemia, sideroblastic anemia, and anemia of chronic disease must each be considered in the differential diagnosis of a microcytic hypochromic anemia. From the preceding discussion, however, it can be seen that the morphologic classification of anemia is not perfect; this is evident in the frequent presentation of anemia of chronic disease as a normocytic anemia and sideroblastic anemia as a normocytic or macrocytic anemia. Iron-deficiency anemia, sideroblastic anemia, and anemia of chronic disease are related beyond a common morphologic presentation; they share a defect in heme synthesis related to the deficiency, utilization, or transport of iron. Taking advantage of the altered handling of iron exhibited by these disorders, differentiation can often be achieved by simple quantitation of serum iron, transferrin, and ferritin. Decreased serum iron or ferritin, increased transferrin or soluble transferrin receptor, or decreased/absent marrow iron stores are consistent with iron-deficiency anemia. Because the defects in hemoglobinopathies and thalassemias are unrelated to iron metabolism, normal iron studies in the presence of a microcytic hypochromic anemia may suggest hemoglobinopathy or thalassemia, but iron overload may occur with frequent transfusion support.

Disorders of DNA Synthesis: Megaloblastic Anemia

The megaloblastic anemias are a group of disorders characterized by a reduced rate of DNA synthesis. RNA synthesis, its processing, and ultimately protein synthesis are, however, unaffected. The resultant dyssynchrony in nuclear (DNA) and cytoplasmic (RNA) development is the morphologic hallmark of the megaloblastic anemias. Deficiencies of vitamin B_{12} or folic acid are by far the most frequent etiologic factors.

Vitamin B_{12}

Metabolism

Vitamin B_{12}, or cobalamin, is composed of a corrin ring linked to a ribonucleotide through one of the nitrogens of its base. The corrin ring resembles the tetrapyrrole ring structure of heme; cobalt occupies the central position of the corrin ring analogous to the position occupied by iron in heme. The unsatisfied valence of the cobalt ion is filled in humans largely by CN(cyanocobalamin) or OH^- (hydroxycobalamin). These cobalamin species each have nutritional properties of B_{12}, yet have no biochemical activity. Rapid tissue conversion to the active coenzymes methylcobalamin and adenosylcobalamin occurs through the action of coenzyme synthetases.

Methylcobalamin and adenosylcobalamin are vital cofactors for two independent metabolic reactions in humans. Methylcobalamin is a coenzyme needed for converting N^5-methyltetrahydrofolate to tetrahydrofolate (FH_4) (Fig. 41.8). FH_4 is an essential element in a number of biochemical reactions; most important is its role as an intermediary coenzyme in DNA synthesis. Conversion of FH_4 to the folate coenzyme $N^{5,10}$–methylene FH_4 is essential for the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), ultimately allowing integration of thymidine [as deoxythymidine triphosphate (dTTP)] into DNA. Therefore, in large part, the impairment of DNA synthesis seen with vitamin B_{12} deficiency is related to abnormalities in folate metabolism. This explains the shared manifestations of vitamin B_{12} and folic acid deficiency.

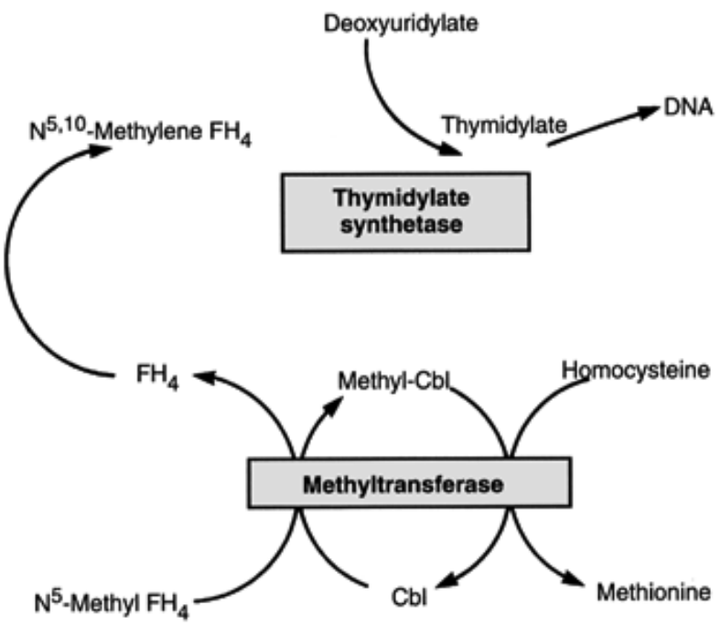

FIGURE 41.8. The role of methylcobalamin in methionine synthesis and its integral relationship to folate metabolism and DNA synthesis. FH_4, tetrahydrofolate; -Cbl, cobalamin. (From Williams W, et al. *Hematology*, 3rd ed. New York: McGraw-Hill, 1983:314, with permission.)

The inability to convert dUMP to dTMP, seen with both vitamin B_{12} and folic acid deficiency, alternatively results in the conversion of dUMP to deoxyuridine triphosphate (dUTP). The excess dUTP ultimately becomes incorporated into DNA in place of dTTP because DNA polymerase is unable to distinguish between these two nucleotides. The substitution of dUTP for dTTP results in errors in strand copying followed by attempts to edit the incorrectly inserted uridylate residue. Subsequent efforts to synthesize DNA correctly obviously fall short, as the requisite thymidylate is in short supply. Repeated cycles of fragmentation and attempted repair slow the synthesis of DNA and result in the characteristic nuclear chromatin pattern of megaloblastic anemia.

The other metabolically active form of cobalamin, adenosylcobalamin, is a coenzyme in humans essential to the conversion of methylmalonyl-CoA to succinyl-CoA, the basic fuel of the Krebs cycle (Fig. 41.9). Although adenosylcobalamin cannot be linked to DNA synthesis, it has been postulated, but not well established, that interruption of this reaction may play a role in the development of the neurologic changes seen in vitamin B_{12} deficiency. Inhibition of the conversion of methylmalonyl-CoA to

succinyl-CoA results in an accumulation of the methylmalonyl-CoA precursor propionyl. In high concentration, propionyl-CoA may replace acetyl-CoA as the usual primer for synthesis of even-chain fatty acids. Consequent errant production and insertion of odd-chained fatty acids into lipid membranes may result in lipid membrane abnormalities such as demyelination and subsequent neurologic impairment. An alternate hypothesis suggests that the impaired conversion of methionine owing to the deficiency of methylcobalamin results in a deficiency of *S*-adenosylmethionine (SAM). SAM is important for certain transmethylation reactions, including some that may be important in the maintenance of myelin.

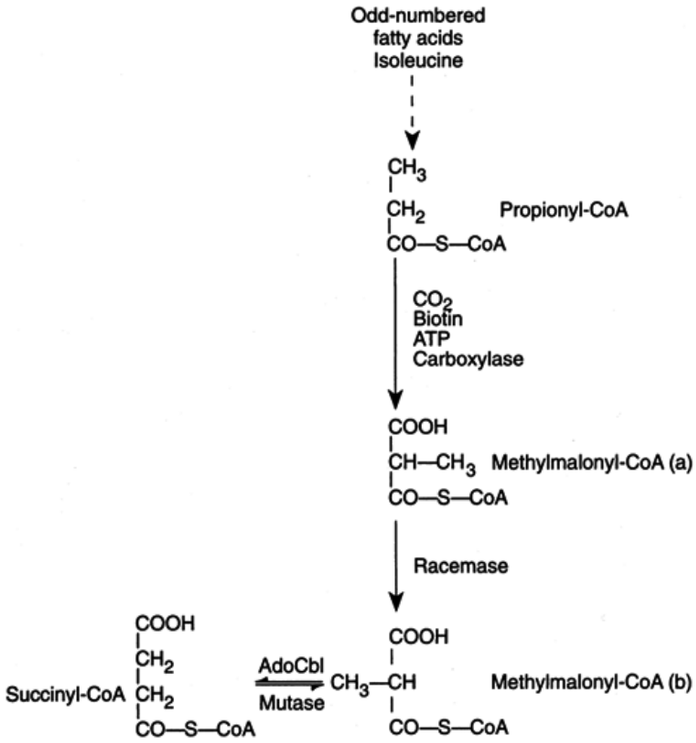

FIGURE 41.9. Adenosylcobalamin as a cofactor in the conversion of methylmalonyl-coenzyme A to succinyl-coenzyme A. AdoCbl, adenosylcobalamin. (From Williams W, et al. *Hematology*, 3rd ed. New York: McGraw-Hill, 1983:315, with permission.)

Vitamin B_{12} Absorption

Synthesized by many bacteria and some molds, vitamin B_{12} is found only in foods of animal origin such as meat, eggs, cheese, and milk. It has been estimated that the minimal daily requirement of vitamin B_{12} is 0.6 to 1.2 µg/day, an amount easily achieved in Western diets, which commonly contain 5 to 30 µg of vitamin B_{12}.

Vitamin B_{12} is released from food sources by the digestion of animal proteins. Free B_{12} is then competitively bound either to intrinsic factor (IF), a high-affinity glycoprotein produced by the parietal cells of the stomach, or to R proteins, a class of B_{12} binding proteins so designated because of their rapid electrophoretic mobility. R proteins are found in a variety of sites, including gastric juice and saliva, and serve to bind the majority of newly ingested B_{12}. Under normal circumstances, however, the R protein–B_{12} complex is short-lived; degradation of R protein by pancreatic proteases occurs in the proximal small intestine, liberating B_{12}, which then avidly binds to IF. IF greatly facilitates the absorption of B_{12}, providing direct and safe transport through the gastrointestinal tract to specific receptors located on the mucosa of the terminal ileum. Once the IF-B_{12} complex is bound, B_{12} is internalized by a poorly understood process.

Not to be overlooked is the enterohepatic circulation of B_{12}. More than 50% of the B_{12} entering the intestine each day arrives through this route. The majority is reabsorbed through IF-dependent mechanisms.

After absorption in the ileum, vitamin B_{12} is released to the circulation, where it is bound by transcobalamin (TC), the B_{12} transport protein. TC exists in three forms, designated TC I, TC II, and TC III; TC II is the major physiologic carrier of B_{12}, although normally binding only 10% to 25% of the plasma concentration of B_{12}. TC II has great capacity for rapid B_{12} transport to appropriate receptors at sites of need (dividing cells) or storage (liver). When bound by the receptor, the B_{12}–TC II complex is internalized by endocytosis, B_{12} is liberated, and TC II is degraded by lysosomal proteases.

TC I and TC III belong to the family of T proteins. Although most of the plasma B_{12} concentration is bound to TC I, this relatively stable complex has little capacity for transfer of B_{12} to tissue sites. TC III is largely synthesized in granulocytes and, although capable of binding B_{12} *in vitro*, is not engaged in the transport of endogenous B_{12} to tissue cells. Under normal circumstances, TC I is approximately 50% saturated with B_{12}, whereas less than 5% of TC II is saturated. The sum of the unsaturated TC I and TC II is referred to as the unsaturated B_{12} binding capacity.

Quantitative Assays

Serum levels of vitamin B_{12} are largely determined using isotope dilution techniques, although cobalamin-dependent microbial

assay systems may still be used. Universal use of IF as a binding protein in radioisotope assays eliminates binding of cobalamin analogs and yields values that compare favorably with those obtained with a microbiological system. Normal serum levels of B_{12} typically are in the range of 200 to 900 pg/mL. The serum B_{12} concentration is but a minute fraction of the total body stores of B_{12}, estimated at 1 to 5 mg, the liver being the primary site of storage.

Abnormalities of B_{12} binding proteins have been reported in a variety of disease states. Quantitation of both serum B_{12} and (unsaturated) B_{12} binding capacity are often cited as a tool in the evaluation of the chronic myeloproliferative disorders. Increases in one or both parameters largely reflect elevations of TC I and TC III liberated from the breakdown of increased numbers of granulocytes in these disease states.

Vitamin B_{12} Deficiency

Five basic mechanisms may lead to B_{12} deficiency: inadequate intake, increased requirement, defective absorption, defective transport, and defective enzyme activity. Defective transport owing to an abnormality of a TC carrier protein is rare, as are abnormalities of the coenzyme synthetases needed for conversion of B_{12} to the active forms of methylcobalamin or adenosylcobalamin. Also uncommon, given the body's reserves of B_{12}, are deficiencies occurring during transient periods of increased B_{12} requirement, e.g., during growth and development, pregnancy, or lactation. Similarly, an inadequate dietary intake of B_{12} is largely limited to strict vegetarians who abstain from all animal proteins, including milk and eggs. Assuming a previously healthy diet, strict avoidance of foods replete with B_{12} for a period of 3 to 5 years is required before achieving complete exhaustion of the body's B_{12} stores. For these reasons, deficiencies of B_{12} are most frequently encountered as a result of defective absorption.

Pernicious Anemia. Pernicious anemia (PA) is the most common cause of impaired B_{12} absorption and is the result of an acquired failure to secrete IF by the gastric parietal cells. The markedly diminished or absent secretion of intrinsic factor is typically associated with achlorhydria; both findings are related to the universal presence of gastric atrophy. PA is most commonly found in individuals of northern European ancestry, although no racial or ethnic group is immune. Typically, the disorder presents after the age of 40. The etiology of the disorder remains speculative. Circumstantial evidence suggests a hereditary basis for the disorder, although neither a mode of inheritance nor a link to any genetic marker is currently known. An autoimmune basis for pernicious anemia has also been proposed based on the frequent finding of autoantibodies in patients with PA and the histologic findings of a lymphoplasmacytic infiltrate in the gastric biopsies of patients with PA. Two types of autoantibodies are found in patients with PA. Approximately 90% of patients have antibodies to parietal cell cytoplasm in their serum. The exact role, if any, of these antibodies in the pathogenesis of PA is uncertain. Antiparietal cell antibodies have also been found in individuals with atrophic gastritis unassociated with PA, in persons with Hashimoto's thyroiditis, and in a small number of normal individuals. Serum antibodies to intrinsic factor have been detected in 55% of patients, whereas assays of gastric juice allow detection of anti-IF antibodies in 75% of patients with PA. Anti-IF antibodies are of two types: blocking antibodies, which block the attachment of B_{12} to IF, and binding antibodies, which prevent the absorption of B_{12} in the ileum. Although these antibodies have shown functional impairment of IF activity *in vivo*, their temporal sequence appears to postdate the onset of disease, thereby negating their role as a primary etiologic agent in this disease process.

Variant Forms of PA. Two rare variant forms of PA are found. Juvenile PA is distinguished from classic PA solely by its clinical appearance in adolescence or early adulthood. A rare congenital form of PA has also been described. Patients with congenital PA have either an absence of IF or a functionally aberrant form of IF. In contrast to other forms of PA, the defect in IF is selective; the appearance and function of the gastric mucosa in all other aspects is normal. The congenital form of PA is inherited as an autosomal recessive defect with hematologic manifestations appearing in infancy. Like classic PA, both juvenile and congenital PA respond to the administration of IF.

Gastrectomy. B_{12} deficiency typically develops 3 to 5 years after total gastrectomy as B_{12} absorption ceases and the body's B_{12} stores are gradually depleted. B_{12} deficiency is less predictable after subtotal gastrectomy; often appearing one to two decades after surgery, it may be related to the slow development of postoperative gastritis and gastric atrophy.

Pancreatic Insufficiency. Loss of the exocrine function of the pancreas, regardless of cause, may result in B_{12} deficiency. Pancreatic proteases are integral to the digestion of gastric R proteins, which compete with IF for B_{12}. Intact R proteins inhibit formation of the B_{12}-IF complex, thereby diminishing absorption in the terminal ileum.

Intestinal Malabsorption. Several small intestinal abnormalities may result in diminished B_{12} absorption. Surgical resection or diseases of the terminal ileum, such as Crohn's disease, effectively remove the site of B_{12} absorption. Malformations of the intestinal tract may predispose to the development of localized pockets of bacterial overgrowth. These proliferative microorganisms may effectively deprive the host of B_{12}. Similarly, competition for B_{12} may be encountered with intestinal infestation by the fish tapeworm *Diphyllobothrium latum*.

Laboratory Evaluation of B_{12} Deficiency. Several tests may be employed in the laboratory investigation of megaloblastic anemia. Serum or plasma quantitation of B_{12} is the usual method of detecting a vitamin B_{12}-deficient state. Less direct and less specific measures of a B_{12} deficiency state, such as urinary excretion of methylmalonic acid or the deoxyuridine suppression test, are seldom needed. After B_{12} deficiency is established, the etiology must be determined. The most frequent test employed to determine whether the patient lacks IF is the Schilling test. Shortly after oral administration of 0.5 to 2.0 µg of radiolabeled B_{12}, a large intramuscular flushing dose of nonlabeled B_{12} is administered, which will saturate B_{12} binding sites. When saturated, the orally ingested radiolabeled B_{12} absorbed by the ileum will be excreted

in the urine. A 24-hour urine collection normally reveals greater than 7% absorption of a 1-µg dose. If excretion is found to be diminished, the test is repeated 1 week later. The subsequent test, however, provides purified IF with the orally administered B_{12}. Improved absorption after administration of IF implies a deficiency of IF, whereas continued poor absorption signifies intestinal malfunction. Unfortunately, the Schilling test has two common pitfalls: inadequate urine collections and underlying renal dysfunction.

Antiparietal cell and anti-IF antibodies have been previously described and may be used as additional tests to help substantiate the diagnosis of PA.

Folic Acid

Metabolism

Folic acid, or pteroylglutamic acid, consists of three parts: pteridine, *p*-aminobenzoic acid, and glutamic acid. It serves as the parent for a large family of compounds having similar nutritional value to which the generic term folate is applied. Folates are widely distributed in a variety of foods, being synthesized by higher plants and microorganisms. Green leafy vegetables, fruits, and dairy products provide the greatest sources of folate in the usual Western diet. Unfortunately, folates are thermolabile, so a large portion of dietary folates may be lost in food preparation, particularly in boiling. A normal balanced diet, however, has no difficulty in meeting the recommended daily allowance for adults of 200 to 400 µg. In sharp contrast to vitamin B_{12}, the body's stores of folate are limited. After cessation of dietary intake, a decline in blood folate levels can be detected within a few weeks, and megaloblastic anemia may ensue in 3 to 5 months.

Most food folates are in the form of reduced methyl or formyl derivatives; approximately 90% are polyglutamates. Absorption occurs predominantly in the upper small intestine. When ingested in the monoglutamate form, folate is readily absorbed. The more prevalent polyglutamates, however, must first be converted to the monoglutamate form through the action of deconjugating enzymes found in the brush borders of intestinal epithelial cells as well as within intracellular lysosomes.

After assimilation by the intestinal epithelial cell, folate is converted to N^5-methyl TH_4, in part through the action of dihydrofolate reductase; it is in this form that folate is found in circulation. Cellular incorporation occurs as N^5-methyl TH_4 relinquishes its methyl group to homocysteine, forming methionine and TH_4, a reaction requiring methylcobalamin as a coenzyme (Fig. 41.8). Intracellular TH_4 may then proceed as a precursor to DNA synthesis or may be converted to an intracellular polyglutamate storage form through the action of an adenosine 5′-triphosphate (ATP)–dependent synthetase. The storage form may undergo later deconjugation ultimately to yield TH_4 at critical times in DNA synthesis. This interconversion of the mono- and polyglutamate forms appears to play a role in the regulation of DNA synthesis.

Folate Deficiency

Folate deficiency may arise from inadequate intake, impaired absorption, increased requirements, or defective folate metabolism. The most frequent cause of folate deficiency is a folate-poor diet. With limited folate reserves, the effects of an unbalanced diet are soon felt by chronic alcoholics, the impoverished, and the “tea and toast” elderly. Diets associated with the development of folate deficiency are characterized by a predominance of starches and grains with relatively little animal protein or fresh green vegetables. Megaloblastic anemia arising from folate deficiency in the setting of general malnutrition may also be complicated by diminished reserves of other hematinic agents.

Intestinal malabsorption is also a common cause of folate deficiency. Although folate absorption occurs principally in the proximal small intestine, receptor sites are found throughout the small bowel. Consequently, for megaloblastic anemia to occur secondary to impaired folate absorption, diffuse small intestinal disease is generally required. Tropical sprue and adult celiac disease (nontropical sprue or gluten-sensitive enteropathy) both bring about such a state of generalized malabsorption, resulting in a deficiency of a variety of nutrients, including folate. Widespread involvement of the small bowel by Crohn's disease may also result in folate deficiency.

Increased folate requirements are seen in several physiologic and pathologic conditions exhibiting an overall increase in cell proliferation and DNA synthesis. Folate deficiency typically occurs during the last trimester of pregnancy, when folate requirements increase approximately fivefold. After delivery, lactation brings further demands for additional folate. Infancy is marked by the greatest rate of growth, and hence increased folate intake is required. Pathologic hyperproliferative states also require additional folates and include a variety of chronic hemolytic anemias: sickle cell anemia, hereditary spherocytosis, thalassemia, and chronic autoimmune hemolytic anemias. This is not surprising if one considers that normal hematopoiesis is responsible for approximately half of total DNA synthesis. Rapidly dividing tumors such as leukemias, high-grade lymphomas, and small cell carcinoma may also usurp the body's folate supply.

Impaired folate metabolism is the desired effect of certain drugs. Chemotherapeutic agents such as methotrexate and aminopterin interfere with the conversion of folate to tetrahydrofolate. Consequently, administration of these agents causes megaloblastic changes in the marrow. More commonly prescribed, but much less frequently the cause of severe megaloblastic changes, are such antifolates as trimethoprim and triamterene. The induction of megaloblastic changes as a side effect of drug therapy is, however, not limited to the antifolates. Several other chemotherapeutic agents that interfere with DNA synthesis (antimetabolites, alkylating agents) are also known to induce similar changes (Table 41.7).

TABLE 41.7. DRUG-INDUCED SUPPRESSION OF DNA SYNTHESIS

Folate antagonists
Methotrexate
Aminopterin
Trimethoprin
Pyrimethamine
Triamterene
Antimetabolites
5-Fluorouracil
Hydroxyurea
Cytosine arabinoside
Alkylating agents
Cyclophosphamide
Nitrogen mustard
Chlorambucil
Busulfan
Melphalan
Nitrous oxide

Aside from these drug-induced defects in folate utilization, inborn errors of folate metabolism have been reported. These include dihydrofolate reductase deficiency and formiminotransferase deficiency, as well as congenital defects of folate absorption.

Laboratory Evaluation of Folic Acid Deficiency

Both microbiological and radioisotopic assays are available for the quantitation of serum folate. Serum levels of folate are, however, quite labile and sensitive to short-term variation in vitamin intake. Quantitation of red cell folate provides a better long-term measure of true tissue folate levels because folate metabolism

ceases in the developing red cell after nuclear extrusion. Thereafter, folate levels remain stable throughout the life span of the erythrocyte. Changes in red cell folate come about over time as red cells are released from a marrow environment of differing folate concentrations. Megaloblastic anemia caused by folate deficiency typically exhibits serum folate concentrations less than 3 ng/mL and red cell folate concentrations less than 100 ng/mL.

The following cautions must be exercised in interpreting the results of serum or red cell folate concentrations. Because serum folates are greatly influenced by short-term dietary variation, quantitation should be obtained before ingestion of a balanced hospital diet replete with folate. Similarly, red cell folate may be affected by the administration of transfusions, and assays should therefore be performed on samples obtained before the administration of red cell products. Finally, because B_{12} is a requisite cofactor for the uptake and utilization of folate by the cell, in its absence, folate is trapped in the serum. Therefore, in vitamin B_{12} deficiency, serum folate may be elevated and red cell folate decreased.

Clinical Features of Megaloblastic Anemia

Vitamin B_{12} deficiency is most frequently insidious in onset, likely reflecting the prolonged period of time required to deplete the body's B_{12} stores. Given our capacity to compensate over time, it is not surprising that patients often present with few signs or symptoms despite a frequently marked degree of anemia. Classically, patients with PA have been described as pale, but not wasted, with lemon-yellow skin reflecting a combination of anemia and mild hyperbilirubinemia. Blue eyes, a broad face and chest, and blond or prematurely gray hair complete the stereotype. Some of these features may reflect the Northern European ancestry of many patients with PA. It is important to remember, however, that no race or gender is immune from this disorder; consequently, many of these features may not be present.

A diagnostic triad of weakness, sore tongue, and paresthesias is cited as the classic symptom complex of vitamin B_{12} deficiency. Indeed, weakness reflects anemia. Glossitis, present in approximately half of patients, is the most visible indicator of generalized epithelial atrophy. Particularly vulnerable is the gastrointestinal tract, where rapid turnover of epithelial cells is a normal event. Gastric atrophy, occurring either as the *sine qua non* of PA or as a secondary complication of other forms of B_{12} deficiency, coupled with villous atrophy of the small bowel, may lead to symptoms of heartburn, bloating, loss of appetite, or diarrhea. Paresthesias are among many neurologic manifestations complicating B_{12} deficiency. Neurologic changes chiefly affect the white matter of the posterior and lateral columns of the spinal cord, leading to symmetrical numbness and tingling of the hands and feet, diminished vibratory or position sense, progressive weakness, and an unsteady or ataxic gait. The terms *subacute combined degeneration* or *combined system disease* are employed to encompass these abnormalities of multinerve pathways. The severity and rate of progression of the neurologic changes do not always correlate with the degree of anemia or other findings of B_{12} deficiency. Consequently, familiarity with this complication of vitamin B_{12} deficiency is mandatory if it is to be recognized and arrested before serious irreversible neurologic changes occur.

The manifestations of folic acid deficiency are often tainted by the myriad of health problems associated with chronic alcoholism and poverty. In fact, associated health problems may be the initiating reasons for seeking medical attention. Hematologic manifestations are similar to those found in megaloblastic anemia attributable to vitamin B_{12} deficiency. The neurologic changes typical of B_{12} deficiency, however, are absent.

Peripheral Blood and Bone Marrow Findings

The peripheral blood and bone marrow findings in folic acid and vitamin B_{12} deficiency are indistinguishable. Recognizing that DNA synthesis is critical to all developing cell lines, it follows that patients with full-blown megaloblastic anemia typically present with pancytopenia. Red cell indices classically reveal macrocytosis; a MCV greater than 120 fl is common. The MCH is elevated, whereas the MCHC is normal. The reticulocyte count is normal or decreased, reflecting the inability of the bone marrow to produce red cells. Unfortunately, however, not all patients present with pancytopenia and macrocytosis. Although anemia is a fairly universal finding, the presence and degree of leukopenia and thrombocytopenia are variable. Superimposed infection may lead to an elevated white blood count at presentation. Likewise, the MCV may appear normal with coexisting iron deficiency or a silent thalassemia trait.

Examination of the peripheral blood smear reveals a number of important clues to the diagnosis (Fig. 41.10). Macroovalocytes and hypersegmented neutrophils are invariably present. Anisopoikilocytosis of moderate to marked degree is present including ovalocytes, teardrop forms, schistocytes, and spherocytes. Basophilic stippling and Howell-Jolly bodies may be seen; two or more Howell-Jolly bodies may be found per cell, unlike in postsplenectomy states. With severe anemia, nucleated red blood cells may be present that exhibit characteristic megaloblastic nuclear changes.

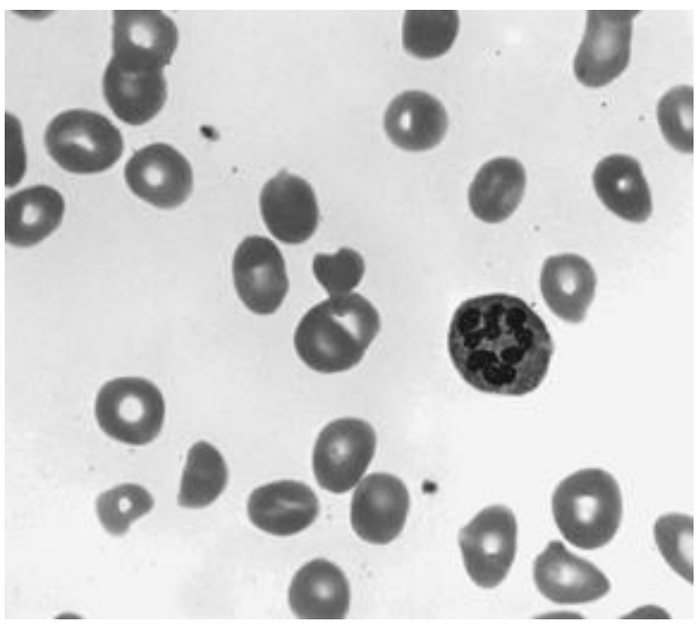

FIGURE 41.10. Megaloblastic anemia is characterized by hypersegmented neutrophils and the presence of well-hemoglobinized macrocytes and macroovalocytes.

Bone marrow aspirate smears reveal an intensely cellular marrow with increased numbers of erythroblasts (Fig. 41.11). Nuclear cytoplasmic dyssynchrony may be found in all myeloid cell lines. The changes in the red cell series, however, often appear

most striking. Changes are most evident in the later stages of erythroid maturation, when cellular enlargement and open fenestrated or sievelike nuclear chromatin contrasts sharply with the smaller size and shrunken, condensed nucleus of the late polychromatophilic and orthochromatic normoblasts. Intramedullary destruction is morphologically manifested as nuclear karyorrhexis or fragmentation. Bizarre nuclear budding or lobulation may also be seen. Although megaloblastic changes in developing neutrophils tend to be overshadowed by those of the erythroid series, they offer important clues to both early and partially treated megaloblastic anemia. Giant bands and metamyelocytes are frequent; as the name implies, these cells are large and often exhibit an increased nuclear:cytoplasmic ratio. Nuclear chromatin appears less mature than anticipated for the stage of maturation indicated by nuclear shape. Premature nuclear segmentation is also common as these giant bands exhibit nuclear folding and twisting as if to form segments of a mature neutrophil. Such changes appear before those of the erythroid series and persist even after normoblastic erythroid maturation returns after therapeutic intervention. Abnormalities may also be seen in the megakaryocytes. These include complex hypersegmentation and a similar open or fenestrated nuclear chromatin pattern.

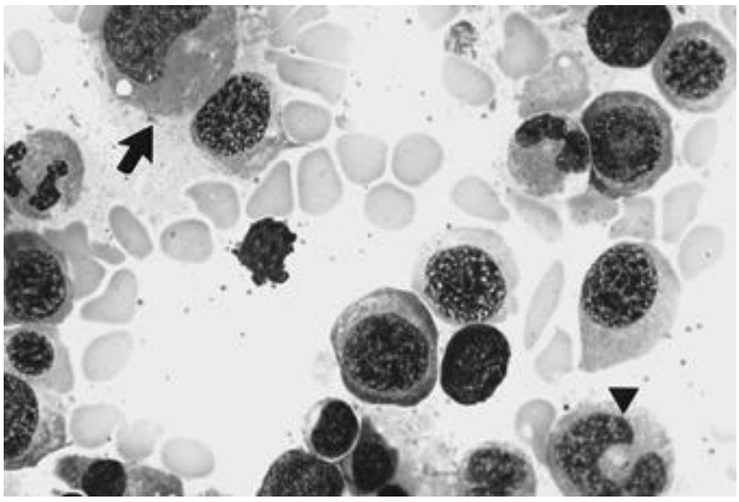

FIGURE 41.11. Bone marrow aspirate smear in megaloblastic anemia demonstrates numerous large erythroblasts having a fenestrated nuclear chromatin. The nuclear appearance has been likened to that of a piece of salami. Nuclear changes are also evident in the developing neutrophils: giant metamyelocytes (*arrow*) and giant bands (*arrowhead*).

Perhaps no other disorder better exemplifies the hazards of interpreting bone marrow trephine biopsies without the benefit of aspirate smears than does megaloblastic anemia. The trephine biopsy is virtually always hypercellular, in many cases approaching 100%. The lag in nuclear maturation results in an accumulation of erythroblasts in the early to middle stages of maturation. This, coupled with the immature appearance of the nuclear chromatin, imparts the picture of a marrow overrun with primitive hematopoietic cells. The temptation to regard this picture as one of acute leukemia can be overcome by careful examination, which demonstrates the presence of all three cell lines, evidence of cellular maturation, and characteristic giant bands.

Abnormal maturation leads to intramedullary destruction of all cell lines, resulting in the paradox of ineffective hematopoiesis: pancytopenia in the presence of a hypercellular bone marrow. Intramedullary red cell destruction results in mild hyperbilirubinemia, increased LDH, and increased serum iron. Red cells are rich in LDH_1 and LDH_2; LDH_1 predominates in immature red cells, which may result in a “flip” of the normal LDH_1:LDH_2 ratio. Iron is liberated during the catabolism of red cells at a rate greater than it can be utilized. Consequently, serum iron increases, transferrin saturation increases whereas synthesis decreases, and iron stores become replete. Marrow sideroblasts may increase in number, and types II and III (ringed) sideroblasts may be found.

Differential Diagnosis

The combined findings of pancytopenia, macrocytosis, and hypersegmented neutrophils are virtually diagnostic of megaloblastic anemia. Individually, however, these findings are not specific, each being associated with a host of disorders largely unrelated to B_{12} or folic acid metabolism. Pancytopenia generally implies diminished marrow precursors, ineffective hematopoiesis, or hypersplenism. Macrocytosis may occur in chronic liver disease, hypothyroidism, pregnancy, normal neonates, marrow failure, chronic hemolytic states with elevated reticulocyte counts, myelodysplastic syndromes, and after administration of a variety of cytotoxic drugs. Hypersegmented neutrophils, although uncommon outside of megaloblastic anemia, may be seen as a congenital anomaly and in iron deficiency, sepsis, renal disease, and chronic myeloproliferative disorders.

Megaloblastic changes in one or more cell lines of the bone marrow are frequently seen after the administration of a variety of chemotherapeutic agents. Most often these changes affect the developing neutrophils to the greatest degree and pose no diagnostic dilemma given the patient's history. Megaloblasts may be seen as one of many changes in the myelodysplastic syndromes or in erythroleukemia. The clinical history, the absence of B_{12} or folic acid deficiency, and the presence of dysgranulopoiesis, dysmegakaryopoiesis, and/or increased numbers of myeloblasts will all help separate these neoplastic conditions from megaloblastic

anemia. Several inborn errors may also lead to megaloblastic changes or frank megaloblastic anemia, including congenital dyserythropoietic anemia, hereditary orotic aciduria, and Lesch-Nyhan syndrome.

Management

Therapy for megaloblastic anemia is aimed both at replenishing the body's stores of vitamin B_{12} or folic acid and at documenting and correcting the underlying cause. Parenteral administration of B_{12}, typically on a monthly basis, is required therapy for PA and malabsorption states, which are not amenable to medical intervention. Folic acid deficiency, most often dietary in nature, is amenable to oral administration of folic acid. Folic acid preparations for parenteral administration are available if required.

Improvement in the patient's hematologic status is initially evident within 3 to 5 days by an increase in the reticulocyte count, which typically reaches a maximum at 10 days. A prompt decrease in serum iron is noted as effective red cell production begins. Amelioration of megaloblastic changes in the red cell series is largely complete within 24 to 48 hours, whereas changes in the neutrophil line persist in the peripheral blood and bone marrow for as long as 10 days. Within 1 to 2 months, all peripheral blood parameters should return to normal.

Neurologic deficits are arrested after the institution of appropriate therapy. Regression is, however, not always complete. Mild deficits of short duration are more apt to resolve than are chronic or severe impairments. It is important to diagnose the cause accurately and to administer the correct hematinic agents appropriately in patients with megaloblastic anemia. This is underscored by the progression of neurologic changes that occurs in B_{12} deficiency inappropriately treated with folic acid despite partial hematologic correction.

Bone Marrow Failure: Inadequate Erythroid Precursors

Included in this section are the anemias that result from an inadequate number of erythroid precursors occurring either as a selective phenomenon or, more frequently, as part of the trilineage suppression that results from a reduction in pluripotent hematopoietic stem cells.

Aplastic Anemia

Aplastic or hypoplastic anemia is typically an acquired defect in pluripotent stem cells, although defects in growth factors, immunoregulatory signals, or the marrow microenvironment have also been proposed as possible mechanisms. Regardless of the etiology, the net effect is a reduction in erythroid, granulocytic/ monocytic, and megakaryocytic cell lines in the bone marrow and their progeny in the peripheral blood. The incidence of aplastic anemia varies worldwide; in the Western nations, five to 10 new cases per million general population are estimated to occur annually. Cases are approximately equally divided into idiopathic and secondary forms, the latter composed largely of chemical or drug injury, radiation exposure, or infection-associated aplasia.

Etiology

Before labeling aplastic anemia as idiopathic, careful exclusion of known etiologic factors must be undertaken. This is particularly true in cases occurring in childhood, adolescence, or early adulthood, when a putative cause is found more frequently than in adulthood.

Drug-Related Injury. Chemical- or drug-related injury to the marrow may arise either as a dose-dependent or an idiosyncratic phenomenon. Marrow ablation is the desired dose-dependent effect of many chemotherapeutic agents. Similar dose-dependent marrow aplasia is encountered as an untoward side effect of exposure to chemicals such as benzene, its derivative trinitrotoluene, arsenic, or alcohol. Hematopoietic suppression associated with heavy alcohol intake is typically self-limited and reversible after cessation of drinking, unlike that found with benzene, trinitrotoluene, and arsenic, which often progress to fatal aplasia. Chronic benzene and arsenic exposure are both associated with the development of dysplasia, largely marked by bizarre megaloblastic changes of the erythroid series. In the case of benzene exposure, such dysplastic changes may progress and evolve to acute myelogenous leukemia (AML); not unexpectedly, the frequency of erythroleukemia is increased compared with that found in *de novo* AML.

Chloramphenicol is perhaps the most widely publicized example of an idiosyncratic drug reaction leading to marrow aplasia. This adverse side effect cannot be related to drug dose or route of administration. Likewise, its occurrence and the rapidity of onset cannot be predicted. This mainly fatal complication has no association with the mild, reversible, dose-dependent erythroid suppression known to occur in approximately half of individuals exposed to large doses of chloramphenicol. Similar idiosyncratic reactions are encountered with quinacrine, phenylbutazone, carbonic anhydrase inhibitors, gold, and a variety of anticonvulsants, including phenytoin, mephenytoin, trimethadione, methsuximide, and carbamazepine. The effect of these agents on the three hematopoietic cell lines is not always uniform, and in some cases selectively results in red cell aplasia, agranulocytosis, or thrombocytopenic purpura.

Ionizing Radiation. The hematopoietic system, like all body cells, is susceptible to damage by ionizing radiation. The untoward effects of radiation are dependent on the nature and quantity of radiant energy, the duration of exposure, and the mitotic rate of the exposed cell population. It is the high mitotic activity of the bone marrow that makes it one of the most vulnerable organ systems to the toxic effect of radiation. Aplastic anemia may ensue after a single exposure to large but sublethal doses of radiation, as well as repeated or long-term exposure to moderate doses.

Infection. Several viruses have been associated with myelosuppression. Most notable is the rare, unexplained, and often fatal aplasia that occurs in association with hepatitis. This unpredictable sequela is most frequently associated with non-A and non-B hepatitis and exhibits no relationship to the severity of liver disease. The time to onset is variable, with most cases becoming manifest approximately 6 weeks after clinically evident

hepatic disease. Human parvovirus (serotype B19) is now recognized as a cause of aplastic anemia. This virus, as well as several others, is responsible for myelosuppression, most frequently manifesting in individuals with an underlying chronic hemolytic anemia. Although granulocytes and platelets may be reduced, a profound exacerbation of the chronic anemia is the major cause of morbidity in these cases. Because of the shortened erythrocyte survival inherent in the underlying hemolytic state, affected individuals are exquisitely sensitive to the abrupt cessation of erythropoiesis caused by the selective cytotoxic invasion of erythroblasts by the parvovirus. Such temporary erythroblastopenia is typically preceded by or associated with an upper respiratory or flulike illness. Although short-term transfusional support may be necessary, these aplastic crises are generally self-limited.

Idiopathic. Aside from the direct toxic effect of various drugs, chemicals, and radiant energy, the pathogenesis of aplastic anemia is not fully understood. Evidence supporting an immunologic mechanism has emerged from a number of observations linking aplasia with disorders of immunoregulation. Support for this concept has been found *in vitro* through alterations in marrow lymphoid populations and *in vivo* by the success in certain individuals of antilymphocyte or antithymocyte globulin as a therapeutic modality.

Clinical Features

The onset of aplastic anemia is variable, in part dependent on etiologic factors. Signs and symptoms of generalized bone marrow failure are evident: pallor, weakness, fatigue, and dyspnea on exertion are associated with anemia; infections and fever are associated with granulocytopenia; and petechiae, ecchymoses, or overt hemorrhage may be associated with thrombocytopenia.

Peripheral Blood and Bone Marrow Findings

Pancytopenia is the rule in the peripheral blood; however, the decrease in erythrocytes, leukocytes, and platelets is often not proportional. In part, this may be related to the susceptibility of the marrow cell lines to the injurious agent. Erythrocytes are usually normochromic and normocytic with little variation in size and shape, although mild macrocytosis may be evident in some cases. Neutrophils are significantly decreased, and lymphocytes predominate on examination of the peripheral smear. Dysplastic features are not common in any cell line unless there has been exposure to toxins such as benzene or arsenic.

The bone marrow trephine biopsy shows a marked reduction in cellularity, largely replaced by fat. Foci of increased cellularity may be found scattered throughout the marrow, most often dominated by erythroblasts. Such hot spots of hematopoiesis may be misleading when aspirated or when only a small core of tissue is available for examination. This underscores the need for a generous sample of tissue in cases of suspected marrow aplasia.

Aspirate smears typically reflect the marked diminution in hematopoietic elements. Lymphocytes and plasma cells predominate; increased numbers of mast cells and histiocytes, the latter often laden with iron or particulate debris, are also frequently seen. Mild cytoatypia may be seen when foci of hematopoiesis are aspirated; however, this is never a striking feature unless exposure to toxins has occurred.

Treatment

The clinical course of patients with aplastic anemia depends on the etiology, the severity of the pancytopenia, the age of the patient, and the response to therapy. In some instances, marrow recovery may ensue after discontinuation of drugs known to act as marrow suppressants. Similarly, removal from the source of a known environmental toxin may initiate marrow recovery. Transient episodes of myelosuppression are amenable to short-term transfusional support. All too often, however, marrow aplasia is severe and irreversible, requiring long-term medical intervention.

Therapy with a number of drugs has met with varying success. Corticosteroids, androgens, lithium carbonate, antithymocyte globulin, and cyclophosphamide have been utilized as marrow stimulants or as immunosuppressive agents aimed at reversing putative immune-mediated aplasia. Repeated transfusions can obviously provide needed red cells and platelets but do little to offset granulocytopenia. Multiple transfusions are, however, complicated by the associated morbidity of iron overload and the risk of posttransfusion infectious complications. Additionally, in young patients with HLA-matched bone marrow donors, repeated transfusions have an adverse effect on bone marrow transplantation, the treatment of choice for this group of patients.

Pure Red Cell Aplasia

As the name implies, pure red cell aplasia is characterized by anemia secondary to a marked reduction in the number of red cell precursors in the marrow. Granulocytes and megakaryocytes are unaffected. To some degree, the aplastic crises known to complicate various chronic hemolytic states can be viewed as an acute form of pure red cell aplasia. Similarly, young children may experience a transient arrest of erythropoiesis after a viral illness (transient erythroblastopenia of childhood). Idiosyncratic drug reactions may also selectively involve the red cell series.

Many cases of pure red cell aplasia are associated with a thymoma; in conjunction, some patients also exhibit myasthenia gravis. Thymectomy will restore normal hematopoiesis in a subset of these patients. Similar to aplastic anemia, an immunologic mechanism has been proposed as a pathogenetic factor in pure red cell aplasia. Accordingly, therapy has included immunosuppressive agents as well as transfusional support.

Constitutional and Hereditary Disorders Associated with Aplastic Anemia

Several hereditary or constitutional syndromes are associated with aplastic anemia or the variant pure red cell aplasia. Manifestations are apparent in childhood and consist of hematologic abnormalities as well as a variety of other anomalies, including skeletal malformations, pigmentary changes of the skin, retarded mental and sexual development, and renal abnormalities.

Fanconi's anemia is inherited as an autosomal recessive disorder. Patients exhibit progressive pancytopenia and marrow aplasia during the first decade of life. Associated findings include increased levels of fetal hemoglobin and expression of i-antigen, reflecting reversion to fetal hematopoiesis. Like ataxia telangiectasia

and xeroderma pigmentosum, Fanconi's anemia is a disorder of defective DNA repair. Cytogenetic analysis reveals evidence of chromosome instability including chromosomal breaks and sister chromatid exchange. Not surprising, therefore, is termination in AML in approximately 10% of cases of Fanconi's anemia.

Diamond-Blackfan anemia predominantly affects the red cell line and may therefore be viewed as a constitutional form of pure red cell aplasia. Anemia is often present at birth and invariably develops within the first 2 years of life. Macrocytosis is common. The marrow shows features common to pure red cell aplasia. Like Fanconi's anemia, fetal hemoglobin and i-antigen expression are increased. Transfusional support is the mainstay of therapy, and a significant number of patients demonstrate improvement in their hematologic status with glucocorticoid therapy. Spontaneous remission has been reported in as many as 20% of cases.

Congenital Dyserythropoietic Anemias

The congenital dyserythropoietic anemias (CDAs) are a group of inherited disorders characterized by ineffective erythropoiesis, morphologic abnormalities involving the erythroid lineage, and mild to moderate anemia. Three main types of CDA have been described, as well as a number of variants. Classification of CDAs is mainly based on the morphologic findings in the bone marrow in conjunction with serologic studies.

Clinical findings include variable anemia, ranging from mild with no symptoms to severe requiring transfusion. Most commonly, however, the anemia is mild to moderate with hemoglobin concentrations between 8 and 11 g/dL. Red blood cells usually are normocytic or macrocytic and may show anisopoikilocytosis and punctate basophilic stippling; the stippling may be pronounced in some cases and serve as the first clue to an underlying CDA. Reticulocytes are usually normal or slightly increased. The red blood cell half-life is decreased to a variable extent in these disorders. The bone marrow shows marked erythroid hyperplasia, inversed myeloid to erythroid ratio, and variable degrees of multinuclearity in the red blood cell precursors. Intramedullary hemolysis occurs due to ineffective erythropoiesis. Myeloid and megakaryocytic lineages are generally unremarkable, although a few cases describing morphologic abnormalities involving these lineages have been reported. Specific chromosomal findings linked to CDAs were recently reported; analysis of erythroid precursors usually shows a hyperdiploid population indicating ineffective cell division that leads to an increased complement of chromosomes.

Hyperabsorption of iron from the gastrointestinal system, as well as frequent transfusion support, frequently leads to secondary hemochromatosis. Transferrin saturation, serum ferritin levels, and stainable iron in the bone marrow are usually increased, but there are no ringed sideroblasts. The intramedullary hemolysis results in elevation of serum LDH, slight hyperbilirubinemia, and suppression of serum haptoglobin, most consistently in CDA II.

In routine clinical practice, the ineffective erythropoiesis is reflected by a suboptimal reticulocyte response for the degree of anemia in the presence of bone marrow erythroid hyperplasia. The diagnosis of CDA is usually made after the exclusion of other causes of congenital and acquired dyserythropoiesis. The prevalence of these disorders may be more common than appreciated because asymptomatic cases with little or no anemia may be missed.

Although ineffective erythropoiesis is generally associated with morphologic evidence of dyserythropoiesis, these findings are not always morphologically apparent. Hence, the diagnosis may rest on clinical suspicion in conjunction with physical findings and additional laboratory studies as discussed below.

Based on morphologic and serologic criteria, CDAs are subgrouped into three types: I, II, and III. CDA I is an autosomal recessive disorder presenting with splenomegaly and mild to moderate macrocytic anemia. The electron microscopic examination of CDA I shows degenerative changes in the nucleus of the erythroid cells; characteristic morphologic features include uneven condensation of chromatin, leading to a spongy nuclear configuration, and interchromatin bridges between nuclei of two separate erythroblasts.

CDA II, the most common of the three CDAs, is inherited as an autosomal recessive disorder. CDA II is distinct from the other types because acidified normal sera (from some, but not all, normal people) lyse CDA II red blood cells. Immunoglobulin (Ig) M antibodies against abnormal cell surface components on CDA II red blood cells mediate this process. Therefore, CDA II is also commonly known as hereditary erythroblastic multinuclearity with a positive acidified serum test. In contrast to patients with paroxysmal nocturnal hemoglobinuria, CDA II red cells are not lysed by the patient's own acidified serum or by isotonic sucrose. An additional feature of CDA II is that these red cells show enhanced agglutination and lysis to anti-i and anti-I.

Splenomegaly and jaundice are usually found in the majority of CDA II patients. Several other diseases have been associated with CDA II, including Sweet's disease, von Willebrand's disease, and Dubin-Johnson syndrome. However, it appears that these are most likely coincidental occurrences rather than true associations. Bone marrow examination shows a variable degree of polychromatophilic and orthochromatic erythroblasts and binuclear or multinucleated erythroid cells. Karyorrhexis is commonly seen.

CDA III is a very rare form of CDA and is also known as familial erythroid multinuclearity and hereditary benign erythroreticulosis. This disorder is inherited as an autosomal dominant trait; although some sporadic cases have been reported, these cases more likely represent spontaneous dominant mutations. Bone marrow examination reveals markedly dysplastic erythroid cells showing giant erythroblasts with up to 12 nuclei, which is the most distinctive finding in CDA III. The most important features differentiating CDA III from CDA I are the presence of splenomegaly and milder erythroid abnormalities in CDA I. In contrast to CDA II, acidified serum lysis test is negative and agglutination and lysis of erythrocytes to anti-i and anti-I are variable.

The defect in CDAs is believed to be intrinsic to all erythroid precursors rather than a subpopulation of cells. Previous studies showed that the abnormality underlying CDA II involves aberration in membrane proteins and lipid composition. Glycoproteins on CDA II erythrocytes show abnormal carbohydrate

structures, leading to the abnormal reactivity with anti-i and anti-I sera. Based on studies of carbohydrate structure, abnormalities in the glycosylation pathway are most likely involved in the etiology of CDA II.

As mentioned above, the diagnosis of CDA requires exclusion of other causes of anemias. Red blood cell folate and serum vitamin B_{12} levels should be used to exclude megaloblastic anemia attributable to these deficiencies. Morphologic abnormalities involving the granulocytic or megakaryocytic lineages, or the presence of ringed sideroblasts, suggest a myelodysplastic syndrome. In such cases, cytogenetic studies may help to establish a precise diagnosis. Hemoglobin electrophoresis may be useful to investigate congenital anemia related to a hemoglobinopathy. Hereditary spherocytosis or other membrane or enzyme disorders may also need to be excluded by specific tests such as osmotic fragility test, membrane protein analysis assays, and enzyme analysis.

Myelophthisic Anemias

Encompassed under the term myelophthisic anemia are the peripheral cytopenias that arise as the result of bone marrow replacement by a variety of disorders. Although most frequently encountered in conjunction with malignant neoplasms metastasizing to or arising within the bone marrow cavity, nonneoplastic disorders may similarly result in marrow replacement. Examples of the former include metastatic carcinoma, leukemia, Hodgkin's and non-Hodgkin's lymphomas, and multiple myeloma. Marrow replacement occurring in the setting of nonneoplastic disease is typically the result of histiocytic proliferation seen either with disseminated granulomatous inflammation such as tuberculosis or in association with a variety of storage disorders.

Marrow infiltration results in varying degrees of anemia, leukopenia, and thrombocytopenia, which may occur singly or in combination. In addition, immature neutrophils and erythroblasts are often present in the circulation, a finding referred to as a leukoerythroblastic reaction. It is easy to conceptualize the reduction in peripheral counts as a crowding-out phenomenon, i.e., normal hematopoietic tissue being replaced by foreign elements. In a similar fashion, immature white and red cells may be squeezed out of the marrow by advancing tumor. It is likely, however, that other mechanisms also come into play, such as an altered and inhospitable marrow microenvironment leading to impaired development, destruction, or premature release of immature hematopoietic elements.

Other changes may also be encountered in the peripheral blood. Reticulocytes are often increased disproportionally to the degree of anemia. This finding may reflect premature release from the marrow. Teardrop-shaped erythrocytes may also be found. Although this shape change has been linked to the aforementioned infiltrative marrow disorders, it is typically a more striking finding in idiopathic myelofibrosis.

Both the diagnosis and etiology of a myelophthisic process rely on bone marrow examination. In many circumstances, the disease process does not diffusely involve the bone marrow. Chances of detection, therefore, are increased by bilateral bone marrow biopsies. Biopsies directed at sites of clinical or radiographically evident disease may also provide an increased yield. Often the aspirate smears may be unrewarding, as many focal lesions are associated with reticulin deposition and are therefore poorly aspirable. Necrosis, when encountered in the aspirate or trephine biopsy, is suggestive of marrow infiltration requiring further investigation.

Accelerated Erythrocyte Destruction

Normal Erythroid Senescence

It is well established that the average natural life span of the human erythrocyte is 120 days. The exact mechanism or terminal events that allow these senescent cells to be recognized and removed from circulation is, however, not well understood. Erythrocytes undergo a number of age-related changes, including diminished intracellular concentrations of glycolytic enzymes, water, and solutes; altered membrane composition; and reduced surface area and volume. These factors undoubtedly have detrimental effects on deformability and functions vital to cellular integrity. However, where and how red blood cells are actually removed from circulation are elusive, as observations to date have elucidated neither the progressive morphologic signs of aging nor the sites where active red cells are lost from circulation each second.

Hemoglobin Catabolism

Senescent red cells liberate hemoglobin, the most of which are catabolized within the reticuloendothelial system of the liver, spleen, and bone marrow. A small amount of hemoglobin, however, is released to circulation where, after dissociation to a-P dimer form, it is bound by haptoglobin, an α_2-glycoprotein synthesized by the liver. The haptoglobin-hemoglobin complex is rapidly cleared by the liver, where catabolism of both hemoglobin and haptoglobin occurs.

Human nature is to conserve, and red cell catabolism is no exception. Within the reticuloendothelial system, hemoglobin is dissociated into its three main building blocks: globin, iron, and protoporphyrin. Globin chains are rapidly degraded with return of their constituent amino acids to the plasma for future protein synthesis, iron is conserved to begin its role again in hemoglobin synthesis, and protoporphyrin is degraded.

The protoporphyrin ring is initially cleaved by heme oxygenase, yielding biliverdin and carbon monoxide. This reaction provides the only source of endogenous carbon monoxide in the body. Biliverdin is reduced to bilirubin and bilirubin is then transported to the liver after solubilization by albumin, where the bilirubin-albumin complex (indirect bilirubin) is rapidly cleared by the liver (Fig. 41.12). Within the hepatocyte, bilirubin is conjugated and excreted in the bile mainly as bilirubin diglucuronide (direct bilirubin). Subsequent hydrolysis by bacterial enzymes present in the ileum and colon frees bilirubin, which is then reduced by anaerobic flora to a family of compounds collectively referred to as urobilinogens. Urobilinogens are largely excreted in the stool. Approximately 10% to 20% of urobilinogen is absorbed from the terminal ileum and redirected to the liver, where it is returned to the bile for excretion. A small amount of urobilinogen escapes this enterohepatic circulation and is excreted by the kidneys.

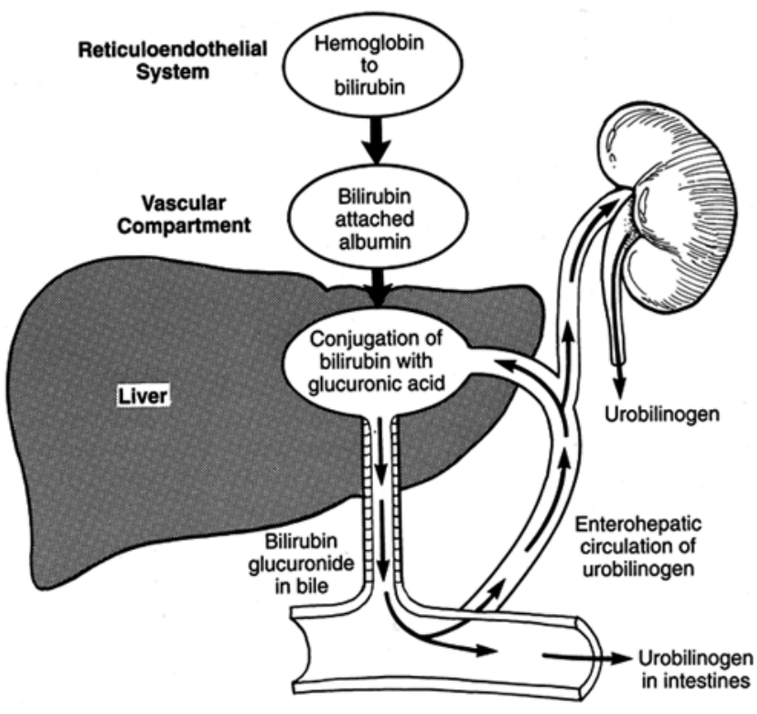

FIGURE 41.12. Hemoglobin liberated from senescent erythrocytes is catabolized in the reticuloendothelial system, and the protoporphyrin ring is converted to bilirubin, which is transported to the liver loosely bound to albumin. In the liver, bilirubin is conjugated and excreted in the bile as bilirubin diglucuronide. Enzymatic hydrolysis occurs in the intestine, with subsequent reduction to a family of compounds, the urobilinogens. Ten percent to 20% of the urobilinogen is reabsorbed and largely returned to the bile; a small amount of urobilinogen escapes the enterohepatic circulation and is excreted into the urine. Elevated levels of unconjugated hemoglobin and urinary urobilinogen are present in the hemolytic anemias. (From Petz LD, Garratty G. The diagnosis of hemolytic anemia. In: Petz LD, Garratty G, eds. *Acquired immune hemolytic anemias*. New York: Churchill-Livingstone, 1980:4, with permission.)

The hemolytic anemias are anemias resulting primarily from increased red cell destruction. By definition, many anemias secondarily associated with a slight reduction in red cell life span are excluded. Disorders associated with defective erythropoiesis leading to marked intramedullary red cell destruction are, by convention, also excluded. The hemolytic anemias are therefore the disorders in which premature extramedullary red cell destruction is the primary cause of the anemia.

Often the terms intravascular and extravascular are used to denote sites of red cell destruction. The term extravascular, however, is somewhat misleading because, in fact, the distinction is between lysis within the systemic circulation and destruction within the sinusoids of the reticuloendothelial system.

Laboratory Findings

Regardless of the mechanism or site of hemolysis, the hemolytic anemias share manifestations of increased red cell catabolism. Although increases in endogenous carbon monoxide production and fecal urobilinogen are measures of hemolysis, the most clinically useful laboratory parameter of increased red cell destruction is serum bilirubin. Elevated bilirubin levels, however, are nonspecific and may be found as a sign of hepatocellular or biliary disease. Elevated levels of indirect bilirubin are viewed as a better measure of hemolysis, provided that disorders of bilirubin conjugation are excluded.

Decreased levels of serum haptoglobin are also found in hemolysis. Although often suggested as an indicator of intravascular red cell destruction, diminished levels of haptoglobin are also found with extravascularly or reticuloendothelial-mediated red cell destruction. It is important to note that haptoglobin is an acute phase reactant; normal values may therefore be encountered in hemolytic disorders complicated by infectious or inflammatory states.

Once haptoglobin is depleted through hepatic degradation of the haptoglobin-hemoglobin complex, free hemoglobin emerges in the circulation (Fig. 41.13). Quantitation of plasma (or serum) free hemoglobin is possible but is fraught with the difficulty of obtaining a blood sample free of the effects of a traumatic venipuncture. In circulation, the free dimeric form of hemoglobin is readily filtered by the glomerulus and absorbed by the proximal convoluted tubules of the kidney. Here hemoglobin may undergo further degradation. Liberated iron is stored in the proximal tubular epithelial cells as ferritin and hemosiderin. When sloughed in the urine, ferritin containing tubular epithelial cells can be detected by using a Prussian blue stain. This measure of increased red cell destruction is most useful in chronic hemolytic states because of the lag phase that occurs between the onset of hemolysis and the detection of hemosiderinuria. The absorptive capacity of the proximal tubular cells for hemoglobin can be overcome, allowing free hemoglobin to pass into the urine. Hemoglobinuria, however, is not detectable until the absorptive capacity of both haptoglobin and the tubular epithelial cells is surpassed.

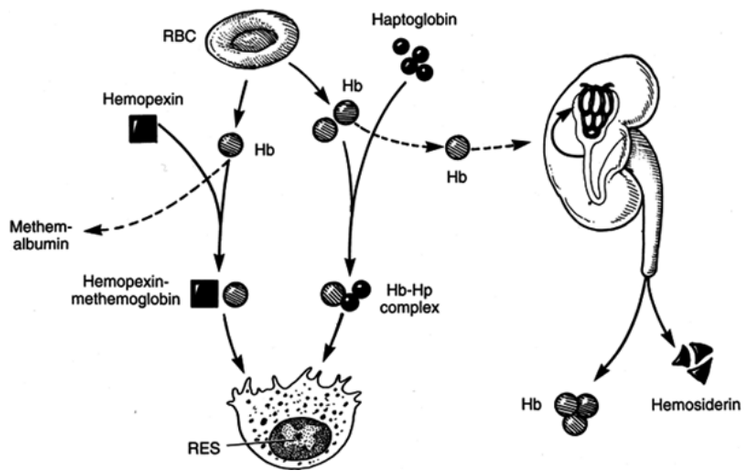

FIGURE 41.13. Intravascular destruction of erythrocytes liberates hemoglobin, which is bound in circulation by haptoglobin. The hemoglobin-haptoglobin complex is cleared by the liver; in the process haptoglobin is consumed. Depletion of haptoglobin results in free dimeric hemoglobin, which is readily filtered and partially excreted by the kidney. Partial reabsorption of hemoglobin occurs in the tubular epithelial cells. In chronic hemolysis, hemosiderin may be detected in the urine with turnover and sloughing of tubular epithelium. Free hemoglobin in the circulation is also oxidized to methemoglobin, which is bound by hemopexin and cleared by the liver analogous to the hemoglobin-haptoglobin complex. With depletion of hemopexin, methemoglobin is bound by albumin to form a methemalbumin. Intravascular hemolysis classically results in decreased haptoglobin, hemoglobinuria, decreased hemopexin, methemalbuminemia, and hemosiderinuria. (From Petz LD, Garratty G. The diagnosis of hemolytic anemia. In: *Acquired immune hemolytic anemias*. New York: Churchill-Livingstone, 1980:3, with permission.)

Plasma hemoglobin not bound to haptoglobin nor removed by the kidney is oxidized to methemoglobin. Subsequently, the oxidized heme moiety undergoes rapid dissociation and is then bound by hemopexin. This complex is cleared by the liver in a manner similar to the haptoglobin-mediated clearance of hemoglobin. After depletion of hemopexin, oxidized heme binds to albumin, forming methemalbumin. Both the depletion of hemopexin and the presence of methemalbumin are two additional

measures of hemolysis, although they offer little practical clinical utility.

Another intracellular constituent of erythrocytes that is readily measurable in the laboratory is LDH. Because LDH is not restricted to erythrocytes, serum elevations may be encountered in a variety of disorders. Isoenzyme fractionation is somewhat more specific, as fractions LDH_1 and LDH_2 predominate in erythrocytes.

In the vast majority of uncomplicated hemolytic anemias, increased red cell destruction provides a stimulus for erythropoiesis. Invariably then, evaluation of suspected hemolytic states should include not only measures of increased red cell destruction but also parameters of accelerated erythropoiesis. These changes are readily apparent in a peripheral blood smear as an increased number of polychromatophilic erythrocytes. A more objective measure is obtained with a reticulocyte count. Brisk reticulocytosis may elevate the mean corpuscular volume. Circulating erythroblasts may also be seen. Bone marrow examination typically reveals an erythroid hyperplasia, which in some cases may be quite striking, as the bone marrow is capable of increasing erythropoiesis six- to eightfold.

Pathophysiologic Classification

A pathophysiologic classification of disorders resulting in shortened red cell survival is presented in Table 41.8. Broad separation is based on the nature of the abnormality: is the defect intrinsic to the red cell, or do extrinsic forces result in hemolysis? With one exception, intrinsic disorders are inherited defects, whereas extrinsic disorders are acquired. Paroxysmal nocturnal hemoglobinuria, the exception, is an acquired intrinsic abnormality.

TABLE 41.8. CLASSIFICATION OF HEMOLYTIC DISORDERS

Inherited hemolytic disorders
Defects in the erythrocyte membrane
Hereditary elliptocytosis
Hereditary pyropoikilocytosis
Stomatocytosis
Abetalipoproteinemia (acanthocytosis)
Enzyme deficiencies of the pentose phosphate pathway
Glucose-6-phosphate dehydrogenase
Defects in globin structure and synthesis
Hemoglobinopathies
Thalassemias
Unstable hemoglobin disease
Enzyme deficiencies of the glycolytic pathway
Pyruvate kinase
Hexokinase
Glucose-phosphate isomerase
Phosphofructokinase
Aldolase
Other
Defects in nucleotide metabolism
Pyrimidine 5′nucleotidase
Acquired hemolytic disorders
Immune-mediated erythrocyte destruction
Transfusion of incompatible blood
Hemolytic disease of the newborn
Autoimmune
Infectious agents
Protozoans
Bacteria
Paroxysmal nocturnal hemoglobinuria
Traumatic erythrocyte destruction
Macrovascular
Microvascular
Chemicals/drugs/venoms
Physical agents

Intrinsic and Inherited Red Cell Abnormalities

Intrinsic erythrocyte abnormalities are commonly grouped as membrane, metabolic, or hemoglobin defects. In keeping with convention, therefore, a discussion of the hemoglobinopathies is not undertaken here, but may be found in Chapter 42.

As inherited defects, these disorders may present a number of clinical features not typically seen with acquired red cell abnormalities. In large part, this reflects the chronic nature of these disorders as well as their capacity to afflict newborns in severe cases. Persistent hyperbilirubinemia often leads to cholelithiasis, in turn complicated by cholecystitis. Hyperbilirubinemia in neonates may lead to the debilitating neurologic disorder kernicterus.

Chronic hemolytic disorders may be complicated by periods or crises of profound anemia. As previously described, individuals may experience an aplastic crisis. Somewhat of a misnomer, the term aplastic crisis refers to a transient, self-limited exacerbation of the underlying anemia resulting from a cessation of erythropoiesis

often seen in association with a recent viral illness. A hemolytic crisis may arise as a complication of a disorder causing splenic enlargement. A sudden increase in spleen size will exacerbate the underlying anemia because the spleen is often the site of red cell sequestration and destruction. A megaloblastic crisis may complicate chronic hemolysis as folate stores are depleted through the increased requirements of compensatory erythroid hyperplasia. Both aplastic and megaloblastic crises are characterized by reticulocytopenia. The abrupt onset and marked erythroid hypoplasia of an aplastic crisis, however, contrast with the slow development and megaloblastic appearance of folate deficiency.

Structural Membrane Defects

The shape and reversible deformability of the normal erythrocyte are properties determined by the membrane skeleton. Lying directly beneath the external lipid bilayer membrane is a complex network of proteins that provide structural support (Fig. 41.14). Spectrin is the major component of the red cell cytoskeleton and consists of two intercoiled, nonidentical filamentous subunits that form heterodimers. The chain heads of each dimer pair bind with opposite subunit heads of another dimer pair to form tetramers. The tails of spectrin tetramers bind with a protein cluster of short actin protofilaments. This interaction is markedly enhanced by protein 4.1. The spectrin-actin-protein 4.1 assembly forms a two-dimensional web that is secured to the overlying lipid bilayer through ankyrin, which anchors spectrin to the cytoplasmic domain of the anion transporter. Additional linkage occurs through the binding of protein 4.1 to glycophorin.

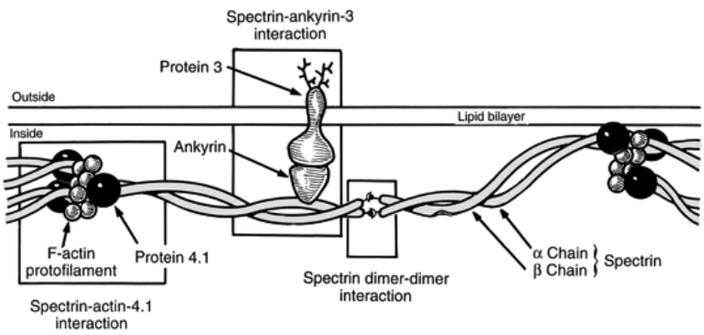

FIGURE 41.14. Schematic illustration of the erythrocyte cytoskeleton. (From Palek J, Lux SE. The red cell membrane skeletal defects in hereditary and acquired hematolytic anemias. *Semin Hematol* 1983;20:189, with permission.)

Defects in the red cell cytoskeleton, arising either from a deficiency of constituent proteins or through defective protein interaction, are a major cause of hereditary hemolytic anemias. Regardless of the mechanism or associated morphologic changes, red cells in this group of disorders exhibit decreased deformability. Consequently, they sluggishly traverse the splenic cords, where they are subjected to an environment hostile to metabolic activity. The metabolic stress further weakens an inherently defective cell, and after a variable number of passages, the cells succumb to reticuloendothelial destruction.

Hereditary Spherocytosis

Hereditary spherocytosis is the descriptive name given to a group of inherited disorders with characteristic spheroidal red cell morphology. It is the most common hereditary hemolytic anemia among people of Northern European ancestry. Its frequency led to the practice of separating anemias into spherocytic and nonspherocytic varieties, nomenclature that, in part, is still utilized today.

At least two distinct forms of spherocytosis are recognized. Approximately 75% of individuals exhibit an autosomal dominant mode of inheritance and cytoskeletal defects, which have been linked either to defective interaction of spectrin with protein 4.1 or to defects in ankyrin. In 25% of cases, an affected parent cannot be identified, negating an autosomal dominant inheritance pattern. This subset of individuals may be heterogeneous, including cases of spontaneous mutation as well as cases of autosomal recessive inheritance. A quantitative deficiency of spectrin has been identified in this group of patients, the magnitude of which directly correlates with clinical severity.

Clinical Features. The severity of the anemia varies, not only between patients, but also within a given patient over the course of time. Approximately 20% of patients have a mild form of the disease. In these individuals, hemolysis is compensated for by accelerated erythropoiesis, resulting in subclinical disease. The majority of patients with hereditary spherocytosis have a moderate lifelong anemia associated with cholelithiasis, intermittent jaundice, and splenomegaly. The hemoglobin level fluctuates, reflecting the precarious balance between the hyperplastic erythron and splenic activity. In approximately 10% of cases, anemia is severe. Transfusional support is often required in infancy and childhood until splenectomy is logistically feasible.

Hematologic Findings. The morphologic hallmark of hereditary spherocytosis is the spherocyte, a generally smaller, spheroidal red cell lacking central pallor and consequently appearing densely hemoglobinized (Fig. 41.15). The spherocytes contrast sharply with the increased number of large polychromatophilic reticulocytes indicative of compensatory erythroid hyperplasia. The interplay between spherocyte and reticulocyte numbers results in a widely variable MCV. Whereas the MCH is normal, the MCHC is increased, a combination of findings generally

unique to hereditary spherocytosis. The number of spherocytes present in the peripheral blood varies but in most cases is quite significant. In the absence of other significant poikilocytosis, the presence of spherocytes is strongly suggestive of either hereditary spherocytosis or a warm autoimmune hemolytic anemia. These two conditions may be distinguished by a direct antiglobulin test.

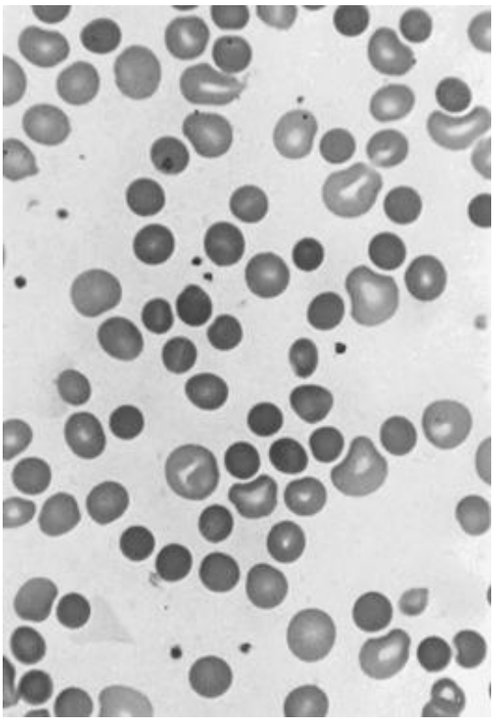

FIGURE 41.15. The peripheral blood smear in hereditary spherocytosis demonstrates a population of small, densely hemoglobinized, spheroidal erythrocytes that sharply contrast with the large polychromatophilic reticulocytes indicative of increased erythropoiesis.

In cases in which the diagnosis is suspected but the peripheral blood findings are inconclusive, an osmotic fragility test may be helpful. This procedure measures the red cell's capacity to withstand hypotonic stress. Because spherocytes exhibit a decreased surface area to volume ratio, their capacity to absorb water in hypotonic salt solutions is impaired. Increased hemolysis usually begins at sodium concentrations less than 0.5%. Exacerbation of this phenomenon may be induced by incubation for 24 hours, during which time the red cells additionally become metabolically stressed.

Treatment. In symptomatic patients, splenectomy is beneficial in removing the site of red cell destruction. After splenectomy, patients still exhibit spherocytes as well as the morphologic changes of a postsplenectomy state. Failure to improve after splenectomy suggests an alternative diagnosis; later relapses suggest hyperplasia of accessory splenic tissue.

Hereditary Elliptocytosis

Hereditary elliptocytosis (HE) is a clinically, genetically, and morphologically heterogeneous group of disorders that are linked through the morphologic finding of more than 20% elliptocytes in the peripheral blood (Fig. 41.16). Based on clinical findings and red cell morphology, three major categories of HE have emerged: the common form, the spherocytic form, and the stomatocytic form.

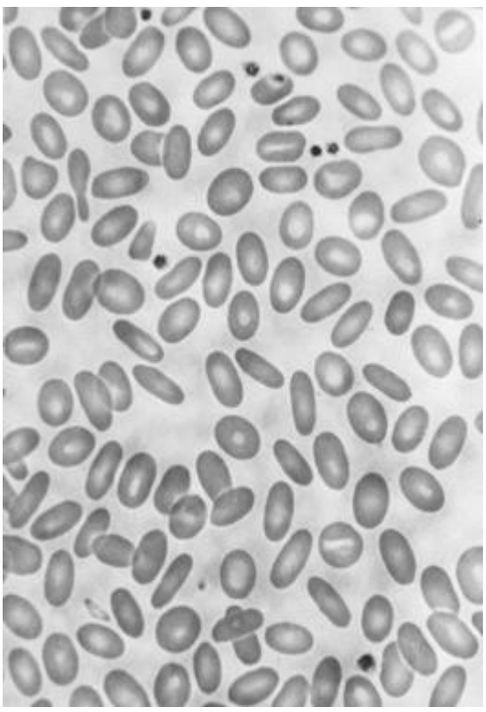

FIGURE 41.16. Numerous elliptocytes characterize the common form of hereditary elliptocytosis.

Clinical Findings. In the common form of HE, the majority of individuals exhibit numerous elliptical red cells with little or no evidence of hemolysis. Several exceptions may occur, leading to clinically symptomatic hemolysis. Moderate to severe hemolysis may occur during the first year of life in some black children, coinciding with morphologic findings in the peripheral blood similar to hereditary pyropoikilocytosis (HPP). The hematologic and clinical picture changes to one typical of common HE over the first 12 months. Unexplainably, a small subset of individuals with common HE will exhibit significant and chronic hemolytic anemia with clinical manifestations similar to hereditary spherocytosis. Additionally, the rare homozygous form of common HE results in severe transfusion-dependent hemolytic anemia. Red cell morphology in this unusual condition found in the offspring

of related HE parents resembles that of HPP. Spherocytic HE represents the dual inheritance of two nonallelic genes: one for mild HE and one for mild hereditary spherocytosis. As might be expected, the peripheral blood shows varying numbers of spherocytes and elliptocytes, either of which may predominate. Clinically mild to moderate hemolytic anemia results.

Stomatocytic HE is an unusual variant limited to Melanesia and surrounding islands. It is associated with changes in red cell antigen expression that appear to serve a protective function against malarial infection.

Several defects in the red cell cytoskeleton have been discovered in HE. The most frequent variant, occurring in common HE, is defective spectrin dimer–dimer interaction owing to an abnormal a chain of spectrin. Quantitative deficiencies of protein 4.1 are associated with the spherocytic form of HE. Heterozygous and homozygous patterns of inheritance are directly related to the magnitude of protein deficiency and clinical severity. Defective binding of ankyrin to the anion transporter has also been described in HE.

Differential Diagnosis. In the typical form of common HE, the diagnosis is easily established by the finding of numerous, fairly uniform elliptocytes in the peripheral blood. Other poikilocytes are few. The reticulocyte count is usually normal or mildly elevated, reflecting the asymptomatic or well-compensated nature of this disorder. The distinction between this form of HE and other disorders in which elliptocytes may be found is easily made on the basis of two observations: the frequency of elliptocytes and the presence of other size and shape changes that may give a clue to an unrelated hematologic condition. The peripheral smears of other forms of HE are not pathognomonic and may show features suggestive of hereditary spherocytosis or HPP. The diagnosis in these cases requires study of family members and may necessitate analysis of cytoskeletal protein composition.

Therapy. In the common form of HE, patients are asymptomatic or very well compensated and require no specific therapy. Splenectomy is the treatment of choice in more symptomatic HE variants.

Hereditary Pyropoikilocytosis

HPP is a rare congenital hemolytic anemia occurring most commonly in blacks. Red cells in this disorder demonstrate increased susceptibility to thermal injury. In contrast to normal erythrocytes, which can withstand temperature to 49°C, red cells in HPP begin to fragment and disintegrate at 45 to 46°C.

The mode of inheritance and the exact cytoskeletal defect(s) are not completely understood. Similar to HE, a defect in spectrin dimer–dimer association has been described that is partly attributable to an abnormality of the α chain of spectrin. The similarity of this structural defect to that seen in HE may explain the partial overlapping in morphologic findings seen early in the course of some cases of common HE.

The peripheral blood findings in HPP are striking and nearly pathognomonic (Fig. 41.17). Poikilocytosis is unmatched by any other disorder. Erythrocytes appear as if they are disintegrating, with fragments, numerous microspherocytes, and wisps of red cell membrane. These changes all lead to a markedly reduced MCV. A similar peripheral blood picture may be found in cases of third-degree burns owing to thermal injury of normal red cells and in clostridial sepsis secondary to the action of a lecithinase

on red cell membranes. As previously noted, infants with common HE may also exhibit similar changes in the peripheral blood, which gradually revert to a picture typical of common HE by 1 year of age.

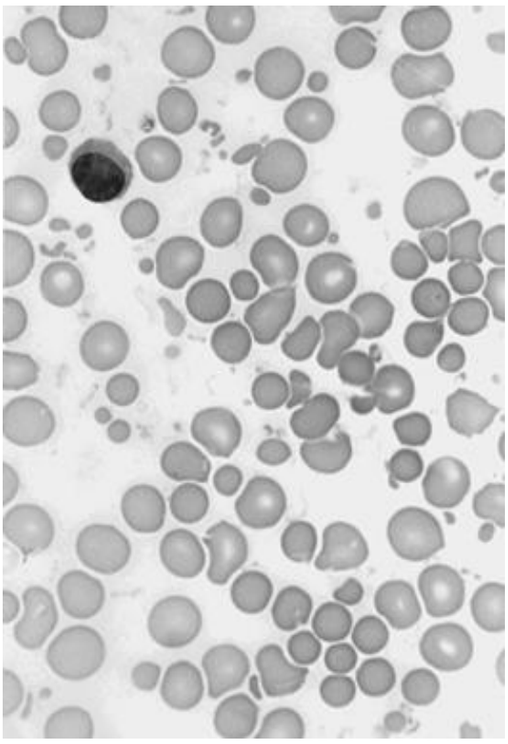

FIGURE 41.17. Striking poikilocytosis characterizes hereditary pyropoikilocytosis. Minute spheroidal erythrocytes result in a marked reduction in mean corpuscular volume. Note the irregular fragments of red cell membrane dusting the background of the peripheral smear.

HPP results in moderate to severe hemolytic anemia, necessitating splenectomy, which serves to diminish or abate hemolysis.

Hereditary Stomatocytosis

Although the precise structural defect is unknown, increased permeability to both sodium and potassium ions is a consistent feature of this rare disorder. Active Na^+-K^+ ATPase pumps are incapable of counterbalancing the flow of cations across the cell membrane. The net influx of sodium brings with it water, resulting in a swollen cell that is susceptible to osmotic and mechanical lysis.

Clinically, hereditary stomatocytosis varies in its expression. Most individuals are asymptomatic or exhibit only mild anemia because of brisk compensatory erythroid hyperplasia.

The morphologic hallmark of hereditary stomatocytosis is the stomatocyte, a cell with a slitlike or “fish-mouth” area of central pallor (Fig. 41.18). In suspension, these cells appear uniconcave or bowl shaped. A small number of similar-appearing cells may appear normally in air-dried smears or may be found in slightly increased numbers in association with a variety of disorders, making it difficult to establish conclusively the presence of hereditary stomatocytosis in its mild form. Evidence of hemolysis (more than 35% stomatocytes) and the absence of other poikilocytes, however, provide convincing evidence for this rare autosomal disorder. The MCV in these patients may be strikingly elevated, reflecting the reticulocytosis and the swollen nature of the stomatocytes.

Symptomatic patients may benefit from splenectomy, provided that splenic sequestration is documented.

Rh_{null} Disease

Rh_{null} disease is a rare hereditary disorder characterized by deletion of all Rh determinants, including the Landsteiner-Wiener antigen. The Rh locus, unlike many other blood group antigens, is restricted to red cells. It appears to be located in part within the red cell membrane; therefore, it is not surprising the deletion results in membrane malfunction.

Morphologically, this disorder is associated with stomatocytes and spherocytes. Clinically, a mild compensated hemolytic anemia is found, which requires no therapy.

Abetalipoproteinemia (Acanthocytosis)

Abetalipoproteinemia is a rare disorder of lipid metabolism. The absence of apolipoprotein B results in the inability to transport triglycerides in the blood. Clinically, the syndrome presents in infancy with steatorrhea; progressive development of acanthocytosis, ataxic neuropathy, and an atypical form of retinitis pigmentosa ensues.

The acanthocytes found in the peripheral blood are dense, contracted erythrocytes with multiple irregularly spaced, broad, spiny projections (Fig. 41.19). This is presumably related to an increase in the relative sphingomyelin content of the red cell membrane, resulting in a rigid cell. The mild shortening of red cell survival is clearly overshadowed by the nonhematologic complications of this disorder.

Acanthocytes may also be found as a complication of severe hepatocellular disease. Unlike abetalipoproteinemia, acanthocytosis in this setting is associated with a severe hemolytic anemia and heralds a poor and often fatal prognosis. The defect is again related to lipid alterations of the red cell membrane, in this case

excess cholesterol resulting from increased high-density lipoproteins in the peripheral blood. Similar acanthocytosis may be seen associated with the hepatocellular dysfunction accompanying neonatal hepatitis.

For unknown reasons, acanthocytes are also found in association with the McLeod blood group, an X-linked disorder in which red cell Kx antigen, the precursor substance for the Kell blood group system, is absent. The McLeod phenotype may be associated with chronic granulomatous disease because of the proximity of the genetic loci for these two disorders.

Congenital Nonspherocytic Anemias: Enzyme Deficiencies Resulting in Shortened Red Cell Survival

Lacking mitochondria, the mature erythrocyte relies on glycolysis for energy production. Approximately 90% of glycolysis occurs through the anaerobic Embden-Meyerhof (EM) pathway as glucose is converted to lactic acid (Fig. 41.20). The metabolically crucial byproducts of this multistep pathway are ATP and nicotinamide adenine dinucleotide (reduced form) (NADH). ATP, the main energy compound of the erythrocyte, is required for active

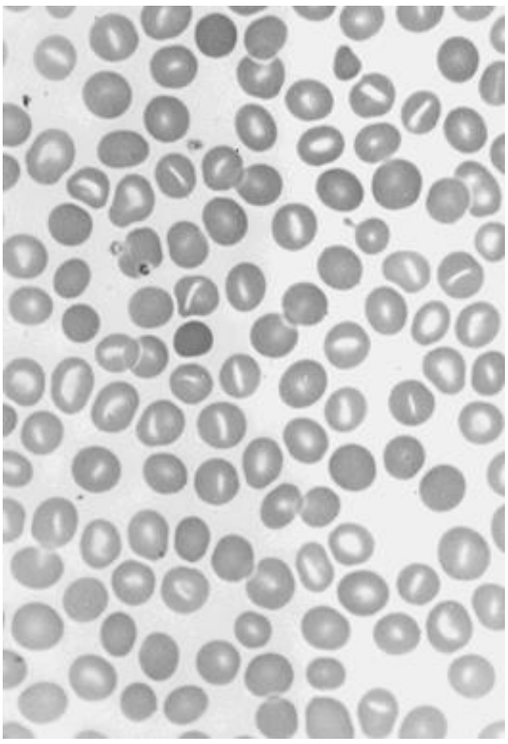

FIGURE 41.18. Hereditary stomatocytosis is characterized by numerous erythrocytes having slitlike central pallor.

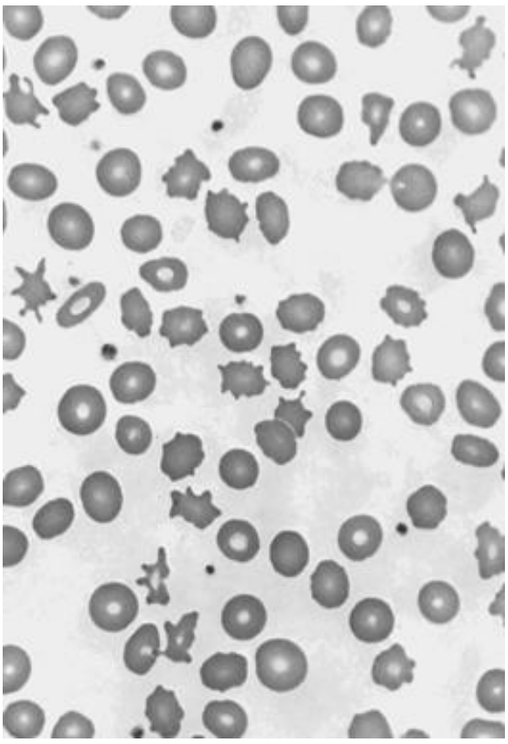

FIGURE 41.19. Acanthocytes are erythrocytes with irregularly placed, broad, blunted projections. They are typically found in significant numbers in abetalipoproteinemia and in end-stage liver disease. In both conditions, plasma lipid abnormalities result in alterations in the composition of the red cell membrane.

cation transport across the red cell membrane. NADH is an essential cofactor for reduction of the small amount of methemoglobin normally produced each day in the red cell.

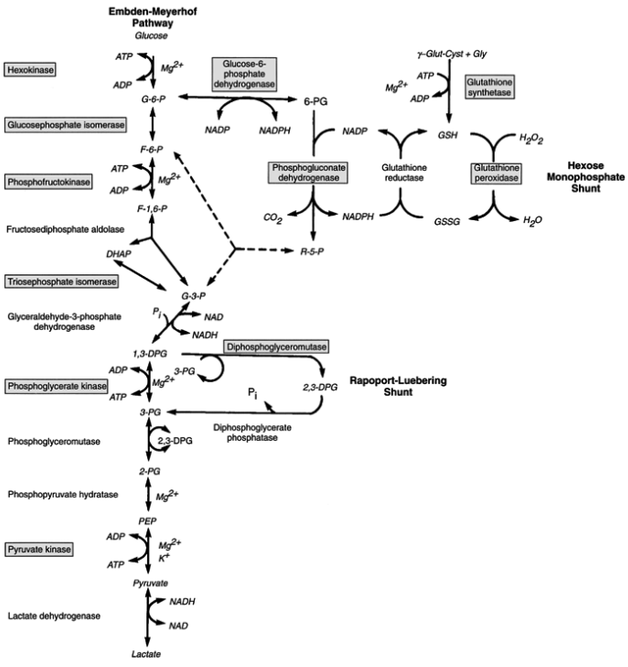

FIGURE 41.20. Glycolytic pathway with related hexose monophosphate shunt (glutathione metabolism) and Rapoport-Luebering shunt [2,3-diphosphoglycerate (2,3-DPG), metabolism].

Integrally related to the EM pathway is the Rapoport-Luebering shunt, which results in the production of 2,3-diphosphoglycerate (2,3-DPG). Activity of this shunt is related to the erythrocyte's ATP and 2,3-DPG requirements. 2,3-DPG plays an essential role as a regulator of oxygen delivery to the tissues by altering the affinity of hemoglobin for oxygen.

Approximately 10% of glycolysis occurs aerobically through the hexose monophosphate (HMP) shunt, a pathway that generates the nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH) required for reduction of glutathione. Reduced glutathione is critical for the protection of hemoglobin from oxidant damage. Unlike the EM pathway, the HMP shunt can increase activity approximately 30-fold in times of oxidative stress.

Given the complexity and vital role of these pathways, it is not surprising that defects in any number of the intermediary enzymes can serve to uncouple the reaction, resulting in red cell injury. For the most part, red cell injury resulting from deficiencies of the HMP or EM pathways are not associated with significant morphologic changes and are broadly categorized as congenital or hereditary nonspherocytic hemolytic anemias.

Enzyme Deficiencies of the Hexose Monophosphate Pathway

NADPH generated by the HMP shunt is a necessary cofactor for maintaining glutathione in a reduced state. Reduced glutathione protects the red cell from naturally occurring and drug-induced oxidants that may potentially damage hemoglobin, membrane proteins, or other intracellular enzymes.

Oxidative damage to red cells is frequently manifested as Heinz bodies, small spheroidal inclusions of denatured hemoglobin visible by supravital staining. Heinz bodies exert their deleterious effects by attaching to the inner membrane of the red cell and causing deformation, alteration of cell membrane permeability, and reduction in red cell deformability. Attempted removal of these harmful inclusions occurs both through exocytosis and through active excision by the reticuloendothelial system of the spleen (Fig. 41.21). Within the spleen, many Heinz body–laden erythrocytes are trapped and destroyed as they lose the pliability needed to traverse the splenic red pulp. Others escape and return to the circulation, appearing morphologically deformed as bite cells or blister cells.

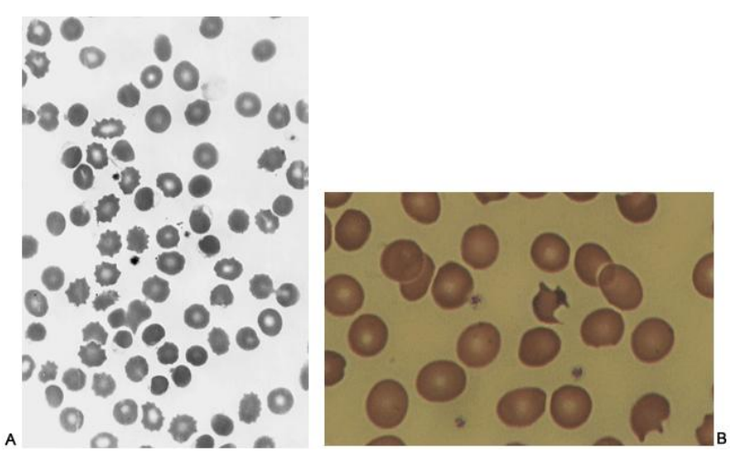

FIGURE 41.21. Blister cells **(a)** and bite cells **(B)** are characteristic of Heinz body–mediated hemolysis. Blister cells appear to have a partially raised or blistered membrane; bite cells appear to have one or more “bites” removed from the cell. Similar bite cells can be found in microangiopathic hemolytic anemia; however, they are then associated with irregular red cell fragments of various sizes and shapes, which are not seen in association with Heinz body–mediated hemolysis.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD), the initial and rate-limiting enzyme of the HMP pathway, accounts for more than 99% of all cases of hemolytic anemia attributable to enzyme deficiencies of this pathway. It is the most prevalent inborn metabolic disorder of red cells. The structure and synthesis of G6PD are controlled by genes on the X chromosome. Numerous variants of the enzyme are found, based on a variety of physiochemical properties. Normal G6PD, or G6PD B, is the most common form of the enzyme found in all population groups. G6PD A, separated based on electrophoretic mobility, exhibits normal enzyme activity and is found in approximately 20% of American black males. An unstable variant of G6PD A, designated G6PD A-, results in enzyme deficiency in aging red cells. G6PD A- is found in approximately 11% of American black males. Another variant, G6PD Mediterranean, found frequently in Sicilians, Greeks, Sephardic Jews, and Arabs, exhibits even greater instability, with a half-life measured in terms of hours compared with 60 days for the normal G6PD B. Together, G6PD A- and G6PD Mediterranean account for the most

common variants associated with clinically significant hemolysis.

With this sex-linked pattern of inheritance, the clinical expression of G6PD deficiency is largely limited to hemizygous males and homozygous females. On occasion, heterozygous females may exhibit hemolysis owing to the variable nature of X chromosome inactivation. Three distinct clinical syndromes are recognized: acute hemolytic anemia induced by oxidant stress, chromic hereditary nonspherocytic anemia, and favism. Although favism is an idiosyncratic reaction occurring on exposure to the fava bean in a subset of G6PD-deficient individuals, the severity of the enzyme defect is the essential element in defining the two remaining clinical syndromes.

Oxidant-Induced Acute Hemolytic Anemia. An acute hemolytic episode associated with oxidant stress is the most frequent expression of G6PD deficiency. It is seen with both G6PD A- and G6PD Mediterranean variants. Administration of a variety of drugs has been associated with acute hemolytic episodes in these individuals (Table 41.9). Additionally, infection is a common precipitating factor. Salmonellae, coliforms, ß-hemolytic streptococci, rickettsiae, influenza, and viral hepatitis have each been associated with hemolysis in G6PD A- individuals through poorly elucidated mechanisms.

Vitamin K (water-soluble analogs)

Laboratory and clinical evidence of acute hemolysis is usually apparent within days of onset of infection or drug administration. Signs and symptoms are often more severe with G6PD Mediterranean, as the enzyme is much less stable. The finding of bite cells or the demonstration of Heinz bodies in this clinical setting are strong evidence for G6PD deficiency. If exposure to the inciting agent is brief, the episode of hemolysis is generally self-limited. Symptoms may also abate as compensatory release of reticulocytes into the circulation occurs. These young red cells demonstrate normal G6PD activity.

Confirmation of the diagnosis requires quantitative G6PD assays. Caution must be exercised in interpreting G6PD levels during periods of brisk reticulocytosis, as enzyme levels during these periods may not reflect steady-state conditions.

Hereditary Nonspherocytic Hemolytic Anemia. G6PD variants that lead to severe enzyme deficiency result in chronic hemolysis. On occasion, this subset of individuals may present in the neonatal period with hemolytic disease of the newborn. Moderate, partially compensated hemolytic anemia is the rule. Splenectomy is generally unsuccessful in diminishing the rate of hemolysis in these individuals.

Favism. Acute, potentially fatal intravascular hemolysis may occur as an idiosyncratic reaction on exposure to fava beans in a subset of G6PD-deficient individuals. G6PD Mediterranean is the most commonly afflicted subtype. Signs and symptoms of brisk intravascular hemolysis occur within hours of ingestion. Maintenance of intravascular volume and renal function together with prompt transfusional support are required.

Miscellaneous Enzyme Deficiencies of the HMP Shunt

Deficiencies of the following HMP pathway enzymes have also been described: γ-glutamyl cysteine synthetase, glutathione synthetase, glutathione reductase, and glutathione peroxidase. Clinical manifestations of these enzymes are widely variable, spanning the recognized clinical syndromes of G6PD deficiency.

Enzyme Deficiencies of the EM Pathway

A syndrome of hemolytic anemia has been described for deficiencies of nearly all enzymes in the EM pathway. Hemolysis occurs in these disorders as the late-developing erythroblasts lose their mitochondrial machinery and begin to rely on glycolysis for energy production.

Pyruvate Kinase Deficiency

Pyruvate kinase (PK) deficiency is the most common enzyme deficiency of the EM pathway. Numerous dysfunctional variants of the PK enzyme are known to exist, affecting, for example, enzyme activity, stability, or kinetic rate. A single copy of a defective gene usually causes no significant alteration of enzyme activity. Hemolytic anemia typically occurs in the double heterozygote, an individual inheriting two mutant genes. The clinical variability of PK deficiency likely reflects the wide range of combinational possibilities.

Hemolytic anemia presenting in infancy or childhood is usually severe, requiring maintenance transfusions and splenectomy, whereas disorders presenting in adulthood are largely compensated and result in mild to moderately severe anemia. Paradoxically, adaptation to anemic hypoxia is facilitated by the PK deficiency itself, which results in a buildup of pathway intermediates proximal to the site of PK activity, including 2,3-DPG. Elevated levels of 2,3-DPG also lead to a peculiar laboratory finding in PK-deficient red cells. By inhibiting enzymes of the HMP pathway, red cells exhibit increased Heinz body formation on exposure to oxidant stress.

Red cell morphology is often unremarkable. In more severe cases, echinocytes may be present, which become even more plentiful after splenectomy. Diagnosis of PK deficiency is based on enzymatic assays demonstrating quantitative or qualitative abnormalities. Hemolysates should be free of contaminating white blood cells, which normally contain high levels of PK.

An acquired form of PK deficiency may occur in conjunction with the myelodysplastic syndromes, myeloproliferative disorders, or AML.

Miscellaneous Enzyme Deficiencies of the EM Pathway

Deficiencies of hexokinase, glucosephosphate isomerase, phosphofructokinase, aldolase, triosephosphate isomerase, and phosphoglycerate kinase have all been reported to result in congenital nonspherocytic hemolytic anemia. With the exception of hexokinase, these enzyme defects have also resulted in impairment of other organ systems, most commonly involving the neuromuscular system.

Disorders of Nucleotide Metabolism

Three uncommon disorders of purine and pyrimidine metabolism in red cells are responsible for hemolytic anemia, the most frequent of which is pyrimidine-5′-nucleotidase deficiency. This enzyme is responsible for degradation of ribosomal RNA during reticulocyte maturation. A pyrimidine-5′-nucleotidase deficiency results in aggregation of residual ribosomes, which are manifested in peripheral blood smears by coarse basophilic stippling. It is an acquired pyrimidine-5′-nucleotidase deficiency seen in lead poisoning that leads to this heralded morphologic clue to the diagnosis. Congenital enzyme deficiencies usually result in moderate anemia. Diagnosis is established through an assay of nucleotidase activity.

A deficiency of adenylate kinase has also been described as a rare cause of congenital nonspherocytic hemolytic anemia, as has hyperactivity of the enzyme adenosine deaminase.

Acquired and Extrinsic Red Cell Abnormalities

Immune-Mediated Red Cell Destruction

The basic antigen-antibody interactions that serve to protect through red cell recognition of nonself can mediate red cell destruction. Such immunohemolytic anemias may be caused by antibodies of the IgG or IgM class, the intrinsic properties of which lead to different modes of red cell injury.

IgM antibodies may cause red cell destruction through two mechanisms: physical agglutination and complement activation, each facilitated by the large pentameric structure of the IgM molecule, which allows it to easily bridge multiple antigenic sites. The capacity of an IgM antibody to mediate red cell destruction is directly linked to its thermal amplitude, the temperature range over which it most avidly binds to an antigen. IgM antibodies are frequently referred to as cold-reacting antibodies because they exhibit increasing binding avidity as temperatures approach 4°C. In contrast, complement activity occurs only near body temperature. Consequently, only IgM antibodies, which exhibit avid binding properties near body temperature where complement is active, cause hemolysis.

When complement is activated, immediate red cell lysis may proceed through completion of the complement cascade. Complement activation may, however, be stalled through a series of protective checks and balances after the liberation of C3b from C3. Red cells coated with C3b may be cleared by phagocytic cells bearing C3b receptors; particularly rich in C3b receptors are the hepatic reticuloendothelial cells (Kupffer cells). Alternatively, C3b may be inactivated to C3d by a plasma inactivator. Importantly, C3d-coated red cells serve as a marker of IgM-mediated hemolysis, a property that is clinically utilized in the Coombs' or direct antiglobulin test (DAT).

In contrast to IgM, antibodies of the IgG class exhibit their greatest binding activity at body temperature. The much smaller size of the IgG molecule makes it less capable of bridging the gap between two or more red cell antigens, a prerequisite to physical agglutination or complement activation. Consequently, IgG-induced hemolysis is not mediated through complement-dependent lysis but rather through reticuloendothelial clearance.

When bound to the red cell surface, the Fc portion of the IgG molecule is exposed, becoming a target for the mononuclear cells of the reticuloendothelial system that bear Fc receptors. Particularly rich in Fc receptors are the splenic macrophages, making the spleen a major site of destruction of IgG-coated red cells. Unlike the rapid demise of IgM-coated red cells, red cells coated with IgG are readily found in circulation. The circulating IgG-coated erythrocytes may be detected by the DAT. The longevity of IgG-coated red cells is determined by the number of antigenic sites per red cell, the serum concentration of the IgG antibody, and the functional capacity of the reticuloendothelial system. When bound through Fc receptor attachment, the erythrocytes undergo a shape change, becoming spherical owing to a loss of red cell membrane. The diminished surface area-to-volume ratio makes these spheroidal red cells increasingly susceptible to hypotonic (or osmotic) stress. These morphologic and physical properties are indistinguishable from the findings of hereditary spherocytosis. Destruction occurs through internalization or

piecemeal destruction by macrophages, as they surround portions of the red cell membrane with fingerlike extensions.

Isoantibodies

Immunohemolytic anemias may be caused by isoantibodies (alloantibodies), i.e., antibodies to blood group antigens. For purposes of this discussion, isoantibodies are antibodies to the major and minor blood group antigens. Isoantibodies may be naturally occurring or may arise on exposure to foreign blood group antigens through blood transfusion or during pregnancy as small amounts of fetal blood leak across the placental barrier to gain access to the maternal circulation.

Transfusion of Incompatible Blood

Antibodies to the ABO blood group antigens are of the IgM class and exhibit a broad range of thermoreactivity. Transfusion of ABO-incompatible blood results in immediate and severe symptoms related to brisk complement-mediated hemolysis. Flushing, hyperventilation, tachycardia, urticaria, and shock occur secondary to the release of vasoactive substances encountered with complement activation; severe pain results from vasoocclusion secondary to red cell agglutination. Disseminated intravascular coagulation and renal failure may also ensue.

Non–ABO-related hemolytic transfusion reactions are IgG mediated. The majority are secondary to antibodies within the Rh system, notably anti-D. Antibodies to c, E, and to the Kell, Kidd, and Duffy systems round out the most frequent causes of non–ABO-related transfusion reactions. These IgG-coated erythrocytes are predominantly cleared by the spleen. A chill/fever reaction typically occurs after approximately 1 hour, the severity of which is related to the antibody titer and the number of antigenic sites. Hemoglobinemia reflects a backwash of hemoglobin into the circulation from the splenic macrophages and consequently never reaches the magnitude seen with intravascular hemolysis of ABO transfusion reactions. Hemolysis is nonetheless thorough, as evidenced by the rise in serum bilirubin.

Very low titers of antibody may lead to a delayed transfusion reaction. In such circumstances, reexposure to a foreign antigen through transfusion will cause an anamnestic rise in antibody titer. Clinically, hemolysis becomes evident 3 to 7 days posttransfusion as the patient exhibits jaundice and signs and symptoms of anemia.

Hemolytic Disease of the Newborn

During pregnancy, tiny amounts of fetal erythrocytes enter the maternal circulation. If these red cells bear foreign (paternally restricted) antigens, they will serve as an immune stimulus. Maternal IgG antibodies have the capacity to cross the placenta and coat fetal erythrocytes, leading to splenic sequestration and destruction. The magnitude of this hemolytic disease of the newborn is related to the titer of the maternal antibody; in severe cases, *in utero* exchange transfusion may be necessary to prevent fetal demise. Historically, anti-D has accounted for the majority of severe cases. With the prophylactic administration of Rh immune globulin, severe cases are now more frequently encountered with antibodies to c, E, or other minor blood group antigens.

Although ABO antibodies are largely naturally occurring and incapable of placental transfer because of their pentameric structure, small amounts of IgG type anti-A and anti-B may also be found, typically in type O individuals. These IgG antibodies are capable of placental transfer and, similar to anti-D, may cause hemolytic anemia. ABO hemolytic disease of the newborn, although much more frequent than that owing to anti-D, is typically less severe.

Anemia and evidence of accelerated erythropoiesis, the hallmarks of hemolytic anemias, are present in hemolytic disease of the newborn. Nucleated red blood cells are frequent and may be striking. Hyperbilirubinemia is largely of the unconjugated type owing to hepatic immaturity. Spherocytes are frequent in ABO-related hemolysis but are a minor feature of Rh incompatibility. In contrast, a strong DAT is more frequent in hemolytic disease of the newborn owing to anti-D; antibodies in the ABO system are loosely bound to the erythrocyte surface, resulting in a weakly positive DAT, and may be detected in the circulation with an indirect antiglobulin test.

Autoimmune Hemolytic Anemias

Autoimmune hemolytic anemias are caused by autoantibodies—self-induced antibodies directed at one's own red cells. The autoimmune hemolytic anemias are divided into two broad categories based on the class and the corresponding thermal activity of the responsible antibody: warm (IgG) and cold (IgM) autoimmune hemolytic anemias. Both warm and cold autoimmune hemolytic anemias may be further stratified into idiopathic and secondary forms.

Warm Autoimmune Hemolytic Anemias

The warm autoimmune hemolytic anemias are predominantly mediated through the binding of IgG antibodies to the erythrocyte's surface, resulting in splenic sequestration and destruction. Consequently, the morphologic hallmarks of this group of anemias is the spherocyte. The severity of the anemia and the number of spherocytes, however, are quite variable. In severe cases, the frequency of spherocytes rivals that seen in hereditary spherocytes. In such cases, the true identity of a warm autoimmune hemolytic anemia is revealed with a positive direct antiglobulin test. Red cells are typically coated with IgG occurring alone or in combination with varying amounts of intact C3. Rarely, the red cells exhibit only C3 on their surface. The responsible antibody may be serologically nonspecific; however, in many cases, preferential reactivity with the Rh locus is apparent. Seldom, however, is the antibody directed at specific Rh determinants.

Idiopathic Warm Autoimmune Hemolytic Anemia. In as many as half of the cases, the warm autoimmune hemolytic anemia is not associated with an underlying disease process and is termed idiopathic. The remaining cases are associated with or secondary to an underlying disease.

Secondary Warm Autoimmune Hemolytic Anemias. Secondary warm autoimmune hemolytic anemias most frequently arise in association with an underlying lymphoproliferative disorder or systemic autoimmune disorder. Chronic lymphocytic leukemia is the most frequently associated lymphoproliferative disease; warm autoimmune hemolytic anemia may be seen in

10% to 30% of cases sometime during the course of the disease. Other lymphoproliferative disorders are less frequently complicated by warm autoimmune hemolytic anemias but may also give rise to cold autoimmune hemolytic anemia. The onset of the anemia may precede the diagnosis of lymphoma/leukemia by months or years. Hence, thorough systemic evaluation is necessary before labeling an individual with an idiopathic autoimmune hemolytic anemia. Systemic lupus erythematosus is the prototype of the systemic autoimmune disorders associated with warm autoimmune hemolytic anemias. Rheumatoid arthritis, lupoid hepatitis, and ulcerative colitis may also exhibit red cell autoantibodies. Clinically significant hemolysis is less frequent than the finding of a positive DAT among these disorders. As in other forms of secondary autoimmune hemolytic anemia, treatment is directed at the underlying disease processes.

Cold Autoimmune Anemias: Cold Agglutinin Disease

As previously discussed, cold-reacting IgM antibodies may cause hemolysis through physical agglutination or complement activation. The thermal range of most IgM antibodies is sufficiently low that dissociation occurs before reaching temperatures compatible with complement activation. Consequently, hemolysis is frequently mild unless a broad range of thermal activity is present or ambient temperature sufficiently cool. Approximately 95% of cold-reacting antibodies show anti-I specificity, the remainder demonstrating activity with the i-antigen normally found on fetal erythrocytes.

Primary Cold Agglutinin Disease. Primary cold agglutinin disease is marked by episodic painful acrocyanosis induced by agglutination of red cells in the peripheral circulation on exposure to cold. It is typically a disease seen in the elderly and is managed largely by avoidance of cold environments. Exclusion of an underlying chronic lymphoproliferative disorder is mandatory. The diagnosis is suspected by the clinical history and the finding of red cell agglutination as blood is drawn or from blood smears prepared at room temperature. Cold agglutinin titers are established by serially diluting the patient's serum and incubating it with a suspension of group O erythrocytes. Normal individuals exhibit low concentrations of cold active anti-I, resulting in physiologic titers less than 1:16. Pathologic titers are typically greater than 1:256 and may exceed 1:100,000 in idiopathic cold agglutinin disease. The DAT typically reveals the presence of C3.

Secondary Cold Agglutinin Disease. Secondary cold agglutinin disease is associated with a variety of infections, the prototype being mycoplasma pneumonia and infectious mononucleosis. Cold agglutinin titers are often used as a supportive test in establishing a presumptive diagnosis of mycoplasma pneumonia. Titers rise within 1 to 3 weeks after the onset of symptoms. Titers typically reach 1:640, although on occasion they may reach values exceeding 1:1,000 and may be associated with symptomatic anemia. In contrast to the anti-I antibodies of mycoplasmal pneumonia, cold agglutinins arising in association with infectious mononucleosis are directed against the i-antigen and require fetal cells for detection. Cold agglutinin disease may occur secondarily in association with a variety of lymphoproliferative disorders. In these cases, the monoclonal IgM antibody expressed by the malignant B-cell clone is the responsible hemolytic agent. As previously stressed, discovery of either a warm or cold autoimmune hemolytic anemia necessitates a thorough investigation to rule out an underlying occult lymphoproliferative disorder.

Paroxysmal Cold Hemoglobinuria. Paroxysmal cold hemoglobinuria (PCH) is a rare acquired hemolytic anemia that may be seen as a complication of syphilis or a recent viral illness, particularly measles, mumps, or infectious mononucleosis. It is the result of an anti-P autoantibody occurring in individuals expressing the nearly universal P_1 and P_2 red blood cell antigens. This 7S IgG antibody, termed the Donath-Landsteiner antibody, binds to the erythrocyte at temperatures below 20°C. This IgG antibody is unique not only in its binding avidity at cold temperatures but also in its capacity to cause complement binding. Subsequent activation of complement occurs with warming; at the same time, the Donath-Landsteiner antibody dissociates from the red cell membrane. This biphasic property is utilized clinically to establish the diagnosis. Hemolysis occurs only after the blood has been chilled and then warmed to 37°C. Bound IgG can be detected in the DAT only when performed at temperatures less than 24°C; at body temperature, only C3 is detected. Clinical hemolysis is precipitated by exposure to cold and results in symptoms similar to those seen in acute intravascular hemolysis associated with ABO incompatibility. The disorder is usually a self-limited, postviral complication. Treatment for syphilis is required for luetic PCH.

Drug-Induced Autoimmune Hemolytic Anemia

The administration of a number of pharmaceutical agents has been complicated by the development of antibody-mediated hemolysis. Although, strictly speaking, many cases are not examples of true autoantibody-mediated hemolysis, these disorders are best considered as a group. Four basic hemolytic mechanisms have been described.

Hapten Mechanism. When given intramuscularly in large doses (greater than 10 million units), penicillin is absorbed to the red cell membrane. The combination of drugs and hapten (red blood cell membrane) serves as an antigen to which formed antibody binds. The antibody is usually of the IgG type and results in hemolysis through reticuloendothelial destruction. Discontinuation of the drug results in abrupt cessation of hemolysis, although the positive DAT usually persists for several months. Penicillin analogs such as cephalothin are also known to cause similar hemolytic complications.

Immune Complex or Innocent Bystander Mechanism. Several drugs, including quinidine, quinine, p-aminosalicylate, phenacetin, ethacrynic acid, and the nonsteroidal antiinflammatory agents, may result in hemolysis through the formation of immune complexes that nonspecifically coat red cells. These drugs bind to plasma proteins, which act as haptens. Antibodies then bind to the circulating drug-protein complex, and the resulting immune complex is deposited on a variety of innocent bystanders such as erythrocytes, platelets, and glomerular endothelium. The antibodies are often IgM, resulting in complement

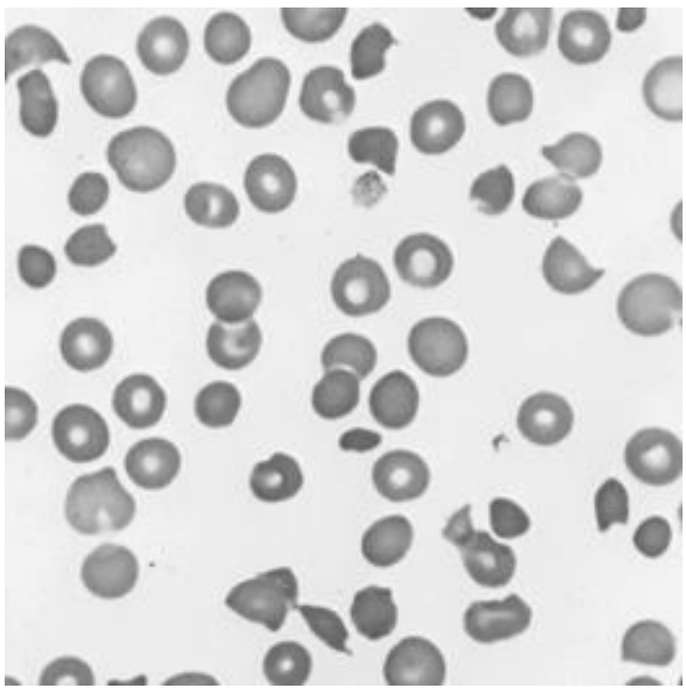

FIGURE 41.22. Variably sized, irregularly shaped erythrocyte fragments characterize the macroangiopathic and microangiopathic hemolytic anemias. Spherocytes may also be found. When seen in conjunction with red cell fragments, the presence of spherocytes should not raise confusion with hereditary spherocytosis or warm autoimmune hemolytic anemia.

deposition. The picture is usually one of acute intravascular hemolysis and does not require large amounts of drug. Renal failure becomes a problem in 50% of patients.

True Autoimmune Hemolytic Anemia: The Aldomet Model. The prototype for this type of drug-related hemolysis is Aldomet (methyldopa). The frequency of antibody formation with Aldomet therapy is directly linked to the dose of drug administered. Overall, approximately 15% of patients treated with Aldomet will develop a positive DAT after 3 months of treatment. The antibody is similar to the true autoantibodies encountered in idiopathic warm autoimmune hemolytic anemia, an IgG antibody exhibiting specificity toward the Rh locus. The exact mechanism of antibody formation is unknown, although it is postulated that a state of unregulated B-cell activity is created by the inhibitory effects of the drug on T-suppressor cells. A positive DAT does not equate to hemolysis, as clinical hemolysis develops in only approximately 1% of patients. Interestingly, it is a more frequent complication at lower dosages. To prevent hemolytic complications, the drug is discontinued after discovery of a positive DAT. Hemolysis seldom occurs after cessation of the drug, although a positive DAT may persist for months to years. L-Dopa, melanemic acid, flufenamic acid, chlordiazepoxide hydrochloride, cimetidine, and cefazolin have also been associated with similar induction of autoantibodies.

Nonimmunologic Absorption of Proteins. Although proven hemolysis is rare, a weakly positive DAT may develop in association with the administration of cephalothin or cephaloridine. These agents cause nonspecific absorption of a wide variety of proteins, including IgG, IgM, and complement to the red cell surface.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an uncommon cause of hemolysis with a pathophysiology uniquely distinct from the hemolytic disorders previously discussed. PNH is an acquired clonal hematopoietic stem-cell disorder characterized by intravascular hemolysis and blood cells with characteristic defects. Multiple membrane proteins have been found to be lacking in the abnormal cells, including erythrocytes, granulocytes, monocytes, platelets, and, sometimes, lymphocytes. These proteins are all linked to the cellular membranes by a glycosylphosphatidylinositol (GPI) anchor. Recent work showed that the first step in the biosynthesis of the GPI anchor, which involves the synthesis of *N*-acetylglucosaminyl-phosphatidylinositol (GlcNAc-PI), is defective in patients with PNH. Although several genes may be involved in this process, *PIG-A*, mapped to the X chromosome, appears to play the primary role and defects within this gene have been found in most studied patients with PNH.

As a consequence of the absence of the GPI anchor protein, the affected proteins are degraded within the cell. The GPI-linked proteins belong to several different groups such as enzymes, receptors, complement regulators, adhesion molecules and other proteins without well-defined functions. These deficiencies can be complete or partial, which influences the severity of the symptoms. Two of the most important proteins lacking on the membrane are decay-accelerating factor (CD55) and membrane inhibitor of reactive lysis (CD59), which ordinarily protect cells from complement-mediated attack. Deficiency of these two proteins, particularly membrane inhibitor of reactive lysis, results in increased red blood cell susceptibility to complement lysis.

Traditional diagnosis of PNH has relied on the demonstration of complement-mediated hemolysis. In the acidified serum lysis test (Ham test), PNH red cells will lyse in acidified serum, which activates complement. The Ham test may not detect a small population of abnormal cells. The sucrose hemolysis test relies on the fact that a low ionic strength medium, such as sucrose, activates complement; PNH red cells will also lyse in serum mixed with isotonic sucrose. Although sensitive, the sucrose hemolysis test is less specific.

However, recent studies utilizing antibodies directed against GPI-anchored proteins such as CD55, CD59, CD16, and CD66b are shown to be much more practical and reliable for diagnosis of PNH. Flow cytometric analysis of granulocytes or red cells incubated with monoclonal antibodies appears to be sensitive and specific and can give information regarding the proportion of abnormal cells.

Although the name implies that PNH is characterized by episodes of hemolysis occurring at night, this classic presentation is not very common. In fact, the clinical manifestations of PNH are highly variable, but all patients have at least some degree of intravascular hemolysis. The extent of hemolysis and the degree of anemia vary greatly from patient to patient. Peripheral blood values and peripheral blood smear features are nonspecific. PNH may present with pancytopenia with marrow hypoplasia or aplasia, and the differential diagnosis of pancytopenia should always include PNH. However, the degree of bone marrow cellularity also varies from hyperplastic owing to erythroid hyperplasia to severe aplasia. Unexplained iron deficiency resulting from persistent hemoglobinuria and hemosiderinuria should also raise suspicion for PNH. Thrombosis, especially venous, is a grave complication of PNH and accounts for approximately one third to one half of deaths in patients with PNH. Patients with PNH/aplastic anemia may have a lower risk of thrombosis (5%). Patients with aplastic anemia appear to have an increased risk of developing PNH. Recent studies showed that GPI anchor–deficient hematopoietic cell populations frequently arise in the setting of long-term survival after aplastic anemia.

The median survival in PNH patients is between 10 and 15 years from the time of diagnosis. The natural course of the disease is often prolonged but marred by episodic bouts of hemolysis and a number of often fatal complications. Myeloid aplasia is accompanied by all the complications of neutropenia and thrombocytopenia. Anemia may be exacerbated by the development of iron deficiency with prolonged intravascular hemolysis or folate deficiency that may accompany brisk hemolysis and reticulocytosis. A small number of patients may develop AML. However, the incidence of AML in PNH appears to be similar to the risk of aplastic anemia patients developing AML. Therefore, it is possible that the PNH clone by itself may not be responsible for the increased risk of developing AML but rather that the aplastic anemia predisposes to clonal hematopoietic disorders such as AML. Some patients are reported to survive for prolonged periods (more than 25 years) and as many as 15% show

spontaneous recovery from PNH with no sequelae attributable to their disease.

Traumatic Red Cell Injury

Excessive physical trauma to the erythrocyte on its circulatory journey may lead to intravascular lysis or cell injury predisposing to premature red cell destruction (Fig. 41.22). Red cell fragments, or schistocytes, serve as the morphologic hallmark of this type of hemolysis. These beaten and battered red cells are of various sizes and shapes. Having withstood the initial injury, these resealed erythrocyte remnants eventually succumb to splenic destruction. Traditionally, the red cell fragmentation syndromes have been separated based on injury sustained in the heart or great vessels (macrovascular) versus that sustained in the prearteriolar or capillary bed (microvascular).

Macrovascular Hemolysis

Although capable of tolerating tremendous shear forces, erythrocytes become increasingly susceptible to injury with alterations in blood flow. Such changes in the macrovasculature occur with outflow disease such as aortic stenosis. A calcified valve is a double-edged sword, as turbulent jet flow is created past a roughened valvular surface. Similarly, prosthetic cardiac devices employed in the surgical repair of valvular or parenchymal defects may present bare or nonendothelialized surfaces injurious to red cells. The mechanical design of early prosthetic valves, which predispose to physical trauma and red cell fragmentation, represent another cause of macrovascular injury; this complication has now largely been resolved.

Hemolysis secondary to macrovascular injury is usually mild and well compensated. Prolonged periods of red cell injury may lead to depletion of iron stores through urinary iron loss accompanying intravascular hemolysis. Exacerbations of hemolysis may be encountered with sudden valvular incompetence and may be a sign of a failing prosthetic implant.

Microangiopathic Hemolytic Anemia

Microangiopathic hemolytic anemia is the result of red cell fragmentation in the prearteriolar or capillary bed. Erythrocyte damage occurs as the force of the blood flow carries red cells through the narrowed or damaged microvasculature. Lysis or sublethal assault occurs through two mechanisms: deposition of a fibrin meshwork that acts as a sieve through which red cells are pushed (Fig. 41.23) or diffuse endothelial damage, which exposes flowing red cells to a rough and hostile surface. The interplay of these two mechanisms can be seen with endothelial damage because the denuded endothelial surfaces cause fibrin deposition.

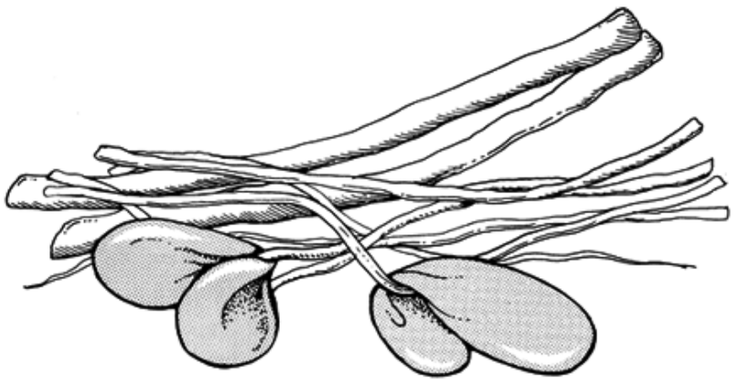

FIGURE 41.23. Fibrin strands in the microvasculature form a sharp mesh, causing fragmentation of circulating erythrocytes.

The causes of microangiopathic hemolytic anemia are numerous (Table 41.10). Disseminated intravascular coagulation, occurring as a complication of infections, disseminated carcinoma, or obstetric catastrophes; thrombotic thrombocytopenic purpura and the related hemolytic uremic syndrome; and malignant hypertension are the most frequent underlying disorders leading to red cell fragmentation and anemia.

TABLE 41.10. CAUSES OF MICROANGIOPATHIC HEMOLYTIC ANEMIA

Thrombocytic thrombocytopenic purpura
Hemolytic uremic syndrome
Disseminated intravascular coagulation
Infections: gram-negative septicemia
Snake bites
Hemolytic transfusion reactions
Obstetric complications: abruptio placentae, amniotic fluid embolism, retained dead fetus, eclampsia
Malignant hypertension
Immunologic disorders: vasculitis
Acute glomerulonephritis
Polyarteritis nodosa
Wegener's granulomatosis
Systemic lupus erythematosus
Scleroderma
Renal and hepatic allograft rejection
Disseminated carcinoma: gastrointestinal, breast, and pulmonary adenocarcinoma
Congenital vascular malformations
Cavernous hemangioma
Hepatic hemangioendothelioma

The peripheral blood findings are similar to those seen with macrovascular red cell injury. Additionally, thrombocytopenia is a frequent finding; this reflects the utilization of platelets and

formation of platelet thrombi in thrombotic thrombocytopenic purpura and hemolytic uremic syndrome or the consumption of platelets occurring with activation of the clotting cascade in disseminated intravascular coagulation.

Multisystem support may be necessary in treatment of the complications of anemia and coagulopathy. Nonetheless, therapy of the primary underlying disease must not be neglected.

March Hemoglobinuria

Repetitive forceful contact of body parts with hard surfaces can lead to erythrocyte lysis within the local microvasculature. This phenomenon was originally described in soldiers subjected to prolonged periods of marching. Indeed, long-distance walking or running is the most frequent cause. Because not all individuals are plagued by this complication, individual factors must come into play that govern the destructive forces affecting the erythrocyte.

Clinically, patients experience self-limited bouts of hemoglobinuria after such episodes of forceful contact. Red cell morphology is generally unremarkable, suggesting immediate lysis of erythrocytes within the local microvasculature. Differentiation from myoglobinuria can be established chemically, whereas other causes of hemoglobinuria must be distinguished based on clinical and laboratory features.

Drugs, Chemicals, and Venoms

Drugs

Administration of a number of drugs may lead to red cell damage and lysis through oxidative injury to hemoglobin, red cell membranes, or intracellular enzymes. Particularly vulnerable are individuals deficient in G6PD. In rare circumstances, the oxidant stress associated with administration of some drugs is sufficient to cause hemolysis in apparently normal erythrocytes.

Chemicals

Copper, arsenic, mercury, and lead are the most common heavy metals known to result in intravascular hemolysis after ingestion or inhalation. These chemicals are highly reactive with membrane thiols and interfere with red cell volume control.

Devastating intravascular hemolysis occurs within 2 to 12 hours of exposure to arsine fumes, produced by the action of water on metallic arsenide. The deficiency of ceruloplasmin found in Wilson's disease leads to the accumulation of copper in tissue, which may result in complications of hemolytic anemia. The introduction of significant amounts of water into the circulation has also been associated with hemolysis. This phenomenon has been reported as a complication of tissue irrigation accompanying prostate surgery or as a complication of near drowning in fresh water.

Venoms

The action of phospholipases released by *Clostridium perfringens* or contained within the venoms of some snakes or spiders can lead to hemolysis through dissolution of the red cell membrane. The most devastating example is the frequently fatal hemolysis of clostridial sepsis. Rapid hemolysis in this disorder is attributable to the phospholipase activity of the toxin and is grossly visible as deep cherry-red plasma. Microscopically, a kaleidoscope of red cell changes is visible, mimicking HPP.

The bite of the brown recluse spider results in necrotic arachnidism, an intense local area of tissue necrosis and ulceration, which may be complicated within days by hemolytic anemia resulting from the sphingomyelinase activity of the spider venom. Similar enzyme activity may be found in the venom of various snakes, particularly pit vipers. The intensity of hemolysis depends on the amount of venom absorbed.

Hypersplenism

Anemia may arise from primary splenic sequestration or destruction through a variety of mechanisms: hyperactivity of the splenic reticuloendothelial function; impediment of transit through the splenic cords; or increased transit time owing to splenic pooling. Prominent splenomegaly is common and results from a variety of conditions, including portal hypertension, extramedullary hematopoiesis, metabolic storage disorders, lymphoreticular neoplasia, and infection.

Anemia may be accompanied by thrombocytopenia and/or neutropenia mediated through the same mechanisms. The term hypersplenism has been used to describe such otherwise unexplained cytopenias. To properly invoke hypersplenism, one must demonstrate paradoxical peripheral cytopenia and marrow hyperplasia, both of which normalize after removal of the spleen or effective therapy of the underlying cause for splenic enlargement.

Polycythemia

A discussion of erythrocyte disorders would not be complete without consideration of polycythemia. Polycythemia, or erythrocytosis, is defined as an increased red cell volume. As with the functional definition of anemia, red cell volume is approached in the more practical quantitative terms of hemoglobin or hematocrit. Erythrocytosis therefore equates to an increased hemoglobin level or hematocrit.

Relative erythrocytosis, or stress erythrocytosis, is secondary to diminished plasma volume and must be distinguished from an absolute erythrocytosis, a true increase in red cell volume. Absolute erythrocytosis may occur as a primary autonomous expansion of red cell mass: polycythemia vera (PV), which is also discussed in Chapter 45.

PV must be differentiated from the many causes of erythrocytosis that occur secondary to the effects of excess erythropoietin. Elevated erythropoietin levels may be physiologically appropriate in response to a state of tissue hypoxia, which may arise through habitation at high altitudes, pulmonary disease, congenital heart disease with right-to-left shunts, hypoventilatory states, and high oxygen–affinity hemoglobinopathies. If the tissue hypoxia is reversed in these conditions, erythropoietin levels fall to normal, accompanied by a return of blood hemoglobin levels to normal.

Inappropriately elevated levels of erythropoietin may be encountered in the absence of tissue hypoxia. Several neoplastic and nonneoplastic disorders are associated with the production or release of erythropoietin or erythropoietin-like substances (Table 41.11). A few endocrine disorders have also been associated

with inappropriate erythrocytosis secondary to the effects of androgens on erythropoiesis. Androgens act by stimulating erythropoietin production and by directly promoting erythroid stem cells.

TABLE 41.11. CLASSIFICATION OF ERYTHROCYTOSIS

Relative: Diminished plasma volume
Absolute
Primary: Polycythemia vera
Secondary:
Physiologically appropriate
High altitude
Pulmonary disease
Pickwickian syndrome
Cardiovascular disease with right-to-left shunt
High oxygen-affinity hemoglobinopathies
Congenitally decreased erythrocyte 2,3-diphosphoglycerate
Physiologically inappropriate
Neoplasms
Renal cell carcinoma
Cerebellar hemangioblastoma
Hepatocellular carcinoma
Uterine leiomyoma
Adrenal adenoma
Ovarian carcinoma
Nonneoplastic renal disease
Renal cysts
Hydronephrosis

The approach to the patient depends on identifying the primary or secondary nature of the erythrocytosis. The peripheral blood and bone marrow findings are largely limited to the elevated red cell mass except in the case of PV, in which characteristic increases in all three cell lines are encountered. Splenomegaly, basophilia, elevated leukocyte alkaline phosphatase levels, and increased levels of vitamin B_{12} or B_{12} binding proteins are additional associated findings of PV. The underlying cause of the decreased plasma volume leading to relative erythrocytosis is usually evident. Similarly, symptoms of hypoxemia are often readily recognizable. Geographic altitude and the extreme obesity of the Pickwickian syndrome are difficult to disguise. Hemoglobin electrophoresis, radiographic evaluation, and quantitative erythropoietin levels are useful after exhaustion of the more common causes of erythrocytosis.

Ideally, one would like to maintain the hematocrit below 52% through periodic phlebotomy. As the hematocrit rises above this level, so does blood viscosity, placing the patient at risk for thrombosis, particularly in areas of low flow rates. Additionally, as viscosity increases, the oxygen-carrying capacity of blood decreases; in cases of hypoxia-related secondary erythrocytosis, this will serve to further stimulate erythropoietin production.

The Thalassemia and Hemoglobinopathy Syndromes

James D. Hoyer

Donald R. Hoffman

Much of our knowledge concerning the structure and function of proteins and the genes that control their production has its origin in studies of the hemoglobin molecule.

The history of these studies is peppered with landmark discoveries. The first observation that more than one form of hemoglobin existed, unrelated to its state of oxygenation, was that of Körber who, in 1866, reported his finding of two distinct hemoglobins in the newborn based on their resistance to denaturation by acid and alkali (1). In 1910, Herrick coined the term *sickle cell* to describe the shape of red cells seen in the blood of a student from the Caribbean who had chronic anemia (2). In 1925, Cooley and Lee (3) suggested that the chronic anemia, splenomegaly, and bone changes seen in a series of five children represented a distinct type of anemia. The link between Cooley's anemia and the hemolytic anemia described in the Italian literature, known as the Rietti-Greppi-Micheli type (4,5 and 6) and later as Mediterranean anemia, had to await the work of Wintrobe and colleagues (7). The term *thalassemia*, a euphonious attempt to convert various previous titles into one word, was first suggested by Whipple and Bradford (8). In fact, the word suggests sea (*thalassa*) in the blood (*-emia*) and shows a degree of Western chauvinism because there probably are more people with thalassemia in Asia than there are people in the Mediterranean basin.

Pauling and colleagues (9) are usually given credit for first demonstrating a chemical abnormality in an inherited hemoglobin disorder when in 1949 they observed an electrophoretic difference between adult hemoglobin (Hb A) and sickle hemoglobin (Hb S). However, 1 year earlier, Hörlein and Weber (10) suggested that abnormal hemoglobin might explain their findings in a patient with hereditary methemoglobinemia [later shown to be Hb-M Saskatoon (11)]. The search for the specific defect in abnormal hemoglobin culminated in 1956 when Ingram (12) pinpointed the amino acid substitution in Hb S. A torrent of discoveries followed this observation. To date, more than 750 structurally abnormal hemoglobins (13) have been defined. Establishing the structural and functional relationships of the various molecular lesions became possible largely through the detailed radiographic crystallographic analysis of the hemoglobin molecule conducted by Perutz and colleagues (14,15) that began in the 1960s and continues.

The genetic basis for many of these disorders became evident to several investigators, and the relationship of the more common forms to malaria was suggested by Haldane (16) in 1949. The exact details of the number of globin genes and the precise definition of the lesions that underlie the various disorders had to await the explosion of knowledge resulting from the development of DNA and RNA technologies. The abilities of the cytogeneticist to look at the details of the chromosome have now converged with those of the “gene prober” to produce a complete picture of the globin genes.

The purpose of this chapter is to relate this knowledge to a discussion of the hemoglobinopathies, emphasizing the laboratory aspects of this varied group of disorders.

STRUCTURE AND FUNCTION OF NORMAL HEMOGLOBIN MOLECULES

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

Normal human hemoglobin molecules consist of two pairs of polypeptide (globin) chains, each of which carries a heme portion. The tetramer is roughly spherical in shape (64 × 55 × 40 Å) with a molecular weight (MW) of 64,400 d; the globin portion makes up approximately 96% of the molecule. The hemoglobins that are produced at various stages of embryonic, fetal, and adult life are listed in Table 42.1. Each of these hemoglobins consists of a pair of α- or α-like (ζ) globin chains and a pair of ß- or ß-like globin chains (δ,γ,ε). There is considerable homology within each of these two groups. The structure of the various globin chains is known precisely (17) and can be considered under four headings. The primary structure consists of 141 amino acids in the α-globin chain and 146 amino acids in the ß- and ß-like globin chains. The primary sequence of the ß and δ chains is very similar and differs in only 10 of the 146 residues. The secondary structure involves the α-helical arrangement of amino acids present in 75% of each globin chain. There are eight α-helical segments in the ß chains (letters A through H) and seven in the α chains. The tertiary structure is represented by the larger folds superimposed on the α-helical arrangement that occur in the nonhelical portions of the molecule. Finally, the quaternary structure involves the interrelationship between the four globin chains.

TABLE 42.1. THE NORMAL HUMAN HEMOGLOBINS

Hemoglobin	Globin Chains	Major Source	Embryo	Neonate	Adult
			%	%	%
Gower 1	ζ_2/ε_2	Yolk sac	50	0	0
Gower 2	α_2/ε_2	Yolk sac	25	0	0
Portland	ζ/γ_2	Yolk sac	25	0	0
Hb F	$\alpha_2/{}^{G}\gamma_2$[a]	Liver, spleen	0	75	<1
	$\alpha_2/{}^{A}\gamma_2$	Liver, spleen	0	75	<1
Hb A	α_2/β_2	Bone marrow	0	25	97
Hb A^2	α_2/δ_2	Bone marrow	0	<1	3

[a] Two structurally and genetically distinct γ-globin chains are normally produced, one with glycine (^{G}) and the other with alanine (^{A}) as the 136th amino acid residue.

The heme portion (MW 614 d) of the hemoglobin molecule consists of a porphyrin ring with an iron atom in its center. This porphyrin ring is held in place by two histidine residues in each

globin chain. The iron atom is covalently bonded to the proximal histidine at F8 (eighth amino acid in the F helix) and is stabilized by a large number of other interatomic links within the heme pocket. There are four heme groups in each hemoglobin molecule, allowing it to bind as many as four molecules of oxygen.

The hemoglobin molecule is beautifully suited to its main function—the delivery of oxygen. It has the ability to pick up oxygen at the relatively high oxygen tension in the lungs and deliver it at the lower oxygen tension in the tissues, remaining soluble throughout, undamaged by the oxygen it carries, and utilizing none of it. The hemoglobin molecule exhibits a cooperative binding effect; that is, as each heme group becomes oxygenated, it is easier for the other heme groups to become oxygenated as well. This is attributable to a complex set of steric changes within the molecule that occur at the interface between the four globin subunits. The differences between oxyhemoglobin and deoxyhemoglobin involve numerous amino acids at or near the points of contact between the globin chains. Therefore, amino acid substitutions in these positions can significantly alter heme function and result in high or low oxygen affinity hemoglobin variants.

Several factors facilitate the delivery of oxygen. Unrelated to the hemoglobin molecule itself are the large surface area and pliability of red cells, the blood flow that is systemically and locally controlled, and the rate of diffusion of oxygen into and through the cells adjacent to capillaries. In addition, the oxygen affinity of some cells, particularly those containing myoglobin, attracts oxygen into those cells. Factors directly related to the hemoglobin molecule, and therefore of importance when considering the hemoglobinopathies, include the amount of hemoglobin circulating and its ability to deliver oxygen. The latter is represented by the difference between the oxygen content of arterial and venous blood and is dependent on the oxygen dissociation curve, which indicates the amount of oxygen delivered or released for a unit decrease in oxygen tension (PO_2).

The oxygen dissociation curve (Fig. 42.1) can be depicted as the relationship between the amount of the hemoglobin that is in the form of oxyhemoglobin (percentage of saturation) and the partial pressure of oxygen (oxygen tension) in the surrounding medium. The sigmoidal shape of this curve is owing to the cooperative binding effect as previously described. The oxygen affinity of hemoglobin is often reported as the P_{50}, which is that partial pressure of oxygen at which the hemoglobin is half-oxygenated; P_{50} is inversely related to oxygen affinity. Oxygen dissociation curves of clinical import are those obtained from whole blood under standard physiologic conditions: temperature of 37°C, a PCO_2 of 40 mm Hg, and a pH of 7.4. The P_{50} for normal men is close to 27 mm Hg; it is slightly higher in women. Under normal circumstances, hemoglobin is 97% saturated in the lungs and approximately 75% saturated at the normal mixed venous oxygen tension of 40 mm Hg.

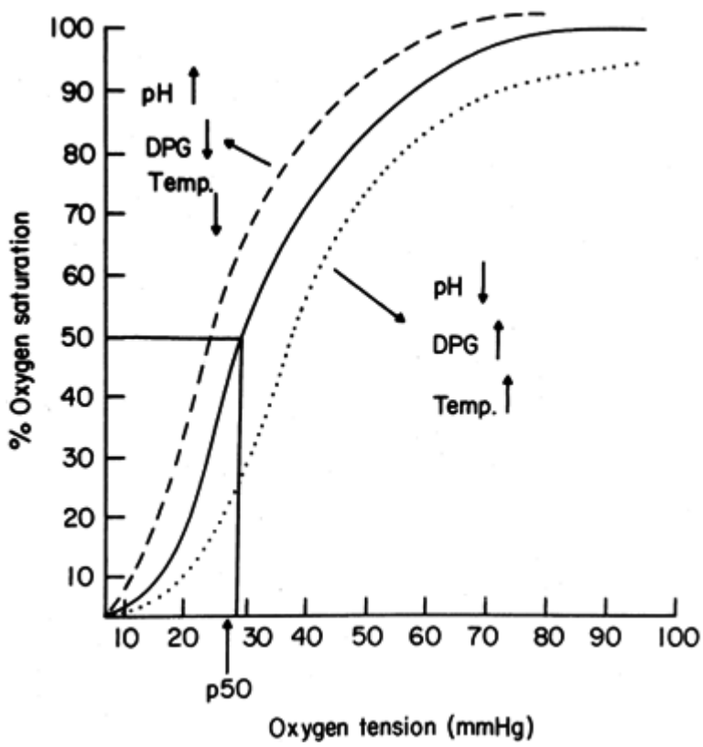

FIGURE 42.1. The oxygen dissociation curve of human adult hemoglobin (Hb A). Alteration in the position of the curve resulting from changes (↑, increase; ↓, decrease) in pH, 2,3-diphosphoglycerate (DPG), and temperature (temp) are indicated by the dashed and dotted lines. (From Weatherall DJ, Clegg JB. *The thalassemia syndromes*, 3rd ed. Oxford: Blackwell Scientific Publications, 1981, with permission.)

There are three main factors, other than the structure of the hemoglobin molecule itself, that affect the shape and position of the oxygen dissociation curve (Fig. 42.1): pH, temperature, and 2,3-diphosphoglycerate (2,3-DPG). Bohr and colleagues (18,19) were the first to show that oxygen affinity was reduced by carbon dioxide. The reciprocal relationship between oxygen affinity and carbon dioxide affinity (an obvious advantage in a system in which oxygen is adsorbed in the lungs and delivered to the tissue, while the reverse is occurring for carbon dioxide) was later shown to be effected by a change in pH. As carbon dioxide is expelled through the lungs, pH increases and oxygen affinity

increases; there is a shift to the left in the oxygen dissociation curve. The lowering of pH that occurs in the tissues has the opposite effect, decreasing the oxygen affinity. Thus, at either end of the system, the Bohr effect of a change in pH is beneficial to the uptake or delivery of oxygen.

Temperature change also alters oxygen affinity (20) in an apparently appropriate fashion. Increase in temperature, with its increased metabolic demands, reduces oxygen affinity and thus increases delivery of oxygen. Conversely, reduction in temperature increases oxygen affinity and reduces delivery of oxygen.

2,3-DPG, the most abundant organic phosphate in the red cell at approximately 5 mmol/L of packed red cells, has a marked effect on the oxygen affinity of hemoglobin (21). 2,3-DPG lowers oxygen affinity in two ways: by binding preferentially to the ß chain of deoxyhemoglobin, thus tending to stabilize it, and by reducing intracellular pH. The concentration of 2,3-DPG within the red cell does not remain constant; it varies inversely with the hemoglobin concentration both in anemic and in normal individuals. Thus, as the hemoglobin falls, the amount of 2,3-DPG increases, oxygen affinity decreases, and more oxygen is unloaded from the hemoglobin.

In summary, hemoglobin, aided by several mechanisms active in the red cell, is a very efficient respiratory pigment. Hemoglobin within the red cell meets the four requirements suggested by Barcroft in 1928 for such a pigment, namely, the ability to (a) carry large quantities of oxygen, (b) take up and release the oxygen at appropriate pressures, (c) remain soluble, and (d) act as a buffer (22).

GENETIC CONTROL

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

Each globin chain is under separate genetic control. The α-gene cluster lies at the extreme end of the short arm of chromosome 16 (16p13.3 pter) (23) and consists of four genes and three pseudo-genes[a] (Fig. 42.2) (24). There are two functional α-genes on each chromosome 16-α1 and α2; they have minor structural differences but transcribe into mRNAs that encode identical α-globin products in unequal quantities; α1 is responsible for approximately one third of the α chains and α2 for approximately two thirds (25).

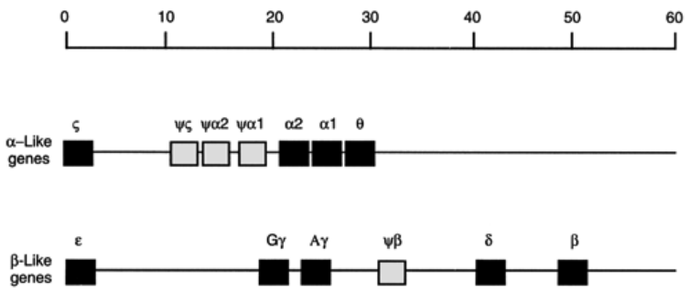

FIGURE 42.2. Relative positions of genes and pseudogenes of the α-like (chromosome 16) and ß-like (chromosome 11) series. The scale represents kilobases; the sequences from left to right represent 5′ (N-terminal) to 3′ (C-terminal) positions on the chromosome.

The ß-globin gene cluster lies on the short arm of chromosome 11 distal to band p14 and between the genes for parathyroid hormone and insulin (26). It consists of five genes (ε, ^{G}γ, ^{A}γ,δ, ß) and one pseudogene (Fig. 42.2). The two γ-genes encode for γ chains that differ slightly structurally, ^{A}γ having alanine and ^{G}γ having glycine as the 136th amino acid residue.

Each globin gene has a similar organization, consisting of three exons and two introns or intervening sequences. All five regions are transcribed into nuclear or pre-mRNA, but the RNA from the introns is spliced out in the formation of cytoplasmic mRNA, which therefore contains only information transcribed from the exons. Regions close to the gene (usually upstream at the N-terminal or 5′-end) are involved in initiating and controlling gene function. Hence, mutations occurring near a gene as well as those within a gene may significantly affect the amount or the structure of its ultimate product.

Under normal circumstances, the product of an α- or α-like gene combines with the product of a ß- or ß-like gene to form a hemoglobin tetramer (Table 42.1). As maturation occurs *in utero* and postpartum, the activity of the genes changes (Fig. 42.3). This change has a downstream direction with the embryonic genes, active in yolk sac erythropoiesis, ceasing to function at approximately the 10th week to be superseded by α- and γ-(hepatic and splenic erythropoiesis); γ-chain production is gradually replaced by ß-chain production starting at approximately the sixth week of fetal life and proceeding until the sixth to 12th month of extrauterine life. By that time, γ-chain production is less than 1% that of the ß chain. Production of the δ chain is approximately 0.5% of total globin-chain production at birth and rises to adult levels by 1 year. (In the vocabulary of the hemoglobin chains, adulthood is reached by approximately 1 year.)

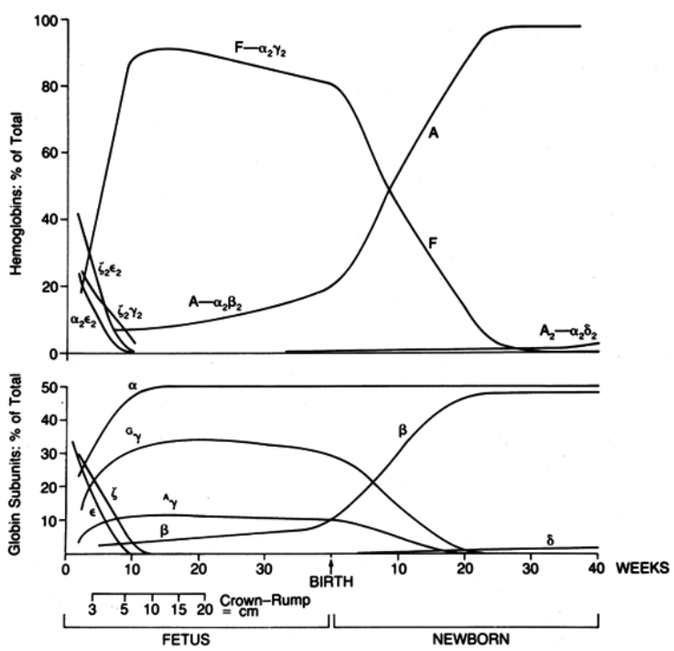

FIGURE 42.3. Changes in globin-chain and hemoglobin production during human development. (From Bunn HF, Forget BG. *Hemoglobin: molecular, genetic and clinical aspects*. Philadelphia: W.B. Saunders, 1986, with permission.)

Clinically, the most significant of these changes is the γ to ß switch, which explains why at birth a normal neonate possesses approximately 75% to 90% Hb F ($\alpha_2\gamma_2$) and 10% to 25% Hb

A ($\alpha_2\beta_2$), whereas by approximately 12 months, the infant possesses less than 1% Hb F, approximately 96% Hb A, and approximately 3% Hb A_2 ($\alpha_2\delta_2$).

CLASSIFICATION AND NOMENCLATURE

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

Most hemoglobinopathies are inherited abnormalities. A few result from *de novo* mutation (27), and there is a small but fascinating group of acquired defects mimicking α thalassemia and persistence of fetal hemoglobin (28,29).

The inherited group of disorders can be divided into three broad categories (Table 42.2):

- *Structural, or qualitative abnormalities*, in which the amino acid sequence of one or more of the globin chains is altered (by substitution, addition, deletion, or fusion) as a result of an incorrect DNA code. Hb S is a common example.
- *Quantitative abnormalities*, in which the production of one or more of the globin chains is reduced or absent (owing to inadequate amounts of mRNA, to unstable mRNA, or to mRNA that contains an untranslatable "nonsense" message) resulting in an imbalance in globin-chain production. These form the various thalassemia syndromes that are classified according to the globin chain whose production is deficient.
- *Hereditary persistence of fetal hemoglobin* (HPFH), in which there is complete or partial failure of the γ to ß switch. As noted later, there is an overlap between HPFH and the ß thalassemias, resulting in a spectrum with HPFH at one end, ß thalassemia at the other, and δß thalassemia as an intermediate.

TABLE 42.2. A CLASSIFICATION OF THE MORE COMMON HEMOGLOBINOPATHIES

Structural defects
Involving Hb S
Without *in vivo* sickling
Hb AS (sickle cell trait)
Hb AS-G-Philadelphia
Hb AS α-thalassemia
Hb S HPFH
With *in vivo* sickling
Hb SS (sickle cell anemia)

Hb E
Unstable hemoglobins (some)
δß-Thalassemia
HPFH
Black type
Swiss type
Greek type
Associated with structural defect
Hb Kenya

Hb, hemoglobin; HPFH, hereditary persistence of fetal hemoglobin.

Because many of these disorders are common, combinations occur as a result of compound heterozygosity for abnormal genes (Fig. 42.4). Furthermore, structural defects, such as Hb Lepore, or Hb E may cause an imbalance in globin-chain production and hence a thalassemia syndrome. In general, the various genetic abnormalities are inherited in a codominant fashion.

Nomenclature commonly used for the hemoglobinopathies is somewhat confusing because as knowledge has been accumulated, it has not always been translated into more accurate designations. The structural hemoglobin variants can be specifically named according to their structural abnormality. Thus, sickle hemoglobin is $\alpha_2\beta_2^{6glu\rightarrow val}$ or $\alpha_2\beta_2^{6(A3)glu\rightarrow val}$, indicating that the sixth amino acid residue [or the third amino acid in the first (a) α helical segment] of the ß-globin chain, which is normally glutamic acid (GAG), is replaced by valine. However, this is difficult to verbalize, if not to write; hence, it is generally referred to as Hb S.

Normal adult hemoglobin is designated Hb A, and fetal hemoglobin as Hb F. As hemoglobin variants were discovered, they were given letters of the alphabet, beginning with Hb C (Table 42.3). However, it was soon realized that the alphabet would not be large enough to accommodate all hemoglobin variants, and a somewhat disorganized system of common nomenclature evolved. Because several hemoglobin variants can show identical mobilities (particularly on alkaline electrophoresis), they may be given the same letter designation followed by the place of origin of the individual carrying the hemoglobin variant. For example, there are several variants with the Hb D designation that all migrate in the S position or alkaline electrophoresis. The most common of these is Hb-D Los Angeles (D-Punjab).

However, other hemoglobin variants have been named in a variety of ways, such as after countries (Hb-Nigeria, Hb-Mexico), states (Hb-Ohio, Hb-Michigan) cities or towns (Hb-Seattle, Hb-Mulmö), urban areas (Hb-Queens), rivers (Hb-Volga), hospitals (Hb-Barts), and even historic figures (Hb-Abraham Lincoln, Hb-Osler). Another area of confusion occurs when hemoglobin variants were given different designations but found subsequently to be structurally identical. For example, Hb G-Philadelphia, $\alpha_2^{68[E17]Asn\rightarrow lys}\beta_2$ has nine different names attached to it.

In the laboratory, the specific designation of the structural abnormality would seem to be the most logical nomenclature to use. However, at least for the common varieties, the exact structure is seldom verified, so the eponym is usually applied.

When referring to heterozygotes, shorthand is used, listing the hemoglobin present in greatest quantity first. Hb AS, for example, refers to a sickle cell trait in which there is approximately 55% Hb A and 45% Hb S. The same system can be applied to double heterozygotes; for instance, Hb SC indicates an individual who inherited a β^s gene from one parent and a β^c gene from the other.

Hb S β thalassemia indicates an individual who inherited a β^s gene from one parent and a β-thalassemia gene from the other (Fig. 42.4).

The nomenclature commonly used for the thalassemia syndromes is relatively simple but somewhat less accurate; the Greek letter of the globin chain that is reduced in quantity is used. Thus, β thalassemia indicates reduction of β-chain production, α thalassemia reduction of α-chain production, and so on. However, there are almost 200 different lesions in or near the α gene that can cause β thalassemia. Attempts to name the various subsets of the thalassemias are discussed later.

The term *trait* is used for heterozygotes (sickle cell trait, Hb C trait) and disease for the homozygote (sickle cell disease, Hb C disease); however, not all authors would agree that sickle cell anemia is synonymous with sickle cell disease. This system becomes unwieldy when four genes are involved, as in α-chain abnormalities such as Hb G-Philadelphia. The adjectives minor and major, used in describing the thalassemias, were originally used in both a clinical and a genetic (heterozygote and homozygote)

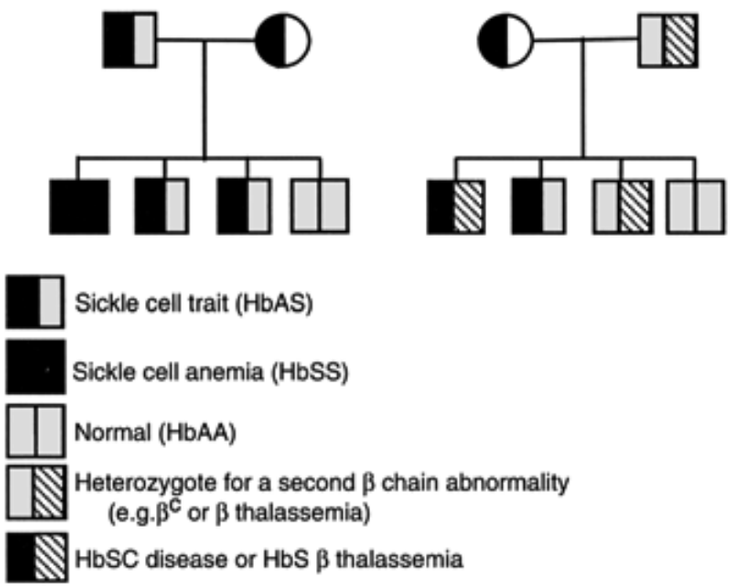

FIGURE 42.4. Inheritance pattern of hemoglobinopathies. β-Globin chain defects are used in these examples. α-Globin chain defects have a more complicated inheritance pattern because two α-globin genes are inherited from each parent. (Reprinted with permission from Hoffman GC. The sickling disorders. *Lab Med* 1990;21:797–807.)

TABLE 42.3. ORDER OF DISCOVERY OF HEMOGLOBIN VARIANTS

Hemoglobin Variant	Year
Hb S	1949
Hb C	1950
Hb D-Los Angeles	1951
Hb E	1954
Hb G (now Hb Korle-bu)	1955
Hb H	1955
Hb I	1955
Hb J	1956
Hb K	1957

Hb, hemoglobin.

sense. As the large number of different thalassemia genes with varying clinical expressions became known, the terms have reverted to a strictly clinical interpretation (Table 42.4).

TABLE 42.4. CLASSIFICATION OF THE THALASSEMIA SYNDROMES ACCORDING TO CLINICAL SEVERITY

Thalassemia major	Severe anemia; red cell transfusion required to maintain life.
Thalassemia intermedia	Moderate anemia; red cell transfusion occasionally required.
Thalassemia minor	Slight if any anemia, microcytic red cells, often with erythrocytosis.
Thalassemia minima	Silent thalassemia; no clinical or hematologic abnormality. Demonstrable by family studies or gene analysis.

INCIDENCE, DISTRIBUTION, AND THE MALARIA HYPOTHESIS

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

Most of the more than 700 hemoglobinopathies are rare and known to occur in a handful of families at the most; the affected individuals are almost exclusively heterozygotes, with homozygotes occurring mainly in consanguineous families. The common abnormalities, particularly those that have reached polymorphic levels in some populations, such as Hb S, Hb C, Hb E, and the α and ß thalassemias achieved their popularity through natural selection.

Inherited abnormalities in the three major components of the red cell (membrane, hemoglobin, and a rudimentary glycolytic pathway) represent some of the best examples of Darwinism in action among human populations. All are related to malaria (30). The remarkably high incidence of stomatocytic elliptocytosis in Melanesia is an example of a membrane abnormality that is beneficial in areas of endemic *Plasmodium falciparum* malaria (31). The parasite has difficulty entering these abnormal red cells. The Duffy blood group provides another striking example (32); *Plasmodium vivax* is unable to enter Duffy-negative red cells. In Africa, Duffy-negative individuals, Fy(a-b-), are found mainly in western regions where *P. vivax* malaria is not found. In this situation, it appears that the blood group distribution preceded and prevented the spread of *P. vivax* from the east (33).

This Duffy relationship is completely different from that with Hb S, whose incidence is greatest where malaria (in this case *P. falciparum*) is most prevalent. There are areas in central Africa in which the incidence of sickle cell trait reaches 40%. This high incidence is maintained (despite the loss of sickle genes from the gene pool with the neonatal death of most Hb SS individuals) because falciparum malaria is much milder and seldom lethal in Hb AS individuals than in normal (Hb AA) individuals. This is an example of balanced polymorphism in which the heterozygote has an advantage over both the normal and abnormal homozygote (34). The high incidence of Hb E in southeast Asia can also be explained by the malaria hypothesis (35).

The distribution of α and ß thalassemias also matches the distribution of malaria. The classic studies of Siniscalco and colleagues (36) in Sardinia and Flint et al. (37) in Melanesia are two among many population studies demonstrating this relationship. In Sardinia, the incidence of ß thalassemia minor [and glucose-6-phosphate dehydrogenase (G6PD) deficiency] is directly related to the incidence of malaria, which in turn is related to the altitude at which the populations live (mosquitoes being limited to valleys by temperature and water requirements). In Melanesia, malaria and α thalassemia were shown to be directly related, the diagnosis of α thalassemia being proved by gene analysis. One exception to the relationship between malaria and α thalassemia is the relatively low prevalence of the latter in central and western Africa, where Hb S is the major hemoglobinopathy. A likely explanation is that two mutations, both beneficial, are unlikely to coexist if both homozygotes are lethal. Hb S seems to have won, perhaps as the more beneficial trait with respect to *P. falciparum* infection.

G6PD deficiency is another guard against malaria, and, like sickle cell trait, has a high incidence in Africa (38).

The incidence of Hb S (present in approximately 8% of African Americans), G6PD deficiency (with a similar incidence), α thalassemia minor (approximately 30% of African Americans have single-gene deletion type), and ß thalassemia minor (3% to 5% among African Americans and individuals of Mediterranean extraction) can be explained by their origin from areas of high malarial endemicity.

LABORATORY APPROACH

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

The diagnosis of all hemoglobinopathies eventually lies in the laboratory. The number and degree of sophistication of the tests needed depend on the clinical needs of the patient population and the interests of the investigator. At one extreme, a simple solubility test to rule out the presence of Hb S may suffice, whereas at the other, precise amino acid sequencing or gene analysis may be required.

There are three main reasons that a laboratory may be asked to investigate the possible existence of a hemoglobinopathy. There may be a hint in the patient's history or physical examination; the blood count may indicate the possibility; or the investigation may be required as part of a screening program for either a population such as neonates or individuals as a preoperative or other type of requirement. Hemoglobinopathies of real or potential clinical significance will usually present with some abnormality in the blood count. However, many of the rarer examples detected in screening programs are noticed because of an abnormal electrophoretic pattern; many of these will be of little or no clinical significance but nevertheless need to be investigated. Whatever the entry point, hemoglobin electrophoresis and a blood count, if not already performed, will almost certainly be required.

In this section, the application and value of the more commonly used tests are discussed. Some more esoteric tests, including those involving molecular and gene studies, are mentioned in later sections dealing with specific diseases.

Blood Count and Red Cell Morphology

Three types of abnormal blood counts are associated with clinically significant hemoglobinopathies:

1. Microcytic hypochromic red cells often without significant anemia (as in thalassemia minor);
2. A hemolytic anemia (as in sickle cell anemia and Hb C disease);
3. A combination of the two (as in thalassemia intermedia and major).

In addition to these common findings, a physiologically appropriate erythrocytosis is associated with high oxygen affinity hemoglobins, and the appropriate anemia is associated with low oxygen affinity hemoglobins.

Red cell morphology may provide a general or specific indication of a hemoglobinopathy. The latter include sickle cells, Hb C crystals, and the bizarre-shaped red cells seen in Hb SC disease.

Less specific and often requiring additional staining techniques are Heinz bodies associated with many unstable hemoglobins and the Hb H inclusions of Hb H disease and some forms of α thalassemia minor. Target cells are particularly common when Hb C or Hb D is present.

Heinz bodies, which consist of aggregates of denatured hemoglobin within the red cell, are seen in two main situations: oxidative hemolysis and instability of the hemoglobin molecule. They are not visible in red cells stained with Wright's or other trichrome stains; vital or supravital stains such as those used to demonstrate reticulocytes are required. Crystal violet or methyl violet has an advantage over stains such as new methylene blue and brilliant cresyl blue because the latter redox stains are themselves able to cause Heinz body formation. However, this latter property may be advantageous in situations in which few Heinz bodies are present. This concept can be carried further by the use of phenylhydrazine, a drug that in correct concentration *in vitro* will cause the formation of many more Heinz bodies in red cells containing an unstable hemoglobin (or with other abnormalities such as G6PD deficiency that predispose to Heinz body formation) than in normal red cells (39,40). Whichever staining method is use, normal controls must be incorporated in the procedure.

Hb H (β_4) is an unstable hemoglobin composed of four ß chains and forms a distinct type of Heinz body when exposed to a redox dye such as brilliant cresyl blue or new methylene blue (41). A suspension of red cells containing Hb H when incubated at 37°C for 1 hour with a few drops of 1% citrate/saline solution of brilliant cresyl blue will contain many round, small-blue-stained inclusions of precipitated Hb H, giving the cell a golf-ball appearance. These inclusions can be distinguished from the precipitated RNA of reticulocytes and the larger Heinz bodies associated with other unstable hemoglobins under similar test conditions.

Solubility Test

The relative insolubility of deoxygenated Hb S compared with other hemoglobins is the basis of a simple test for its presence (42).

Several acceptable commercial kits are available that consist of a mixture of a lysing agent and a reducing agent in a high-phosphate buffer solution. When red cells containing Hb S are present, the hemoglobin S will precipitate forming an opaque solution that is readily distinguished from the clear pink solution obtained with other hemoglobins.

False-positive results are rare and may be attributable to incomplete lysis of red cells because of erythrocytosis or to the presence of large amounts of protein in the patient's plasma, lending an opacity to the solution. The presence of many nucleated red blood cells in the peripheral blood can also cause a false-positive result. False-negative results, conversely, are not uncommon and depend mainly on the amount of the Hb S present. When less than 20% to 25% Hb S is present [as may occur in a transfused or exchange-transfused patient with sickle cell anemia, in an individual with both sickle cell trait (Hb AS) and two-deletion α thalassemia (α—/α—), in a severely anemic patient, and most important, in a neonate with sickle cell anemia or trait], the result is often negative. Doubling the quantity of blood tested alleviates this problem.

A positive solubility test indicates only the presence of Hb S or any hemoglobin containing the Hb S mutation (such as Hb C-Harlem, a doubly substituted hemoglobin variant) but does not provide a quantitative measure and does not therefore distinguish sickle cell trait, sickle cell anemia, or any combination of Hb S and another hemoglobinopathy.

Electrophoresis

Electrophoresis on various media is usually the first step in demonstrating and specifying a hemoglobin variant. Four commonly used techniques are outlined here: electrophoresis at alkaline pH (43,44), acid electrophoresis (45,46,47 and 48), isoelectric focusing (IEF) (49,50 and 51), and electrophoresis of separated globin chains (52,53).

Alkaline electrophoresis is a popular method used in the evaluation of hemoglobinopathies. It is also often called cellulose acetate electrophoresis, as this is the support medium used by many laboratories. In alkaline solution (tris-ethylenediaminetetraacetic acid (EDTA)-borate buffer at pH 8.6), all hemoglobin molecules have a net negative change and thus will migrate toward the anode when placed in an electric field. The amino acid substitution in many hemoglobin variants alters their net charge and thus their electrophoretic mobility (Fig. 42.5). Because substitution of either different amino acids or the same amino acid at different points in a globin chain may result in identical alterations in net change, electrophoresis at alkaline pH seldom provides a specific diagnosis. For example, although the substitution occurs at different positions, Hb C, Hb E, and Hb O-Arab all have a glutamic acid to lysine substitution, and thus they migrate together on alkaline electrophoresis. Similarly, many of the Hb D or Hb G variants co-migrate with Hb S or alkaline electrophoresis.

However, many types of hemoglobin that migrate together on alkaline electrophoresis can be separated utilizing electrophoresis at an acid pH (pH 6.0). The most commonly used method utilizes agar as the support medium and a citrate-citric acid buffer. The separation of variants depends not only on change differences but also on the ability of the variant to combine with a compound within the agar, termed agaropectin. This molecule combines with Hb variants at the surface of the molecule, most notably Hb C and Hb S. Most Hb variants with a substitution in the internal portion of the globin subunit do

not show an altered electrophoretic mobility from Hb A on this medium. Acid electrophoresis is most useful for differentiating Hb C from Hb E and Hb O-Arab and to confirm homozygous Hb S (i.e., that a single band on the S position or alkaline electrophoresis is composed only of Hb S and not Hb S and another Hb variant). The migration pattern of many common Hb variants on both alkaline and acid electrophoresis is shown in Fig. 42.6).

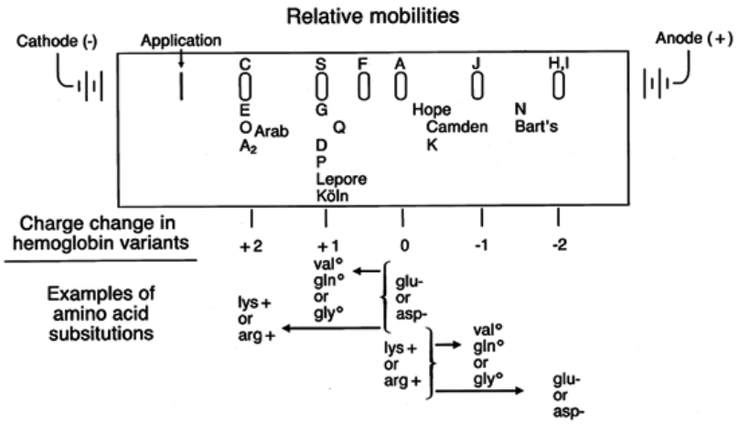

FIGURE 42.5. Hemoglobin electrophoresis at pH 8.6 (alkaline electrophoresis). At this pH, the hemoglobin molecule has an overall negative charge and migrates toward the anode. An amino acid substitution, which alters the overall charge of the molecule, will alter the electrophoretic mobility relative to Hb A.

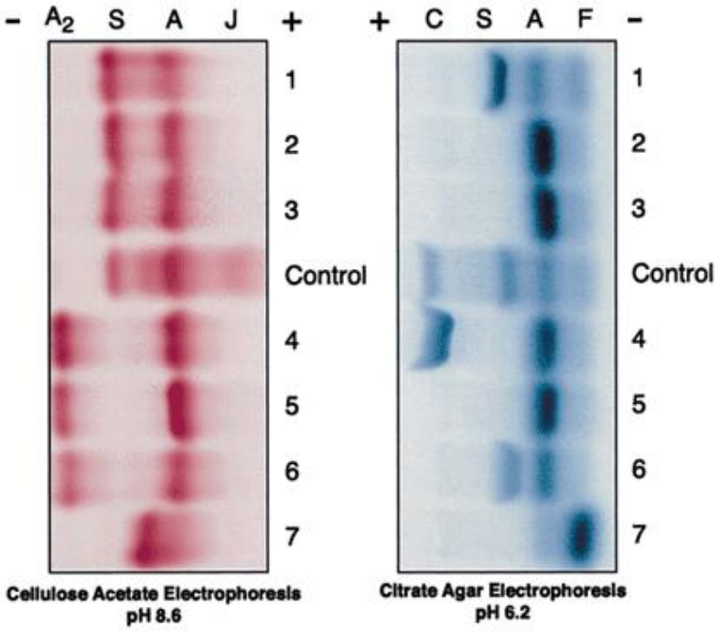

FIGURE 42.6. Examples of common hemoglobin variants on both cellulose acetate and citrate agar electrophoresis. 1, Hb S trait; 2, Hb G-Philadelphia trait; 3, Hb D-Punjab trait; 4, Hb C trait; 5, Hb E trait; 6, Hb O-Arab trait; 7, increased Hb F in a neonate.

IEF is another popular method used by laboratories that have a large number of specimens or very small sample volumes, such as laboratories that perform newborn screening. This electrophoretic method utilizes carrier ampholytes, small proteins that are able to carry both current and pH (Zwitterions). These compounds have MWs of 300 to 1,000 and are used in mixtures of 50 to 100 individual compounds. The ampholytes are incorporated into the support medium (either agarose or polyacrylamide). When a current is applied to the support medium, these ampholytes will gradually establish a pH gradient throughout the gel (for example, a pH range of 6 to 8 for hemoglobin analysis). High voltages must be used because the carrier ampholytes are present in high concentrations. Samples (RBC lysates) then placed on the gel will travel to their isoelectric point (the point at which they carry a net zero charge), where migration stops. Unlike alkaline electrophoresis, there is no danger of running the gel too long and running fast variants off the end of the gel. Because of minor differences in isoelectric points of various hemoglobin variants, IEF gives better separation of hemoglobin variants that show similar mobilities on alkaline electrophoresis. The bands present are much sharper than those seen on alkaline electrophoresis. Some hemoglobin variants, such as Hb-Malmö, show separation from Hb A, which is not seen on alkaline electrophoresis. Additionally, minor bands (such as Hb H, Hb-Barts, and δ-chain variants) are easily seen. However, minor bands (owing to glycosylated hemoglobins) and aging bands (methemoglobin,

glycerated hemoglobin) are also seen and may cause confusion in interpretation. Some typical patterns obtained with IEF are shown in Fig. 42.7 and Fig. 42.8.

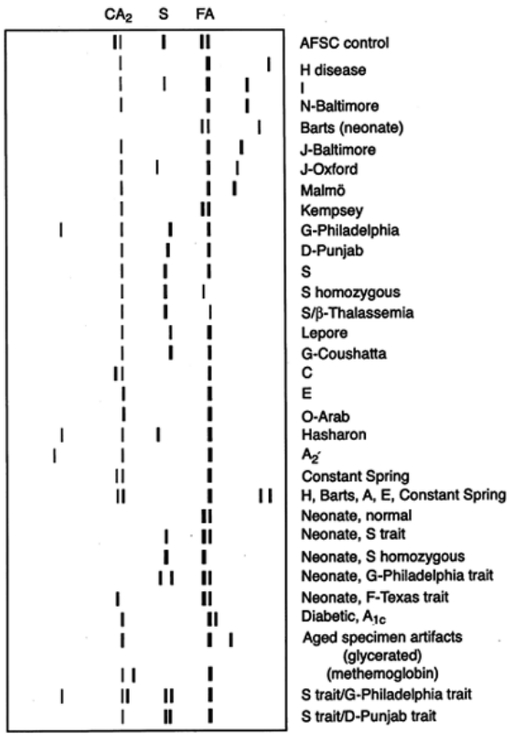

FIGURE 42.7. Isoelectric focusing. The electrophoretic mobilities of many hemoglobin variants are shown. (From Fairbanks VF, Klee G. Biochemical aspects of hematology. In: Burtis CA, Ashwood ER. *Tietz' textbook of clinical chemistry*, 2nd ed. Philadelphia: Saunders, 1994:2037, with permission.)

Globin-chain electrophoresis is an ancillary procedure in which a hemoglobin lysate with mercaptoethanol (to remove heme) and 8 mol/L urea (to dissociate the globin chains). When the resultant preparation is run on cellulose acetate, the α- and ß-globin chains are clearly separated. Furthermore, any hemoglobin variants present will often show altered mobility from the normal globin chains. Globin-chain electrophoresis is usually run at both an alkaline and acid pH, as some hemoglobin variants show slight differences in mobility. This method often gives additional information on hemoglobin variants that have similar mobilities by other methods. Examples of different variants are shown in Fig. 42.9 and Fig. 42.10. A summary of the electrophoretic mobilities of many hemoglobin variants is given in Fig. 42.11.

Although the references cited here and the instructions provided by manufacturers enable one to produce clear electrophoretic patterns, there are a few practical points that require emphasis. The clarity of separation depends to a significant degree on the specimen used and its handling. Blood collected in Na-EDTA as an anticoagulant is adequate for most purposes and may be stored for at least 24 hours at room temperature. This permits overnight mailing without special handling. Unstable hemoglobins are an exception because, if very unstable and therefore present in small amounts, they may disappear during such storage.

Given an adequate blood sample, there are several approaches to preparing it for electrophoresis. Because most plasma proteins such as albumin that are present in a significant quantity have an electrophoretic mobility much greater (faster) than any hemoglobin, the washing of red cells before preparing a lysate need not be tremendously thorough. In fact, if only a small quantity of blood is available, as in a capillary tube sample, rinsing can be omitted for screening purposes. Nevertheless, washing the red cells before preparing a lysate provides the best specimen.

Generally, application is best made with one of the several commercially available applicator wells, thus ensuring uniform and reproducible amounts. The quantity of lysate applied can be doubled when the amount of an abnormal hemoglobin under investigation is known to be small in cord blood specimens, for example, where the amount of Hb A and its variants are low compared with Hb F, or when attempting to demonstrate an abnormal Hb A_2 when an α-chain defect is suspected. The concentration and amount of lysate required for IEF are less than those for the other techniques.

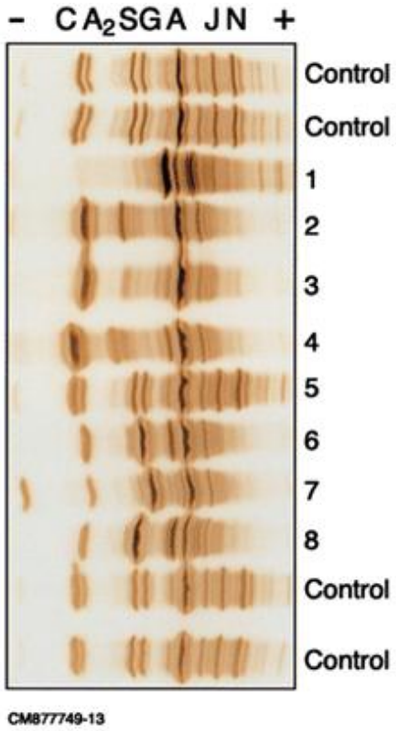

FIGURE 42.8. Isoelectric focusing gel with examples of common hemoglobin variants. 1, increased Hb F in a neonate. There is also Hb-Barts present, indicating alpha thalassemia; 2, Hb O-Arab trait; 3, Hb E trait; 4, Hb C trait; 5, control consisting of Hbs C-S-G, J, and N; 6, Hb D-Punjab trait; 7, Hb G-Philadelphia trait; 8, Hb S trait. Most specimens also show the aging bands owing to glycerated Hb and methemoglobin.

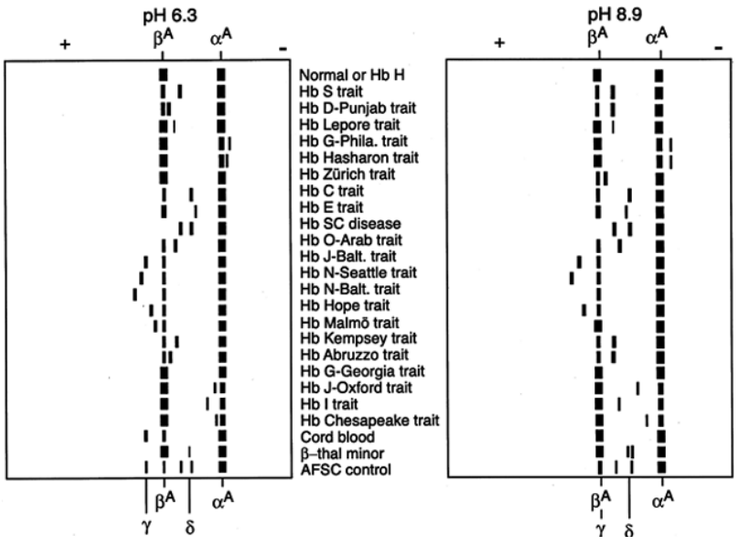

FIGURE 42.9. Globin chain electrophoresis. Examples of both α- and ß-chain variants are shown. (From Fairbanks VF, Klee G. Biochemical aspects of hematology. In: Burtis CA, Ashwood ER. *Tietz' textbook of clinical chemistry*, 2nd ed. Philadelphia: Saunders, 1994:2036, with permission.)

It is helpful to keep the concentration constant because quantitative comparisons of the electrophoretic bands are often of value. In this context, the density of the carbonic anhydrase band is often useful because its concentration in the mature red cell is constant and therefore is usually proportional to the amount of lysate applied.

Quantitation

The quantitation of normal and variant hemoglobins is often of diagnostic importance. With a well-prepared electrophoretic pattern, “eyeballing” the plate is often as useful as more specific quantitation. Estimating the relative proportions of Hb S and Hb A can often be done in this manner. In those circumstances in which a more precise estimate is required, densitometry can be used on cellulose acetate plates. However, this method has disadvantages, particularly when comparing large with small quantities, as when measuring Hb A_2 as a percentage of a relatively large amount of Hb A; the smaller quantity is usually overestimated. Elution of the hemoglobin bands from the electrophoretic plates and direct measurement of their hemoglobin content provide even greater accuracy, but the method is time-consuming and seldom justified.

For some hemoglobins, specific methods of quantitation are readily available and simple to perform. Hb F can be quantitated base on its resistance to alkali (54); toluene may be used in place of carbon tetrachloride called for in this method. Hb A_2 can be measured by elution from an anion-exchange column (55,56), Hb-Barts and Hb H by elution from a cation-exchange column (57).

High-Performance Liquid Chromatography

High-performance liquid chromatography (HPLC) is a method that has been available for many years but not routinely used in the analysis of hemoglobinopathies. However, in the past few years, HPLC instruments have become available that are compact, user friendly, and dedicated to the detection of hemoglobins and their variants (58,59). Run lengths have been shortened from more than 20 minutes to 6 to 7 minutes. These instruments are approved by the U.S. Food and Drug Administration for the measurements of Hb S, A_2, and F but also give useful information for other hemoglobin variants that may be present (Fig 42.12). These instruments generally utilize a weak cation exchange column. Gradually increasing the ionic strength of the eluting solution causes the hemoglobin protein to come off the column at a particular retention time. Amino acid substitutions that are present in the hemoglobin variant will alter the

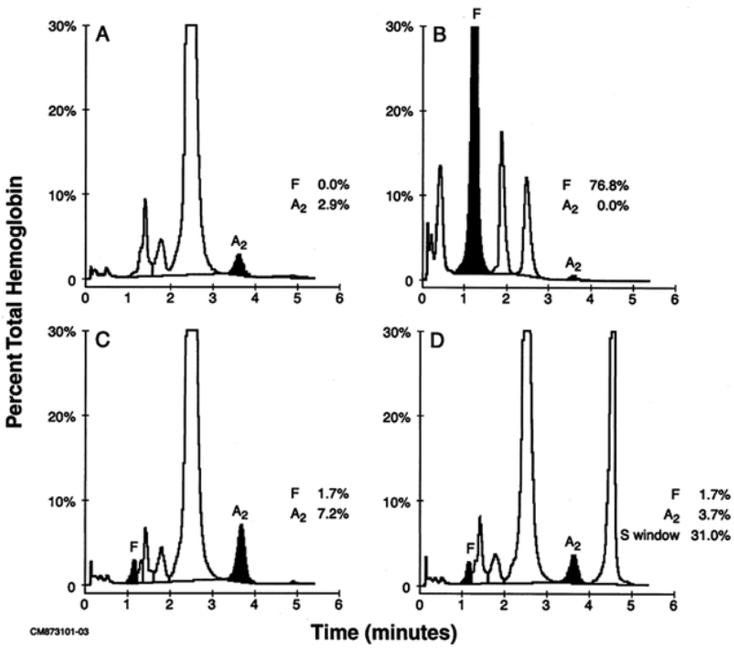

FIGURE 42.12. High-performance liquid chromatography. **A**, Normal adult; **B**, neonatal specimen with high Hb F (a hemoglobin variant is also present); **C**, ß-thalassemia trait with elevated Hb A_2; **D**, Hb S trait.

retention time relative to Hb A. There is some analogy between the retention times obtained by HPLC and the patterns seen on alkaline electrophoresis. Amino acid substitutions that give the molecule an overall more negative change at alkaline pH will run faster than Hb A. Similarly, these same substitutions usually result in a shorter retention time than Hb A on the HPLC column. Conversely, those amino acids substitutions that would result in a more positively changed molecule on alkaline electrophoresis will usually result in a longer retention time than Hb A on HPLC. This method also has the advantage that Hb C does not co-elute with Hb A_2, and so Hb A_2 can be measured in the presence of Hb A_2. Hb E and O-Arab, however, still co-elute with Hb A_2 by this method.

Globin-Chain Synthesis

All the methods described so far provide a static view of the hemoglobin content of red cells. Under some circumstances, particularly in the thalassemia syndromes, the relative rates of production of the various globin chains provide useful information. These globin chain-synthesis studies (60) require the separation and quantification of globin chains that have been generated in a reticulocyte-enriched preparation in the presence of an adequate supply of all necessary amino acids, one of which (usually leucine) is radiolabeled. The latter is then used as an indicator of the quantity of various globin chains produced. The individual globin chains are separated by high-pressure liquid chromatography. In many situations, such as in the diagnosis of the α-thalassemia syndromes, this methodology has been replaced by specific gene identification.

Molecular Methods

Molecular methods are available for the diagnosis of hemoglobinopathies and thalassemias but are generally restricted to use at major medical centers. Most α thalassemia mutations are attributable to deletions of one or both α chains; either Southern blot or polymerase chain reaction (PCR) methods can be utilized to detect most of these mutations. Molecular detection of ß-thalassemia mutations is more difficult because most mutations are nondeletional and there are a far greater number. In many geographic regions, however, relatively few mutations account for the majority of cases. Specific molecular assays can then be set up to look for only those specific mutations (25,61,62 and 63).

In very unusual cases, DNA sequencing of the three coding regions (exons) of the α- and ß-globin genes can be performed to definitely identify the mutation present in hemoglobin variants. This is particularly useful in confirming previously undiscovered hemoglobin variants or those hemoglobin variants that do not separate from Hb A on electrophoretic methods by HPLC (owing to neutral change substitutions). This process is accomplished by PCR-based assays using primers that flank the three exons and has been made much simpler with the advent of automated DNA sequencing machines. DNA sequencing can also be used to identify α-thalassemic mutations as well. However, these also require primers that will amplify the noncoding portions (introns) of ß-globin genes.

THALASSEMIA SYNDROMES

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

The thalassemia syndromes result from an imbalance in globin-chain production that is almost always owing to underproduction of one or two types of globin chains; rare examples in which overproduction of a globin chain causes the imbalance have been reported (64).

The thalassemia syndromes are classified according to the deficient globin chain or chains and according to their clinical severity (Table 42.3). The two largest groups are the α and ß thalassemias; δ and γ thalassemia is much less common and of little clinical significance. Therefore, they are discussed only briefly here.

δ Thalassemia

δ Thalassemia has been reported in the heterozygous and homozygous states (65). Hb A_2 ($\alpha_2\delta_2$) is reduced in the heterozygote and is usually absent in the homozygote because the genetic lesion results in failure to produce any δ-globin chains (δ^0); δ^+ thalassemia, in which there is a reduced production of δ chains, has also been reported (66). Neither the heterozygote nor the homozygote exhibits any clinical or hematologic abnormality. Co-inheritance of δ and ß thalassemia results in a form of ß thalassemia with a normal level of Hb A_2 (65). Reduction or absence of Hb A_2 is also seen in δß thalassemia, some forms of HPFH, and in association with Hb Lepore.

γ Thalassemia

Because a normal individual inherits two pairs of γ-globin genes, one pair coding for ^{G}γ-globin chain and the other for ^{A}γ-globin chains, which differ in possessing glycine or alanine as the 136th amino acid residue, several different forms and combinations of γ thalassemia might be expected. ^{G}γ Thalassemia appears to be the most common but even in the homozygote results only in slight reduction in the total quantity of Hb F in the fetus and newborn and in no clinical or hematologic abnormality in the adult (67). Homozygous loss of the activity of both ^{G}γ- and ^{A}γ-globin genes has not been reported and probably would be incompatible with life.

α Thalassemia

α Thalassemia results from a deficiency of α-globin chains and, except in very rare circumstances, is an inherited disorder (25,68). Most α-thalassemia syndromes are caused by a deletion of all or part of one or both α-globin genes on chromosome 16.

There are eight known deletions involving one of the α-globin genes. Two of these, which involve deletions of -3.7 kb and -4.2 kb, are very common worldwide and are found in multiple ethnic groups (69). These are probably the most common single gene disorders in the world. Single-gene deletion α thalassemia has an incidence of approximately 30% among African Americans (70), and the incidence is as high as 80% in some areas of Papua New Guinea (37). There are 21 known mutations that involve the deletion of both α-globin genes. The three most common are (a) the $--^{SEA}$ mutation found in southeast Asians, (b) the $--^{MED-1}$ deletion found in the Mediterranean population, (c) a 20.5-kb deletion that involves

all the α^2 and the 5′ end of the α^1 gene, also found in the Mediterranean population (69).

There are at least 32 known types of nondeletional α-thalassemia mutations; most are extremely rare. Fourteen mutations result in the synthesis of hyper-unstable hemoglobins, and five are owing to terminating codon mutations, such as Hb-Constant Spring. The remainder of the mutations affects some aspect of mRNA translation (69).

Because the normal complement of α-globin genes is four, there are five possible combinations of deletion (Table 42.5). Deletion of both genes from the same chromosome is called α thalassemia 1, whereas deletion of only one gene is known as α thalassemia 2; this apparently illogical nomenclature arose because the double deletion was described first. α Thalassemia 1 is particularly prevalent in southeast Asia and in the Mediterranean basin but is very rare among African Americans.

The severity of the clinical and hematologic effects is directly related to the number of genes deleted or affected (Table 42.5). As a consequence of the deficiency of α-globin chains, there is a relative excess of γ-globin chains in the fetus and infant and of ß chains in the adult; these excess chains can themselves form tetramers: γ_4 (Hb-Barts) and $ß_4$ (Hb H). These two hemoglobins are of little physiologic value because of their exceedingly high oxygen affinity. They are both unstable, a characteristic that underlies the hemolytic component of Hb H disease. On hemoglobin electrophoresis, they are fast migrators (Fig. 42.14) and can be quantitated by separation on cation-exchange columns (57). Various reticulocyte stains such as brilliant cresyl MA blue and new methylene blue cause Hb H to precipitate within the red cells, giving them a typical golf-ball appearance (41).

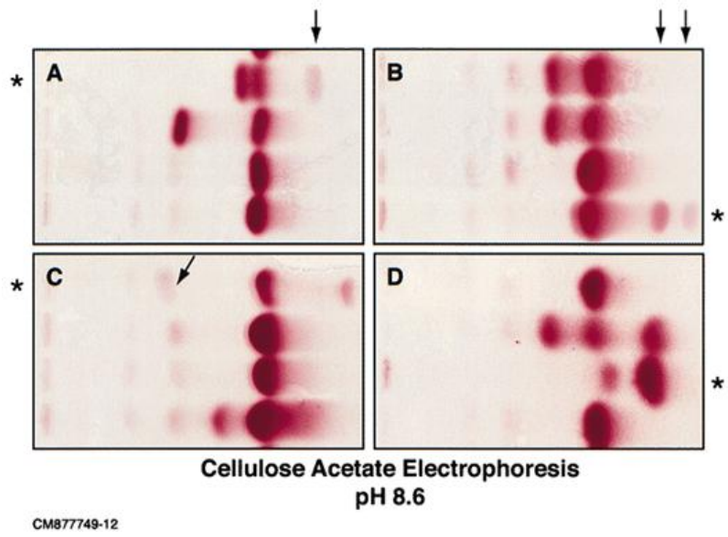

FIGURE 42.14. Cellulose acetate electrophoresis. **A:** Specimen from a neonate. Hb-Barts is present (*arrow*) indicating α thalassemia. **B:** Specimen from a 3-month-old. In addition to Hb-Barts, there is also a small amount of Hb H (*double arrow*). **C:** Hb H-Hb-Constant Spring. There is a fullness in the Hb A_2 area indicating the presence of Hb-Constant Spring. **D:** Hb-Barts hydrops fetalis. There is no Hb A present. The majority of the hemoglobin is Hb-Barts, with a small amount of Hb-Portland.

Heterozygous a Thalassemia 2

This form of α thalassemia is very common, but because it is associated with minimal imbalance between α- and δ- or ß-chain production, there is no clinical effect and the blood count, including the mean cell volume (MCV), is normal. In the adult, the diagnosis may be inferred from family studies or proven by gene studies; in the neonate, there is a slight increase (1% to 3%) in Hb Barts (71).

Heterozygous a Thalassemia 1 and Homozygous a Thalassemia 2

These genetic disorders result in α thalassemia minor (71) with the blood count typical of all forms of thalassemia minor (low MCV, minimal if any anemia). Because α-globin chains are present in all three normal hemoglobins, they are equally affected by a slight deficiency and there is no change in the relative percentages of Hb A, Hb A_2, and Hb F. It might be expected that the imbalance between α- and ß-globin chain production would result in the presence of a small amount of Hb H ($ß_4$) in the adult. This is usually not the case in the α thalassemia 2 homozygote. However, in the α thalassemia 1 heterozygote, Hb H can be precipitated in red cells by staining with brilliant cresyl blue, but it is not present in sufficient quantity to be detected by routine electrophoretic methods (72). Because α thalassemia 1 is exceedingly rare in African Americans but is quite common in southeast Asians, the cost-effectiveness of performing Hb H stains in individuals with thalassemia minor and normal levels of Hb A_2 and Hb F depends on the ethnic origin of the population under study.

In the neonate with either form of α thalassemia minor, an increase in Hb Barts (γ_4) in the range of 4% to 10% is usually found (71). This finding is a useful side benefit of neonatal screening programs for hemoglobinopathies because it provides positive evidence for a diagnosis using simple techniques and can be helpful information when an African-American child presents later in life with a microcytic hypochromic blood picture associated with normal levels of Hb A_2 and Hb F.

Hb H Disease

Hb H disease (clinically classified as a form of thalassemia intermedia) is a moderate to severe hemolytic disease (68,73). The

Hb H tetramer (β_4) is unstable and forms Heinz bodies (denatured hemoglobin) within the red cell. These inclusions are recognized by the reticuloendothelial system, and a portion of the red cell or the complete red cell may be removed from the circulation. The morphology of the red cells is often bizarre.

The clinical severity of Hb H disease is related to the amount of Hb H in the red cells, which in turn depends on the underlying genetic lesion. The most common type is the double heterozygote for α thalassemia 1 and α thalassemia 2 in which three α-globin genes are deleted (because α thalassemia 1 is rare among African Americans so also is Hb H disease). In southeast Asians, another frequent cause of Hb H disease is the combination of two deleted α-globin genes, a gene for the elongated α-globin chain of Hb-Constant Spring and one normal α-globin gene (--/$\alpha^{CS}\alpha$) (74,75). The mutant α-globin chain of Hb-Constant Spring is produced in small quantities (1% to 2%), and the α-globin chain deficiency therefore is nearly equivalent to that resulting from a deleted α gene (76).

The Hb-Constant Spring mutation changes the normal termination signal at codon 142 (TAA) to a codon that codes for glutamine (CAA). Thus, an additional 31 amino acids are added to the α-globin chain until the next termination codon is reached (75) (Fig. 42.13). This abnormal α globin is produced in very low amounts (1% to 2%) and so acts as an α-thalassemia mutation. The heterozygote for Hb-Constant Spring is clinically and hematologically normal. The homozygote for Hb-Constant Spring has mild normocytic hemolytic anemia with splenomegaly, not the typical thalassemia minor picture that might be expected (77,78). Hb-Constant Spring migrates between carbonic anhydrase and Hb A_2 on cellulose acetate at alkaline pH. Because the quantity is small, it may be overlooked unless specifically looked for (Fig. 42.14).

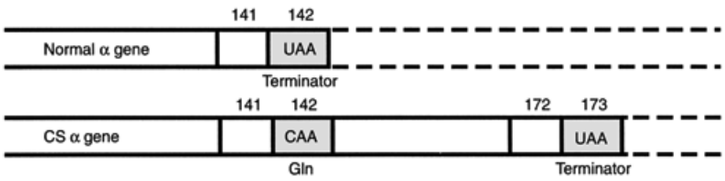

FIGURE 42.13. Substitution in mRNA of the abnormal α-globin chain of Hb-Constant Spring (CS).

In addition to the Hb-Constant Spring, there are four other Hb variants with elongated α chains. These differ only in the amino acid which is present at codon 142: Hb-Seal Rock (79) (GAG), Hb-Icaria (lysine) (80), Hb-Koya Dora (serine) (81),

TABLE 42.5. THE α-THALASSEMIAS RESULTING FROM GENE DELETION: NOMENCLATURE, CLINICAL EFFECT, AND PERCENTAGES OF Hb BARTS (γ_4) AND Hb H(β_4).

α-Genes	Subtype	Disorder	Hb Barts (Neonatel) (%)	Hb H (Adult) (%)

and Hb-Paske (tyrosine) (82). Similar to Hb H-Constant Spring, cases of Hb H disease in combination with Hb-Icaria (80,83) and Hb-Paske (82) have been described.

Homozygous a Thalassemia 1 (Hb-Barts Hydrops Fetalis)

Deletion of all four α-globin genes results in absence of α-globin chain production and is incompatible with life. Affected fetuses are hydropic, die *in utero* or soon after premature birth, and possess Hb-Barts (γ_4), 10% to 30% Hb-Portland [$(\zeta)_2\gamma_2$], and a small amount of Hb H (84,85) (Fig. 42.14). Hb-Portland is probably the main deliverer of oxygen because it has an oxygen dissociation curve not far from the physiologic one, compared with Hb-Barts, which has very high oxygen affinity (68). The blood smear shows large hypochromic red cells with many reticulocytes, nucleated red cells, target cells, and red cell fragments. Hb-Barts hydrops fetalis is rarely seen in populations outside southeast Asia and southern China, where it is the most common cause of hydrops fetalis.

ß-Thalassemia Syndromes

Any imbalance in globin-chain production involving a reduction or absence of ß-globin chains results in ß thalassemia. The simple concept of heterozygotes (ß thalassemia minor) and homozygotes (ß thalassemia major), although broadly applicable to these syndromes, is complicated by many possible genetic lesions. In contrast with α thalassemia, the mutations resulting in ß thalassemia are almost exclusively point mutations (86). Of the almost 200 known ß-thalassemia mutations, 179 are nondeletional mutations. In contrast, only 17 deletional forms of ß thalassemia have been described (87). These nondeletional mutations occur in or near the ß gene and may interfere with the initiation, transcription, termination, or splicing of mRNA; mutations within the gene may produce nonsense codes that stop transcription or splicing of mRNA or produce sense codes that result in a ß-globin chain so unstable that it is found only in red cell precursors (e.g., ß-Terre Haute) (88). The large number and variety of genetic causes are reflected in a spectrum of clinical syndromes in heterozygotes, homozygotes, and compound heterozygotes that range from silent ß thalassemia through thalassemia minor and intermedia to thalassemia major. For most practical purposes, it is possible to divide the genetic lesions into those resulting in the absence of ß-globin chain production ($ß^0$) and those resulting in reduction of ß-chain production ($ß^+$). Many of the ß-thalassemia alleles are clustered in particular populations so that, for instance, six alleles account for 92% of genes for ß thalassemia found in the Mediterranean area (86). This makes specific prenatal screening with gene probes less complicated than might be expected from the large total number of known alleles. These genetic lesions, affecting only the production of ß-globin chains, underlie the pure ß thalassemias.

Another group of lesions, mostly relatively large deletions, in addition to the ß gene, involves other regions of the ß-like gene cluster, including the γ and δ genes. These result in the δß and γδß thalassemias and HPFH.

ß Thalassemia Minor

ß Thalassemia minor is seldom symptomatic and requires no therapy (86). The uniformly microcytic red cells, typical of all types of thalassemia minor, are usually the first indication of its presence. Anemia, if present, is mild, and slight erythrocytosis is common. It is not possible to distinguish between $ß^0$ thalassemia minor and $ß^+$ thalassemia minor (or other forms of thalassemia minor) on a hematologic basis. However, as a group, individuals, usually black, with $ß^+$ (mild) thalassemia minor have less anemia and a higher MCV than those with $ß^0$ or $ß^+$ (severe) thalassemia minor (89). The three types are most easily distinguished when a sickle gene also segregates within the family; the S/$ß^0$-thalassemia compound heterozygote will have no Hb A, the S/$ß^+$-thalassemia compound heterozygote will have Hb A levels falling between 5% and 30%.

An approximate doubling of the level of Hb A_2 ($\alpha_2\delta_2$) is the hallmark of $ß^0$ and $ß^+$ thalassemia minor. Hb F may be normal and, when increased, is seldom greater than 5%.

Normal levels of Hb A_2 and Hb F are found occasionally in phenotypic examples of ß thalassemia minor. Several families have been reported in which one parent of an offspring with typical ß thalassemia major had phenotypic ß thalassemia minor with a normal Hb A_2 level. The presence of a separate gene for ß thalassemia, either in *cis* or in *trans*, is an explanation in at least some of these families (65). Hb A_2 may be reduced in iron deficiency states (90); hence, Hb A_2 may fall within the reference range when iron deficiency and ß thalassemia minor coexist.

ß Thalassemia Major

Almost all $ß^0$-thalassemia homozygotes, many $ß^+$ homozygotes, and compound heterozygotes present as thalassemia major. The deficiency of ß-globin chains is masked at birth by the production of γ-globin chains (Hb F), but as the switch from γ-globin chain production to ß-globin chain production proceeds, the severity of the clinical and hematologic expression increases. Diagnosis of the majority of cases that have not been anticipated by prenatal study of the parents or antenatal study of the fetus (86) is usually made during the second month of life. Where appropriate medical facilities are available, transfusion therapy aimed at maintaining a hemoglobin level above 10.0 or 12.0 g/dL should be instituted at the time of diagnosis, to be followed by chelation therapy to reduce iron overload (91).

If no therapy or inadequate therapy is given, a series of clinical and hematologic events ensue mainly as a result of hypoxia owing to the severe anemia (91). Anemia develops for two main reasons: dyserythropoiesis and hemolysis. The excess α-globin chains in the erythron do not form a soluble tetramer, α_4, comparable with the Hb-Barts (γ_4) and Hb H ($ß_4$) found in the α thalassemias. However, the excess α-globin chains damage the red cell precursors and mature red cells so that, despite the vast erythroid hyperplasia, red cell production is reduced and the red cells formed have a shortened life span. In untreated patients, the erythroid hyperplasia causes expansion of the marrow cavity with deformities of the facial, cranial, and long bones; extramedullary erythropoiesis causes splenomegaly and hepatomegaly; the persistent hypoxia retards mental and physical growth. In many

countries, this picture has been relegated to textbooks by optimal transfusion therapy.

In an untreated patient, the small amount of hemoglobin produced consists almost entirely of Hb F (90%) with little ($ß^+$ thalassemia major) or no Hb A ($ß^0$ thalassemia major). The distribution of Hb F among the red cells is not uniform, and those with the most Hb F have the longest life span, thus accentuating the percentage of Hb F in the circulation.

The bone marrow in untreated ß thalassemia major shows vast erythroid hyperplasia, megaloblastic, dysplastic, and bizarre precursors with many degenerate forms that reflect the intramedullary destruction of the α-globin chain–laden precursors. Although the formation of a relatively soluble tetramer $α_4$ comparable with Hb-Barts ($γ_4$) and Hb H ($ß_4$) found in α thalassemia does not occur, aggregates of ß-globin chains can be demonstrated in red cell precursors and in mature red cells (particularly after splenectomy) by supravital staining (92). The morphology may suggest erythroleukemia (FAB M6) even to the extent of exhibiting periodic acid–Schiff-positive inclusions. Iron is present in large amounts, and ringed sideroblasts may be present in moderate numbers. Anemia is severe, MCV and mean corpuscular hemoglobin (MCH) are low, but the mean corpuscular hemoglobin concentration (MCHC) may be only slightly reduced despite the apparent pallor of the red cells in a peripheral blood smear. There is marked variation in red cell size and shape. Reticulocytosis and polychromasia are present, but because of the ineffective erythropoiesis, not in the quantity expected for the degree of anemia; erythroid precursors at various stages of maturation are also found in the peripheral blood.

There is biochemical evidence of hemolysis, including increased unconjugated bilirubin levels. Serum iron and transferrin are increased even in the untransfused individual. The urine may appear brown owing to the presence of dipyrroles.

The pattern of hemoglobin electrophoresis depends on the type of ß thalassemia major. Hb A will be absent in untransfused homozygous $ß^0$ thalassemia; a variable amount will be seen in homozygous $ß^+$ thalassemia. Homozygous $ß^+$ thalassemia with relatively large amounts of Hb A, clinically classified as thalassemia intermedia, is a particularly common type among Africans and African Americans. In $ß^0$-thalassemia major Hb F represents approximately 90% of the hemoglobin present; however, this is 90% of very little. Hb A_2 may be low, normal, or, less often, increased in percentage but is always proportionally high compared with Hb A. Unexpectedly low levels of Hb A_2 may be accounted for by the selective survival of red cells with the greatest amount of Hb F, which also contain the lowest amounts of Hb A_2 (93).

δß-Thalassemia

The absent or reduced production of δ- and ß-globin chains that occurs in the δß type of thalassemia is usually the result of deletion of all or part of both the δ- and ß-globin genes (94,95). Ten different δß-thalassemia mutations have been described (96). Because two chains are underproduced, it might be assumed that the resulting thalassemias would be more severe than their ß-thalassemia counterparts. This is not the case because the deletion is associated with a significant persistent production of the γ chains of Hb F, thus diminishing the α:non-α-chain imbalance. The δß thalassemias form part of the spectrum that lies between ß thalassemia and HPFH.

Heterozygous δß thalassemia is often hematologically indistinguishable from other types of thalassemia minor, although the red cell indices may be closer to normal. In a few instances, the indices may be normal. These types can be classified as a silent form of thalassemia. δß Thalassemia minor is readily distinguished from other forms of thalassemia minor by the presence of 5% to 20% Hb F, which is heterogeneously distributed among the red cells, and a normal or reduced level of Hb A_2.

Homozygous δß thalassemia is a mild disorder, clinically classifiable as a thalassemia intermedia or even minor (97). Anemia is mild (8.0 to 12.0 g/dL) with microcytic hypochromic red cells and evidence of reticulocytosis. Hemoglobin electrophoresis shows 100% Hb F with no Hb A or Hb A_2.

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

HPFH comprises a group of disorders, clinically benign and usually hematologically normal, in which Hb F production persists throughout life. Several distinct genetic lesions underlie the various types of HPFH (95,98,99). In seven types, there is a large deletion involving both the δ and ß genes, which in at least one instance may bring an enhancer at the 3+ end of the deletion into close apposition with the α genes, probably accounting for their continued expression. A very similar deletion results in δß thalassemia; however, the DNA enhancer sequence is included in the deletion, perhaps accounting for the lower level of γ-globin chain (and Hb F) production and the imbalance in α:non-α-globin chain production typical of the disorder. The other types of HPFH are nondeletional and associated with single-base substitutions that occur in or near promoter sequences of the $^Aγ$- and $^Gγ$-globin genes (99). There is even evidence that some types may be attributable to genetic lesions unconnected with the γδß-gene complex (98).

The amount of Hb F varies from one type of HPFH to another (Table 42.6) as does its distribution among the red cells. HPFH may be subdivided into those in which all red cells contain Hb F (pancellular types) and those in which only a portion of the red cells contain Hb F (heterocellular types). The distinction is made based on the acid-elution technique of Kleihauer et al. (100,101) (Hb F is acid resistant as well as alkali resistant) or by the use of anti-Hb F antibodies (102,103). The latter is more sensitive; however, it may be difficult with either technique to be sure of the distribution of Hb F, particularly when at a low level. The discovery of several types of HPFH with a heterocellular distribution of Hb F reduces the value of demonstrating the type of distribution of Hb F among red cells because a heterocellular distribution is also found in all other forms of increased Hb F in adults (29).

Hb, hemoglobin.

Hemoglobin Lepore

Hb Lepore in the heterozygote is associated with a typical thalassemia minor blood count and in the homozygote with thalassemia

intermedia or even major (104). This unusual hemoglobin is composed of a pair of normal α-globin chains and a pair of non-α-globin chains that consist of the beginning (N-terminal end) of a δ-globin chain and the end (C-terminal) of a ß-globin chain. This globin chain is the product of a fusion gene that has arisen from unequal chromosomal crossover (Fig. 42.15). The exact point of crossover and therefore the proportion of δ and ß gene present in the Lepore gene varies. Three different hemoglobins have been reported: Hb $Lepore_{Hollandia}$, Hb $Lepore_{Baltimore}$, and Hb $Lepore_{Boston}$, the last being the most common (104). As a result of the crossover, the δ and ß genes are represented only by the fusion gene that in the adult heterozygote would be expected to produce approximately 50% of the non-α-globin chains; however, Hb Lepore makes up only approximately 10% of the circulating hemoglobin. This deficient production results in an imbalance between α- and non-α-globin chain production, causing thalassemia minor in the heterozygote with its typical hematologic picture. Homozygous Hb Lepore (105) presents as thalassemia major or thalassemia intermedia. The circulating hemoglobin consists of approximately 75% Hb F and 25% Hb Lepore with no Hb A or Hb A_2.

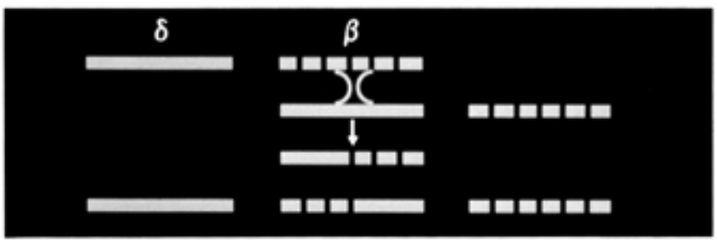

FIGURE 42.15. Unequal crossover in chromosome 11 between the δ and ß genes, resulting in the production of the δß fusion gene of the non-α-globin chain of Hb Lepore with no normal δ- and ß-globin genes in *cis* and the ßdelta; fusion gene of Hb anti-Lepore with normal δ- and ß-globin genes in *cis*.

Hb Lepore migrates with Hb S on cellulose acetate in alkaline buffer and with Hb A in acid citrate agar. By HPLC, Hb Lepore migrates with Hb A_2. The finding of approximately 10% of a hemoglobin migrating like Hb S on cellulose acetate and in the A_2 position on HPLC in an untransfused patient is virtually diagnostic of Hb Lepore.

The converse of Hb Lepore is Hb anti-Lepore (Fig. 42.15) (105). In this situation, δ and v genes in *cis* are intact with the addition of an anti-Lepore gene that is responsible for the production of a small amount of a non-α chain made up of the beginning of a ß- and the end of a δ-globin chain. The amount of Hb Anti-Lepore produced is small, and the imbalance of globin-chain production is minimal. The blood count and all red cell indices are normal. Three different anti-Lepore hemoglobins have been reported; as in the case of Hb Lepore, they differ in the point at which chromosomal crossover has occurred.

Differential Diagnosis of Thalassemia Minor

Thalassemia minor is a benign syndrome with few if any symptoms but with an abnormal hematologic picture that is often described as a microcytic hypochromic anemia (Table 42.7). The anemia is slight or nonexistent in Africans but usually present in Asians, and the hypochromasia, as measured by the MCHC, is seldom more than slight. The striking features of the blood count are the low MCV, the high red cell count, and the lack of anisocytosis as measured by the red cell distribution widths (RDW). Iron-deficiency anemia and iron-deficient erythrocytosis are the main differential diagnoses. Morphologically, the red cells of thalassemia minor differ little from those of mild iron deficiency; the presence of target cells is not a useful discriminator; however, basophilic stippling occurs in thalassemia minor but is seldom seen in iron deficiency. Various regression formulas have been proposed to distinguish the blood counts of iron deficiency and thalassemia minor, indicating whether the patient's iron status or hemoglobin should be studied first. England and Fraser (106) suggested that thalassemia is the probable diagnosis if the result of the formula MCV - RBC - (5 × Hb) × 3.4 is negative. Green and King (107) suggested the formula (MCV^2 × RDW) ÷ (Hb × 100), with a result less than 73 indicating thalassemia minor.

TABLE 42.7. BLOOD COUNTS OF 10 PATIENTS WITH ß-THALASSEMIA MINOR[a]

Patient	Hb (g/L) 120–160[b]	RBC (10^{12}/L) 4.5–5.5[b]	MCV (fl) 80–100[b]	RDW <15	A'_2 (%) 1.5–3.5[b]
1	124	5.7	64	13.3	6.2
2	132	7.2	65	12.5	5.2
3	127	6.2	65	12.7	6.5
4	125	6.0	64	14.4	6.3
5	140	7.2	58	14.2	6.8
6	113	6.1	58	13.6	7.3
7	120	6.0	63	14.7	6.2
8	140	6.0	61	12.8	6.5
9	126	6.0	69	15.2	6.3
10	125	5.5	71	14.4	6.6

[a] The counts, with minimal or no anemia, increased red cell count (RBC), low mean cell volume (MCV), and normal red cell distribution width (RDW) might be found in any type of thalassemia minor. The approximate doubling of the Hb A'_2 percentage confirms the specific diagnosis of ß-thalassemia minor.

[b] Reference range.

Hb, hemoglobin.

Whichever pragmatic approach is adopted, three factors need to be kept in mind. First, because iron deficiency and thalassemia minor are common disorders, coincidence of the two is not uncommon. Second, the Hb A_2 level is reduced in iron deficiency, and occasionally the Hb A_2 level in an individual with ß thalassemia minor and iron deficiency may fall within the normal range (90). Third, because thalassemia minor may be caused by a structurally abnormal hemoglobin (e.g., Hb Lepore) or may coexist with an abnormal hemoglobin (e.g., Hb S α thalassemia), the complete study of a patient with the blood picture of thalassemia minor should include hemoglobin electrophoresis. In addition to indicating the presence of a hemoglobin variant, hemoglobin electrophoresis may provide other useful diagnostic information. It can be argued that with increased Hb A_2, indicated by the presence of an Hb A_2 band significantly denser than

the carbonic anhydrase band, with or without an increased Hb F band in a patient with a thalassemic blood picture, is strong enough evidence for the diagnosis of β thalassemia minor without specific quantification of Hb A_2. Similarly, the combination of an electrophoretic band suggesting 10% to 15% Hb F and a thalassemic blood count strongly suggests δβ thalassemia minor. α Thalassemia minor is often a diagnosis of exclusion; a thalassemic blood count with normal levels of Hb A_2 and Hb F and normal iron studies is consistent with such a diagnosis. Specific evidence for the presence of one or more defective (thalassemic) α-globin genes may come from the presence of increased quantities of Hb-Barts at birth (Table 42.5), the presence of rare Hb H inclusions in the αα/– – type (heterozygous α thalassemia 1) but not in the α—/α— (homozygous α thalassemia 2), and by the use of α-gene probes.

STRUCTURAL HEMOGLOBIN VARIANTS

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

More than 750 structural hemoglobin variants have been reported, most of which are rare and of no clinical or hematologic significance. An updated compendium of all reported examples is published regularly (13). A few generalizations can be made. Except in the case of two of the most common variants, Hb S and Hb C, structural alterations affecting the surface of the hemoglobin molecule seldom have any deleterious effect. Conversely, almost all variants in which the structural defect lies near the heme pocket, lies at points of contact between globin chains, or affects their helical structure are associated with alterations in the stability or function of the molecule.

The various types of genetic lesions that underlie the structurally abnormal hemoglobins include:

- Single-base substitutions within a DNA triplet codon that result in an amino acid substitution (e.g., Hb S, $\alpha_2\beta_2^{6\ Glu\rightarrow Val\ A\rightarrow T}$, GAG to GTG);
- Two separate base substitutions probably arising from chromosomal crossover involving two abnormal genes (e.g., Hb C-Harlem, $\alpha_2\beta_2^{6\ Glu\rightarrow Val}$, 73 Asp→Asn, a combination of the substitutions found singly in Hb S and Hb-Korle Bu) (108);
- Deletion of one or more amino acid residues (e.g., Hb-Leiden, $\alpha_2\beta_2^{6\ or\ 7\ Glu\rightarrow 0}$) (109,110);
- Shortening of globin chain by premature termination (e.g., Hb-McKees Rocks) (111);
- Elongation of globin chain by insertion (e.g., Hb-Grady, $\alpha_2^{116+118\ duplicated}\beta_2$ (112);
- Elongation by mutation in chain terminator (e.g., Hb-Constant Spring $\alpha_2^{171}\beta_2$ (75); Hb Tak (113);
- Elongation by frame-shift mutation (e.g., Hb-Wayne) (114);
- Fusion of globin chains (e.g., Hb Lepore $\alpha_2\delta\beta_2$ (104).

The Sickling Disorders

Hb S ($\alpha_2\beta_2^{6\ glu\rightarrow val}$) results from a point mutation in the sixth codon of the β chain, so that GAG is replaced by valine (GTG). Geographically, Hb S is found in highest concentration in Africa. In west central Africa, it is found in highest concentration the modern countries of Nigeria and Ghana as well as in Gabon and Zaire. On the eastern coast, it is found in highest concentration in Kenya with a decreasing percentage proceeding southward. Hb S is also found in the northeastern corner of Saudi Arabia, a localized area of east central India, and in low concentration (less than 1%) in areas of Greece, Sicily, and Turkey. Many, but not all, of these areas correspond to endemic areas of falciparum malaria. In American blacks, the prevalence of Hb S trait is 8.0% and that of sickle cell anemia is 0.14% (115). There is evidence from studies of DNA segments (haplotype analysis) near the β-globin gene locus (using restriction length polymorphisms) that the mutation probably occurred in several different population groups and then reached polymorphic levels through its beneficial effect in areas of endemic malaria (34,116). There are slight differences between these groups in the severity of sickle cell anemia.

The pathophysiologic basis of the various sickling disorders is the tendency for molecules of Hb S to precipitate within the red cell in the form of liquid crystals or tactoids under conditions of reduced oxygen tension (Fig. 42.16). The characteristic sickle cell is the result. This tendency to precipitate depends on the concentration of Hb S within the red cell, the nature of any other

TABLE 42.8. SOME COMBINATIONS OF Hb S AND α-THALASSEMIA, β-THALASSEMIA, OR GLOBIN CHAIN STRUCTURAL ABNORMALITIES

	Percentage in Adults						
Hemoglobinopathy	**Hb A**	**Hb S**	**Hb X**	**Hb A_2**	**Hb F**	**Sickle Cells**	**Clinical Severity**

Hb SC	0	50	50	N	N	±	2
Hb SD-Los Angeles	0	50	50	N	N	±	2
Hb SN	0	50	50	N	N	0	1
Hb SO	0	50	50	N	N	+	3
Hb AS-G-Philadelphia	25	25	50[a]	N	N	0	1

[a] Approximately 25% Hb G (migrating with Hb Sl and 25% of the hybrid $\alpha^G_2\beta^S_2$ (migrating as Hb C).

N, normal; Hb X, abnormal hemoglobin other than Hb S; 0, sickle cells absent; +, sickle cells present; ±, sickle cells possible; 1, benign; 2, moderately severe; 3, similar to sickle cell anemia.

hemoglobin present, as well as the oxygen tension. Thus, at the normal PO_2 of postcapillary venules, sickle cells will form in a homozygote (Hb SS, sickle cell anemia) whose red cells contain approximately 90% Hb S, whereas they will not form in a heterozygote (Hb AS, sickle cell trait) whose red cells contain approximately 55% Hb A and only 40% Hb S. The severity of a sickling disorder is directly related to the tendency of red cells to sickle (Table 42.8).

FIGURE 42.16. Electron micrograph of a portion of a sickled red cell in a renal biopsy. The tactoids of Hb S molecules are seen arranged in tubular fashion cut horizontally, vertically, and tangentially. (From Hoffman GC. The sickling disorders. *Lab Med* 1990;21:797–807, with permission.)

In Hb SS, a continuous cycle (Fig. 42.17) of peripheral deoxygenation and sickling and central oxygenation and desickling occurs as red cells pass from periphery through the lungs. Two events may alter this cycle. Repeated deformation of the red cell membranes eventually leads to the formation of irreversibly sickled red cells. Sickled red cells, unsuited to pass through small blood vessels, may block some of those vessels, causing local stasis, further deoxygenation of the red cells, and further sickling; the temporary or permanent loss of blood flow to a distal tissue segment causes the pain typical of the vasoocclusive sickle cell crisis (117).

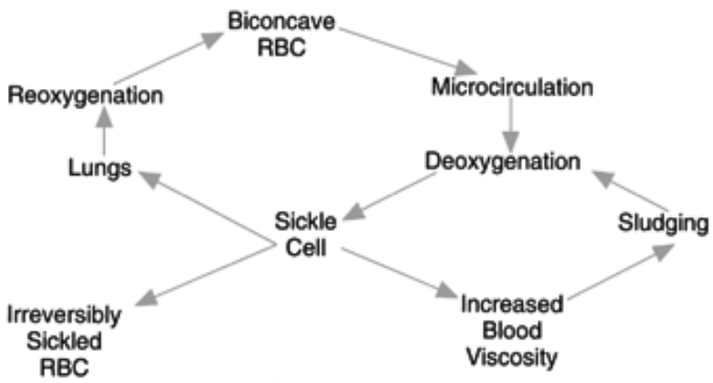

FIGURE 42.17. The sickling cycle that occurs in patients with sickle cell anemia. Vasoocclusive (painful) crises may develop if "sludging" leads to blockage of blood vessels. (From Fishleder AJ, Hoffman GC. A practical approach to the detection of hemoglobinopathies: part II. The sickle cell disorders. *Lab Med* 1987;18:441–443, with permission.)

Sickle Cell Trait

Sickle cell trait (Hb AS) is an essentially benign disorder because, under normal physiologic conditions, sickle cells are not formed (115). There is, however, some evidence that in rare hypoxic situations, sickle cells may form *in vivo*; sudden death among individuals involved in strenuous exercise at high altitudes is more common among African Americans than among whites and may be associated with *in vivo* sickling (118). Localized hypoxia in renal papillae is the probable explanation for the instances of painless hematuria, usually from the left kidney, which may occur rarely in sickle cell trait but more commonly in sickle cell anemia and Hb SC disease. Isosthenuria may also occur.

The blood count is normal; hemoglobin electrophoresis shows approximately 40% Hb S, 55% Hb A, with a normal or slightly increased amount of Hb A_2 (Fig. 42.18), and the solubility test gives a positive result.

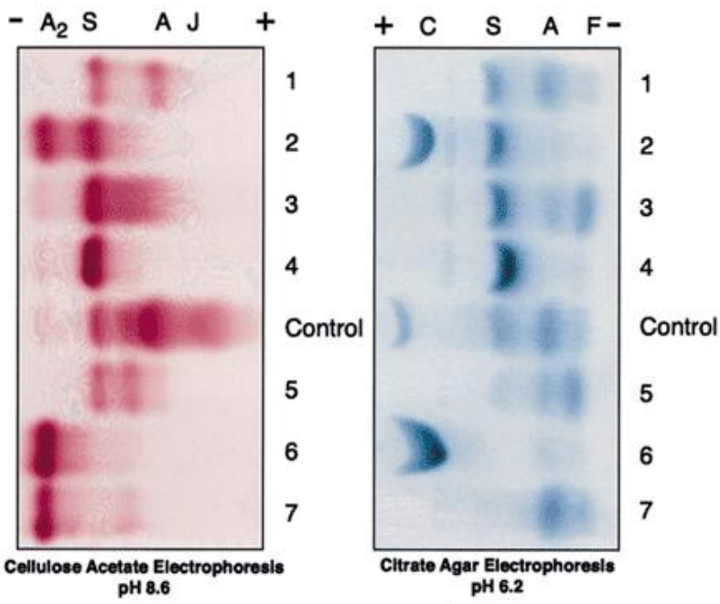

FIGURE 42.18. Examples of many conditions discussed in the text on both cellulose acetate and citrate agar electrophoresis. 1, Hb S trait; 2, Hb S/C disease; 3, Hb S/β+thalassemia. The small amount of Hb A is better seen on citrate agar electrophoresis. Hb F is also elevated. 4, Homozygous Hb S; 5, Hb S/Hb D Punjab in an infant. Hb F is elevated. 6, Homozygous Hb C; 7, homozygous Hb E.

Sickle Cell Anemia

The varied clinical manifestations of sickle cell anemia are the result of the altered hematologic properties of the abnormal sickle erythrocyte. There is a chronic hemolytic anemia owing to shortened red cell survival. This hemolytic process is often associated with gallstone formation. There are various acute vasoocclusive crises that are caused by obstruction of the microcirculation by the sickled cells. These include painful crises (musculoskeletal, abdominal), the acute chest syndrome, splenic sequestration crises, neurologic crises (seizures, strokes), and the hand-foot syndrome (in children). Hematologic crises include aplastic crises (often secondary to parvovirus infection) and megaloblastic crises (secondary to folate deficiency). There is chronic end organ damage that is the sequela of both multiple vasoocclusive events and chronic anemia. These include cardiac (myocardial hypertrophy), pulmonary (multiple infarcts), genitourinary (concentrating defects, nephrotic syndrome, renal failure, priapism), skeletal (bone infarctions, aseptic necrosis of the femoral/humeral head), neurologic (deficits secondary to strokes), ocular (proliferative retinopathy, glaucoma) and dermatologic (lower leg ulcers). One complication of particular note is the phenomenon of autosplenectomy. Owing to repeated infarcts, the spleen by adulthood is not more than a fibrotic nub. Because of this, these patients have increased susceptibility to infections, particularly by encapsulated organisms such as *Pneumococcus*. There are also general systemic manifestations such as impairment of growth and sexual development (119,120).

The severity of the disease, as reflected by the degree of anemia and frequency of the painful crises, varies widely from individual to individual and between ethnic groups. The disease is usually mild among Saudi Arabians; there is little variation among the genetically distinct types of sickle cell anemia found in Africa (121). These variations depend in part on the level of Hb F, which tends to inhibit gelation, and on the number of α

genes; the coexistence of one or two α-gene deletions reduces the MCHC and the tendency for Hb S to gel. A third major factor in the morbidity and mortality of sickle cell anemia is infection, usually bacterial, that is at least in part a reflection of the functional asplenia of infancy and childhood and splenic infarction in the adult. During fetal and early neonatal life, the presence of Hb F reduces the sickling tendency. Accordingly, signs or symptoms of the disease do not develop until the third or fourth month of life. The first vasoocclusive events usually do not appear until 6 to 12 months. In milder forms of the disease, they may not appear for several years. Rare asymptomatic cases occur.

Early childhood is a particularly dangerous time for patients with sickle cell anemia, partly because of their inability to describe symptoms but mainly because of potentially lethal complications that may occur in addition to vasoocclusive episodes. Overwhelming infection, particularly pneumococcal, may prove lethal in a matter of hours, and acute splenic sequestration of red cells that may be equivalent to loss of one third of the blood volume is a medical emergency. The importance of prenatal or neonatal diagnosis cannot be overstated; it allows the parent and pediatrician to take prompt action when indicated and to provide prophylaxis against infection. Vasoocclusive episodes or painful crises may occur at any age. They occur sporadically and vary widely in frequency from patient to patient (122). A precipitating event is often not obvious; however, infection, bacterial or viral, precedes approximately one third of crises, probably as result of pyrexia (123). Any organ may be affected. The spleen, enlarged during the first years of life, is seldom palpable after the age of 7 years owing to repeated infarctions.

The degree of anemia varies widely (average hematocrit, 24.6 ± 3.8) (124); the hemoglobin level may fall precipitously during the temporary “aplastic” crises that are associated with parvovirus infection (125) as well as during sequestration crises; hyperhemolytic episodes are seldom if ever the cause. Several long term approaches to therapy of sickle cell anemia, in addition to supportive measures during crises, have been suggested. The roles of red cell transfusion, exchange transfusion, and hypertransfusion protocols such as those used in the treatment of β thalassemia major remain a matter of controversy, even when considered during times of particular risk such as major surgery and pregnancy (126,127,128 and 129). Hydroxyurea can increase the production of Hb F and thus reduce the tendency for the Hb S to form tactoids (130). Replacing the red cell factory either *in toto* by bone marrow transplantation (131) or in part by specific gene replacement are possible future alternatives.

The main laboratory features of sickle cell anemia include variable but usually moderate to severe normocytic anemia, primarily hemolytic, in types associated with sickle cells and reticulocytosis; the presence of Howell-Jolly bodies and target cells, indicating hyposplenism or splenic infarction; 90% to 95% Hb S with 5% to 10% Hb F and no Hb A on hemoglobin electrophoresis (Fig. 42.18); and a positive solubility test.

Sickling Disorders Involving a Second Hemoglobinopathy

The more common combinations of Hb S with other hemoglobinopathies are listed in Table 42.8. Inheritance of a β^S gene from one parent and a second β-gene variant from the other results in a compound heterozygote such as Hb SC disease or Hb S β^0 thalassemia. An α-gene variant can be inherited by an individual who has either sickle cell trait or sickle cell anemia, for instance, Hb AS/G-Philadelphia or Hb SS/G-Philadelphia.

The combination of hemoglobin S and C (Hb SC disease) produces a sickling syndrome with clinical manifestations that are milder than that of sickle cell anemia. The prevalence is 0.13% in African Americans. The hemolytic anemia is mild to moderate and complications from the hemolytic anemia are less frequent. Growth, development, sexual maturation, and body habitus are usually normal; life expectancy is only slightly shortened. Painful vasoocclusive crises (abdominal, musculoskeletal, neurologic) are less frequent and infarctive damage (e.g., bone, lung) are usually less disabling. Approximately half of patients have splenomegaly. Although asplenia occurs in only 25% of patients, painful splenic infarcts are common, and episodes of acute splenic sequestration may also occur. Because the function of the spleen is usually intact, the frequency of pneumococcal infections (meningitis sepsis) is not increased. The frequency of cerebrovascular accidents is approximately equal to that of sickle cell anemia patients. Interestingly, renal papillary necrosis and proliferative retinopathy are more frequent in Hb SC disease. Aseptic necrosis of the femoral head is approximately half as frequent as in sickle cell anemia; however, aseptic necrosis of the humeral head is more common. Although there are fewer complications at time of delivery, pregnant women with Hb SC disease have a higher rate of spontaneous early abortions (132,133 and 134).

In the peripheral blood smear classic sickle cells are rare; more often one sees irregular, boat-shaped cells. Characteristic SC poikilocytes are normally seen. These are dense, very misshapen cells that often contain Hb C crystal. Target cells and spherocytes can also be seen (135). Hemoglobin electrophoresis at alkaline pH shows approximately equal amounts of Hb S and Hb C (Hb A_2 is contained within the latter). Acid electrophoresis is necessary for confirmation to distinguish Hb SC from Hb S/O Arab and Hb S/E (Fig. 42.18).

Hb D-Los Angeles and Hb O-Arab also copolymerize with Hb S and therefore produce sickling disorders (136,137). Acid electrophoresis is needed to distinguish Hb S/D-Los Angeles from homozygous Hb S as these two variants show identical mobilities on alkaline electrophoresis but are different on acid electrophoresis. Acid electrophoresis will differentiate Hb S/O-Arab from Hb S/C (Fig. 42.18).

In contrast, Hb S in combination with HPFH (Hb S/HPFH) is a benign disorder. Patients do not usually have anemia, and there are no vasoocclusive events. Hemoglobin electrophoresis in the compound heterozygote usually shows approximately 60% Hb S and 40% Hb F with no Hb A (138,139).

Sickling Disorders Involving a Thalassemic Gene

Hb S β^0 thalassemia may be indistinguishable clinically from sickle cell anemia, although splenomegaly usually persists in the adult; hematologically, the low MCV and MCH of Hb S β^0 thalassemia help to distinguish the two (140). Hb S β^+ thalassemia is usually a less severe sickling disorder than either sickle cell anemia

or Hb S β^0 thalassemia and may present as thalassemia intermedia (141). The β^+-thalassemia gene is responsible for the production of some Hb A, ranging from 5% to 30% of the circulating hemoglobin. The amount of Hb A is inversely related to the severity of the disease. Hemoglobin electrophoresis shows more Hb S than Hb A, a finding that in itself is virtually diagnostic of Hb S β^+ thalassemia in an untransfused individual; in addition, there is increased Hb A_2 and a small amount of Hb F (Fig. 42.18).

α Thalassemia of either the one- or two-gene deletion variety may be inherited by individuals also having sickle cell trait or sickle cell anemia. In sickle cell trait, the percentage of Hb S is determined by the number of α genes—approximately 35% to 40% when the normal four α genes are functioning, 30% to 35% when three α genes are functioning (this combination of Hb AS with single-gene deletion α thalassemia is found in approximately 30% of individuals with sickle cell trait), and 25% when only two α genes are functioning (found in approximately 3% of individuals with sickle cell trait) (142). Iron deficiency also lowers the percentage of Hb S in sickle cell trait (90). Inheritance of α thalassemia in individuals with Hb C trait (Hb AC) has a similar effect on the proportion of Hb C. This effect occurs because the β^S- and β^C-globin chains have a positive charge relative to β^A and therefore are less likely to combine with the limited number of σ-globin chains, which are also positively charged. The reverse occurs when an abnormal β-globin chain (e.g., many examples of Hb J) has a relatively negative charge, and the percentage of the abnormal hemoglobin increases when combined with α thalassemia (143).

Hb C Disorders

Hb C ($\alpha_2\beta_2^{6\ Glu\rightarrow Lys}$) occurs in 2.4% of African Americans; 0.02% are homozygotes (Hb CC) (144). The mutation for Hb C apparently occurred in the Ghana and Upper Volta region of western Africa, where as many as 25% of the population in some areas are heterozygotes. Hb C is found almost exclusively in blacks (145).

Hb C trait (Hb AC) is an entirely benign disorder. The blood count is normal, but the blood smear shows many normochromic target cells. Hemoglobin electrophoresis shows approximately 45% Hb C and 55% Hb A (Fig. 42.6). Iron deficiency or the deletion of one or two α-globin genes results in a lower percentage of Hb C. Hb A_2 migrates with Hb C on cellulose acetate, and they are eluted together from ion-exchange columns; therefore, it is necessary to use chromatographic methods (such as HPLC) for the quantitation of Hb A_2 in the presence of Hb C.

Hb C disease (Hb CC) is associated with a mild to moderate chronic hemolytic anemia and splenomegaly (146). Apart from the aplastic crises and cholelithiasis, patients homozygous for Hb C have few complications and do not experience vasoocclusive crises, sequestration crises, or infections prevalent among patients with sickle cell anemia. The red cells show the unusual combination of reduced MCV but increased MCHC (147). The blood smear shows even more target cells than Hb C trait; it also contains occasional spherocytes, a reflection of the increased MCHC. Intracellular or extracellular Hb C crystals, blocklike structures 1 to 3 μm in length, may be seen in the blood smear and are pathognomonic of Hb C. In Hb C disease, there is at least 90% Hb C on cellulose acetate electrophoresis at pH 8.4, with a slight increase in Hb F and no Hb A (Fig. 42.18). In acid agar, pH 6.0, the normal or slightly increased amount of Hb A_2 may be visible, migrating as Hb A. This apparent combination of Hb C with a small amount of Hb A must not be confused with Hb C/β^+ thalassemia; the absence of Hb A on cellulose acetate is helpful in this distinction. Hb E and Hb O migrate with Hb C on cellulose acetate but can be distinguished by acid agar electrophoresis (Fig. 42.6).

Compound heterozygotes for Hb S and Hb C are discussed in the section on the sickling disorders. Hb C/β^0 thalassemia and Hb C/β^+-thalassemia are moderate and mild hemolytic anemias, respectively. The electrophoretic pattern of Hb C/β^0 thalassemia is indistinguishable from that of Hb C disease (Hb CC), but the MCV is somewhat lower (50 to 70 fl) than in Hb CC (mean, 72 fl) (148). In Hb C/β^+ thalassemia, the quantity of Hb C exceeds that of Hb A, and in Hb C/α thalassemia, the reverse is found in a manner analogous to the proportions of Hb S and Hb A in the Hb S β^+ and Hb S α thalassemia.

Hemoglobin E

Hb E ($\alpha_2\beta_2^{26\ Glu\rightarrow Lys}$) is the second most common hemoglobin variant worldwide after Hb S. It occurs mainly in southeast Asian populations and is common in Thailand, Laos, and Cambodia; it is rare in ethnic Vietnamese or Chinese. It has also been reported rarely in blacks and whites (149).

Hb E trait (Hb AE) is a benign disorder associated with microcytic red cells (average MCV 72 fl) but no anemia, not unlike thalassemia minor (150). The proportion of Hb E is 30% to 35% (a useful differential point from Hb C trait, in which the abnormal hemoglobin usually makes up 40% to 50%) (Fig. 42.6). This proportion may be even lower when there is concomitant iron deficiency or α thalassemia.

Homozygous Hb E (Hb EE) is also a benign disorder, but there may be mild anemia, and the red cells are more microcytic than in Hb E trait, mimicking β thalassemia minor (151). Red cells contain more than 90% Hb E and a slightly increased quantity of Hb F, but no Hb A (Fig. 35.18).

In contrast to the mild nature of Hb E disease, the combination of Hb E/β^0 thalassemia may present as thalassemia intermedia or even thalassemia major (152). There is a greater degree of anemia and microcytosis than in homozygous Hb E. The electrophoretic pattern may be similar to that of a homozygote for Hb E but usually shows more Hb F.

Hb E migrates with Hb C, Hb O, and Hb A_2 on cellulose acetate at pH 8.4 but can be distinguished by electrophoresis in acid citrate agar, where it migrates with Hb A (Fig. 42.6). Furthermore, Hb E is mildly unstable and may be precipitated by heat (50° to 60°C) or 17% isopropanol; however, there is no evidence of hemolysis even in the homozygote. The thalassemic nature of this variant can be explained by the amino acid substitution at β^{26}, which creates a new splicing sequence and interferes with mRNA processing. If the new splicing site is used, a defective mRNA is likely produced; if the original splicing site is used, Hb E is produced. Thus, this mutation acts similar to other β+ thalassemia mutations that affect mRNA splicing (153).

OTHER HEMOGLOBIN VARIANTS

Hb G-Philadelphia (α68(E17)Asn→lys) is the most common α-chain variant seen in the United States and is found primarily in African Americans (144). Because of this, it can be seen in combination with ß-chain variants also seen in African Americans, such as Hb S or Hb C. These combinations produce electrophoretic patterns with multiple bands but do not cause any clinical symptoms. Hb G-Philadelphia trait is clinically benign but is often associated with the α-thalassemia 2 trait (154,155).

Hb-Hasharon (α47[CE5] asp→his) is found in two distinct ethnic groups either in descendants of Ashkenazi Jews of Central Europe or Italians from the Ferrara district of Italy. Although this hemoglobin variant is unstable *in vitro*, it is not associated with clinical or hematologic effects (156,157).

Hb J-Baltimore (ß16(A13)gly-asp) (158) Hb N-Baltimore (ß95(F62)lys-glu) (159), and Hb I-(α16(A14)lys-gly) (160) are "fast" hemoglobin variants that are uncommonly seen. These variants are clinically benign; however, they will give spuriously high Hb A_1c values using some ion-exchange chromatography methods (161).

HEMOGLOBIN VARIANTS AFFECTING STABILITY OR FUNCTION

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

Amino acid substitutions, deletions, or additions that affect the heme pocket, the points of contact or interaction between globin chains, their secondary helical structure, or the hydrophobic interior of the subunit almost invariably alter the stability or function of the hemoglobin molecule. These variants may be divided into the unstable hemoglobins, hemoglobins with high or low oxygen affinity, and the hereditary methemoglobins (Hb Ms). This separation is not absolute; for instance, an unstable hemoglobin may also have an altered oxygen affinity and result in slight methemoglobinemia.

Unstable Hemoglobins

Hemolysis associated with the precipitation of denatured hemoglobin (Heinz bodies) within the red cell results from two main aberrations: oxidative hemolysis affecting either normal red cells or red cells deficient in one of the enzymes in the glycolytic pathway and the presence of an unstable hemoglobin. More than 150 unstable hemoglobin variants have been identified (13,162). Of these, approximately 70 result in clinical and laboratory evidence of hemolytic anemia. The remainder are unstable in vitro but do not produce clinical syndromes. Most are ß-globin chain defects, which on the whole are more severe than α-globin chain defects because the latter affect only one of four α genes as opposed to one of two ß genes. Table 42.9 contains examples chosen to demonstrate the differences in severity (which are unrelated to the quantity of unstable hemoglobin in the circulation), the proportion of abnormal hemoglobin, and associated functional defects.

TABLE 42.9. UNSTABLE HEMOGLOBINS—APPROXIMATELY 150 VARIANTS[a]

Hb	Globin Chain	Affected Abnormal Hb	Percentage of O_2 Affinity	Clinical Severity
Köln	ß	10	Increased	Mild
Gun Hill	ß	30	Increased	Mild/moderate
Zurich	ß	25	Increased	Mild
Hammersmith	ß	30	Decreased	Severe
Cranston	ß	30	Increased	Mild
Hasharon	α	15	Normal	Normal
Kansas	ß	45	Decreased	Normal
Terre Haute	ß	0	—	Moderate/severe

[a] These hemoglobins (Hb) are all heterozygotes and indicate the globin chain affected, the percentage of abnormal hemoglobin found in the circulation, their oxygen affinity, and clinical severity. In cases (e.g., Hb Indianapolis and Hb Hasharon) in which the percentage of abnormal hemoglobin is significantly less than 50% (ß-globin abnormalities) or 25% (α-globin abnormalities), the imbalance also results in a thalassemia syndrome.

The denatured hemoglobin in the form of single or multiple Heinz bodies becomes linked to the inner side of the red cell membrane, decreasing the pliability of the red cell and its ability to traverse the microcirculation, particularly in the spleen. The Heinz bodies may be removed from the red cell together with a portion of the red cell membrane, leaving a "bite" cell, or the whole red cell may be removed from the circulation. Not surprisingly, splenectomy results in an increased number of circulating red cells containing Heinz bodies, while at the same time lengthening the red cell life span.

Hb Köln (ß98(FG5)val→met) is the prototype of unstable Hb variants and is the most common unstable Hb encountered. The substitution occurs at the ß98 position, which is the fifth amino acid at the "FG corner." This substitution is just inside the heme pocket (which accounts for its instability) but is also a contact point between the α_1, and $ß_2$ subunits. Thus, Hb Köln has been considered a high oxygen affinity Hb variant. It is found in many different ethnic groups and has probably arisen several times as a *de novo* mutation (163).

In addition to the anemia, reticulocytosis, and bilirubinemia common to most hemolytic anemias, there are laboratory tests that may indicate the presence of an unstable hemoglobin. Two simple screening tests for an unstable hemoglobin involve applying a physical or ionic stress to the hemoglobin molecule. Heating a buffered lysate at 60°C for half an hour or 50°C for 1 hour will cause flocculation of any unstable hemoglobin present (164). The addition of 17% isopropanol to an equal volume of buffered lysate (the Carrell test) will also cause flocculation, within 10 minutes, of unstable hemoglobin (165). In either test,

the flocculus may be small if the quantity of unstable hemoglobin is small. The flocculus is white if heme has been lost but retains the red color of hemoglobin if heme remains attached to the precipitated hemoglobin. Hemoglobin electrophoresis may demonstrate an abnormal fraction, but several unstable hemoglobins migrate with Hb A.

It is always worthwhile to perform all available tests and even repeat them on a fresh sample of blood because the amount of unstable hemoglobin present may be small and its instability not marked.

Hemoglobins with Altered Oxygen Affinity

The presence of hemoglobins with increased or decreased oxygen affinity results in a resetting of the homeostatic mechanism that controls the amount of circulating hemoglobin. Thus, a hemoglobin with increased oxygen affinity will accept at least normal amounts of oxygen in the lungs but will unload less oxygen to the tissues. This relative hypoxia will turn on the production of erythropoietin and increase the number of circulating red cells (and hemoglobin) so that more oxygen can be delivered to the tissues. A physiologic equilibrium will be reached at a hemoglobin level above or at the upper limit of a reference range based on individuals with functionally normal hemoglobin. The reverse occurs when a hemoglobin of low oxygen affinity is present, and the physiologic level of hemoglobin may be below the reference range. In rare instances, the oxygen affinity of the hemoglobin (e.g., Hb-Kansas, $\alpha_2\beta_2^{102asn\rightarrow Thr}$) may be so low that the uptake of oxygen in the lungs is impaired. Despite the ease with which oxygen is delivered to the tissue, the level of hemoglobin lies within the normal reference range (166).

More than 70 hemoglobin variants with an oxygen affinity high enough to cause erythrocytosis have been identified (13). Affected individuals are asymptomatic except for those rare examples in which the red cell mass is large enough to cause hyperviscosity. Therapy is seldom indicated, and pregnancy involves no risk despite the high maternal oxygen affinity relative to that of the fetus.

The presence of a high oxygen affinity hemoglobin may be first suspected from the blood count. Other laboratory findings include an abnormal electrophoretic pattern in approximately 70% of examples. Measurement of the P_{50} (the oxygen tension at which 50% of the hemoglobin is saturated) will confirm the diagnosis. Oxygen affinity is inversely proportional to the P_{50}, and in general the hemoglobin level or degree of erythrocytosis is directly related to the P_{50}.

Many unstable hemoglobins also have an increased oxygen affinity that may explain the high hemoglobin level found in individuals whose hemoglobin has this combination of defects. More than 25 examples of unstable hemoglobins with reduced oxygen affinity have been reported (167).

The M Hemoglobins

Seven structurally abnormal hemoglobins exist only as methemoglobin because the heme iron is stabilized in the oxidized Fe^{3+} or ferriheme form (13,168,169 and 170). In four, the amino acid substitution involves one of the histidines between which the heme is suspended: Hb M-Boston, $\alpha_2^{58His\rightarrow Tyr}\beta_2$; Hb M-Iwate, $\alpha_2^{87His\rightarrow Tyr}$ Hb M-Saskatoon, $\alpha_2\beta_2^{63His\rightarrow Tyr}$; Hb M-Hyde Park, $\alpha_2\beta_2^{92His\rightarrow Tyr}2$ (also known as Hb M-Milwaukee-2). In Hb M-Milwaukee-1, $\alpha_2\beta_2^{67Va\rightarrow Glu}$, the substituted glutamate in the heme pocket forms a similar bond, fixing the ferriheme. There are two examples of fetal M hemoglobins (Hb F-M-Osaka, $\alpha_2\gamma_2^{63His\rightarrow Tyr}$ and Hb F-M-Fort Ripley, $\alpha_2\gamma_2^{92His\rightarrow Tyr}$), which cause cyanosis at birth and disappear as γ-globin chain production switches to ß-globin chain production. The substitutions in the γ chains are analogous to those in the ß chains of Hb M-Saskatoon and Hb M-Hyde Park.

The cyanosis seen in individuals with Hb M is only in part owing to hypoxia; methemoglobin imparts a brownish color to whole blood, which appears blue when seen through the skin. Most patients are asymptomatic; however, Hb M-Saskatoon and Hb M-Hyde Park have been associated with compensated hemolysis and oxidant drug-induced hemolysis.

Diagnosis is often suggested by the appearance of the patient and a family history of cyanosis. In the laboratory, the absorption spectra of the hemoglobin from affected individuals when it has been fully oxidized with ferricyanide differ from methemoglobin A, but only slightly one from another, with absorption peaks in the 580- to 600-nm range (170,171). Most of the M hemoglobins do not separate from Hb A on alkaline electrophoresis; however, IEF, particularly if the specimen is oxidized with ferricyanide, allows good separation of Hb Ms from Hb A.

HEMOGLOBINOPATHIES IN THE FETUS AND NEWBORN

Part of "42 - The Thalassemia and Hemoglobinopathy Syndromes"

The earlier the diagnosis of the severe hemoglobinopathies such as sickle cell anemia and ß thalassemia major can be made, the sooner appropriate therapy and prophylaxis can be instituted. Prenatal diagnosis (172,173) is seldom available outside major hemoglobinopathy centers because it usually involves the study of DNA from chorionic villus cells, amniocytes, or a fetal blood sample. Obtaining these samples exposes the fetus to some danger; therefore, only in fetuses proven to be at risk (by study of both parents) and in situations in which the parents would consider termination are such studies usually undertaken. The earliest diagnosis can be made from DNA of chorionic villus cells. DNA has the added advantage that it can survive transport across vast distances, allowing remote areas to take advantage of the gene analysis. Amplification of segments of the DNA by PCR techniques increases the material available for study.

The gene for Hb S can be specifically detected (Fig. 42.19), but the situation is different for ß thalassemia major because of the many different lesions, inside and outside the ß gene that may cause it. Such techniques as restriction endonuclease mapping and linkage analysis of restriction fragment length polymorphisms and oligonucleotide probes may be required. The vast amount of genetic data (61) has shown that within any one population, there are usually only a few lesions that need to be considered.

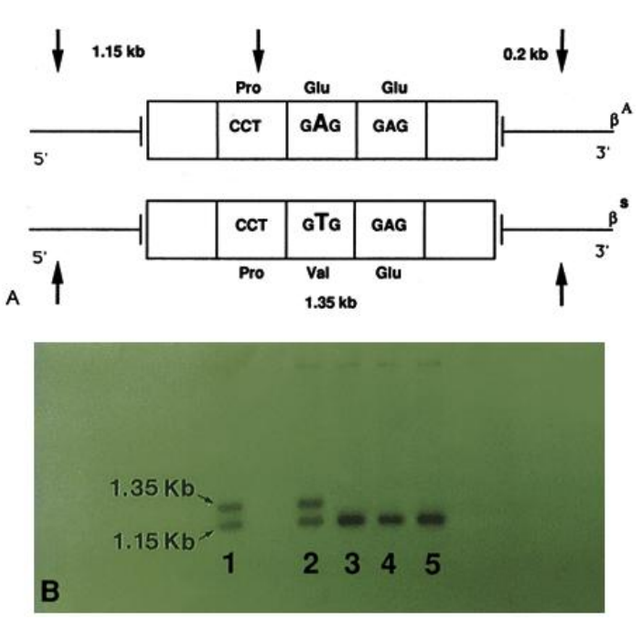

FIGURE 42.19. A: ß-Globin gene with MST II restriction sites (*arrows*). The nucleotide triplets coding for the 5th, 6th, and 7th amino acids are enlarged to illustrate the mutation causing loss of a restriction site in the β^S-globin gene. (Adapted from Law DJ, Frossard PM, Rucknagle DL. High sensitive and rapid gene mapping using miniaturized blot hybridization: application to prenatal diagnosis. *Gene* 1984;28:153–158.) **B:** Autoradiograph of MST II digestions using ß-globin gene probe: β^A, 1.15 kb; β^S, 1.35 kb. Lanes 1 and 2, sickle cell trait; lanes 3–5, normal adult.

The ample availability of cord blood at delivery allows application of many of the methods used in studying adults (174,175 and 176).

The ready availability also permits screening of all populations at risk, and in many states, it is mandated that all newborns be tested for hemoglobinopathies. However, there are significant limitations and pitfalls.

In the case of sickle cell anemia, hemoglobin electrophoresis on cellulose acetate at alkaline pH shows approximately 75% Hb F and 25% Hb S with no Hb A. It is the latter that is important, and it may be difficult to confirm that no Hb A is present. Because Hb A and its variants, particularly in heterozygotes, are present in small quantities, it is advisable to double the amount of hemolysate applied. Electrophoresis in citrate agar will help to confirm the identity of Hb S and make the presence or absence of Hb A more clearcut (Fig. 42.20). It must be remembered that Hb F and Hb S without Hb A is a pattern also present in Hb S $ß^0$ thalassemia and Hb S HPFH; study of the parents will usually clarify the diagnosis.

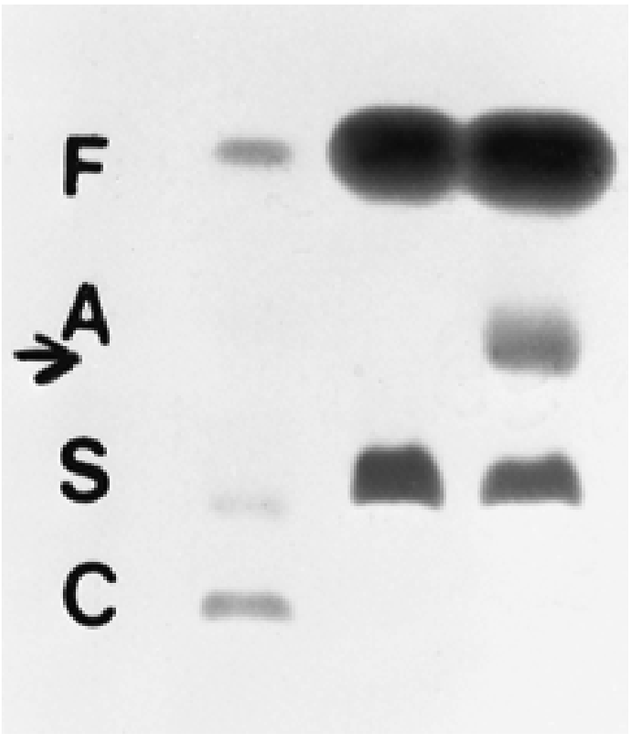

FIGURE 42.20. Hemoglobin electrophoresis in agar using a citric acid–citrate buffer at pH 6.2. **Left lane:** A control mixture of Hb C, Hb S, and Hb F. **Middle lane:** Cord blood from a neonate with sickle cell anemia shows Hb S and Hb F, but not Hb A (a similar pattern would be seen in Hb S-$ß^0$ thalassemia and Hb S HBFH). **Right lane:** Cord blood from a neonate with sickle cell trait shows Hb S, Hb F, and Hb A.

The presence of maternal Hb A may result in a diagnosis of sickle cell trait when in fact the infant has sickle cell anemia. This trap may be avoided by noticing the presence of a Hb A_2 band, which should not be present in cord blood, and therefore must be of maternal origin.

In ß thalassemia major, cord blood electrophoresis will show 100% Hb F. $ß^+$ Thalassemia, conversely, will show a small amount of Hb A, and the pattern will be difficult to distinguish from normal.

ACUTE LEUKEMIA

Part of "43 - Acute Leukemias and Myelodysplastic Syndromes"

Pathogenesis

Acute and chronic leukemias are malignancies that arise from uncontrolled clonal proliferations of hematopoietic cells. The normal cellular control mechanisms are thought to be inoperative in leukemia owing to changes in the genetic code that are responsible for regulation of cell growth and differentiation. It is often mistakenly believed that acute leukemias are hyperproliferative disorders that result in the production of new cells at a rapid pace. However, it is almost paradoxically true that leukemia cells may actually have cycling times that are several times slower than normal bone marrow cells. These leukemic cells mature slowly and incompletely and survive longer than their normal marrow counterparts because of the failure to achieve normal and final maturation. It is believed, for example, that AML cells may actually have doubling times of approximately 30 days and require 50 to 75 doubling times before there is a significant accumulation of malignant cells. This final accumulation may occur over a period of 1 to 10 years and thus makes it difficult to truly access the initiation of disease.

Leukemias undoubtedly arise as a result of multiple transformation steps, or “hits.” Significant evidence has been gathered that strongly implicates cellular oncogenes as key players in this leukemic transformation process. Oncogenes typically play an important role in normal cellular control and regulation and only display their oncogenic potential when their genetic structure or control elements are mutated, rearranged, amplified, or activated. Amplification and promotion of oncogenic activity may occur when the normal transcriptional promoter and control regions of these genes are disrupted. Various retroviruses have also been implicated as a cause or initiator of leukemia. We also know that leukemias may secondarily arise as a result of exposures to a variety of environmental and iatrogenic therapies.

Immunosuppression, for example, is known to increase the risk of leukemia and lymphoma in organ transplant patients receiving such therapy. Ionizing radiation as well as alkylating agents may also contribute to the problem of secondary leukemias.

Leukemias, in general, are defined as malignant neoplasms of the hematopoietic system arising in the bone marrow. As the bone marrow is replaced with the malignant cells, the excess malignant cells escape into the peripheral blood, hence the derivation of the name leukemia: white (leuk-)/blood (-emia). In a simplistic fashion, it is easiest to classify leukemias based on (a) the natural course of disease, i.e., acute versus chronic, and (b) the basic cell type involved (lymphoid versus myeloid). Acute leukemias are the result of a block in normal hematopoietic differentiation, leading to an accumulation of immature lymphoid or myeloid cells. This accumulation of leukemic blasts, as described above, is the result of a block in maturation and differentiation rather than an increased rapidity of differentiation. Acute leukemias are characterized by a rapidly fatal course of days to weeks, if untreated. This is in contrast to the chronic leukemias, which are typically associated with an indolent, albeit progressive, course of disease. Chronic leukemias are characterized by a proliferation of differentiated cells, as opposed to the immature blasts seen in the acute leukemias. Table 43.1 outlines the various acute and chronic leukemias; Figure 43.1 is a schematic diagram of their relationship to normal hematopoiesis. The relative incidence of the four major subgroups of leukemias is as follows: acute lymphoblastic leukemia (ALL), 10%; B-chronic lymphocytic leukemia (CLL), 30%; acute myelogenous leukemia (AML), 45%; and chronic myelogenous leukemia (CML), 15%.

TABLE 43.1. CLASSIFICATION OF LEUKEMIA

Acute leukemia
Acute lymphoblastic leukemia (ALL)
FAB: L1, L2, L3
IPh: B-precursor ALL
T-cell ALL
B-ALL (Burkitt's leukemia/lymphoma)
Acute myelogenous leukemia
FAB: M0-M7
Acute biphenotypic leukemia
Myelodysplastic syndromes (preleukemias)
Refractory anemia
Idiopathic refractory sideroblastic anemia

Clinical Manifestations

The clinical manifestations of acute leukemia are related to three major effects: (a) the replacement of normal bone marrow elements, leading to complications resulting from anemia, thrombocytopenia, and leukopenia; (b) the complications of either tissue infiltration or leukostasis owing to a marked increase in peripheral cell counts; and (c) the release of physiologic factors that may lead to significant complications, for example, disseminated intravascular coagulation. It is likely that the pancytopenia and suppression of normal elements seen in acute leukemia are the result of a physical displacement of normal bone marrow elements; it is also quite likely that unrecognized suppression factors are involved that actively suppress normal hematopoiesis. The normal bone marrow is more than a simple factory assembly line and involves complex interactions between hematopoietic

stem cells and stromal cells, endothelial cells, and other environmental factors that lead to cellular differentiation. It is likely then, that any disturbance in this normal marrow equilibrium, such as leukemia, would be associated with marrow suppression; thus, the goal of any therapy should be to decrease and eliminate the leukemic population to allow recovery of the normal bone marrow elements.

Diagnostic Modalities

The diagnosis of acute leukemia may be a multistep process involving multiple laboratory diagnostic modalities (Table 43.2). Morphology remains the most important and significant diagnostic modality despite the impressive array of technology that is available in the clinical laboratories. The morphologic examination of the peripheral blood, bone marrow aspirate, and bone marrow biopsy specimen is an important ingredient in the morphologic evaluation and diagnosis of acute leukemia.

TABLE 43.2. DIAGNOSIS OF ACUTE LEUKEMIA

Karyotyping
In situ hybridization
Molecular diagnostics
Gene rearrangement studies
Oncogenes/translocations

Cytochemical enzymatic stains have been available since the early part of this century and have provided investigators with a wealth of knowledge over the years concerning the various subtypes of acute leukemia. This old fashioned laboratory test remains quite effective in confirming the diagnosis and classification of acute leukemia, as various enzymatic products are more likely associated with particular myeloid or lymphoid cells. The particulars of the various cytochemical stains are described in subsequent sections.

Newer diagnostic modalities have arisen that provide important biological, diagnostic, and prognostic information in the acute leukemias. Immunophenotyping with monoclonal antibodies has provided a consistent method of subclassifying the acute leukemias into either myeloid or lymphoid origin, as well as delineating various subsets within each of these two broad leukemic subgroups. This is detailed in the subsequent sections. Cytogenetic analysis has also provided a wealth of knowledge concerning the biology of leukemia as well as important diagnostic and prognostic information. Cytogenetic studies have allowed us to recognize the importance of reciprocal translocations, deletions, and other chromosomal abnormalities, which have significantly contributed to our biological knowledge of leukemia. Specific cytogenetic abnormalities are associated with particular subtypes of acute leukemia and have been shown over the past decade to have significant, independent prognostic information. Another diagnostic modality available for the evaluation of acute leukemia is molecular diagnostics. These techniques allow the evaluation of the immunoglobulin and T-cell receptor genes, as well as analyses of various oncogenes involved with particular chromosomal translocations.

ACUTE LYMPHOBLASTIC LEUKEMIA

Part of "43 - Acute Leukemias and Myelodysplastic Syndromes"

Pathogenesis and Clinical Manifestations

ALL is a clonal malignancy of lymphopoietic precursor cells, arising primarily within the bone marrow. The etiology behind the development of ALL is unknown but is not thought to be associated with radiation or exposure to toxic agents. The onset of symptoms in patients with ALL is usually acute and rapidly progressive. The clinical manifestations of ALL relate primarily to the suppression of normal bone marrow elements: weakness, fatigue, and malaise owing to anemia; fever, infection, and unresponsiveness to antibiotics owing to leukopenia; and bleeding owing to thrombocytopenia. Skeletal pain as a result of marrow expansion is also not an uncommon finding, whereas lymphadenopathy and hepatosplenomegaly are common but are usually not prominent findings. Virtually any organ may be infiltrated by the leukemic cells; involvement of the leptomeninges may result in various central nervous system (CNS) symptoms, whereas the testes are a frequent source of residual disease in young boys with ALL.

Incidence

ALL is the most common cancer in children under the age of 15 years and is the second or third leading cause of death in this age group. Approximately 80% of ALL cases occur in childhood and approximately 80% of childhood acute leukemia is of lymphocytic origin. Thus, ALL is typically considered a pediatric neoplasm and is encountered much more frequently in institutions

having a sizable pediatric population. Childhood ALL has a peak incidence at approximately 4 years of age, is slightly more common in boys than in girls, and is slightly more common in whites than in nonwhites. ALL can also occur in adulthood but has a peak incidence range between the ages of 2 and 10 years.

Laboratory Findings

Although we typically equate leukemia with disorders having markedly elevated white blood counts (WBCs), the absence of leukocytosis does not eliminate the possible diagnosis of acute leukemia. ALL is a good example of the variation in presenting WBC. Approximately 40% of ALL cases will have a presenting WBC of less than 10.0×10^9/L; approximately 40% of patients will have a WBC between 10.0 and 50.0×10^9/L. Only 20% of cases will have a significant leukocytosis exceeding 50.0×10^9/L and only one half of those patients will have a marked leukocytosis greater than 100.0×10^9/L. The differential count of the WBC in patients with ALL shows predominantly lymphoblasts along with an expected neutropenia. Differentiation to mature lymphocytes is not seen. Other laboratory abnormalities that are commonly found in patients with ALL include elevated serum lactate dehydrogenase (LDH) and serum uric acid.

Morphology and FAB Classification

ALL can be classified either morphologically or immunologically. The French-American-British (FAB) morphologic classification of acute leukemia has designated subtypes FAB-L1, -L2, and -L3 (Table 43.3). The revised FAB classification of ALL is based on weighing various criteria: nuclear-to-cytoplasmic ratio, the number of nucleoli, nuclear membrane irregularity, and cell size (Table 43.4).

TABLE 43.3. FAB CLASSIFICATION OF ACUTE LYMPHOBLASTIC LEUKEMIA

Cytologic Feature	L1	L2	L3
Size	Predominant small cells	Heterogeneous, intermediate to large cells	Large cells
Cytoplasm	Scant	Variable to moderately abundant	Moderately abundant
Nucleoli	Small/inconspicuous	≥1; prominent to large	≥1; prominent and large
Nuclear chromatin	Homogeneous and intermediate reticular	Heterogeneous with some having finely reticular chromatin	Finely reticular
Nuclear shape	Regular and round	Irregular	Regular to round
Basophilic cytoplasm	Slight to none	Slight to none	Intense
Vacuolation	Slight to none	Slight to none	Prominent; sharply punched out

FAB, French-American-British.

TABLE 43.4. REVISED FAB SCORING SYSTEM FOR L1 AND L2 VARIANTS

	Score	
Criterion	**Present**	**Absent**
High N/C ratio in 75% of cells	+1	0
Low N/C ratio in 25% of cells	-1	0
Nucleoli: 0–1 (small) in 75% of cells	+1	0
Nucleoli: ≥1 (prominent) in 25% of cells	-1	0
Irregular nuclear membrane in 25% of cells	-1	0
Large cells are 50% of total	-1	0
FAB-L1	0 to +2	
FAB-L2	-1 to -4	

FAB, French-American-British; N/C, nuclear:cytoplasmic.

The distribution of FAB-L1 and -L2 differs in children and adults. Approximately 80% to 85% of cases of ALL in children are FAB-L1 compared with 35% to 40% in adult ALL. Most of the remaining cases of ALL are classified as FAB-L2. Only 1% to 3% of ALL cases in adults and children are of the FAB-L3 subtype. This latter type of leukemia is a leukemic manifestation of Burkitt's lymphoma and is discussed in a subsequent section. FAB classification was useful for prognostic evaluation in the past; however, with present-day protocols for treatment of high-risk patients, the prognostic significance of morphologic classification is diminished. In fact, a recent proposal by the World

Health Organization (WHO) utilizes both immunophenotype and cytogenetic findings for classification of these neoplasms.

In FAB-L1 ALL, most of the leukemic cells are small with little to scant cytoplasm and absent, to inconspicuous at best, nucleoli. The chromatin pattern is clearly homogeneous and is not as finely reticular as those found in other types of leukemia. Nuclear irregularity is minimal (Fig. 43.2). In the FAB-L2 ALL, the most significant difference from FAB-L1 is that the leukemic cells are larger and more heterogeneous. FAB-L2 cells typically have variable to moderately abundant amounts of cytoplasm and importantly have one or more prominent nucleoli and a finer chromatin pattern compared with FAB-L1. Irregular nuclear shapes are commonly seen (Fig. 43.3). FAB-L3 ALL is characterized by a proliferation of large, homogeneous cells having deeply basophilic cytoplasm and sharply punched-out cytoplasmic vacuoles (Fig. 43.4). The nuclear chromatin is uniform and typically coarser than is found in FAB-L1 and FAB-L2. This type of ALL is actually the peripheralized version of Burkitt's lymphoma and thus should be considered as an acute leukemia more from a historical than a biological perspective. The WBC may be normal to slightly elevated with only a low percentage of circulating leukemic “blasts.” The bone marrow typically shows only partial replacement with the leukemic cells. Because of its association with Burkitt's lymphoma, FAB-L3 ALL is typically associated with ileocecal tumor masses in the Western countries.

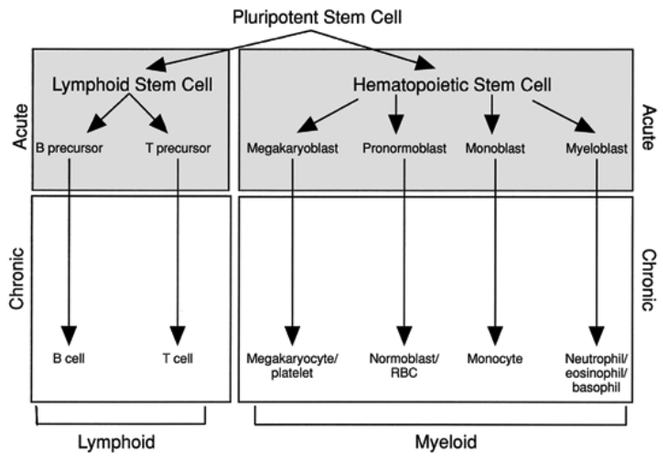

FIGURE 43.1. This schematic diagram outlines the relationship of the acute and chronic myeloid and lymphoid leukemias to normal hematopoietic and lymphoid development. The acute leukemias represent clonal expansions of immature precursor cells, whereas chronic leukemias represent proliferations of differentiated and mature lymphoid and hematopoietic elements.

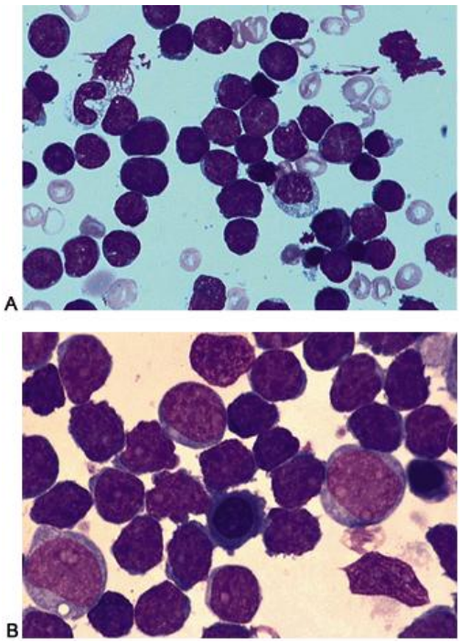

FIGURE 43.2. Acute lymphoblastic leukemia L1. **A:** Bone marrow with L1 blasts; **B:** bone marrow with primarily L1 blasts and occasional L2 blasts.

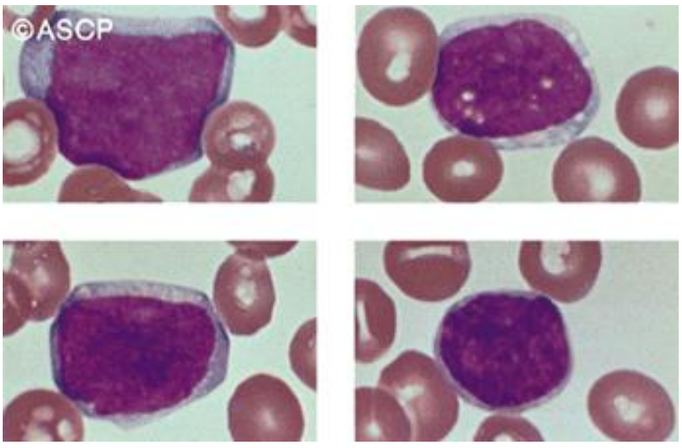

FIGURE 43.3. Acute lymphoblastic leukemia bone marrow examples of L2 blasts.

Morphologic Variants

Uncommon morphologic variants of ALL have been recognized. A “hand-mirror” cell variant of ALL has been described in which the cytoplasm loses its spherical shape and appears to have a handle. The elongated cytoplasmic handle has been described as the result of cellular motility or locomotion and has been regarded by some as a poor prognostic sign in ALL. This has not been widely accepted and is likely to be more of a laboratory artifact rather than having true biological significance.

Granular ALLs have also been described, characterized by the presence of azure granules within the cytoplasm of the leukemic lymphoblasts. These granules are reported to be negative with myeloperoxidase (MPO). This subset of ALL is not considered to have significant clinical or prognostic importance. However,

recognition of this variant is important in avoiding diagnostic problems that might arise in differentiating ALL from AML.

Shen and colleagues described a group of childhood ALL that presented with significant residual myeloid activity. These cases were referred to as “ALL with left shift.” Clinically, these patients had a longer duration of complete remission that appeared to be the result of either a smaller tumor load or lesser endogenous suppression of normal hematopoiesis. Diagnostically this may create a problem because the marrow is only partially replaced by the leukemic blasts and may be easily confused with AML unless appropriate diagnostic tests are performed.

It has been recognized for approximately 20 years that some cases of ALL may present with significant hypereosinophilia. These patients may have ALL present simultaneously with the hypereosinophilia, present initially as hypereosinophilia to be followed with a diagnosis of ALL, or present as ALL and relapse with a concurrent ALL and hypereosinophilic picture. The eosinophils may occasionally be slightly dysplastic in appearance, but no other evidence of myeloid differentiation is typically identified. Complications related to hypereosinophilia have been described in some patients, including endocarditis and respiratory complications. It has been postulated that the eosinophilia is secondary to release of eosinophilic growth factors from the leukemic cells. A t(5;14) (q31;q32) translocation has been identified in some cases of ALL with hypereosinophilia.

Cytochemistry

The role of cytochemical staining in the diagnosis of ALL is more relevant to exclude the diagnosis of AML rather than to find supportive evidence for the diagnosis of ALL (Table 43.5). Historically, the periodic acid–Schiff (PAS) reaction has classically been considered a diagnostic stain for ALL. However, only 40% to 60% of ALL cases show positivity with PAS, and PAS positivity can occasionally be found in AML. Thus, PAS lacks both sensitivity and specificity for ALL. Nonetheless, PAS positivity in ALL is characterized by large chunks or blocks of PAS-staining cytoplasmic material (Fig. 43.5). This can be distinguished from the diffuse PAS reaction seen in granulocytic cells. This enzyme stains primarily the glycogen present within the cytoplasm of leukemic blasts. Thus, PAS positivity in an acute leukemia should be looked at as suggestive, but certainly not diagnostic, of an ALL. Acid phosphatase (ACP) has been evaluated as a possible marker for T-cell ALL. T lymphocytes and most T lymphoblasts show focal, punctate, perinuclear positivity with ACP. However, not all T-cell ALLs show this pattern of staining, and a significant number of B-precursor ALL show positivity with ACP, thus limiting its utility as a stain to differentiate between T-cell and non-T-cell ALL. Myeloblasts may also show a focal staining with ACP. Oil red O, which stains lipid material, is an excellent marker for ALL-L3 or Burkitt's leukemia/lymphoma. The oil red O stain distinctly stains the vacuoles that are seen in this subtype of leukemia/lymphoma.

TABLE 43.5. CYTOCHEMICAL STAINING IN ACUTE LYMPHOBLASTIC LEUKEMIA

Stain	L1	L2	L3
MPO	-	-	-
SBB	-	-	-
CAE	-	-	-
NSE	-[a]	-[a]	-
PAS	+(70%)	+(70%)	-
ACP	-/+[b]	-/+[b]	-
MGP	-	-	+
ORO	+	+	+
TdT	+	+	-

[a] Faint positivity may be seen.

[b] Most T-cell acute lymphoblastic leukemia and some B-precursor acute lymphoblastic leukemia, will be positive.

MPO, myeloperoxidase; SBB, Sudan black B; CAE, chloroacetate esterase; NSE, nonspecific esterase; PAS, periodic acid–Schiff; ACP, acid phosphatase; MGP, methyl green pyronine; ORO, oil red O; TdT, terminal deoxynucleotidyl transferase.

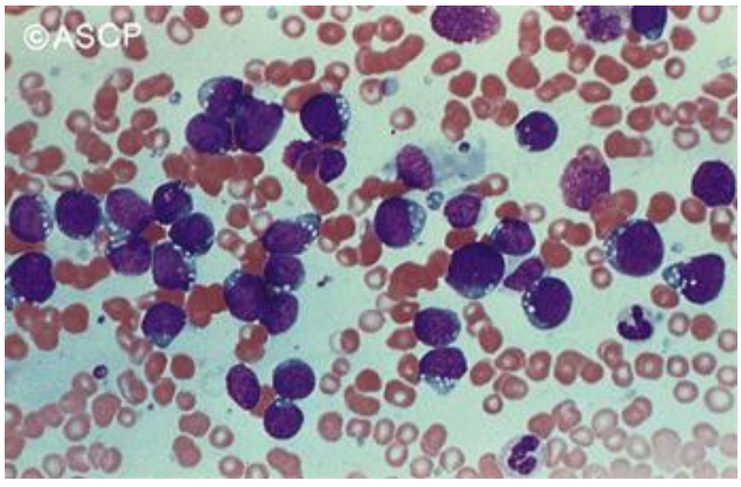

FIGURE 43.4. Acute lymphoblastic leukemia L3-Burkitt's leukemia/lymphoma.

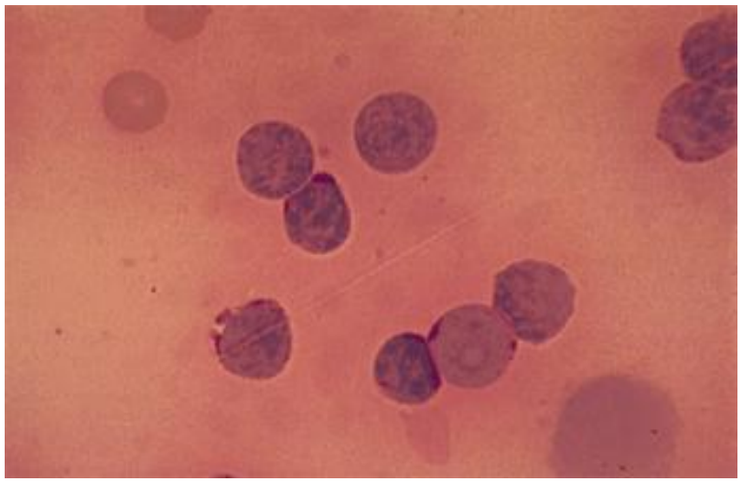

FIGURE 43.5. Periodic acid–Schiff stain of acute lymphoblastic leukemia L1.

Terminal deoxynucleotidyltransferase (TdT) is a DNA polymerase that contributes to the recombination heterogeneity seen in immunoglobulin and T-cell receptor gene rearrangements. This enzyme is active during lymphoblast development and is expressed in 95% to 99% of ALL cases. ALL-L3 lacks this enzyme, as it biologically represents a maturing lymphocyte rather than a true leukemic blast. Unfortunately, 5% to 10% of AMLs also express this nuclear antigen, thus limiting the absolute lineage specificity of the TdT assay. TdT may be detected by either

immunofluorescence, immunoperoxidase, or enzyme immunoassay methods (Fig. 43.6). TdT can be identified in ALLs of either T- or B-precursor immunophenotypes.

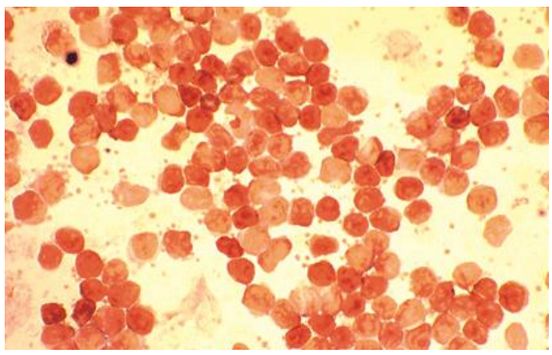

FIGURE 43.6. Terminal deoxynucleotidyltransferase immunoperoxidase stain of a B-precursor acute lymphoblastic leukemia.

Immunophenotype

The most consistent and effective means of classifying ALL is based on immunophenotyping data (Table 43.6). Approximately 80% to 85% of ALLs can be classified as malignant counterparts of bone marrow B-precursor cells. Ten percent to 15% of ALL will be identified as T-cell ALL, thus having immunologic characteristics of immature T cells or thymocytes. The remaining 1% to 3% of ALLs will immunologically represent mature B cells having surface immunoglobulin and correspond to the FAB-L3 subgroup or Burkitt's leukemia/lymphoma.

Historical Terminology

The terminology used in subclassifying ALLs has at best been confusing for those involved with diagnostic hematology (Table 43.7). This growth in confusion has paralleled our increased sophistication in immunophenotyping and represents an evolution of knowledge concerning these leukemias.

TABLE 43.7. TERMINOLOGY USED FOR ACUTE LYMPHOBLASTIC LEUKEMIA

B-Precursor ALL[a]
T-Cell ALL[a]
B-Cell ALL[a]
Non-T, non-B-cell ALL
Non-T-cell ALL
Common ALL
CALLA-positive ALL
Pre-B-cell ALL
Pre-pre-B-cell ALL
Pro-B-cell ALL

[a] Currently preferred terminology.

ALL, acute lymphoblastic leukemia; CALLA, common acute lymphoblastic leukemia antigen.

CD10 (CALLA)

The breakthrough in subclassifying ALLs came with the development of a polyclonal heteroantiserum against a case of non-T, non-B-cell ALL; this antibody was called anti-common ALL antigen, or anti-CALLA (CD10). Patients with CALLA-positive ALL were found to have a much better prognosis than those with either B- or T-cell ALL. This development was considered a major breakthrough for the role of immunophenotyping in evaluating acute leukemias. These CALLA-positive ALLs made up the majority, but not all, of the non-T-, non-B-cell ALLs. Because of their reactivity with the CALLA antiserum (and subsequently with a monoclonal antibody against CALLA), these cases were called “common” ALLs. After this development, several B lymphocyte–associated differentiation antigens were recognized by a variety of monoclonal antibodies. This monoclonal antibody explosion led to a rapidly increasing knowledge of lymphoid development and the realization that virtually all the CALLA-positive, non-T-, non-B-cell ALLs were indeed of early B-cell lineage. Although other terminologies have been and are used to describe immunologic subgroups of ALL, we refer to those leukemias reactive with B cell–associated antibodies as B-precursor ALL.

B-Precursor ALL

A tremendous diversity of immunophenotypes can be identified in B-precursor ALL. Practical experience with immunophenotyping finds that the diagnosis of ALL is actually quite simple, to the relief of the diagnostician. However, it should also be recognized that there is only limited correlation between the FAB subtypes and immunologic results (Fig. 43.7).

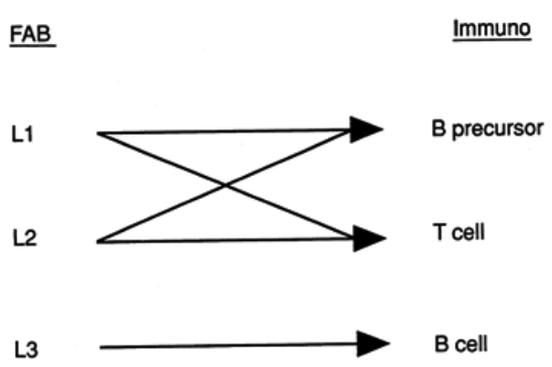

FIGURE 43.7. Correlation of FAB and immunophenotype in acute lymphoblastic leukemia.

The complexity of the various immunologic subgroups recognized within the B-precursor ALLs, however, has increased as the number of monoclonal antibodies to immature B cells has grown. It has been postulated that the different stages of leukemic expression are representative of stages of normal pre–B-cell development and that, by inference, leukemias arise by clonal proliferation of cells arrested at a particular stage of normal maturation.

The CD19 antigen is recognized as an early pan–B-cell marker and is present in more than 95% of ALL cases. Intracytoplasmic localization of the CD22 antigen has also been found at an early stage of normal B-cell differentiation; surface CD22 does not appear until later in immature B-cell development. The expression of CALLA or CD10 antigen occurs at the next level of development, followed by CD24. The fluorescence intensity of CD10 diminishes as the B-cell precursor undergoes maturation and CD20 expression begins.

CD10 is thought to be lost before surface CD22 expression. As can be gleaned from Fig. 43.8 and Fig. 43.9, most ALL cases will show expression of HLA-DR, CD19, and CD10 with either CD34 or CD20 typically being found. Some important exceptions and subgroups need to be recognized and are discussed further. Lack of CD10 expression appeared to be associated with a poorer prognosis.

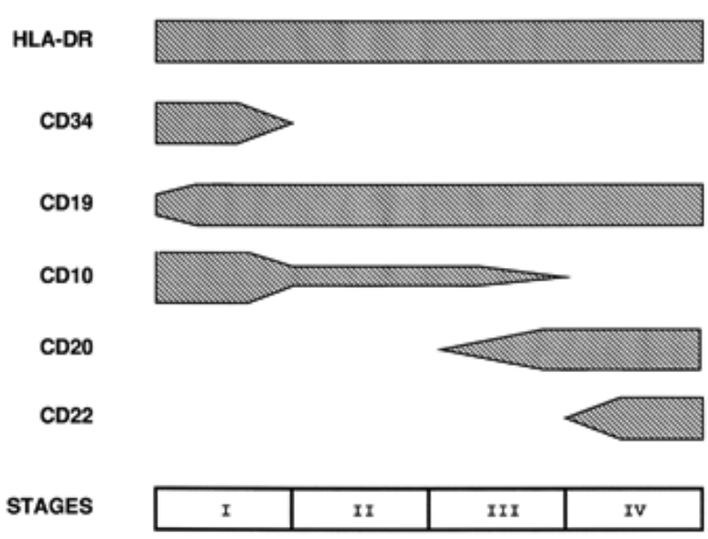

FIGURE 43.8. Proposed immunophenotypic stages of B-precursor lymphoid development. The narrower bars indicated decreased fluorescent intensity expression of that particular antigen (for example, CID 10).

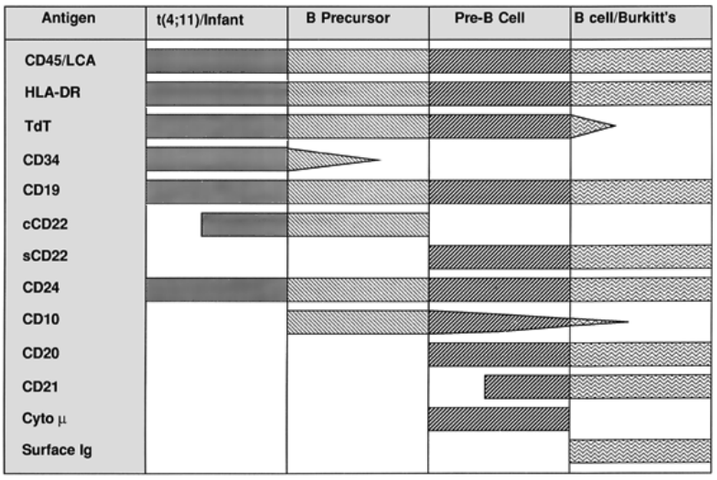

FIGURE 43.9. Immunophenotypes of B-precursor and B-cell acute lymphoblastic leukemia (ALL). The various antigens are listed in the left column. Four types of B-precursor and B-cell ALL are listed in the respective columns. cCD22 and sCD22, cytoplasmic and surface expression, respectively; Cyto μ, cytoplasmic expression of the immunoglobulin μ heavy chain.

The earliest stages of recognizable B-cell development are characterized by positivity with HLA-DR, TdT, CD34, and CD19. This early B-lymphoid immunophenotype (with or without CD7) has been commonly associated with leukemias having translocations involving 11q23, in particular the t(4;11) translocation (Fig. 43.9). These t(4;11) leukemias commonly present in infancy, have a marked leukocytosis, and have an extremely short survival without response to chemotherapy. In addition, many of these leukemias will have a monocytic component at the time of diagnosis or relapse and are frequently associated with biphenotypic features. All these findings suggest that 11q23 leukemias arise very early in B-lymphocyte differentiation. Although earlier immunologic stages of B-cell differentiation are theoretically possible, characterized by HLA-DR, TdT, CD34, and CD7 expression and perhaps cytoplasmic expression of B-lineage antigens, only rare leukemias have been definitively identified with these findings.

In the latter stages of B-cell development, CD34 expression is absent, CD10 has diminished in intensity, and CD20 and/or CD22 can be identified for the first time. Cytoplasmic μ heavy chain is detectable at this latter stage and typifies the so-called pre–B-cell ALL (Fig. 43.8 and Fig. 43.9). No intact surface immunoglobulin can be identified. The terminology pre-B cell is used as an indication that these cells have evidence of B-cell commitment, i.e., cytoplasmic immunoglobulin heavy chain, but without an intact immunoglobulin molecule being identified. This subgroup constitutes 10% to 15% of the B-precursor ALL group and is commonly associated with a t(1;19) translocation.

The CD34 antigen also needs to be discussed in relation to the B-precursor ALL group. As mentioned earlier, CD34 is a hematopoietic progenitor cell antigen present very early in B-cell development. As the mature B cell goes through maturation and undergoes immunoglobulin heavy chain rearrangement, CD34 expression is lost. Most reports have described CD34 positivity in 50% to 60% of cases of B-precursor ALL. CD34 expression may also provide important prognostic information in ALL.

B-Cell ALL: Burkitt's Leukemia

The final and most differentiated type of ALL has detectable surface immunoglobulin. This corresponds to the original B-cell ALL group and morphologically represents ALL, FAB-L3, or what has been called Burkitt's leukemia/lymphoma; TdT reactivity is usually absent in such neoplasms. B-cell ALL will show positivity with CD21 in addition to the previously described B cell–associated monoclonal antibodies: HLA-DR, CD19, CD20, CD22, and CD24 (Fig. 43.9). CD10 expression is found in one third to one half of B-cell ALL cases and is of much weaker intensity than that found in the typical B-precursor ALL.

T-Cell ALL

T-cell ALL (T-ALL) accounts for 10% to 15% of all ALL cases. It is usually associated with a marked leukocytosis; a mediastinal mass is found in more than 50% of cases; male patients are favored;

and median age is approximately 14 years. These patients have a high incidence of CNS relapse and a poorer survival than patients with B-precursor ALL. This survival difference has led some to conclude that immunophenotype may provide prognostic information. However, multivariate analysis has not shown that a T-cell phenotype is independent of WBC and age, both of which typically represent high risk factors in T-ALL.

The morphologic features of T-ALL are not uniquely specific for this subtype, but some findings need to be noted. The T-ALL cases are more likely to have a FAB-L1 appearance, having scant cytoplasm and relatively dense chromatin. A high mitotic rate is typically found and nuclear convolution may be evident. This latter finding, however, is neither a sensitive nor a specific feature of T-ALL and cannot be reliably used to differentiate this immunophenotypic subgroup from B-precursor ALL.

The anti-CD7, CD5, and CD2 monoclonal antibodies are the most sensitive markers that react with the leukemic blasts of T-ALL. In general, these three antigens are expressed in virtually all cases of genuine T-ALL (Fig. 43.10). Reactivity with other T-cell monoclonal antibodies in T-ALL in general correspond to intrathymic patterns of expression. The CD3 antigen has generally been reported in less than one third of cases of T-ALL and T-lymphoblastic lymphoma, as evaluated by flow cytometric techniques. In contrast, several studies observed CD3 expression in 95% of T-ALL/lymphoblastic lymphoma cases utilizing cryostat sections. This difference in results is related to the cytoplasmic detection of CD3 in cryostat sections. Several studies have now shown that cytoplasmic CD3 is present much earlier in thymic differentiation before the surface expression of CD3 and before the expression and rearrangement of the T-cell receptor gene. These data confirm that CD3 positivity is not relegated to the final stages of thymocyte development and can be a useful marker of early T-cell differentiation if a cytoplasmic method of detection is utilized. Cytoplasmic CD3 must therefore be considered as an essential antigen to be looked for if other markers of T-cell differentiation are equivocal.

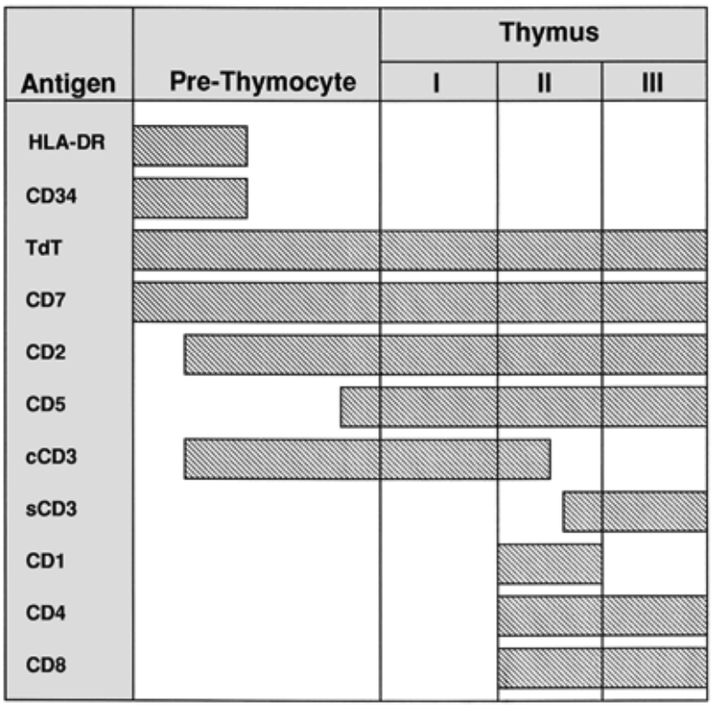

FIGURE 43.10. Correlation of immunophenotype and thymic stage of development in T-cell ALL. The respective antigens are listed in the left column and the various stages of thymic development in the rest of the table. cCD3 and sCD3, cytoplasmic and surface expression of the CD3 molecule, respectively.

Although CD7 has been promulgated as being the earliest marker of T-cell differentiation, one must exercise great caution in using this marker in isolation as evidence of T-cell differentiation. As is discussed later, 5% to 10% of AML cases show expression with this marker. Likewise, the sole expression of CD2 without any other T cell-associated marker should lead one to exercise caution before diagnosing the case as definite T-ALL because this marker can be identified in as many as 5% of AML cases. Thus, if one identifies only one of the pan–T-cell markers listed above in a case of acute leukemia, it is essential that a wide battery of both T-cell markers, especially cytoplasmic CD3, and myeloid markers, including megakaryoblast-associated glycoproteins, be used to confidently distinguish between a T-cell and a myeloid process. Obviously, morphologic, cytochemical, and clinical findings are essential in confirming this distinction. Although CD1, surface CD3, CD4, and CD8 provide interesting information regarding the corresponding stage of thymic development of T-ALL, not much is gained from a diagnostic viewpoint, as these antigens are almost always expressed in conjunction with CD2, CD5, and CD7.

Other antigens not typically associated with T cells can be identified in T-ALL. Essentially all cases express the common leukocyte antigen CD45. CD10 (anti-CALLA) positivity is usually found in approximately 10% to 20% of cases of T-ALL.

HLA-DR expression has also been found in 10% to 40% of T-ALL. Leukemic blasts in this disorder are also strongly positive for TdT. CD34, a hematopoietic progenitor cell antigen, can be found in 10% to 20% of all T-ALL cases. This is in sharp contrast to 50% to 60% positivity found in B-precursor ALL. CD11b, CD11c, and CD15 are all antigens that are more typically associated with myeloid processes but can also be found in 20% to 60% of T-ALL cases. Thus, one cannot use these antigens as strict evidence of a myeloid component.

Another interesting finding (but currently of uncertain clinical significance) is the recognition of different subtypes of T-ALL based on the type of T-cell antigen receptor present on the leukemic blasts. More than 95% of peripheral T-cell lymphocytes express the α/ß heterodimer T-cell receptor, with the remainder expressing the γ/δ T-cell receptor. A higher percentage of T cells within epithelial locations express the γ/δ receptor than the α/ß receptors. Within the thymus, γ/δ rearrangement is thought to occur before the α/ß rearrangement process. Several investigators have now reported T-ALLs that express the γ/δ receptor. These have been identified primarily based on the expression of surface CD3 without CD4 or CD8. Although the status of the antigen receptor T-ALL has provided us with important biological information, no clinical or prognostic difference has been found between T-ALL with α/ß receptor and T-ALL with γ/δ receptor. It is uncertain whether the identification of this subgroup has any clinical or prognostic importance.

Lymphoblastic Lymphoma

Malignant lymphoma, lymphoblastic type, is a high-grade lymphoma that occurs predominantly in older children and young adults; males are more frequently affected, and a mediastinal mass is often found. This neoplasm is often morphologically characterized by convoluted nuclei with fine chromatin and a high mitotic rate. Both precursor T-cell and B-cell ALL may present primarily as extramedullary tumors. The distinction between these disorders is usually based on the presentation of disease: tissue presentation generally indicates lymphoma, whereas marrow or blood presentation indicates leukemia. Most lymphoblastic lymphomas are T cell in origin and are reactive with multiple T cell–associated antibodies. This lymphoma can be distinguished from other types of lymphoma based on TdT positivity.

Cytogenetics

Cytogenetic analysis may provide the most important prognostic information for childhood ALL. Several studies have now shown that by using high-resolution banding techniques, more than 90% of ALL patients had demonstrable clonal chromosomal abnormalities. Large international studies have shown that children and adults with ALL can be prognostically stratified according to the type of chromosomal abnormalities. Hyperdiploidy (more than 50 chromosomes) has been consistently shown to be a favorable prognostic feature and is an independent prognostic predictor of therapeutic response. In contrast, three particular translocations in ALL have been associated with very poor prognoses, short survivals, and poor responses to induction chemotherapy. These include the Philadelphia chromosome or t(9;22), t(4;11), and t(8;14). The Philadelphia chromosome occurs in approximately 5% of childhood ALL and as many as 20% to 25% of adult ALL. Some of these may represent the blast crisis

phase of chronic myelogenous leukemia, although molecular studies clearly indicate that many of these are *de novo* presentations of acute leukemia. ALL patients with the t(9;22) translocation typically are older, have marked leukocytosis, and have a B-precursor immunophenotype.

The t(4;11) translocation or any ALL involving 11q23 has been reported in as many as 5% of cases of ALL. These cases typically have a FAB-L2 morphology, may frequently be associated with biphenotypia, and may occasionally show lineage switch to a monoblastic component (Fig. 43.11). The t(4;11) leukemias are most commonly identified in infant ALL (less than 2 years of age), usually present with marked leukocytosis, and have a median survival of less than 1 year. Splenomegaly is commonly identified. The immunophenotype of this subgroup of ALL shows HLA-DR, CD34, and CD19 positivity; CD10 and CD20 are typically negative.

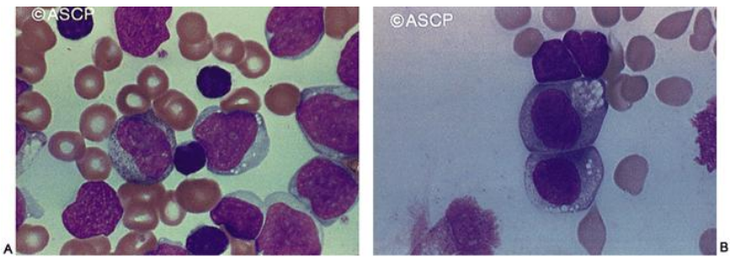

FIGURE 43.11. An acute leukemia with a t(4;11) translocation demonstrating both lymphoid (L2) **(a)** and monocytic **(B)** features.

The t(12;21)(p13;q22) translocation was recognized with advent of molecular based testing. Approximately 25% of childhood ALL is associated with this “cryptic” chromosome rearrangement. It is usually not recognized by routine cytogenetic studies but easily identified by fluorescent *in situ* hybridization and polymerase chain reaction. One of the most significant implications of this finding is its association with a clinically favorable prognosis.

The t(8;14) translocation and its variants, t(2;8) and t(8;22), are always found in the B-ALL (surface immunoglobulin-positive) and FAB-L3 morphology subtype, i.e., the Burkitt's leukemias/lymphomas. These patients have short survivals and are characterized by surface immunoglobulin expression.

The t(1;19)(q23;p13), E2A-PBX fusion, is found in 25% of ALL patients with cytoplasmic Ig positivity. It was considered to have a poor prognosis in the past because it was resistant to antimetabolite based regimens. However, recent protocols for high-risk ALL appear to improve treatment response.

Several clinical, hematologic, and laboratory criteria have been used to determine prognosis in patients with ALL (Table 43.8). Clinical, hematologic, and cytogenetic findings are essential components for predicting therapeutic outcomes of patients with ALL. Major determinants for the prognosis of ALL include the initial WBC, the degree of mediastinal involvement, and age. Children from 2 to 8 years of age do better than those younger or older, and infants less than 1 year of age have a particularly poor prognosis. In children between the ages of 2 and 8 years having WBCs less than 10.0 × 10^9/L, a 90% cure rate can be achieved. Patients of any age presenting with WBCs greater than 50.0 × 10^9/L have the shortest survivals, and those with intermediate WBCs show intermediate survivals. The previously discussed cytogenetic factors have also been shown to be prognostically independent of age and WBC and clearly add to the overall prognostic database.

TABLE 43.8. PROGNOSTIC GROUPS OF CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA

Good prognosis (20%)	WBC <10.0 × 10^9/L 2–8 yr of age
Average prognosis (60%)	WBC <10.0 × 10^9/L <2 or 8 yr of age or WBC 10.0–50.0 × 10^9/L Any age
Poor prognosis (20%)	WBC 50.0 × 10^9/L

WBC, white blood cells.

ACUTE MYELOGENOUS LEUKEMIA

Part of "43 - Acute Leukemias and Myelodysplastic Syndromes"

Pathogenesis

The AMLs are a heterogeneous group of malignancies originating in the hematopoietic, or myeloid, stem cell. The neoplastic proliferation seen in AML consists of myeloblasts or partially differentiated myeloid cells. This failure to show complete maturation by the neoplastic clone results in an accumulation of immature precursor cells and gradual replacement of normal bone marrow elements. To restate an earlier contention, AML is not a disorder of rapidly proliferating cells but rather an accumulation of incompetent, long-surviving cells. The various subgroups or variants of AML basically reflect maturation arrest at various points in hematopoietic/myeloid differentiation. Thus, referring to Fig. 43.1, one can rationalize the existence of the various morphologic subtypes of AML based on whether the granulocytic,

monocytic, erythroid, or megakaryocytic arm of myeloid differentiation is involved.

The exact cause of this leukemia is obviously unknown. However, various risk factors for the development of AML are known, including chemical exposures, such as to benzene; alkylating-agent chemotherapy; ionizing radiation; preceding myelodysplastic syndromes (MDSs); aplastic anemia; paroxysmal nocturnal hemoglobinuria; syndromes with chromosome instability, such as Fanconi's anemia, ataxia-telangiectasia, and Bloom's syndrome; Down's syndrome; and rare forms of familial inheritance.

Clinical Manifestations

The most common clinical findings of AML at presentation are very similar to those described in patients with ALL. Symptoms are primarily related to increasing suppression of normal bone marrow elements leading to anemia, thrombocytopenia, and neutropenia. Splenomegaly is mild to moderate. Lymphadenopathy can be found in as many as one third of AML patients but is not as uniform or pronounced as in ALL. Thymic involvement is exceedingly uncommon in AML. Cutaneous infiltration, however, is relatively common, occurring in as many as 10% of AML patients. This and other forms of extramedullary involvement, such as the gingival tissue, are most commonly associated with those leukemias having a monocytic component. The terms chloroma, granulocytic sarcoma, myeloblastoma, and extramedullary myeloid tumor all refer to the collection of leukemic cells in an extramedullary organ. These extramedullary tumors may occur in soft tissues, the orbital region, ovaries, testes, gastrointestinal tract, breast, skin, and other sites. CNS involvement in AML is not as common as in ALL but must still be considered as a possible complication of disease.

Incidence

AML is primarily a disease of adults. It constitutes approximately 45% of all leukemias but more than 80% of all adult acute leukemias and less than 20% of childhood acute leukemia.

Laboratory Findings

In AML, the WBC is elevated in more than half of patients at the time of diagnosis. Pancytopenia is a constant feature of this leukemia. The number of blasts in the peripheral blood varies according to the subtype of AML and depends on the degree of maturation and differentiation that characterizes that particular leukemic subtype. As many as 10% of patients will have WBC counts that are greater than 100.0×10^9/L, with some patients approaching 500.0×10^9/L. Patients with WBCs greater than 50.0 to 100.0×10^9/L are at risk of developing complications owing to hyperleukocytosis. Leukophoresis is mandated in these patients and is an essential part of the therapeutic process. Serum uric acid level is typically elevated in approximately two thirds of patients with AML. Serum LDH level is typically not higher than in ALL.

Morphology and FAB Classification

The French-American-British (FAB) group on acute leukemia has morphologically subclassified the AMLs into seven major subtypes: FAB-M1 to FAB-M7 (Table 43.9). The FAB classification of AML basically relies on the degree of granulocytic, monocytic, erythroid, and megakaryocytic differentiation. This is based on the morphologic appearance of cells, the number of leukemic blasts, and cytochemical findings with myeloid-associated enzymatic stains. Important variants of these seven subtypes also exist. The National Cancer Institute has proposed revised standards for the classification of AML, including another subtype based on immunophenotyping (FAB-M0). The various subtypes of AML are listed in Table 43.9. The incidences of the AML subgroups are listed in Table 43.10.

TABLE 43.9. FAB CLASSIFICATION OF ACUTE MYELOGENOUS LEUKEMIA

M0	Acute leukemia, undifferentiated; myeloid immunophenotype
M1	Acute myelogenous leukemia (AML) without maturation
M2	AML with maturation
M3	Acute promyelocytic leukemia (APL)

FAB, French-American-British classification.

The importance of the FAB classification of AML lies not in its ability to provide important prognostic information to the patient but rather its ability to provide precise and consistent classification of AML subtypes. The ability to reproduce the various FAB subgroups morphologically and cytochemically is well proven and allows knowledge interaction and consistency between institutions and physicians.

The basic definition of an AML is a leukemia that has more than 30% myeloblasts in the bone marrow. However, in the recent WHO classification, the required percentage of blasts for diagnosis of AML is decreased to 20% in the bone marrow and peripheral blood. Myeloblasts may be grouped into three different subtypes: I, II, and III. Type I myeloblasts are undifferentiated blasts that have no evidence of granulocytic differentiation, i.e., they contain no cytoplasmic granulation or Auer rods (Fig. 43.12). Auer rods are absolutely specific for a leukemic myelogenous process and consist of abnormally fused primary granules. Auer rods are needle- to fusiformlike eosinophilic rods that are found in the cytoplasm of leukemic myeloid cells and stain red to purple with Wright-Giemsa stain.

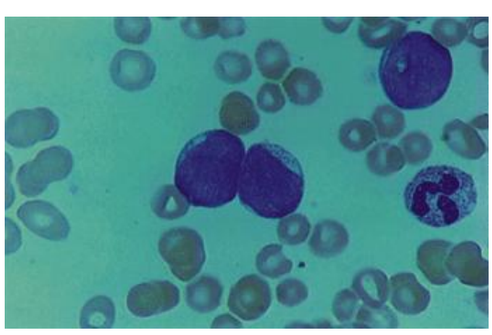

FIGURE 43.12. Type I (left cell) and II (right cell) myeloblasts.

Type II blasts are leukemic blasts that have relatively few cytoplasmic granules (Fig. 43.12). It is too rigid to specify the exact number of these granules; however, most morphologists would define type II blasts as having fewer than eight to 12 granules per cell. The type III blasts are cells intermediate between type II blasts and promyelocytes. Obviously, this distinction may be quite difficult to make at times, but it is generally relegated to cells that have the nuclear characteristics of blasts (fine chromatin and prominent nucleoli) but with more granules than in the type II blasts. The cytoplasm retains its basophilic appearance.

The National Cancer Institute's expanded definition of blasts is listed in Table 43.11 and includes the type I, II, and III blasts discussed previously. Also included in their basic definition of blasts are the abnormal promyelocytes seen in FAB-M3, the monoblasts and promonocytes of FAB-M4 and FAB-M5, and the megakaryoblasts of FAB-M7. Erythroblasts, including early pronormoblasts, are not included in the definition of a leukemic blast. Specific criteria for each subtype is summarized in Table 43.12

TABLE 43.11. EXPANDED BLAST DEFINITION: NATIONAL CANCER INSTITUTE

Type I blast: no granules
Type II blast: few granules
Type III blast: multiple granules, central nucleolus, fine chromatin
Abnormal promyelocytes of M3
Monoblasts/promonocytes of M5
Megakaryoblasts of M7
Erythroblasts should *not* be included

TABLE 43.12. CLASSIFICATION OF ACUTE MYELOGENOUS LEUKEMIA

FAB Subtype	Diagnostic Criteria
M0	No morphologic evidence of differentiation
	Negative cytochemical staining with MPO/SBB/NSE
	Positivity with myeloid markers (CD13, CD33, etc.) and negative lymphoid markers
M1	≥90% blasts in bone marrow
	<10% of marrow showing granulocytic differentiation
	>3% of blasts with MPO or SBB positivity
M2	≥20% blasts and <90% blasts in marrow
	≥10% of marrow showing granulocytic differentiation
	≤20% monocytic cells
M3	≥20% of marrow or abnormal promyelocytes
M3v	Same as M3 except composed of hypogranular variants
M4	≥20% blasts
	≤80% myeloblasts and granulocytic precursors in marrow
	20% monocytic cells in marrow (morphology/NSE stain/serum lysozyme)
M4e	Same as M4 with increased number of atypical/immature marrow eosinophils
M5a	≥80% monoblasts
M5b	≥80% of monoblasts/promonocytes/monocytes
	<80% monoblasts in marrow
M6	≥50% nucleated RBC
	Prominent dyserythropoiesis
	≥20% myeloblasts in nonerythroid cells
M7	≥20% blasts
	Identification of megakaryoblasts by ultrastructural cytochemistry or by immunophenotyping

MPO, myeloperoxidase; SBB, Sudanblack b; NSE, nonspecific esterase; RBC, red blood cells.

FAB-M0: AML Without Maturation

The FAB-M0 group of AML is myeloid leukemia with a minimal differentiation that has a demonstrable myeloid lineage by immunophenotyping or ultrastructural studies. These AMLs consist of small- to intermediate-size leukemic blasts without any evidence of granulocytic differentiation (Fig. 43.13). Cytochemical staining with MPO, Sudan black B (SBB), and nonspecific esterase (NSE) is negative. Thus, from a strict morphologic and cytochemical analysis, these cases would have been classified as ALL in the past. However, by flow cytometric immunophenotyping, these cases show reactivity with one or more myeloid-associated markers, such as CD117 (C-kit) CD13, CD33, or CD15, while lacking any expression of lymphoid-associated markers.

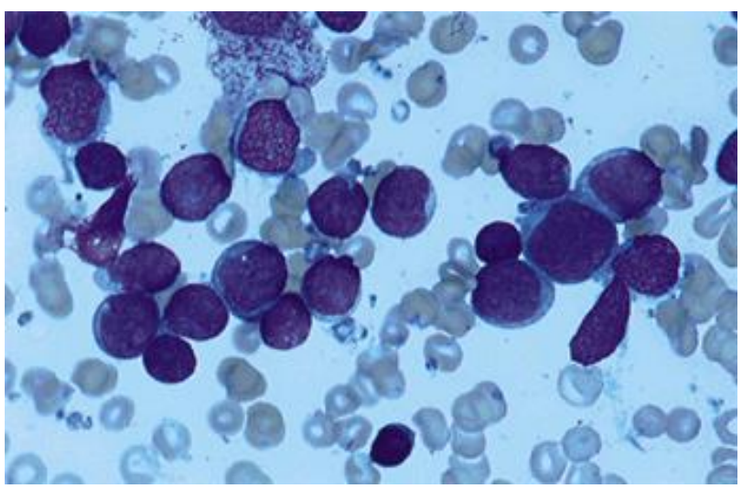

FIGURE 43.13. Acute myelogenous leukemia M0.

FAB-M1: AML Without Maturation

In these AMLs without maturation, there is minimal evidence of cytoplasmic granulation and minimal numbers of Auer rods. The blasts are intermediate in size with finely reticular chromatin, small amounts of grayish-blue cytoplasm, and typically one or more prominent nucleoli (Fig. 43.14). Basic FAB criteria

for AML-M1 include the following: (a) the sum of total blasts is greater than 90% of the bone marrow cells; (b) less than 10% of bone marrow cells shows evidence of granulocytic differentiation at or beyond the promyelocyte stage; and (c) at least 3% of the leukemic blasts demonstrate MPO and/or SBB positivity. The differential diagnosis in this disorder includes ALL-L2, AML-M5a, and AML-M7. Immunophenotyping and cytochemical staining are usually necessary to make the distinction between these subtypes of leukemias.

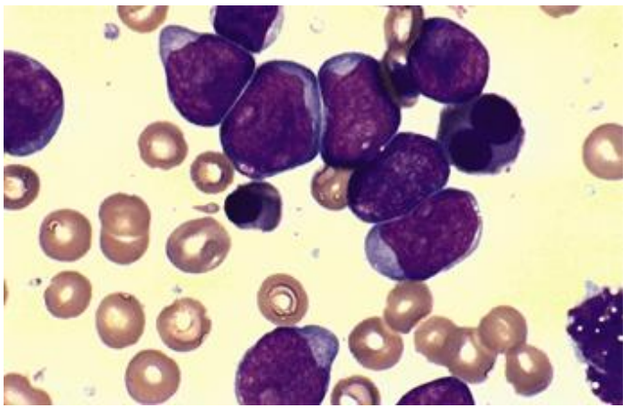

FIGURE 43.14. Acute myelogenous leukemia M1.

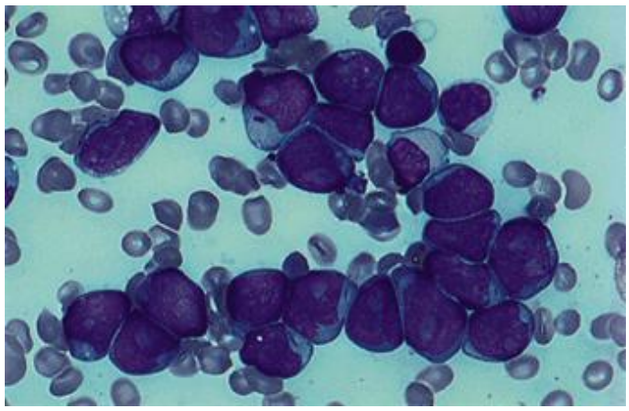

FIGURE 43.15. Acute myelogenous leukemia M2 with numerous single Auer rods.

FAB-M2: AML with Maturation

The AMLs with maturation are the most common subtype of AML. These leukemias show clear evidence of differentiation at or beyond the promyelocyte stage, and Auer rods are commonly identified (Fig. 43.15). These cells usually have more cytoplasm than is found in FAB-M1 leukemic cells, and fewer undifferentiated blasts are seen. From a diagnostic viewpoint, this subtype of AML is easy to diagnose and creates little diagnostic consternation. The basic FAB criteria for FAB-M2 include the following: (a) the sum of blasts is 20% or greater but less than 90% of the bone marrow cells; (b) more than 10% of the bone marrow cells shows evidence of granulocytic differentiation; and (c) monocytic cells constitute fewer than 20% of the bone marrow cells. It should also be noted that dysplastic features may be identified in the granulocytic, erythroid, and/or megakaryocytic series. Frank panmyelosis is uncommon but can be seen in some cases. Although most bone marrow specimens are hypercellular and show frank replacement of all bone marrow elements, some patients, mainly the elderly, may have bone marrows that are moderately hypocellular.

The differential diagnosis of FAB-M2 would include a leukemoid reaction, a MDS that does not meet the criteria of AML, and possibly other types of AML having a granulocytic component such as FAB-M3, FAB-M4, or possibly FAB-M6.

A specific bone marrow chromosome abnormality, t(8;21), has been observed in some cases of FAB-M2. The percentage of patients with the t(8;21) translocation has varied from 30% to less than 5% of FAB-M2s in various reports in the literature. Patients having AML-M2 with a t(8;21) are believed to have a good prognosis. The morphologic features of FAB-M2 with a t(8;21) include larger myeloblasts, easily identified and numerous Auer rods, and a distinctive dysmyelopoiesis in the developing granulocytic cells. This dysmyelopoiesis has been described as a “crushed” orange granularity in the cytoplasm of the granulocytic cells. These patients usually aberrantly express CD 19 and/or CD56.

FAB-M3: Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) can be diagnosed when 20% or more of the bone marrow cells are abnormal promyelocytes. These promyelocytes have abnormally dense and heavy granulation. One of the characteristic features of APL are the so-called faggot cells, which are cells that contain multiple Auer rods that may be bundled, intertwined, or fused together (Fig. 43.16 and Fig. 43.17). The granules of the promyelocyte are larger and darker staining than normal and at times may be so numerous as to obscure nuclear borders. Intensely basophilic cytoplasm may be present in some cells. The nuclear features, which are frequently ignored or even obscured by the granulation, typically have a monocytoid, bilobed, or kidney-bean shape. It is uncommon for this type of AML to have a significant percentage of blasts. In a large series of APLs, the median blast count was only 12%. These patients are typically leukopenic at presentation and are clinically characterized by disseminated intravascular coagulation (DIC) and bleeding.

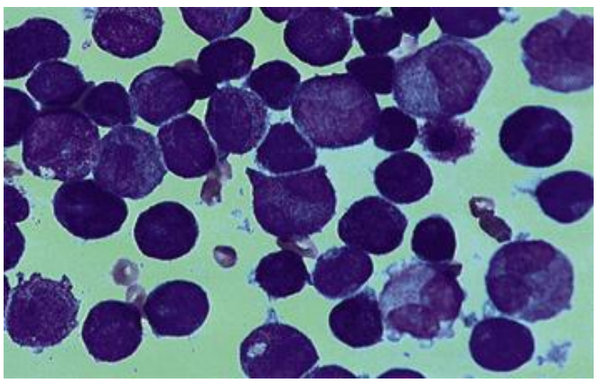

FIGURE 43.16. Acute myelogenous leukemia M3 (acute promyelocytic leukemia).

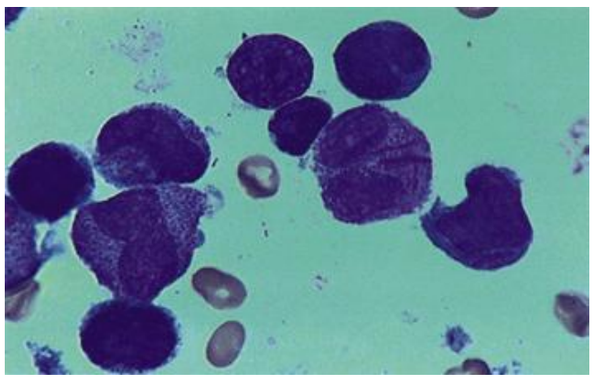

FIGURE 43.17. Acute myelogenous leukemia M3 (acute promyelocytic leukemia Faggot cell).

Approximately 20% of APLs are a variant form of FAB-M3

and are designated as microgranular or hypogranular APL (M3v). The leukemic cells in this FAB-M3 variant are characterized by sparse and/or fine granulation and a strikingly irregular nuclear shape (Fig. 43.18). Their identity as abnormal promyelocytes may be obscured by the scarcity of granulation and the nuclear shape. Cells containing multiple Auer rods are usually present, but they may be extremely difficult to identify because they are certainly less abundant than in the typical hypergranular FAB-M3. The variant form of APL has the same incidence of DIC described previously but will more likely present with leukocytosis at the time of diagnosis. The obvious differential diagnostic problem relates to the confusion with acute myelomonocytic (M4) or acute monocytic (M5b) leukemia.

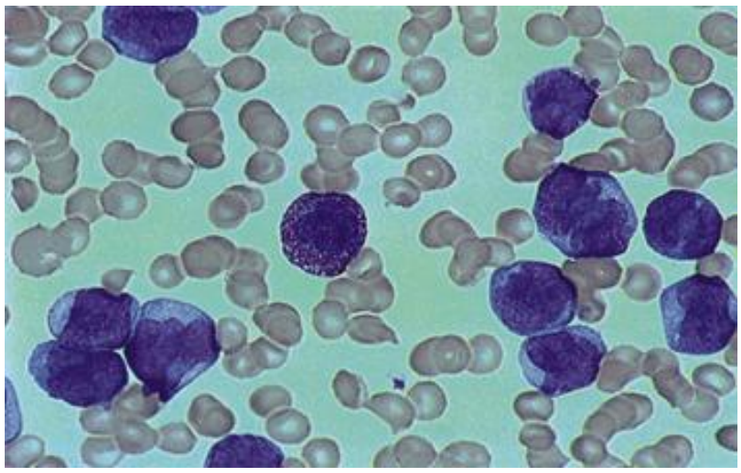

FIGURE 43.18. Acute myelogenous leukemia M3 variant (hypogranular acute promyelocytic leukemia).

APL may occur at any age but is most common in young adults, with a median age of diagnosis of 35 to 40 years. The most outstanding clinical feature associated with APL is the high frequency of DIC. This is owing to the release of procoagulant factors from the cytoplasmic granules, which leads to activation of the coagulation cascade. In many patients, there are severe DIC and hemorrhage before or during induction of therapy, when the malignant cell contents are lysed and released. Hemorrhage is the cause of death in many patients. Thus, it is essential that this subgroup of AML be accurately diagnosed rapidly so that appropriate chemotherapy and supportive care can be initiated. If the DIC and hemorrhage are adequately controlled and treated, patients with this subgroup of AML probably have the best prognostic outcome of any AML group. Recognition of this particular subgroup is especially important because a specific regimen including all-*trans* -retinoic acid (ATRA) causes leukemic cells to overcome maturation arrest.

The differential diagnosis of APL includes other types of AML with granulocytic components, such as FAB-M2, FAB-M4/M5, and benign agranulocytosis with a promyelocyte arrest. In cases of benign agranulocytosis, the platelet count and hemoglobin are generally normal, in contrast to the pancytopenia seen in APL. In addition, in agranulocytosis, the bone marrow is not hypercellular and Auer rods are obviously not identified. The major difficulty in the diagnosis of APL is the distinction of microgranular APL (M3v) from FAB-M4 or M5b. Evaluation with cytogenetic and molecular studies typically resolves this issue. Demonstration of t(15;17)(q22;q12-21) or t(11;17) is diagnostic of APL and essential for diagnosis. The immunophenotypic studies in typical APL include myeloid phenotype (CD13, CD33) and lack of HLADR, CD34.

FAB-M4: Acute Myelomonocytic Leukemia

Acute myelomonocytic leukemia and FAB-M2 are the most common AMLs, together accounting for approximately two thirds of all AML cases. The FAB-M4 subgroup of AML is probably the most difficult subgroup of AML in which to perform a reliable differential count, as this is a very heterogeneous-appearing leukemia. Both granulocytic and monocytic differentiation are present in varying proportions in the bone marrow (Fig. 43.19). It may be difficult to identify the granulocytic and monocytic component, as hybrid cells clearly exist in this type of leukemia. The criteria for the diagnosis of FAB-M4 includes the following elements: (a) the sum of all blasts is greater than 20%; (b) the sum of myeloblasts and granulocytic precursor cells account for less than 80% of the bone marrow cells; (c) more than 20% of the bone marrow cells are of the monocytic lineage as demonstrated by morphology, NSE cytochemical stain, or elevated serum lysozyme level (three times normal). Thus, granulocytic and monocytic precursors coexist in proportions varying reciprocally from 20% to 80%. Auer rods may also be identified in approximately half of the cases. Because of the difficulty in the morphologic identification of both promonocytes and hybrid

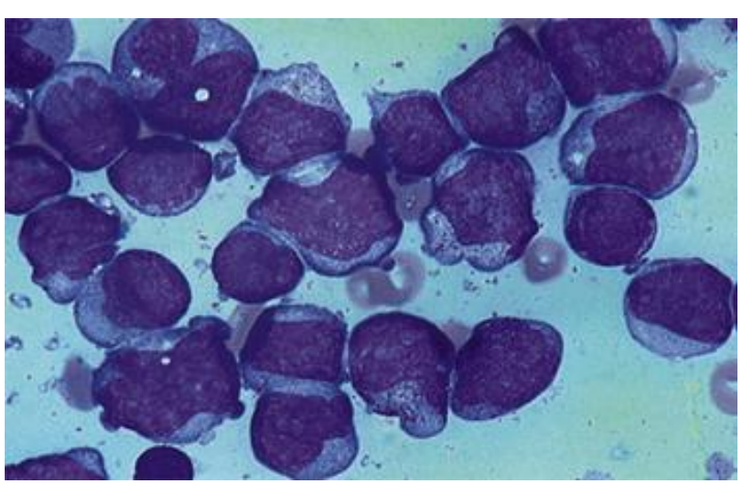

FIGURE 43.19. Acute myelogenous leukemia M4.

granulocytic/monocytic cells in bone marrow, additional diagnostic criteria utilizing NSE and elevated serum lysozyme levels have been used. Organomegaly, lymphadenopathy, and other sites of tissue infiltration may commonly be encountered.

A variant of FAB-M4 exists, which has been called FAB-M4 with eosinophilia (M4e). Criteria for diagnosis include the usual diagnostic criteria for FAB-M4 and an increased number of atypical, immature bone marrow eosinophils (Fig. 43.20). The immature and atypical eosinophils contain an abundance of large basophilic-staining granules in addition to the large, red eosinophilic granules that characterize a mature eosinophil. Abnormalities of chromosome 16, including inversion of 16(p13;q22) or deletion of 16q22, are consistently identified in this variant. This type of leukemia has a high rate of remission after the initial induction of therapy compared with other types of AMLs, and diagnosis of this variant is considered a good prognostic sign.

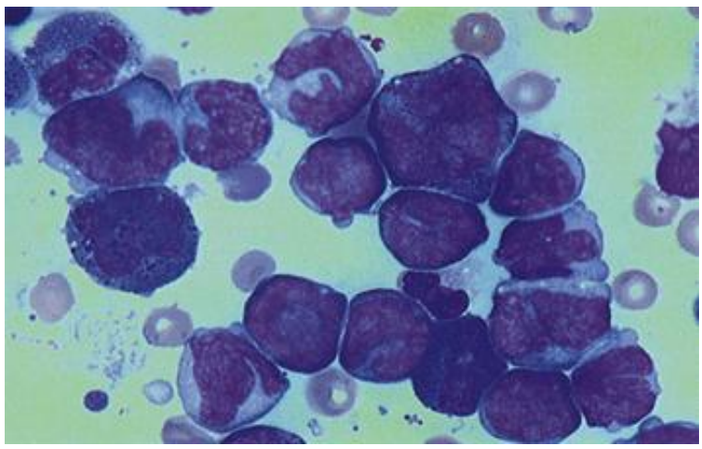

FIGURE 43.20. Acute myelogenous leukemia M4 with eosinophilia.

Morbidity owing to an increased incidence of CNS relapse with leptomeningeal infiltration and pulmonary involvement, however, may occur in this subtype of AML.

FAB-M5a: Acute Monoblastic Leukemia and FAB-M5b: Acute Monocytic Leukemia

FAB-M5a is characterized by a predominance of monoblasts that are large and have relatively abundant cytoplasm. Some azurophilic granules may be identified in the cytoplasm that are MPO negative. The nucleus is typically round to oval with finely reticular chromatin and prominent nucleoli. Typically, the nucleus is displaced to one side with an ample amount of cytoplasm wrapping around the nucleus (Fig. 43.21). The sole criterion for diagnosis of FAB-M5a is the existence of more than 80% monoblasts in the bone marrow. This differs slightly from the criteria for FAB-M5b, in which more than 80% of the marrow cells are monoblasts, promonocytes, or monocytes but less than 80% of the marrow cells are monoblasts. In other words, FAB-M5b shows more differentiation than FAB-M5a. Nuclear folding and irregularity are common in FAB-M5b, and more azurophilic granulation is identified than in FAB-M5a (Fig. 43.22). Both FAB-M5a and FAB-M5b are associated with a high incidence of extramedullary infiltration; DIC may also develop in patients with FAB-M5, second in incidence only to FAB-M3 among classes of AML. NSE cytochemical stains are positive in the FAB-M5 leukemias. Auer rods may be seen in a small percentage of monoblasts but are certainly much less frequent than in the granulocytic types of AML. AML-M5a is more commonly diagnosed in the pediatric age group.

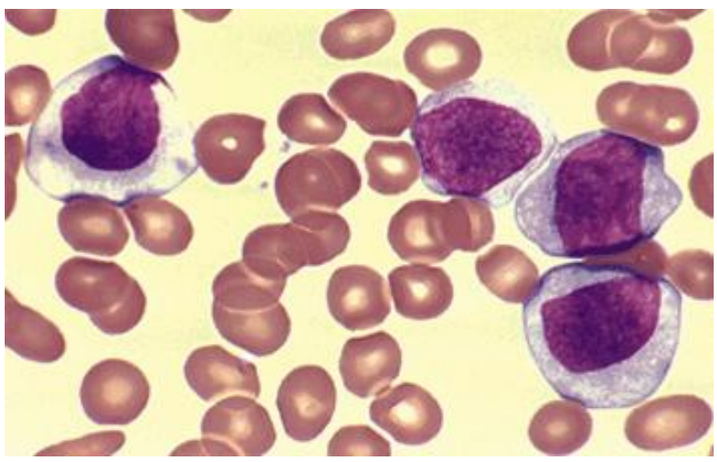

FIGURE 43.21. Acute myelogenous leukemia M5a.

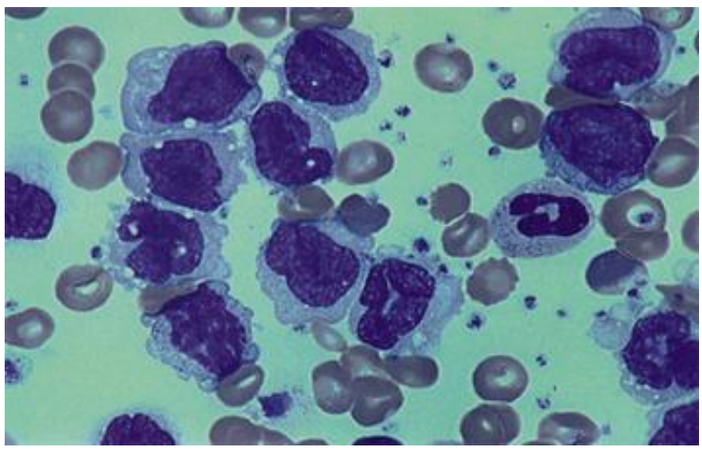

FIGURE 43.22. Acute myelogenous leukemia M5b.

FAB-M6: Acute Erythroleukemia (Di Guglielmo's Syndrome)

Acute erythroleukemia is a relatively uncommon variant of AML and may have multiple presenting appearances. One form,

which has previously been called erythemic myelosis, is characterized by bizarre and markedly atypical megablastoid changes accompanied by extreme erythroid hyperplasia within the bone marrow (Fig. 43.23). Few, if any, myeloblasts can be identified. Normal granulocytic and megakaryocytic precursors are not identified and are replaced by giant, multinucleated, and markedly dysplastic erythroblasts. In other cases of FAB-M6, the marrow contains more differentiated, albeit dysplastic, erythro-blasts at the time of presentation along with a definite population of granulocytic cells, including myeloblasts (Fig. 43.24). In 1985, the following criteria were established by the FAB group for the diagnosis of erythroleukemia in determining blast percentage: (a) 50% or more of all nucleated bone marrow cells must be erythroblasts; (b) dyserythropoiesis is prominent; (c) 20% or more of the nonerythroid cells in the bone marrow are myeloblasts.

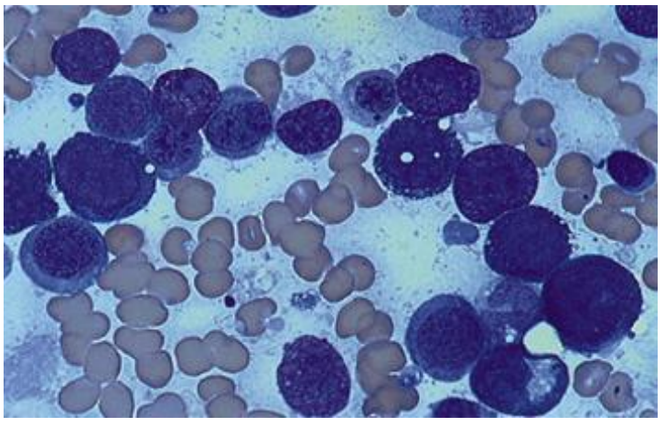

FIGURE 43.23. Acute myelogenous leukemia M6 (erythemic myelosis).

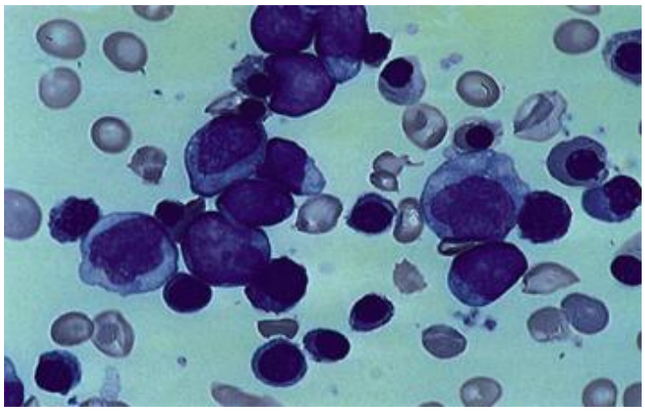

FIGURE 43.24. Acute myelogenous leukemia M6.

Erythroleukemia will frequently evolve into other types of AML such as FAB-M1, M2, or M4. Auer rods may be identified in the myeloblasts in these cases. The leukemic erythroblasts frequently contain a “frothy” or “foamy” vacuolation in the cytoplasm. Progression of the disease is frequently marked by an increase in myeloblasts and a decrease in erythroblasts. A striking erythroblastemia may be identified in the peripheral blood. It is quite common for erythroleukemia to evolve from MDSs or as a secondary leukemia in patients who have received prior radiation and/or alkylating-agent chemotherapy. The differential diagnosis for erythroleukemia includes B_{12}/folate deficiency, heavy metal intoxication (such as arsenic), drug effects (such as with antineoplastic agents or chloramphenicol), congenital dyserythropoietic syndromes, MDSs, and potentially other types of AML. The dysplastic erythroblasts are typically PAS positive, which reflects a cytoplasmic maturation defect. This cytochemical finding is not restricted to leukemia and can be identified in benign disorders, such as ß thalassemia, iron deficiency, sideroblastic anemia, and heavy metal intoxication.

FAB-M7: Acute Megakaryoblastic Leukemia

Acute megakaryoblastic leukemia has only recently been added to the FAB classification. The diagnostic criteria for diagnosis includes (a) more than 20% blasts in the bone marrow and (b) definitive identification of megakaryoblastic involvement by a platelet peroxidase reaction by electron microscopy or reactivity with megakaryocyte-specific monoclonal antibodies. The differential diagnosis of megakaryoblastic leukemia includes ALL-L2, AML-M0, AMLM1, and AML-M5a. As can be seen from this differential diagnostic list, there is a morphologic heterogeneity to FAB-M7. The blasts may vary from small- to medium-sized to large, bizarre blasts typically having high, nuclear:cytoplasmic ratios (Fig. 43.25). The nuclear chromatin may be dense and homogeneous or fine and reticular. There is typically scanty basophilic cytoplasm, which may or may not be vacuolated. Indeed, the degree of basophilia may be comparable with that found in erythroleukemia, reflecting the close developmental relationship between erythroid and megakaryoblastic precursors. An irregular cytoplasmic border may be noted in some of the megakaryoblasts resembling pseudopods. Very fine granulation can be identified in the cytoplasm of some blasts. Intermediate forms between undifferentiated blasts and definitive micromegakaryocytes may also be seen (Fig. 43.26). Some cases may show little if any differentiation and resemble the lymphoblasts of FAB-L2.

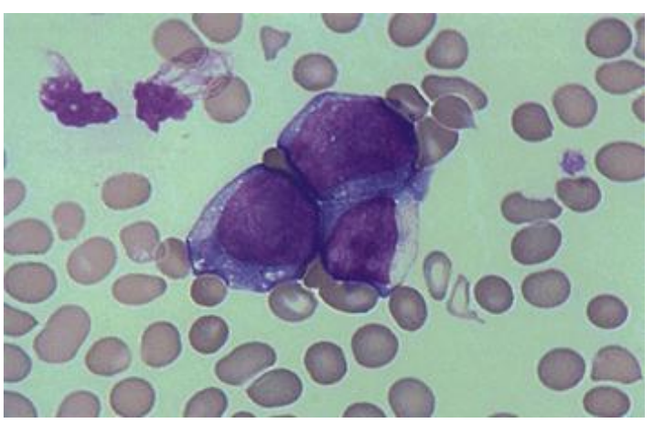

FIGURE 43.25. Acute myelogenous leukemia M7.

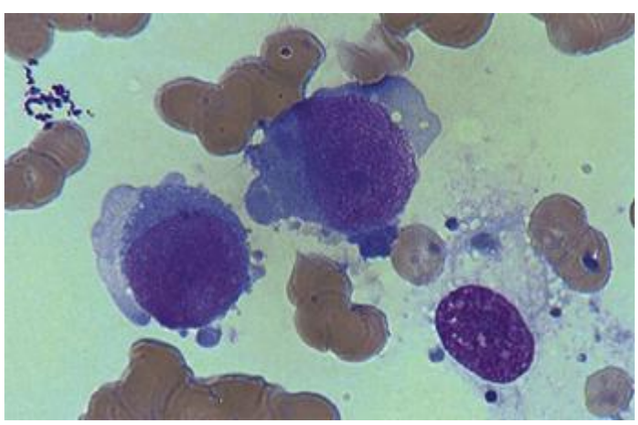

FIGURE 43.26. Acute myelogenous leukemia M7.

The diagnosis of FAB-M7 relies on multiple criteria including peripheral blood and bone marrow aspirate smear morphology, bone marrow trephine section histology, routine cytochemical stains, immunophenotyping, and ultrastructural studies (Table 43.13). In some cases, the peripheral blood and bone marrow aspirate morphology may be sufficient to make the diagnosis,

whereas in other cases, more sophisticated diagnostic modalities may be needed to confirm the diagnosis of FAB-M7. Some cases of FAB-M7 have morphologic features suggestive of a megakaryoblastic process, including the presence of circulating micromegakaryocytes, atypical platelets, or the presence of myelofibrosis and atypical megakaryocytes in the bone marrow sections (Fig. 43.27).

TABLE 43.13. DIAGNOSIS OF ACUTE MEGAKARYOBLASTIC LEUKEMIA

Aspirate morphology
Trephine section histology
Routine cytochemistry
Immunophenotyping
Ultrastructure

Cytochemically, megakaryoblasts show no reactivity with MPO or SBB. A diffuse, coarse granular positivity is typically seen with PAS, not to be confused with the chunky staining seen in ALL (Fig. 43.28). Megakaryoblasts show no reactivity with α-naphthyl butyrate esterase but can manifest strong reactivity with the acetate substrate of NSE (Fig. 43.29). This latter discrepancy between the butyrate and acetate substrates of NSE can be a very useful diagnostic feature of FAB-M7. Immunophenotyping with monoclonal antibodies reactive with platelet glycoprotein (Gp) IIb/IIIa or Gp IIIa (CD41 and CD61) has provided a more sensitive and reproducible method of detecting megakaryoblasts. These antibodies are discussed in more detail in the subsequent section on immunophenotyping.

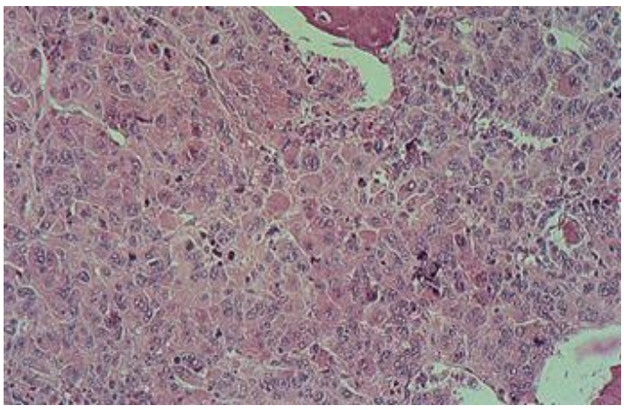

FIGURE 43.27. Acute myelogenous leukemia M7 (bone marrow biopsy).

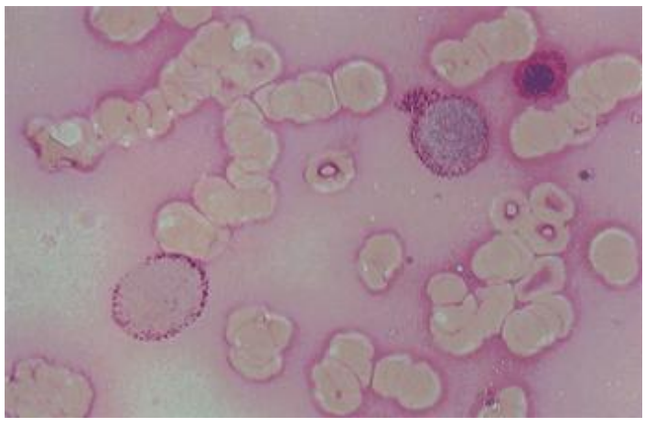

FIGURE 43.28. Acute myelogenous leukemia M7: periodic acid–Schiff cytochemical stain.

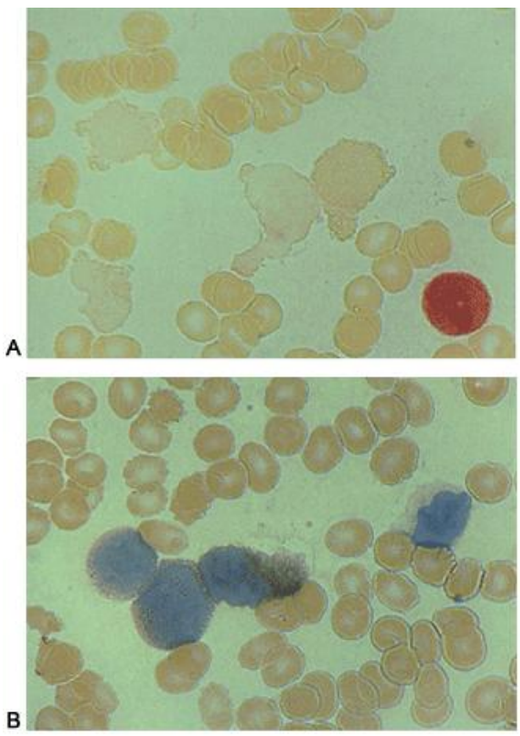

FIGURE 43.29. Acute myelogenous leukemia M7 nonspecific esterase stain. **A:** butyrate; **B:** acetate substrates.

The standard for the diagnosis of FAB-M7 is the demonstration of CD41/CD61 or platelet peroxidase by ultracytochemistry with electron microscopy. Ultrastructural peroxidase activity is found in the nuclear envelope and endoplasmic reticulum but is absent from the granules and Golgi of the leukemic megakaryoblasts. This pattern is distinctly opposite that found in myeloblasts by ultracytochemistry.

Acute megakaryoblastic leukemia is commonly associated with patients that have Down's syndrome, therapy-related acute leukemias, and blast crises of chronic myeloproliferative disorders. Clinical features of FAB-M7 are variable and can occur in both children and adults. A marked leukocytosis is relatively uncommon in M7 and typically is not associated with extramedullary involvement, lymphadenopathy, or hepatosplenomegaly.

Acute Myeloid Leukemia, Not Otherwise Specified

Some of the cases of AML not fitting in the above groups are placed in this category. Rare cases of AML with basophilic differentiation as commonly demonstrated by ultrastructural studies

are called acute basophilic leukemia. The basophilic differentiation is usually detected by toluidine blue or electron microscopy. Extramedullary myeloid tumors, so-called granulocytic sarcoma, are also included in this category. The third group is acute panmyelosis with myelofibrosis, which presents with marked pancytopenia and panmyeloid proliferation. Because they usually show an increased number of atypical megakaryocytes, differentiation from AML-M7 may be difficult in some cases. In fact, some consider this entity as AML-M7 with marked myelofibrosis. The lack of splenomegaly and prominent hematopoietic dysplasia help to distinguish this disorder from chronic myeloproliferative disorders.

Cytochemistry

Table 43.14 shows the distribution of cytochemical staining in AML. In general, it can be noted that the AMLs with a granulocytic component will stain with MPO, SBB, and chloroacetate esterase (CAE) (Fig. 43.30 and Fig. 43.31), and those with a monocytic component will react with NSE and ACP (Fig. 43.31 and Fig. 43.32). Megakaryoblastic staining was previously discussed.

TABLE 43.14. CYTOCHEMICAL STAINING IN ACUTE MYELOGENOUS LEUKEMIA

Stain	M1	M2	M3	M4	M5	M6	M7
MPO	+	+	+	+	-	+/-	-
SBB	+	+	+	+	-	+/-	-
CAE	+/-	+	+	+	+/-	+/-	-
NSE-b	-	-	-	+	+	-	-
NSE-a	-	-	-	+	+	-	+
ACP	-	-	-	+	+	-	+
PAS	-/+	-/+	-	-	+/-	+	+
TdT[a]	-	-	-	-	-	-	-

[a] Between 10% and 20% of AML will be TdT positive.

MPO, myeloperoxidase; SBB, Sudan black B; CAE, chloroacetate esterase; NSE-b, nonspecific esterase butyrate; NSE-a, nonspecific esterase acetate; ACP, acid phosphatase; PAS, periodic acid–Schiff; TdT, terminal deoxynucleotidyltransferase.

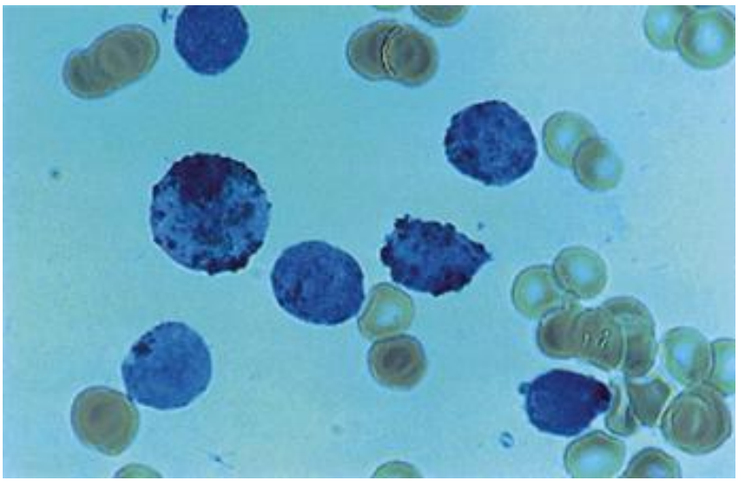

FIGURE 43.30. Myeloperoxidase stain of acute myelogenous leukemia M2.

MPO is an enzyme present within the primary granules of the granulocytic series, including granulocytes, eosinophils, and some basophils. Monocytes also contain peroxidase granules but are present in very small numbers and never pose a serious problem when interpreting such a stain. Lymphoid and erythroid cells do not stain with MPO. We have found MPO to be the most sensitive marker for granulocytic differentiation; however, MPO stains will fade with time; for this reason SBB is also commonly used and is a good alternative to MPO. SBB stains intracellular lipids that are within the primary granules of the granulocyte series. This is easily detected within myeloblasts and the rest of the granulocyte series. Lymphoblasts, however, may also, show an occasional rare, small positive granule. Thus, one must interpret SBB with some caution. CAE, or specific esterase/Leder stain, is confined to the primary granules of differentiated granulocytes. Myeloblasts are typically lacking in this enzyme. Monocytes, lymphocytes, and erythroid cells are negative with this enzyme stain. CAE is not as sensitive as MPO or SBB.

NSE is a particularly useful stain for the monocyte series. Little, if any, staining of the granulocytic series will be found. T lymphocytes and T lymphoblasts typically show a distinct punctate, perinuclear positivity that is easily distinguished from monocyte staining. The butyrate esterase gives a clearer and more definitive stain compared with the acetate substrate of NSE and is the preferred monocyte-associated enzyme stain. It gives a deep, brick-red stain that is easy to interpret and distinguish

from background staining, as opposed to the faint positivity seen with the acetate substrate of NSE. The acetate NSE activity can also be found in megakaryocytes, platelets, and some basophils and plasma cells. Fluoride sensitivity is used by some laboratories to help differentiate between different NSE-positive cells. The NSE reactivity found in monocytes is blocked by fluoride and is partially blocked in megakaryocytes. NSE staining found in lymphocytes and lymphoblasts, however, is not sensitive to fluoride treatment. Occasional cases of B-precursor ALL also show a faint blush in the Golgi area of such lymphoblasts; this is also fluoride resistant.

As mentioned in the ALL section, PAS may stain some cases of AML, thus limiting its diagnostic use as a specific ALL marker. TdT reactivity can also be found in as many as 20% of AML cases, although it is usually dimmer and positive in a lower percentage of cells than in typical ALL.

Immunophenotype of AML

The diagnosis of AML is usually a straightforward diagnosis made based on morphology and cytochemical staining. Immunophenotyping of potential cases of AML should be done for the following reasons (Table 43.6): (a) to distinguish AML from ALL (the most practical reason to analyze a potential AML) and (b) to provide correlation with the FAB morphologic subtype of AML.

The two situations that commonly pose the most difficult problem for diagnosing an AML are leukemias with no or minimal evidence of differentiation (FAB-M0 and FAB-M1) and those of megakaryoblastic differentiation (FAB-M7). Pan-myeloid monoclonal antibodies, CD13, CD33, and CD117, have been universally used to distinguish AML from ALL on an immunologic basis. Overall, 90% to 98% of AMLs will react with these markers. Moreover, these reagents have appeared to be highly specific for myeloid cells and are expressed in all FAB morphologic subtypes of AML. Some FAB-M0 and FAB-M1 AMLs tend to express CD33 only, suggesting that those leukemias are of earlier myeloid development than other AML. In addition, acute megakaryoblastic leukemias (FAB-M7) may not express either CD13 or CD33 or tend to express CD13 and/or CD33 in a lower percentage of blasts with weaker intensity than in more classic AML.

The use of a panel of myeloid-associated monoclonal antibodies is necessary to access any possible correlations between an immunophenotype and the FAB morphologic classification (Fig. 43.33). Reports in the literature have demonstrated that myeloid monoclonal antibody reactivity may correspond to broad categories of morphologic differentiation: myeloblastic (FAB-M1 and M2), promyelocytic (FAB-M3), monocytic (FAB-M4 and M5), erythroid (FAB-M6), and megakaryocytic (FAB-M7). FAB-M1 and M2 acute myeloid leukemias react with the pan-myeloid markers CD13, CD33, and CD117. CD15 also reacts with most cases of FAB-M1 and M2. Monocyte-associated

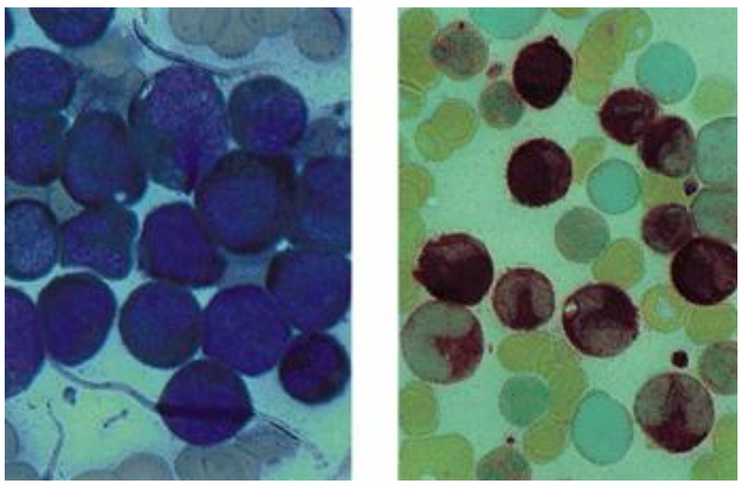

FIGURE 43.31. Sudan black B **(left)** and nonspecific esterase (butyrate) **(right)** stain of acute myelogenous leukemia M4.

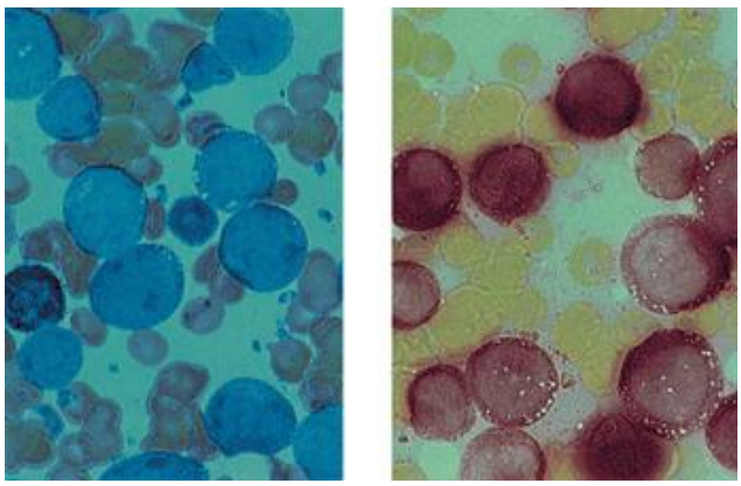

FIGURE 43.32. Nonspecific esterase (butyrate) stain of acute myelogenous leukemia M5a.

monoclonal antibodies (CD11b, CD14, CD36, and CD64) are usually nonreactive in cases of AML M1 and M2; CD14, however, has been detected in as many as 15% of such AML cases. Monoclonal antibodies more restricted to the mature stages of granulocytic differentiation, such as CD10, CD16, and CD24, do not react with the myeloblasts in these leukemias.

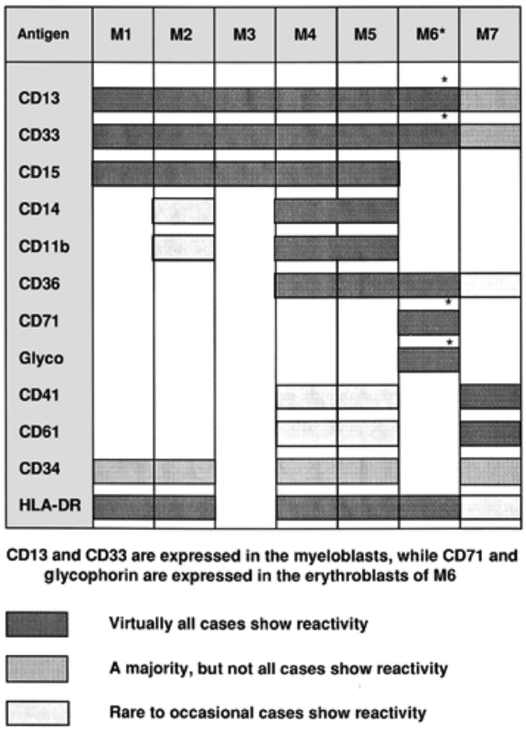

FIGURE 43.33. Correlation of FAB (French-American-British classification) subtype of acute myelogenous leukemia with immunophenotype.

HLA-DR expression is a common finding in AML. This reflects the normal distribution of HLA-DR or myeloid precursor cells up to, but not including, the promyelocyte stage. The lack of reactivity of HLA-DR antibodies in most cases of APL is consistent with the observation that the normal promyelocyte is HLA-DR negative. However, occasional genuine cases of APL may be HLA-DR antigen positive. The hypogranular variant of APL has a pattern of reactivity similar to that of the typical granular form. HLA-DR negativity is not exclusive to APL because as many as 10% of AMLs (FAB-M1 and M2) may not express the HLA-DR antigen. Hence, although HLA-DR negativity is common in APL, it does not appear to be a 100% sensitive and specific diagnostic feature of this unique subtype of AML.

The monocytic leukemias (FAB-M4 and M5) are also reactive with the pan-myeloid monoclonal antibodies, CD13, CD15, and CD33, and uniformly express the HLA-DR antigen. CD11b, CD11c, CD14, CD36, and CD64 antigens are also displayed by the majority of acute myelomonocytic and monocytic leukemias. CD14 expression is thought to be acquired at some point after the development of the monoblast and before maturation to the monocyte stage. This suggests that CD14 reactivity would be expected to be most prominent in the FAB-M4 and FAB-M5b leukemias. However, CD14 is commonly found in almost all cases of monoblastic leukemias (FAB-M5a). Interestingly, CD14 has recently been identified in a significant number of B-cell, non-Hodgkin's lymphomas, confirming that this antigen is not myeloid restricted.

No specific and sensitive marker of early erythroid development is currently available for the diagnosis of erythroleukemia (FAB-M6). The transferrin receptor CD71 is reactive with some myeloblasts in addition to all erythroblasts in the erythroleukemias. However, labeling of blasts with CD71 can also be observed in other types of AML and may be detected in some cases of ALL as well. Antiglycophorin antibodies appear to react only with cells that are morphologically obvious as erythroblasts, beginning at the basophilic normoblast stage, and thus will not label the early pronormoblasts. This finding is consistent with studies showing that these glycophorin antibodies label only the post-CFU-E stages of erythrocyte development.

The diagnosis of acute megakaryoblastic leukemia by immunophenotyping with monoclonal antibodies directed against megakaryoblast-associated antibodies has allowed a rapid and easier method of diagnosing this poorly recognized subtype of acute leukemia. Monoclonal antibodies against platelet glycoprotein IIb/IIIa or IIIa (CD41 and CD61) are routinely used in the diagnosis of acute megakaryoblastic leukemia (FAB-M7). Although factor VIII–related antigen activity may be observed in rare cases of megakaryoblastic leukemia, the reactivity of megakaryoblasts with platelet glycoprotein IIb/IIIa or IIIa is more sensitive than labeling for factor VIII–related antigen.

Although immunophenotyping is generally accepted as the standard for diagnosing acute megakaryoblastic leukemia, it must be realized that some false positivity can be seen with these antibodies. This is most generally seen in myeloid leukemias that have a monocytic component. The increased reactivity of these megakaryoblast-associated glycoproteins appears to be nonspecific background labeling, reaction with platelet membrane components adhering to monocytic cells. In general, it has been our experience that the expression of these megakaryocyte-associated glycoproteins in the monocytic leukemias has been of much weaker intensity and fails to give a distinct uniform population on the fluorescence histograms but rather a “smearing” of intensities. Our policy has been to interpret a CD61-positive immunophenotype with some caution and to correlate the findings closely with morphologic and cytochemical findings. Immunocytochemical detection of these glycoproteins on glass-slide smears may also be of value in determining whether the positivity seen is truly on the leukemic cell or merely attributable to nonspecific adherence.

Other antigens not typically associated with myeloid cells can also be identified in AML. CD34 can be found in 30% to 40% of all AML and has been associated with a poorer prognosis than CD34-negative AML. The CD34 antigen can be useful in evaluating a specimen containing a mixture of myeloblasts and differentiated myeloid or lymphoid cells. CD38 has classically been used as an early thymocyte marker but is now recognized to be present on activated T cells as well as being an excellent plasma cell marker. Not surprisingly, it can also be identified in AML. CD4 is the receptor for HLA class II antigen that characterizes the T-helper subset of T lymphocytes. This antigen is not restricted to T cells and can be identified in monocytes, monocyte precursors, and monocytic leukemias. As previously discussed, CD7 is a pan–T-cell antigen that can be found in 5% to 10% of all AML cases; CD7 can be found in all subtypes of AML. Although some have suggested that the presence of CD7 reflects an early bone marrow precursor, other data do not support this concept. CD45, the common leukocyte antigen, is found in virtually all cases of AML.

In summary, immunophenotyping with monoclonal antibodies in AML is at its best when trying to distinguish between ALL and AML. One must use great caution in using the immunophenotype to aid in the FAB subclassification in these leukemias. Although the immunophenotype may suggest a relationship to a particular FAB subgroup, one must still rely on morphology, cytochemistry and cytogenetic findings to make the final diagnosis. The lack of DR expression suggests the possibility of an APL, expression of CD14, CD11b, and CD64 are associated with monocytic leukemias, and CD71 and glycophorin antibodies certainly react with erythroid cells. The final area in which immunophenotyping has been of great diagnostic utility is the identification of megakaryoblast-associated antigens for the diagnosis of acute megakaryoblastic leukemia.

ACUTE BIPHENOTYPIC LEUKEMIA

Part of "43 - Acute Leukemias and Myelodysplastic Syndromes"

Considerable interest has developed over the past decade in the acute leukemias that have immunophenotypes that do not fit into the accepted sequence of normal lymphoid or myeloid cell development. Perhaps the most controversial and confusing of these immunologically aberrant cases have been the so-called acute biphenotypic leukemias. A plethora of terminologies (hybrid, mixed-lineage, bilineal, biclonal, biphenotypic) has added

to the confusion in this area. Such phenotypes imply that either malignant transformation leads to aberrant gene expression (“lineage infidelity”) or that coexpression of lineage-specific markers occurs normally in the differentiation of hematopoietic cells (lineage “promiscuity”). The clinical significance of biphenotypia in acute leukemia has not been uniformly determined or accepted. Such studies have uniformly lacked consistent guidelines for classification. Some studies have suggested that the biphenotypic leukemias have a worse clinical prognosis than nonbiphenotypic ALL or AML, whereas other reports have not confirmed that a clinical significance exists. The difficulty in evaluating biphenotypic leukemias may be demonstrated by looking at the reported frequency of biphenotypic leukemia in the literature. This frequency has varied from less than 1% of acute leukemia cases in some studies to almost 50% of acute leukemia cases in others. This widely variable incidence range cannot be rationally explained solely based on the clinical variability between different population groups. Indeed, this variability, along with the lack of consensus as to the clinical or biological significance of biphenotypia in acute leukemia is undoubtedly owing to several contributing factors: the use of inconsistent and variable diagnostic criteria, the inevitable subjectiveness of immunophenotypic interpretation, and the lack of a standard and uniform panel of monoclonal antibodies utilized in immunophenotypic analyses.

Figure 43.34 is a schematic drawing outlining the diverse groups that compose what we have called biphenotypic leukemia. Leukemias with the Philadelphia chromosome or 11q23 translocations have clearly been associated with biphenotypic processes. Identification of other immunologic and cytogenetic subgroups will be essential in further characterizing and understanding these intriguing leukemias and the cellular counterparts from which they arise.

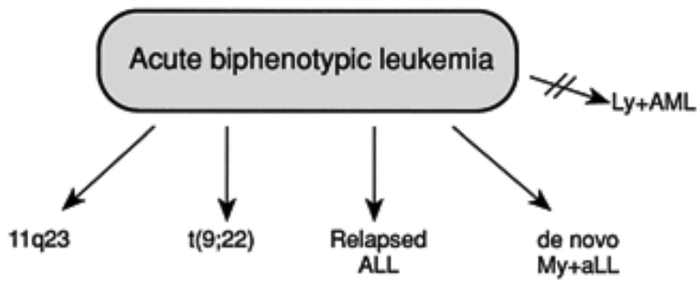

FIGURE 43.34. Proposed schema of subtypes of acute biphenotypic leukemia. Biphenotypic leukemias are broadly represented by cases having an 11q23 translocation, a t(9;22) translocation, relapsed acute lymphoblastic leukemia (ALL), and *de novo* myeloid antigen–positive ALL (My + ALL). Cases having lymphoid antigen–positive acute myelogenous leukemia (Ly + AML) probably do not represent true acute biphenotypic leukemia.

MYELODYSPLASTIC SYNDROMES

Part of "43 - Acute Leukemias and Myelodysplastic Syndromes"

The MDSs are a heterogeneous group of bone marrow disorders generally characterized by cytopenias and morphologic abnormalities of the erythroid, granulocytic, and megakaryocytic cell lines within a hypercellular bone marrow. Bone marrow myeloblasts may be increased but do not reach the 20% blast level necessary for a diagnosis of AML. Although MDS does not meet the morphologic criteria for the diagnosis of AML, distinction from AML may be difficult and a proportion of cases will ultimately evolve to overt AML. Patients who do not evolve into AML frequently will experience complications related to chronic transfusion or bone marrow failure.

MDS usually occurs in individuals older than the age of 50, although genuine cases of MDS may rarely be seen in the pediatric age group. In general, however, the diagnosis of MDS in children should be made very cautiously. Patients with MDS typically present with symptoms of variable duration related to the degree of the underlying cytopenias.

Historical terms that have been used to describe MDS include preleukemia, early leukemia, smoldering leukemia, subacute leukemia, atypical leukemia, and hematopoietic dysplasia. The MDSs do not include disorders that are known to predispose an individual to the development of acute leukemia, such as chromosomal breakage syndromes. Although the MDSs are classified as distinctly different from the chronic myeloproliferative disorders, there are certainly individual cases that have features of both MDS and chronic myeloproliferative diseases. Such cases may present with neutrophilia and granulocytic hyperproliferation together with striking dysplastic features or thrombocytosis and dysplastic neutrophils and megakaryocytes.

Diagnosis

A diagnosis of MDS should be considered in a setting of unexplained cytopenias and ineffective hematopoiesis in an adult patient. Most MDSs will show quantitative and qualitative evidence of dyserythropoiesis, dysgranulopoiesis, and dysmegakaryopoiesis. An iron stain for ringed sideroblasts and the percentage of blood and bone marrow myeloblasts are essential in accurately classifying the MDS. These and other features are listed in Table 43.15 and are described below.

TABLE 43.15. MORPHOLOGIC FEATURES OF MYELODYSPLASIA

Dyserythropoiesis
Megaloblastoid changes
Multinucleation
Nuclear/cytoplasmic asynchrony
Nuclear karyorrhexis
Ringed sideroblasts
Dysgranulopoiesis
Pseudo Pelger-Huet changes
Hypogranulation
Abnormal granules
Basophilia
Decreased or absent myeloperoxidase
Decreased leukocyte alkaline phosphatase
Dysmegakaryopoiesis
Large, bizarre platelets
Hypogranular platelets
Bizarre megakaryocytes
Uninuclear megakaryocytes

Dyserythropoiesis

Dyserythropoiesis may include megaloblastoid changes, irregular nuclear shapes and forms, multinucleation, internuclear

bridging, abnormal chromatin, ringed sideroblasts, or nuclear karyorrhexis. Dyssynchrony between nuclear and cytoplasmic development is probably the most reliable and significant evidence of dyserythropoiesis (Fig. 43.35). For example, a red cell precursor showing evidence of hemoglobinization in the cytoplasm, while still maintaining an earlier or open chromatin pattern, would be described as dyssynchronous. The peripheral blood smear may show significant anisopoikilocytosis and occasional nucleated red blood cells. The term ringed sideroblasts has been used to describe erythroblasts that contain cytoplasmic iron that wraps around at least one third of the nucleus. This iron is located in the mitochondria and results in ineffective erythropoiesis and subsequent marrow destruction of red cells and precursors. Ringed sideroblasts are not found in normal marrow and are easily distinguished from normal sideroblasts, which have scattered cytoplasmic iron granules.

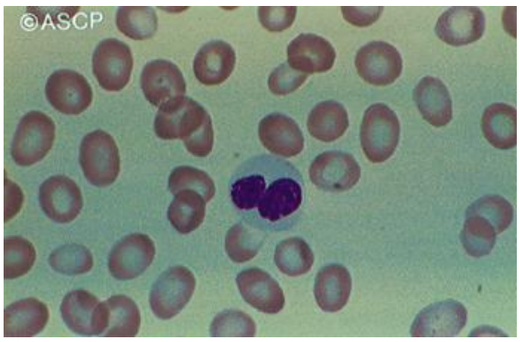

FIGURE 43.35. Dyserythropoiesis.

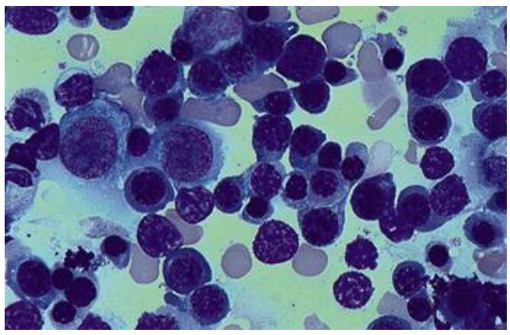

FIGURE 43.36. Dysgranulopoiesis (pseudo–Pelger-Huét change).

Dysgranulopoiesis

Dysgranulopoiesis can be effectively summarized as morphologic evidence of hypolobulation or hyposegmentation of the nucleus and/or hypogranulation of the cytoplasm (Fig. 43.36). The hyposegmentation of the nucleus, i.e., the presence of only two nuclear lobes, has been called pseudo–Pelger-Huét change. The determination of this hyposegmentation must be made on a well-prepared blood or bone marrow smear, and care must be taken to distinguish that two lobes are not overlapping each other. Likewise, hypogranulation is best identified on a Wright-Giemsa stain smear. Smears stained with only Wright stain may sometimes appear faint, leading to a mistaken diagnosis of hypogranulation. In addition, granulocyte enzymatic stains, such as MPO, SBB, and leukocyte alkaline phosphatase, may be negative if this dysplastic hypogranulation is marked. Occasionally, one may see abnormally dense chromatin or ringed nuclei, both of which represent uncommon forms of dysgranulopoiesis. Abnormal granulation and basophilia are other manifestations of dysgranulopoiesis.

Dysmegakaryopoiesis

Abnormalities of peripheral blood platelets and bone marrow megakaryocytes are common in the MDSs. Dysplastic platelets on the peripheral blood smear may appear as either hypogranular platelets or as large, bizarre platelet forms. Examination of the bone marrow aspirate smear and/or bone marrow biopsy specimen may show megakaryocytes with separated nuclear lobes instead of a lobulated nucleus, large bizarre nuclei with dysplastic features, open nuclear chromatin, high nuclear:cytoplasmic ratios, and large accumulations, or sheets, of megakaryocytes in the bone marrow biopsy (Fig. 43.37). Abnormally small megakaryocytes with single, round nuclei have been described in the MDSs having a chromosomal deletion of the long arm of chromosome 5 (5q-syndrome).

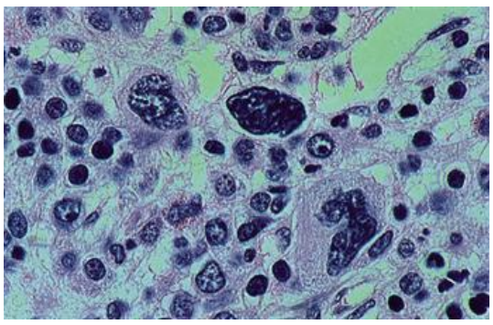

FIGURE 43.37. Dysmegakaryopoiesis.

FAB Classification

The FAB classification scheme for MDS is listed in Table 43.16. However, the recent proposal by WHO redefined some of the categories in the FAB classification (Table 43.17). One of the most important changes was decreasing the blast count from 30% to 20% for diagnosis of AML. The high-grade myelodysplastic process is also consolidated in one category, refractory anemia with excess blasts (RAEB), with two types based on blast count. Chronic myelomonocytic leukemia is designated as myelodysplastic/myeloproliferative syndromes because they typically have features of both disorders. Finally, WHO recognizes the two categories as a separate entity: 5q-syndrome and refractory cytopenia with multilineage dysplasia.

TABLE 43.16. FAB CLASSIFICATION OF MYELODYSPLASTIC SYNDROMES

Refractory anemia
Idiopathic refractory sideroblastic anemia
Refractory anemia with excess blasts (RAEB)
RAEB in transformation
Chronic myelomonocytic leukemia
Myelodysplastic syndrome, unclassified (NOS)
Therapy-related myelodysplasia

NOS, not otherwise specified.

TABLE 43.17. PROPOSED WORLD HEALTH ORGANIZATION CLASSIFICATION OF MYELODYSPLASTIC SYNDROMES

Refractory anemia
Refractory anemia with ringed sideroblasts
Refractory cytopenia with multilineage dysplasia
Refractory anemia with excess blasts
Type 1: 5% to 9% blasts in blood or marrow
Type 2: 10% to 19% blasts in blood or marrow
5q-syndrome
Therapy-related myelodysplastic syndrome
Myelodysplastic syndrome, unclassified

It should also be noted that secondary or therapy-related MDS is also a newly recognized distinct clinicopathologic entity occurring in patients after exposure to radiation and/or alkylating-agent chemotherapy for primary neoplastic or nonneoplastic disorders.

Refractory Anemia

This subtype of MDS is basically a chronic, unexplained anemia occurring in adult patients older than the age of 50. It may also be referred to as refractory cytopenia, as it is not purely restricted to anemia (Table 43.18). Classically, patients with refractory anemia show erythroid hyperplasia in the bone marrow accompanied by a low reticulocyte count in the peripheral blood. This combination is referred to as ineffective erythropoiesis and is a characteristic hallmark of this type of MDS. Ringed sideroblasts are not increased (less than 15%) in these cases, and it is important to note that minimal to no dysplastic changes are identified in any cell line; no increase in myeloblasts are seen. This subgroup of MDS consists mainly of patients who have unexplained anemias despite erythroid hyperplasia. Obviously, other causes of chronic anemia must be ruled out, including vitamin B_{12}/folate deficiency, drug or toxin exposure, congenital dyserythropoietic anemias, aplastic anemia, or other uncommon causes of anemia.

TABLE 43.18. FAB CLASSIFICATION IN MYELODYSPLASTIC SYNDROMES

Refractory anemia
Chronic unexplained anemia/refractory cytopenia
Reticulocytopenia
No blasts in peripheral blood
Bone marrow normocellular or hypercellular
Erythroid hyperplasia/mild dyserythropoiesis
Minimal to no dysplastic changes
<5% myeloblasts
Ringed sideroblasts are not increased
Idiopathic refractory sideroblastic anemia
Findings similar to those described for refractory anemia
<5% myeloblasts
Dysplastic features are uncommon
Erythroid hyperplasia; hypercellular bone marrow
Dyserythropoiesis
>15% ringed sideroblasts
Chronic anemia, transfusion dependent
Dimorphic peripheral blood (hypochromic and normochromic)
Ineffective erythropoiesis
10% evolve to AML
Refractory anemia with excess blasts
Chronic clinical course
Pancytopenia
All three cell lines are dyspoietic
Bone marrow failure is common
Hypercellular bone marrow
<5% myeloblasts in blood
5% to 20% myeloblasts in bone marrow
No Auer rods
Ringed sideroblasts may be present
30% to 40% evolve to AML
Refractory anemia with excess blasts in transformation
20% to 30% myeloblasts in bone marrow
Or 0 to 30% myeloblasts with Auer rods
Or >5% myeloblasts in blood
Same clinical features as refractory anemia with excess blasts
60% to 80% evolve to AML
Chronic myelomonocytic leukemia
Males more than females
Hepatomegaly/splenomegaly in 30% to 50%
Anemia, thrombocytopenia
Leukocyte count is variable
Monocytes >2 × 10^9/L
Hypercellular marrow
Significant myelodysplastic changes may not be found
Increased serum/urine lysozyme
Easily confused with AML-M4 or M5b

AML, acute myelogenous leukemia.

Idiopathic Refractory Sideroblastic Anemia

The morphologic features of idiopathic refractory sideroblastic anemia (IRSA) are similar to those described for refractory anemia except for the presence of 15% or more ringed sideroblasts. The criteria for IRSA are listed in Table 43.18. The pathologic ringed sideroblasts have iron granules located in a perinuclear location, reflecting mitochondrial iron deposition (Fig. 43.38). It is important to rule out hereditary and secondary causes of sideroblastic anemia, including hereditary sideroblastic anemia, exposure to drugs (e.g., antituberculosis agents, chloramphenicol), alcohol-induced sideroblastic anemia, chronic lead poisoning, and various other diseases, including some autoimmune disorders. These patients have a significant erythroid hyperplasia but do not have increased numbers of myeloblasts. Dysplastic features are uncommon in granulocytic and megakaryocytic precursors and, when present, may portend a more aggressive clinical course. Most patients become transfusion dependent, and only 10% to 15% of cases of IRSA progress to an AML. The peripheral blood smear classically shows a dimorphic blood picture with both normochromic, normocytic red blood cells and hypochromic, microcytic red blood cells (Fig. 43.39). This dimorphism

reflects the heterogeneity of erythroid differentiation in the bone marrow. This dimorphic blood picture is quite distinct and should always raise the possibility of IRSA when encountered.

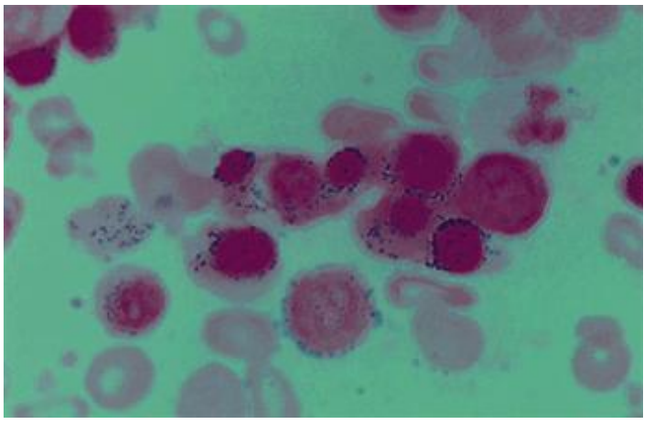

FIGURE 43.38. Idiopathic refractory sideroblastic anemia with ringed sideroblasts.

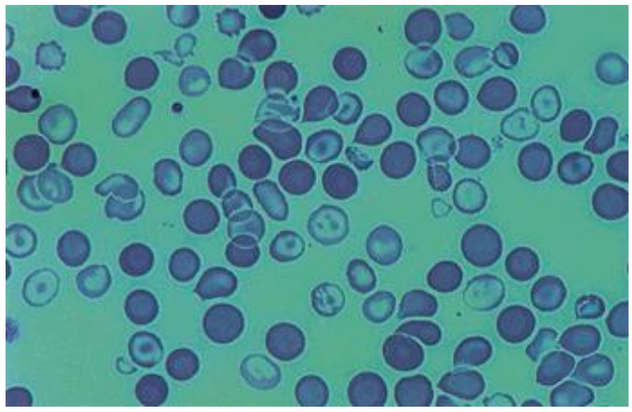

FIGURE 43.39. Dimorphic peripheral blood smear in idiopathic refractory sideroblastic anemia.

Refractory Anemia with an Excess of Blasts

Refractory anemia with an excess of blasts (RAEB) is typically associated with pancytopenia and significant dysplastic features in the granulocytic series. Erythroid and megakaryocytic dysplasia may also be found. The basic diagnostic criterion for RAEB is a hypercellular bone marrow containing between 5% and 20% myeloblasts. The criteria for the diagnosis of RAEB are listed in Table 43.18. It is important to note that a significant number of patients in this subgroup of MDS will eventually evolve into an overt AML. Ringed sideroblasts may be identified; however, the increased myeloblasts allow for distinction from IRSA.

RAEB is separated into two subgroups based on the blast count. Type 1 is characterized by a blast count between 5% and 9% in the blood or bone marrow, and type 2 includes patients with a blast count of 10% to 19%. It is determined that patients with a blast count greater than 10% usually have a more aggressive clinical course and are more likely to develop overt leukemia. The category of RAEB in transformation (RAEB-t) in the FAB classification was eliminated by the WHO classification.

Secondary/Therapy-Related MDS

Therapy-related MDS is a form of MDS occurring in patients previously treated with chemotherapy and/or radiation for neoplastic or nonneoplastic disease. The incidence of a secondary MDS or AML has been variously estimated at 2% to 10% of patients treated as such and may be related to the amount, duration, and repetition of exposure to the therapeutic agent and the age of the individual involved. Long-term alkylating-agent therapy and the type II topoisomerase inhibitors (epipodophyllotoxins) are the most commonly implicated in dysplastic transformation. Topoisomerase inhibitors particularly are associated with abnormalities of chromosome 11q23. The median onset of secondary MDS is approximately within 5 years of therapy, with a range of approximately 2 to 15 years. Approximately one third of these patients will present with a MDS before the evolution to a frank AML. Typically, these patients present with unexplained cytopenias and observed dysplastic abnormalities in the blood and bone marrow. Panmyelosis with dysplastic features in all myeloid lines are typically found. The prognosis of patients with therapy-related MDS is abysmal, with a median survival of less than 6 months.

5q-Syndrome

These patients usually present with macrocytosis and thrombocytosis. Bone marrow evaluation typically shows erythro-blastopenia, megakaryocytic hyperplasia with unique morphology (hypolobulated mononuclear smaller size). These patients have a much better prognosis compared with the other MDS categories but usually become transfusion dependent.

Cytogenetics in MDS

Several recurring chromosome defects are found in patients with *de novo* MDS, including complete or partial loss of chromosome 5 or 7, loss of the long arm of chromosome 5 or 7, trisomy 8, or multiple, miscellaneous complex chromosome defects.

Prognosis

There are varying reports of the frequency that MDS evolves to overt AML. Data in the literature regarding the evolution to AML vary according to the subtype of MDS (Table 43.19). Generally, refractory anemia and IRSA show the lowest incidence of transformation to AML, whereas RAEB shows a much higher incidence of leukemic progression.

TABLE 43.19. PROGNOSTIC FACTORS IN MYELODYSPLASTIC SYNDROMES

Low risk
Refractory anemia with normal platelets, WBC
Numerous ringed sideroblasts
Normal CFU capacity
Absence of chromosomal abnormalities
High risk
Severe pancytopenia
Refractory anemia with excess blasts in transformation
Low CFU capacity
Chromosomal abnormalities

WBC, white blood cells; CFU, colony-forming unit.

The survival of patients with MDS varies, with some patients surviving many years and others only a few months. Death may be owing to bone marrow failure if progression to AML does not occur. The age of patients, the degree of cytopenia, the percentage of blasts, the degree of abnormal chromosome abnormalities, and *in vitro* culture changes have all been used to predict the survival of patients with MDS.

Chronic Lymphoproliferative Disorders, Immunoproliferative Disorders, and Malignant Lymphoma

Fred Randolph Dick

The lymphoproliferative disorders represent a spectrum of diseases with a broad morphologic, functional, and clinical diversity. The classification in Table 44.1 is based on the following: diseases classified as the *chronic lymphoproliferative disorders* predominantly affect the blood and bone marrow with varying degrees of tissue involvement. Chronic lymphoproliferative disorders include neoplastic proliferations of peripheral B-cells, T-cells, and NK-cells (1). Although these processes are classified as "chronic" lymphoproliferative disorders, some of them do not follow an indolent course. The *immunoproliferative disorders* are predominantly bone marrow-based diseases with varying degrees of tissue involvement. They are neoplasms of B-cells at the terminal stage of functional development, and thus are characterized by production of a monoclonal immunoprotein. The *malignant lymphomas* are predominantly tissue-based disorders; however, they also may have blood and marrow involvement, especially late in the course of disease. The morphology, functional cell of origin, and clinical course of malignant lymphomas is highly variable. The *acute lymphoblastic leukemias* will be discussed in a separate chapter. They are diseases of precursor B-cells and T-cells. Similar to the chronic lymphoproliferative disorders, they are predominantly blood- and bone-marrow–based disorders, but follow an "acute" course if untreated.

TABLE 44.1. CLASSIFICATION OF LYMPHOPROLIFERATIVE DISORDERS

Chronic Lymphoproliferative Disorders
Peripheral B-cell
Chronic lymphocytic leukemia
Prolymphocytic leukemia
Hairy-cell leukemia
Peripheral T-cell
Chronic lymphocytic leukemia
Prolymphocytic leukemia
Large granular lymphocyte leukemia
Sezary syndrome
Adult T-cell leukemia/lymphoma
Immunoproliferative Disorders
Plasma cell myeloma
Plasmacytoma
Waldenström's macroglobulinemia
Heavy chain disease
Benign monoclonal gammopathy
Amyloidosis
Malignant Lymphomas
Non-Hodgkin's lymphoma
B-cell lymphomas
T-cell and NK-cell lymphomas
Hodgkin's disease
Postransplant lymphoproliferative disorders
Acute Lymphocytic Leukemia (derived from precursor B- and T-cells) will be discussed in a separate chapter.

CHRONIC LYMPHOPROLIFERATIVE DISORDERS OF B-CELL TYPE

Part of "44 - Chronic Lymphoproliferative Disorders, Immunoproliferative Disorders, and Malignant Lymphoma"

Chronic lymphoproliferative disorders of B-cell type vary widely in their clinical course, ranging from less than 3 years for prolymphocytic leukemia (PLL), to 7 years or more for most subtypes of chronic lymphocytic leukemia and hairy-cell leukemia. Morphologically, they show a "mature" appearance with condensation of nuclear chromatin; however, some element of morphologic "immaturity" may be present.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is a common neoplastic disease characterized by proliferation of small, morphologically mature lymphocytes (1, 2 and 3). CLL involves the blood and bone marrow, and also frequently the lymph nodes, spleen, and liver. It is a disease with a male predominance and a median age of approximately 65, being rarely seen in individuals less than 40 years of age (4). It usually follows an indolent course, and many patients are diagnosed by finding an elevated lymphocyte count incident through evaluation for another disease. Most cases of CLL are of B-cell type, and the following discussion applies to B-cell CLL. T-cell CLL, which is very rare, is biologically distinctly different from B-cell CLL and will be discussed in a subsequent section.

Diagnostic Features

Unlike most other lymphoproliferative diseases, there is no cytologic feature of the individual cell in CLL that is diagnostic. Thus, the diagnosis rests on finding increased numbers of nearly morphologically normal-appearing lymphocytes.

To diagnose CLL, there should be a peripheral blood lymphocytosis greater than 5,000/mm^3 and a marrow lymphocytosis greater than 30% (3). At diagnosis, most patients have a white blood cell count (WBC) of greater than 15,000/mm^3 with a median count of about 30,000 to 40,000/mm^3. Some cases may have a WBC well over 100,000/mm^3. Because CLL is a clonal process, there is frequently a monotonous look-alike appearance to the lymphocytes on smears (Fig. 44.1). Cytoplasm usually is small to moderate in amount, pale blue, and agranular; the nuclear chromatin frequently shows exaggerated chromatin clumping compared with a normal lymphocyte.

The bone marrow in CLL usually aspirates freely, and marrow sections may range from normocellular to hypercellular (Fig. 44.2). When the marrow is less extensively infiltrated, the lymphocytes in the marrow may be present in focal aggregates (Fig. 44.2A) or may be diffusely intermixed with residual normal marrow elements (Fig. 44.2B). This latter pattern is called an interstitial infiltrative pattern. Frequently, a mixed focal and interstitial pattern may be seen. As the marrow becomes more extensively infiltrated, focal or interstitial patterns are gradually lost, and the infiltrate diffusely obliterates the marrow space (Fig. 44.2C). As illustrated in Fig. 44.2D, lymphocytes in CLL

on sections are indistinguishable from normal mature lymphocytes.

When the blood and marrow counts are near the lower limits described above, and the diagnosis is in question, immunologic cell surface marker studies may be helpful in establishing the diagnosis and in ruling out post-splenectomy lymphocytosis, a chronic reactive lymphocytosis (5) or other chronic lymphoproliferative disorders. Clonality, as evidenced by a weakly reacting surface immunoglobulin with a restricted light chain, and CD5 and CD23 positivity are characteristic of CLL (Table 44.2) (6, 7 and 8). In cases with a low WBC in the range of 5,000 to 15,000/mm^3, it may be easier to make the diagnosis using peripheral blood immunology than with bone marrow examination, because the bone marrow in these cases also may show a low percentage of lymphocytes, and characteristic spreading focal aggregates may be absent. If immunologic marker studies are available, immunologic evaluation of the peripheral blood is the method of choice to confirm the diagnosis, especially if therapy is not contemplated (6).

TABLE 44.2. SPECIAL STUDIES IN THE DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF CHRONIC LYMPHOPROLIFERATIVE DISORDERS OF B-CELL TYPE

SIg	CD5	CD20	CD23	CD25	CD11c	FMC7	CD79b	TRAP	
CLL	weak	+	weak	+	-/+	-/+	-	-	-/+
PLL	strong	-/+	+	-	-/+	-	+	+	-/+
HCL	strong	-	+	-	+	+	+	-	+

SIg, surface immunoglobulin

TRAP, tartarate resistant acid phosphatase

PLL, prolymphocytic leukemia

HCL, hairy-cell leukemia

-/+, Typically negative with occasional exceptions

Morphologic Variability And Differential Diagnosis

Although most cases of CLL will fit the description above, there are some features that may lead to an altered appearance. These are listed in Table 44.3 and illustrated in Fig. 44.3.

TABLE 44.3. MORPHOLOGIC VARIABILITY IN B-CELL CHRONIC LYMPHOCYTIC LEUKEMIA

Smears
Downey II appearance
Prolymphocytes
Nuclear contour irregularity (folds, clefts)
Hairy cytoplasm
Sections
Prolymphocytes and growth centers
Clefted cells
Reticulin fibrosis

Up to 15 of cases of CLL may have numerous cells with a morphologic appearance similar to Downey II-like reactive (atypical) lymphocytes (Fig. 44.3A) (9). These cells are more readily identified on rapidly dried, thinly smeared blood films than on marrow smears. In CLL, these Downey II-like lymphocytes usually have neither cytoplasmic granules nor the marked morphologic variability seen in reactive processes. The importance of the finding of Downey II-like lymphocytes in CLL is to recognize it as a variant and not report the cells as “atypical/reactive” lymphocytes. Because CLL is a disease of individuals more than 30 to 40 years of age, CLL should be considered in a reactive-appearing lymphocytosis in older patients.

Many cases of CLL will have rare cells with the appearance of prolymphocytes, and occasional cases may have numerous prolymphocytes at presentation (Fig. 44.3B). Lymphocytes with nuclear contour irregularity in the form of folding or clefting also can be seen in CLL. In addition, there may be other atypical cells with larger than normal nuclear size or abundant eccentric cytoplasm suggesting plasmacytoid morphology. When greater than 10% prolymphocytes are present or >15% clefted, large or plasmacytoid lymphocytes are present, the CLL is diagnosed as “atypical CLL” (10, 11). The prolymphocyte in CLL as illustrated in Fig. 44.3B has partly dispersed, partly clumped chromatin, increased cytoplasmic basophilia, and a prominent single nucleolus with perinucleolar chromatin clumping. Prolymphocytes in CLL are morphologically similar to the prolymphocytes of PLL (PLL)(see later, Fig. 44.7). However, in CLL there may be more variability than in PLL because of the presence of large blastlike prolymphocytes called reticular lymphoblasts or paraimmunoblasts (9, 12). As shown in Table 44.4, more than 25% of cases of CLL at diagnosis will have greater than 5% prolymphocytes on smears (12). When the percentage of prolymphocytes exceeds 10%, the case is said to represent an atypical CLL with prolymphocytes (CLL/PL), and when the percentage

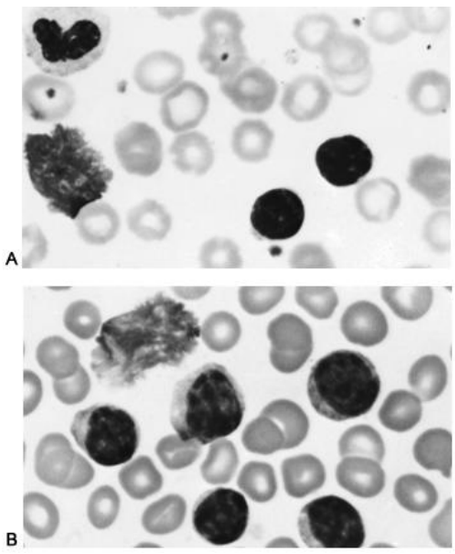

FIGURE 44.1. Chronic lymphocytic leukemia (CLL) lymphocytes on blood smear. Lymphocytes almost as small as erythrocytes (**A**) are rarely seen in CLL. Lymphocytes in CLL are more typically medium sized like those shown in **B**. Note the exaggerated chromatin clumping in some of the lymphocytes. Wright's stain 1200X. (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:325–357).

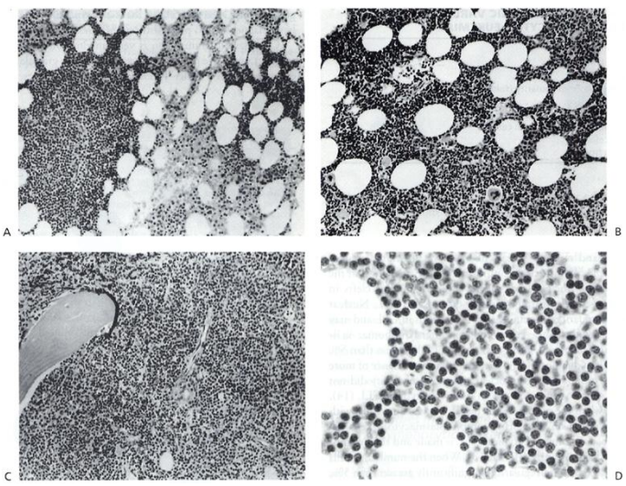

FIGURE 44.2. Chronic lymphocytic leukemia (CLL) bone marrow sections. The focal pattern shown in **A** is characterized by aggregates that have spreading of lymphocytes into and surrounding fat cells at the periphery. This spreading characteristic is especially evident in the aggregate in the upper right field of **A**. An interstitial pattern shown in **B** is characterized by diffuse infiltration of lymphocytes throughout the marrow space with many residual fat cells and admixed normal marrow elements. Extensive diffuse replacement of the marrow is shown in **C**. On high power examination in **D**, note minimal nuclear contour irregularity, clumped chromatin, uniformity, and absence of mitotic activity. Hematoxylin and eosin, 120X (**A,B,C**), 600X (**D**). (**A**, From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984;1:325–357).

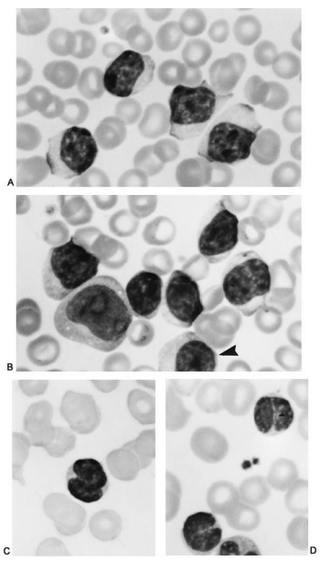

FIGURE 44.3. Morphologic variability in the peripheral blood of chronic lymphocytic leukemia (CLL). **A:** Downey II-like lymphocytes are large lymphocytes with abundant cytoplasm and peripheral basophilia. **B:** Prolymphocytes in CLL. Note the size gradation in this field from small lymphocytes to medium-sized lymphocytes to a typical prolymphocyte (arrow) to a large blastlike prolymphocyte. **C, D:** Nuclear contour irregularity in lymphocytes in CLL. Note the folded nucleus in **C** and the clefted nuclei in **D**. Clefted cells in CLL have more cytoplasm than the small cleaved cells of follicle-center lymphoma. Wright's stain 1200X. (**A** and **D**, From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984;1:325–357).

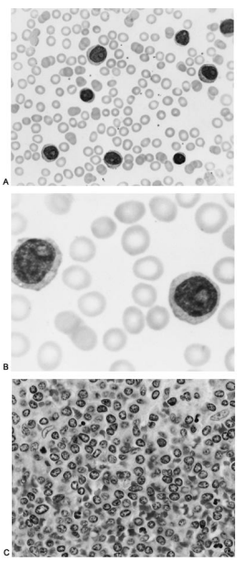

FIGURE 44.7. A, B: Typical prolymphocytes in the blood of prolymphocytic leukemia. **C:** Prolymphocytes on sections in prolymphocytic leukemia may have the uniform appearance illustrated here, or may show more variability in cell size with admixed mature lymphocytes and blastlike prolymphocytes. Wright's stain 1200X (**A, B**). Hematoxylin and eosin, 600X (**C**). (**A** and **B**, From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:325–357)

of prolymphocytes at diagnosis exceeds 55%, an alternate diagnosis of a more aggressive disease, PLL, should be considered (10, 11, 12 and 13).

TABLE 44.4. PERCENTAGE OF PROLYMPHOCYTES ON INITIAL DIAGNOSTIC FILMS OF CLL[a]

Percentage of Prolymphocytes	Number of Cases	Percentage of Cases
< 5	198	74
6–10	40	15
11–20	24	9
> 20	4	2
Total CLL cases	266	100

CLL, Chronic lymphocytic leukemia

[a] Data from 266 cases of CLL with peripheral blood lymphocytes >15,000/mm^3 seen at the University of Iowa Hospitals and Clinics from 1960 to 1975. Differentials were done on initial diagnostic bone marrow and/or peripheral blood smears, and the percentage of prolymphocytes is per 100 lymphoid cells. Marker studies were performed on only a small percentage of the cases and some T-cell CLLs may be included. (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984; 1: 325–357)

The cells with nuclear contour irregularity that can be seen in the blood and marrow smears of CLL are illustrated in Fig. 44.3C and Fig. 44.3D. This nuclear contour irregularity usually is in the form of subtle nuclear folds; however, sharp nuclear clefts in some cells also are consistent with the diagnosis of CLL. Nuclear contour irregularity also can be seen on sections in CLL and may be confused with mantle-cell or follicle-center lymphoma. As illustrated in Table 44.5, 85% of cases of CLL have less than 5% of such cells at diagnosis (12). In one study, the presence of more than 5% lymphocytes with nuclear contour irregularity did not appear to alter the prognosis of an otherwise typical CLL (14). However, when the number of clefted cells plus larger cells with eccentric cytoplasm suggesting lymphoplasmacytoid cells exceeds 15%, a diagnosis of atypical CLL is made and the prognosis is altered significantly (10, 11, 13). When the number of cells with nuclear contour irregularity is significantly greater than 5%, an alternative diagnosis of a leukemic phase of a non-Hodgkin's lymphoma such as mantle-cell lymphocytic lymphoma, follicle-center lymphoma, Sézary syndrome, or a chronic lymphoproliferative disorder of T-cell type should be considered. The distinction between an atypical CLL with increased nuclear contour irregularity and a leukemic phase of mantle-cell lymphocytic lymphoma may be very difficult, but flow cytomery may be helpful (see Table 44.23 in the discussion of lymphomas) (1, 6, 7, 8, 15). Leukemic mantle-cell lymphoma like CLL is CD5 positive but is usually CD23 negative. Cyclin D1 on section material also may be helpful (16). Follicle-center lymphoma and splenic lymphoma with villous lymphocytes (SLVL) when presenting in a leukemic also may be confused with CLL but they are both CD5 and CD23 negative (1, 8).

TABLE 44.5. PERCENTAGE OF LYMPHOCYTES WITH IRREGULAR NUCLEAR CONTOUR ON INITIAL DIAGNOSTIC FILMS OF CLL[a]

Percentage Irregular Nuclear Contour	Number of Cases	Percentage of Cases
< 5	225	85
6–10	30	11
11–20	11	4
Total CLL cases	266	100

CLL, chronic lymphocytic leukemia

[a] Data from 266 cases of CLL with peripheral blood lymphocytes >15,000/mm^3 seen at the University of Iowa Hospitals and Clinics from 1960 to 1975. Differentials done on initial diagnostic bone marrow and/or peripheral blood smears. The percentage irregular nuclear contour is per 100 lymphoid cells. Marker studies were performed on only a small percentage of the cases and some T-cell CLLs may be included. (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984;1:325–357)

TABLE 44.23. IMMUNOLOGIC FINDINGS USEFUL IN SUBCLASSIFYING NON-HODGKIN'S LYMPHOMAS IN THE BONE MARROW

Lymphoma Type	Characteristic Phenotype
B-Cell	
Small lymphocytic	Clonal Surface Ig+ (weak), CD5+, CD23+, CD43+
Lymphoplasmacytoid	Clonal Cytoplasmic Ig+ (in plasmacytic cells), CD5+/-, CD23-
Mantle cell	Clonal Surface Ig+ (stronger), CD5+, CD23-, Cyclin-D1+
Marginal zone B cell	Clonal Surface Ig+, CD20+, CD11c+/-, CD43-/+, CD5-, CD23-
Follicle center	Clonal Surface Ig+ (intense), CD5-, CD23-, CD43-, CD10+
Diffuse large B cell	Clonal Surface Ig+, CD20+
Lymphoblastic	Precursor B-cells without SIg or CD20, but with CD10 (CALLA), CD19 and TDT
Burkitt's	Clonal Surface Ig+, CD20+
T-Cell	
Peripheral T cell	T-cells (of mature phenotype) with CD2, CD5, CD4 or CD8
Lymphoblastic	Precursor T-cells with TDT

Some cases of CLL will show a mixture of atypical features (Downey II-like cells, prolymphocytes, and cells with nuclear contour irregularity), giving a very heterogeneous appearance to a disease that is typically said to be characterized by monotony of cell type. A combination of the data from Table 44.4 and Table 44.5 (12) indicate that 45 of 266 cases (17%) had greater than 10% prolymphocytes and/or cells with nuclear contour irregularity. The diagnosis of atypical CLL in these cases still is tenable, although it may be necessary to use immunologic marker studies or lymph-node biopsy to exclude other diagnoses. It may be useful to enumerate the number of prolymphocytes and cells with nuclear contour irregularity on peripheral blood differentials of patients with chronic lymphoproliferative disorders, because greater than 10% to 15% of these cell types in CLL appear to have diagnostic and prognostic significance.

Cytoplasmic granulation is very uncommon in B-cell CLL, and if granules are present, a diagnosis of large granular lymphocytosis, discussed under T-cell and NK-cell disorders, or a reactive

process should be considered. Immunologic marker studies should assist in the differential diagnosis.

Occasionally, the cells in cases of CLL (as well as PLL or low-grade lymphomas) will show artifactual hairy cytoplasmic projections (Fig. 44.4). A repeat smear or bone-marrow biopsy may help solve the problem; however, a tartrate-resistant acid phosphatase (TRAP) stain or immunologic marker analysis also may be helpful to distinguish CLL from hairy-cell leukemia or splenic lymphoma with villous lymphocytes.

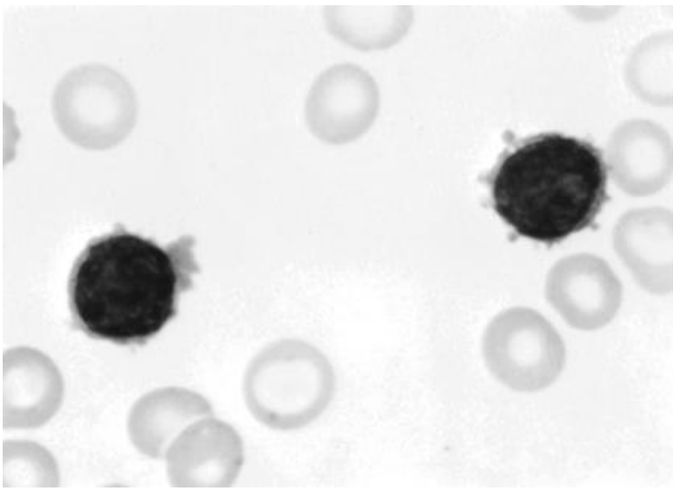

FIGURE 44.4. Artifactual hairy cytoplasmic projections in peripheral blood cells from chronic lymphocytic leukemia. The cell at the right also has a prolymphocytic appearance. Wright's stain 1200X.

Growth centers are frequently present in the lymph nodes of patients with CLL (17, 18) and less often on bone-marrow sections (illustrated in Fig. 44.5). Growth centers are thought to be the sites of proliferation of cells in CLL because many of the cells in growth centers are large and have basophilic cytoplasm, dispersed chromatin, nucleoli, and increased mitotic activity. These cells on sections are prolymphocytes that correspond to the prolymphocytes seen on blood and marrow smears. Prolymphocytes also can be diffusely distributed throughout the marrow or be admixed with small mature cells with clefted nuclei. This may lead to confusion with lymphoma on section material.

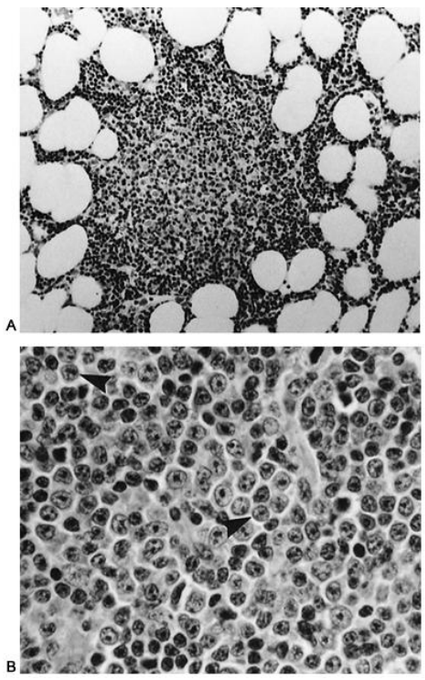

FIGURE 44.5. A: Growth center in the bone marrow of chronic lymphocytic leukemia. Note the central pallor of the aggregate resulting from focal increase in prolymphocytes. **B:** Increased concentration of prolymphocytes from a growth center. Note the gradation in size from mature lymphocytes to prolymphocytes with partly dispersed chromatin (arrowheads), to large blastlike prolymphocytes with dispersed chromatin, corresponding to the cells on smears illustrated in Fig. 3B. Hematoxylin and eosin, 120X (**A**), 600X (**B**). (**A**, From Dick, FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:325–357)

Rare cases of CLL will aspirate poorly and show increased marrow reticulin (19). This finding should not cause confusion with hairy-cell leukemia, which characteristically shows increased reticulin. A TRAP stain and immunophenotyping may assist in the diagnosis if cytology and histology are not characteristic of either diagnosis.

Special Studies In The Diferential Diagnosis of Chronic Lymphocytic Leukemia

Immunologic marker analysis as outlined above in Table 44.2 and in Table 44.23 in the discussion of lymphomas below, is a useful adjunct to the diagnosis of CLL, especially in cases with low WBC or in the differential diagnosis for other lymphoproliferative disorders (1, 6, 7 and 8, 15, 20, 21, 22 and 23).

High-resolution agarose gel electrophoresis and immunofixation have shown that about 42% of patients with CLL will have a small monoclonal serum immunoglobulin, usually IgM or free light chain type (24). An additional 14% will have only free light chains in the urine. In 5% or fewer cases of CLL, the amount of monoclonal protein is large enough to be identified on conventional serum protein electrophoresis (2). A monoclonal protein on serum protein electrophoresis in CLL may be associated with a worsened prognosis, and if the WBC is only mildly elevated, the presence of a significant IgM monoclonal paraproteinemia should stimulate a morphologic reevaluation of the case for plasmacytoid differentiation to rule out Waldenström's macroglobulinemia, which is discussed in a later section.

Of special interest is the development of a warm autoimmune hemolytic anemia in about 15% of patients with CLL (2). In addition, depression of normal immunoglobulins is seen in CLL, leading to immune deficiency (2).

Over half of patients with CLL will have a clonal chromosomal abnormality after culture with B-cell mitogens. The most common finding is trisomy 12 (10, 11, 25, 26). Survival is adversely affected in patients with trisomy 12. In addition, atypical CLL is correlated with trisomy 12. DNA content studies are nearly normal in a majority of cases (27, 28), and antigen-receptor gene rearrangement studies show clonal rearrangement, as

would be expected of a B-cell neoplasm (29). Rarely, the additional finding of a T-cell antigen receptor rearrangement may be seen in B-cell CLL (30).

Change with Progression and Transformation

Although CLL is a disease of the mature lymphocyte, it does not always remain morphologically mature or remain functional at the early B-cell stage. The various transformations and secondary tumors that can arise in CLL are shown in Table 44.6.

TABLE 44.6. TRANSFORMATION AND SECONDARY TUMORS IN CLL

Prolymphocytic transformation
Cleaved-cell transformation
Large-cell lymphoma (Richter's syndrome)
Plasma-cell myeloma
Acute lymphoblastic leukemia
Hodgkin's disease
Acute nonlymphocytic leukemia

There may be a progressive increase in prolymphocytes resulting in morphology similar to atypical CLL or even PLL (see Fig. 44.3B) (13, 31, 32). Increasing numbers of clefted cells may accompany an increase in prolymphocytes, and rarely, increased nuclear clefting may be the predominant feature (Fig. 44.3C, Fig. 44.3D). When there is a sustained progressive change in morphology towards atypical CLL with increase in the percentage of atypical cells, patient survival and response to therapy are adversely affected (13).

The cell of CLL has the ability to undergo a dramatic morphologic transformation to a cell that is much larger than a prolymphocyte, and is morphologically typical of large-cell lymphoma (17, 32, 33). There can be marked variability in this transformation from one case to the next, as illustrated in Fig. 44.6. The term “Richter's syndrome” has been applied to this transformation. Large-cell lymphoma arising in CLL frequently occurs at an extra marrow site; however, the bone marrow and occasionally the blood may be involved. In rare instances, lymphoma with characteristics indistinguishable from Hodgkin's disease may occur in CLL (35, 36).

CLL may rarely present with concomitant plasma-cell myeloma or may subsequently undergo apparent transformation to plasma-cell myeloma, with production and secretion of immunoglobulin (37). Transformation to an entity typical of acute lymphocytic leukemia is rare (38).

When another morphologic type of lymphoproliferative disorder arises in CLL, it does not automatically imply that that tumor has arisen from the same clone; it may be a new tumor. This is most likely the case for Hodgkin's disease and myeloproliferative disorders arising in CLL (39). Special studies such as chromosome analysis or gene probe analysis showing the exact pattern in both tumors will confirm that they are derived from the same clone. The appearance of a new pattern observed by these techniques suggests that either a new tumor has developed or clonal evolution of the original tumor has occurred (33, 34, 38).

Staging, Therapy, and Prognostic Features

The National Cancer Institute-Sponsored Working Group recommends a simplified scheme for the staging of CLL (Table 44.7) (3). A more complicated staging scheme was developed by Rai in 1975, which is still used by some clinicians (3).

Morphologic features also have been shown to determine prognosis in CLL. As stated in the previous section, increasing numbers of prolymphocytes on smears alters prognosis. In addition, patients with more than 15,000 prolymphocytes per cubic millimeter at presentation do significantly worse than those with 15,000 or fewer prolymphocytes per cubic millimeter independent of the percentage of prolymphocytes (13). The infiltrative pattern of marrow involvement in CLL has been correlated with survival. Patients with a focal or interstitial infiltrate (i.e., less extensive involvement) have been shown to have a better prognosis and a lower stage of disease than patients with diffuse extensive marrow involvement (40). Also, as mentioned in the

previous section, chromosomal abnormalities are associated with prognosis (10, 26).

CLL is essentially a noncurable disease; thus, therapy is directed at treatment of symptoms and palliation. Patients with early-stage disease and low WBC count may be observed without therapy. If therapy is necessary because of massive adenopathy, splenomegaly, anemia, decreased platelet count, or significantly increasing white cell count, single-agent chemotherapy is used. As the disease becomes nonresponsive, multiagent therapy is instituted (2, 3).

Prolymphocytic Leukemia

PLL is an uncommon form of leukemia that is closely related to CLL (13, 41, 42 and 43). Similar to CLL, it predominantly affects males and has a median age of onset in the sixth to the seventh decade. It differs from CLL however, in that there is a predominance of prolymphocytes. PLL frequently presents with a very high WBC count, anemia, thrombocytopenia, and splenomegaly; it differs from CLL in that adenopathy is less conspicuous in PLL. Clinically, PLL is more aggressive than CLL, with a median survival of approximately 2 to 3 years. A majority of cases of PLL are of B-cell type. PLL of T-cell type will be discussed in a later section.

Diagnostic Features

The morphology of the cell in the peripheral blood of PLL is quite characteristic. Prolymphocytes are large lymphoid cells with abundant, moderately blue cytoplasm (Fig. 44.7). The nuclear chromatin is partly condensed and partly open with a reticular pattern. A single prominent nucleolus is present and frequently is accentuated by perinucleolar chromatin clumping. The exact percentage of prolymphocytes in the blood needed to confirm a diagnosis of PLL is not well defined; however, more than 55%, with the remainder being more mature lymphocytes, is a proposed minimum (13). The bone marrow is frequently extensively infiltrated. When the marrow is not extensively involved, the distribution may be focal and/or interstitial, similar to CLL (42, 44). On high-power magnification (Fig. 44.7C), the lymphoid cells have the appearance of prolymphocytes in CLL; however, more uniformity usually is seen than in atypical CLL with increased prolymphocytes. Cases of PLL that do not have markedly elevated WBCs have been reported (45). These may be cases of PLL that are diagnosed early in the course of the disease. When the diagnosis is in question, immunologic marker studies may be of help. B-cell PLL shows strongly reacting SIg with a restricted light chain compared with the weak-reacting SIg of CLL. If additional evidence is needed, PLL frequently is CD5 negative, CD23 negative, and is positive with FMC7 and CD79b (Table 44.2) (1, 6, 7, 20).

Morphologic Variability and Differential Diagnosis

In some cases of PLL, the peripheral blood prolymphocytes may show considerable numbers of smaller lymphoid cells with more condensed chromatin and prominent nucleoli. This variant needs to be distinguished from CLL, which also may occasionally show evident but not large nucleoli. Blastlike prolymphocytes with completely dispersed chromatin also may be a prominent feature in some cases of PLL, suggesting a diagnosis of acute

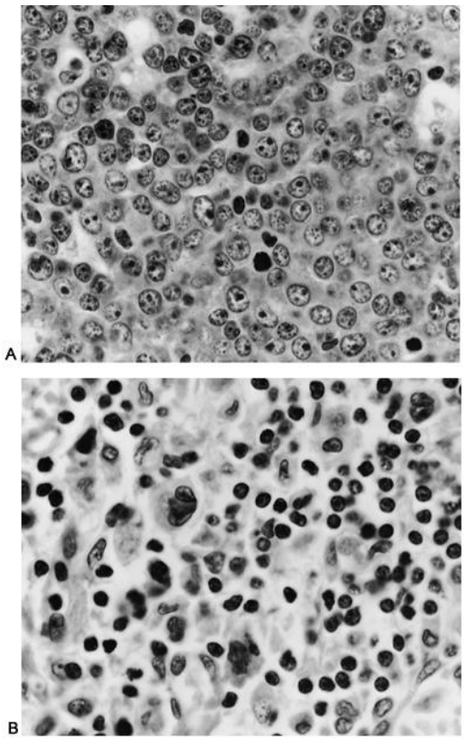

FIGURE 44.6. Large-cell lymphomas (Richter's syndrome) arising in chronic lymphocytic leukemia (CLL). **A:** Cells in this lymphoma from a lymph node biopsy are the size of blastlike prolymphocytes. Note the marked uniformity of this tumor compared to the tumor in **B**. **B:** This lymphoma from a patient with CLL shows marked pleomorphism of the large cells (with admixed residual CLL lymphocytes). This form of Richter's syndrome can be mistaken for Hodgkin's disease. Hematoxylin and eosin, 600X. (B., From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In Koepke JA, ed Laboratory Hematology. New York: Churchill Livingstone 1984;1:325-357)

TABLE 44.7. CLINICAL STAGING IN CLL

Stage	Criteria	Percentage of Total	Survival (yrs)
A	Less than three sites of involvement[a]	55	[b]
B	Three or more sites of involvement	30	7
C	Anemia (< 10 gm/dL) or thrombocytopenia (< 100 × 10^9/L)	15	2

[a] Sites of involvement include spleen, liver, cervical nodes, axillary nodes, and inguinal nodes.

[b] Survival for stage A is not significantly different from the age matched general population.

(Adapted from Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984;1:325–357)

leukemia. Granules or vacuoles may be present in some cases. Very large, blastlike prolymphocytes may cause confusion with peripheral blood involvement by large-cell lymphoma or monoblastic leukemia. Some cases of PLL will show a greater spectrum of cells, ranging from mature lymphocytes with marked clumping of chromatin to more blastlike cells. These cases with variability in cell type suggest the possibility that the process has evolved from a CLL through prolymphocytic transformation, and cases with morphologic features intermediate between CLL and PLL may be very difficult to clearly diagnose as either PLL or CLL/PL because CLL/PL may show immunophenotypic features intermediate between CLL and PLL (13). Cases of PLL with a moderate amount of nuclear contour irregularity will suggest the possibility of a leukemic transformation of a lymphoma. Rare cases of PLL (as well as CLL and mantle-cell lymphoma) will have cytoplasmic projections, suggesting the possibility of a variant of hairy-cell leukemia or SLVL. Finally, TRAP stain may be positive in PLL and thus should not be used alone to distinguish PLL from hairy-cell leukemia.

Other Special Studies

Serum protein studies performed on PLL have shown occasional cases with monoclonal gammopathy (43). Clonal chromosomal abnormalities are frequently seen in PLL cells using B-cell mitogens. A 14q+ was the most frequently observed abnormality in B-cell PLL in one study (46). Catovsky's group has reported a high incidence of p53 mutation in PLL relative to CLL and other B-cell malignancies perhaps explaining its aggressive biology (47). Despite the partially transformed appearance of the cells in PLL and the chromosomal abnormalities, the cellular DNA content is normal in most cases, and there is a low percentage of cases in S-phase (48).

Change With Progression and Transformation

Because PLL is uncommon and also is a tumor of relatively transformed lymphoid cells, transformation to a large-cell process is very rare.

Staging, Therapy, and Prognostic Features

A widely accepted staging system similar to CLL does not exist for PLL; however, there are occasional cases of PLL with a low WBC that appear to be early-stage disease (45). Patients with PLL do not respond very well to conventional CLL management. Combination chemotherapy will induce remission in many patients; however, remission usually is short-lived.

Hairy-Cell Leukemia

Hairy-cell leukemia is an uncommon disease characterized by a proliferation of medium-sized lymphoid cells with hairy cytoplasmic projections (49). The disease predominantly involves the bone marrow and spleen, and the patient may or may not have a “leukemic” blood picture. There is a male predominance with a median age of onset in the sixth decade. The patient frequently presents with nonspecific constitutional symptoms, pancytopenia,

and splenomegaly, and the disease usually follows a very indolent course. Virtually all cases are of B-cell origin.

Diagnostic Features

The most characteristic diagnostic feature of hairy-cell leukemia is the appearance of hairy cells on blood and marrow smears (Fig. 44.8). Hairy cells range in size from that of a medium-sized lymphocyte to a monocyte. The cytoplasmic border has a frayed or shaggy appearance, and the cytoplasm is blue-gray with a variegated dark and light consistency. Cytoplasmic granules are uncommon. The nucleus generally is round to oval or slightly indented with a partly clumped, partly open or reticular chromatin, and a single indistinct nucleolus. The WBC usually is decreased, but hairy cells are found easily in the blood in most cases. The TRAP stain is classically positive in hairy-cell leukemia. Typical flow cytometry features are shown in Table 44.2 (1, 6, 7 and 8, 20). Typically, hairy cells are CD5 and CD23 negative and are positive for CD25 and CD11c. CD103 also may be used in difficult cases.

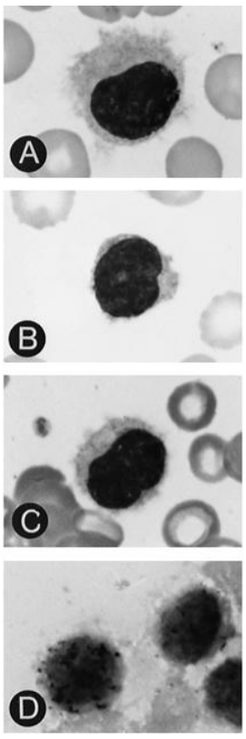

FIGURE 44.8. A, B, C: Typical hairy cells from the blood or marrow. **D:** Tartrate-resistant acid phosphatase (TRAP) stain. Note dispersion of positive granules throughout the cytoplasm. Wright's stain 1200X (**A**,**B**,**C**). TRAP stain 1200X (**D**).

In rare cases, it may be impossible to identify hairy cells on the blood and marrow smears, whereas other cases may have a markedly elevated WBC count with numerous hairy cells. A monocytopenia is characteristically seen in the peripheral blood and is a good differential diagnostic feature. The bone marrow in hairy-cell leukemia usually does not aspirate freely, and there may be a “dry tap.” Thus, in some cases with a dry tap and very few hairy cells in the peripheral blood, cells showing the characteristic hairy-cell morphology may be very difficult to find, and sufficient material may not be available for flow cytometry. Also, unfortunately, characteristic hairy-cell morphology is not as readily identified on touch preparations of bone marrow as on aspirates. In these cases, the diagnosis must rest more heavily on the appearance of cells on the sections and a TRAP stain on rare cells that aspirated or come from touch preps. The use of monoclonal antibodies on section material may be helpful if there are no cells on the blood or aspirate and touch preps (50, 51).

On bone marrow sections, the marrow usually is moderately to extensively replaced by hairy cells (Fig. 44.9). When the marrow is less extensively replaced, there is an interstitial pattern with varying numbers of normal marrow elements admixed. Characteristic hairy cells on sections have a bland-appearing lymphoid nucleus with mild to moderate nuclear contour irregularity and abundant pale cytoplasm between widely separated nuclei. Occasionally, the marrow will show some crush artifact resembling fibrosis (Fig. 44.9D). The spindle-shaped cells in this situation are hairy cells that have been strung out by the encasing reticulin fibers after being crushed. Although overt fibrosis is rarely seen on sections in hairy-cell leukemia, background reticulin usually is moderately increased on reticulin stain (Fig. 44.9E).

Morphologic Variability and Differential Diagnosis

Most cases of hairy-cell leukemia fit the description given above. However, some cases are difficult to diagnose as hairy-cell leukemia because of deviation from the norm (52, 53, 54, 55, 56, 57 and 58). Some of these appearances are listed in Table 44.8 and are illustrated in Fig. 44.10.

Hairy-cell leukemia can be mistaken for a number of other processes. Cases with elevated WBC and small hairy cells with round nuclear contour (Fig. 44.10A) can be mistaken for CLL (58). Rare cases of hairy-cell leukemia have abundant, clear nonhairy cytoplasm, giving them an exaggerated “fried egg” appearance of a Downey II/atypical lymphocyte (Fig. 44.10B, Fig. 44.10C) (53). Cases with large cells and more prominent nucleoli can be mistaken for PLL or even acute lymphoblastic leukemia (Fig. 44.10D) (52, 54). Cases with a monocytoid appearance can be mistaken for monocytic leukemia (Fig. 44.10E) (52). Cases with multilobulated nuclei can be mistaken for lymphoma (Fig. 44.10F) (55, 56), and cases with minimal marrow involvement and hairy cells in the 5% to 20% range and no obvious infiltrate in sections may be mistaken for normal.

Patients with splenomegaly, pseudofibrosis on sections, and minimal numbers of hairy cells on blood and marrow smears can be misdiagnosed as having agnogenic myeloid metaplasia (52). Patients with hypoplastic marrow and minimal splenomegaly can be misdiagnosed as having aplastic anemia (57). A focal or paratrabecular infiltrative pattern can be misinterpreted as evidence of lymphoma.

Of special note is the existence of a small percentage of cases that are midway morphologically and immunologically between PLL and hairy-cell leukemia and do not respond to conventional therapy for hairy-cell leukemia (54). There is also a set of cases with some morphologic and immunologic overlap between CLL and hairy-cell leukemia (58).

Cases of PLL and non-Hodgkin's lymphoma with hairy cytoplasm (SLVL) should be distinguished from hairy-cell leukemia (59, 60). In addition to marker studies, a helpful differential diagnostic feature is that most other lymphoproliferative disorders do not have the abundant pale cytoplasm in combination with the bland appearance of the nucleus seen in hairy-cell leukemia on sections. In addition, the infiltrate in hairy-cell leukemia is more interstitial or diffuse in the bone marrow and localized in the red pulp of the spleen. Lymphomas are distributed in a more focal pattern in the bone marrow and are more prone to have white pulp distribution in the spleen.

TRAP and Other Special Studies

Hairy cells are characterized by TRAP positivity (Fig. 44.8D) (61, 62). Many normal hematopoietic cells (including lymphoid cells) are acid-phosphatase positive; however, the reaction in most normal and neoplastic cells is inhibited by tartaric acid. Thus, a positive TRAP stain has become a cytochemical marker for hairy-cell leukemia. Unfortunately, a positive TRAP stain is not diagnostic, because a number of other processes may be TRAP positive. Also, the cells of some cases of hairy-cell

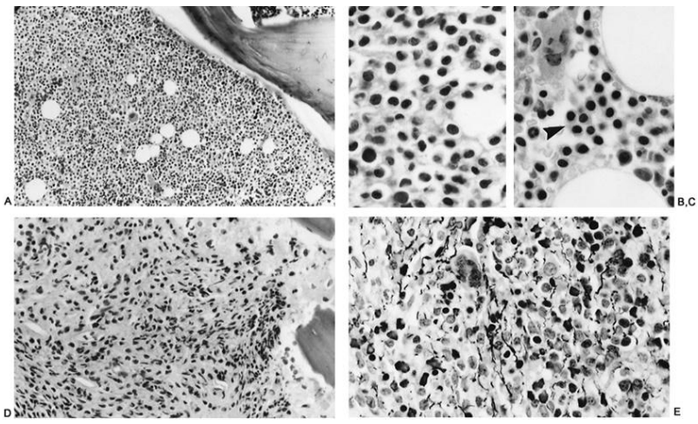

FIGURE 44.9. Trephine biopsy sections in hairy-cell leukemia. **A:** Note the diffuse infiltrate of hairy cells with scattered normal marrow elements. **B:** Note the mild-to-moderate nuclear contour irregularity. The halo around the hairy cells is from artifactual retraction in formaldehyde. **C:** Note the small collection of hairy cells in the center of field (arrow) from a marrow with minimal infiltration. These cells, which were fixed in B-5 fixative, do not show as much retraction artifact as formaldehyde fixation. **D:** Crush artifact, a frequent occurrence in hairy-cell leukemia, may resemble marrow fibrosis. **E:** Reticulin is frequently extensively increased even though overt fibrosis is not seen. Hematoxylin and eosin, 120X (**A**), 600X (**B,C**), 240X (**D**), Reticulin stain 600X (**E**).

leukemia react only weakly, or only rare strongly positive cells may be found. However, the TRAP stain is a good screening test when the diagnosis of hairy-cell leukemia is in question.

Patients with hairy-cell leukemia usually have a polyclonal gammopathy; however, rare cases of monoclonal gammopathy occur. This finding, in addition to the association of PCA-1 with hairy-cell leukemia, suggests to some investigators that hairy-cell leukemia may be more closely related to the plasma cell than other chronic lymphoproliferative disorders (63).

Many other sophisticated studies have been performed on hairy-cell leukemia, including cytogenetics (64), DNA content (27), electron microscopy (65, 66) and gene rearrangement (29); however, the studies of greatest diagnostic importance are the TRAP stain and immunologic markers.

Change with Progression and Transformation

Transformation and secondary hematologic malignancies in hairy-cell leukemia are rare (67, 68 and 69). Rarely, skeletal lesions, including osteosclerosis and lytic bone lesions or massive lymphadenopathy, may develop (70, 71 and 72).

Staging, Therapy, and Prognostic Features

Hairy-cell leukemia is an indolent disease and, if diagnosed in an asymptomatic patient, can be followed for many years without therapy. There are several therapeutic modalities available to treat symptomatic hairy-cell leukemia, which are capable of inducing long-term remission of the symptoms of disease. Splenectomy may help for chemotherapy failure. Treatment of hairy-cell leukemia by the types of chemotherapy used in other B-cell malignancies can result in a poor outcome; thus, it is very important to avoid erroneously diagnosing hairy-cell leukemia as some other B-cell process.

Chronic Lymphoproliferative Disorders of T-Cell Type

The chronic T-cell processes listed in Table 44.1 are a heterogeneous group of rare disorders with varied clinical presentation and prognosis (1, 73, 74, 75, 76 and 77). Unless these processes are thought of and studied with markers to determine their T-cell nature, they may not be readily diagnosed. Features that should lead to the suspicion that a patient with lymphocytosis in the blood or marrow has a T-cell lymphoproliferative disorder rather than a more common form of chronic B-cell leukemia include: skin lesions, cytoplasmic granules, cytopenia or lymphocytosis out of proportion to the extent of marrow involvement, and nuclear contour irregularity. Nuclear contour irregularity, when present in a T-cell process, may show more complexity (convoluted, cerebriform, or lobulated) (Fig. 44.11 and Fig. 44.12) than the simple clefting or folding of the nucleus seen in the B-cell processes that have nuclear contour irregularity.

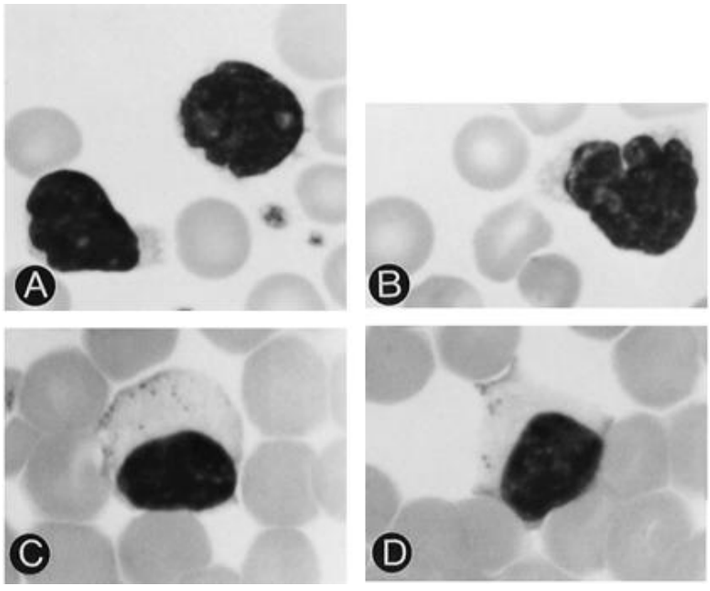

FIGURE 44.11. A, B: Cells of a chronic T-cell leukemia. Note the complex nuclear contour in the cells illustrated. **C, D:** Large granular lymphocytes. Note the abundant cytoplasm and multiple cytoplasmic granules. Wright's stain 1200X. (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. T-Cell Chronic Lymphocytic Leukemia

T-cell CLL is a very rare disease (76, 78, 79 and 80). It is seen in older individuals and frequently is associated with splenomegaly and

skin involvement. Cases of T-cell CLL may have cells with nuclear contour irregularity similar to the cells in Figure 44.11A and Figure 44.11B. However, they also may have a lymphocytosis morphologically indistinguishable from typical B-cell CLL. Earlier literature included large granular lymphocyte (LGL) leukemia as T-cell CLL; however LGL now is recognized as an entity distinct from T-cell CLL. Most cases of T-cell CLL are of helper T-cell phenotype (CD4); however, rare cases of cytotoxic/suppressor (CD8) CLL have been described (78, 79). A clonal immuno-marker such as the restricted light chain seen in CLL is not available to confirm clonality in T-cell lymphoproliferative disorders. Thus, in the differential between T-cell CLL (or other T-cell lymphoproliferative disorders) and a reactive T-cell lymphocytosis, molecular studies for T-cell clonality may be helpful (75). In addition, an abnormality involving chromosome 14 (q11;q32) is a frequent finding (76, 78).

T-cell CLL is less responsive than B-cell CLL to therapy. Because of the biologic similarity of T-cell CLL to T-cell PLL, some authors have suggested that T-cell CLL is merely a small-cell variant of T-cell PLL and recommend that they be lumped together as one entity, namely T-cell PLL (80).

T-Cell Prolymphocytic Leukemia

A T-cell phenotype is seen in approximately 20% of PLLs. T-cell PLL is similar clinically and morphologically to B-cell PLL, except that T-cell PLL is more likely to have adenopathy and skin infiltrates, and the prolymphocytes may have a higher nuclear cytoplasmic ratio, a greater degree of nuclear contour irregularity, and less prominent nucleoli than B-cell PLL (73, 74 and 75, 81). In addition, a small-cell variant of T-cell PLL has been described, which may overlap with T-cell CLL as described above (80). Similar to B-cell PLL, a small subset may pursue a more indolent course (82). A majority of cases of T-cell PLL are of helper phenotype (CD4); however, cases of cytotoxic/suppressor (CD8) phenotype also are reported (75). Similar to T-cell CLL, a clonal chromosomal abnormality involving chromosome 14 (q11;q32) is seen in a majority of cases (83).

Large Granular Lymphocyte Leukemia

LGL leukemia usually is an indolent disease characterized by a proliferation of mature-appearing lymphocytes with abundant cytoplasm and cytoplasmic granules (Fig. 44.11C and Fig. 44.11D) (1, 73, 74, 75 and 76, 84, 85). LGLs normally comprise about 15% of peripheral blood lymphocytes and they may be elevated above this level in reactive processes as well as in LGL leukemia. There are two types of LGL leukemia: the T-cell type, which is the most common, and the NK type (8, 75). The lymphocytes of the T-cell type express CD2, CD3, CD8, CD16, and are +/- for CD57. LGL leukemia cases with the NK-cell phenotype are distinguished from the T-cell type in that they are +/- for CD56 and CD57 and don't express CD3. The usual case of LGL leukemia presents with neutropenia and/or red-cell aplasia, mild splenomegaly, a mild peripheral blood lymphocytosis, and relative marrow sparing by the lymphoid infiltrate, which is focal, nonparatrabecular, or interstitial. Occasional cases are associated with rheumatoid arthritis or a positive rheumatoid factor. Although this disorder may not have a markedly elevated WBC count or an infiltrative character, most cases with a T-cell phenotype have been shown to be clonal, “neoplastic” processes by molecular techniques (75), a feature that may be useful in distinguishing this disorder from transient proliferations of LGLs (86). Cytogenetic studies have shown evidence of clonality in some cases; however, cytogenetic evaluation has been hampered because of the poor response of granular lymphocytes to mitogenic stimulation (87).

LGL also may be the cell of origin for rare cases of acute

leukemia and lymphoma (87, 88 and 89). These cases show more cytologic immaturity than typical LGL leukemia.

Sézary Syndrome

Sézary syndrome and mycosis fungoides are closely related, uncommon disorders of older individuals, and together they constitute the category called cutaneous T-cell lymphomas (73, 90). Sézary syndrome is primarily a disorder of the skin with secondary blood involvement. It is characterized by diffuse erythroderma resulting from infiltration of mature-appearing helper T cells with markedly convoluted nuclear contours. The disease shows varying degrees of lymphocytosis in the peripheral blood with Sézary cells, as illustrated in Fig. 44.12A and Fig. 44.12B. The bone marrow is relatively spared (91, 92). The diagnosis usually rests on a combination of clinical and morphologic features. A skin biopsy will show a bandlike infiltrate of small, convoluted lymphoid cells immediately beneath the epidermis. When the skin biopsy is not diagnostic, the identification of convoluted lymphocytes (Sézary cells) in the blood may be used to help substantiate the diagnosis. A small percentage of convoluted cells indistinguishable from the neoplastic Sézary cells (similar to those shown in Fig. 44.12A) can be seen in benign skin disorders; however, the presence of more than 15% to 20% of these cells or the presence of larger convoluted lymphoid cells similar to those shown in Fig. 44.12C and Fig. 44.12D are supportive of the diagnosis of Sézary syndrome (93, 94). The cells of Sézary syndrome as well as mycosis fungoides are T-helper (CD4+) cells and usually are CD7 negative (95). Immunophenotyping may be of some assistance in the differential diagnosis of Sézary syndrome with other T-cell malignancies involving the skin. When the differential diagnosis rests between Sézary syndrome and a reactive process, and skin biopsy and blood morphology are equivocal, molecular techniques for clonal T-cell gene rearrangement may provide help (96).

Mycosis fungoides characteristically lacks morphologic evidence of blood involvement and shows multifocal skin lesions rather than the diffuse involvement of Sézary syndrome. However, late in the course of mycosis fungoides with dissemination, large, atypical, convoluted lymphoid cells similar to those shown in Fig. 44.12 may be seen in the blood.

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma is an aggressive T-cell disorder caused by human T-lymphocytotrophic virus 1 (HTLV-1) (8, 73, 90, 97). It is seen predominantly in southwestern Japan, but also has been described in the Caribbean, the southeastern United States, and elsewhere. Morphologically, it is characterized by a proliferation of small to medium-sized lymphoid cells with marked nuclear lobulation similar to the cells illustrated in Fig. 44.11A and Fig. 44.11B. These cells infiltrate lymph nodes, bone marrow, blood, and skin. There may be relative marrow sparing compared with the involvement in the peripheral blood. While a majority of patients demonstrate a “leukemic pattern,” a subset of patients present with more of a “lymphoma-type” disease (97). Lytic bone lesions and hypercalcemia are common. The T-cells in adult T-cell leukemia/lymphoma are of helper (CD4) phenotype and usually are CD7 negative (8, 75, 97). The diagnosis usually is made by a combination of clinical, morphologic, and immunologic studies and is confirmed by antiviral antibodies or identification of the virus. This disorder usually has a very rapidly progressive course and responds poorly to aggressive combination chemotherapy, with a median survival of 1 year or less; however, some cases may follow a more indolent course.

IMMUNOPROLIFERATIVE DISORDERS

Part of "44 - Chronic Lymphoproliferative Disorders, Immunoproliferative Disorders, and Malignant Lymphoma"

Immunoproliferative disorders are neoplastic proliferations of plasma cells and B lymphocytes at the terminal stage of functional differentiation, and are characterized by the production and secretion of a monoclonal immunoprotein called a monoclonal gammopathy. “Disease” in immunoproliferative disorders may be caused by proliferation of the neoplastic cell and/or by secretion of an abnormal protein that has a pathologic effect. These disorders are almost exclusively in older individuals and their clinical course may be indolent or rapidly progressive. The immunoproliferative disorders include: plasma-cell myeloma, plasmacytoma, Waldenström's macroglobulinemia, heavy-chain disease, benign monoclonal gammopathy, and primary amyloidosis.

Plasma-Cell Myeloma

Plasma-cell myeloma is a relatively common hematologic disease characterized by proliferation of clusters and sheets of neoplastic plasma cells primarily in the bone marrow, resulting in focal bone lesions, diffuse osteoporosis, bone pain, fractures, and cytopenia (98, 99). The neoplastic proliferation usually produces a monoclonal gammopathy, which may result in hyperviscosity syndrome, coagulation abnormalities, immune deficiency, renal failure, or development of amyloidosis. Plasma-cell myeloma is seen primarily in older individuals (in the sixth to seventh decade) with a male predominance. It generally is a progressive malignant disorder; however, its course is variable, and prognosis is based to a large degree on the tumor burden present at diagnosis.

Diagnostic Features

The diagnosis of plasma-cell myeloma is dependent on a combination of clinical and laboratory features. From a laboratory standpoint, the diagnosis of plasma-cell myeloma should be suspected whenever there is a monoclonal gammopathy, and the bone marrow contains increased atypical plasma cells with a prominent single nucleolus and partially dispersed chromatin, sometimes referred to as “myeloma cells” (Fig. 44.13 and Fig. 44.14). The following morphologic changes are consistent with a diagnosis of plasma-cell myeloma:

1. The presence on marrow smears of 10% or more atypical plasma cells (Fig. 44.13A and Fig. 44.14A). These cells may infiltrate in an interstitial pattern, in multiple small clusters, or in sheets. The median percentage of atypical plasma cells on smears in patients with plasma-cell myeloma is about 30%. It is important to perform an actual differential (100 or more cells on three different

slides) to quantitate the number of plasma cells; plasma cells can easily be overestimated! Also, binucleation of plasma cells should not be considered an atypical feature; reactive plasma cells also are frequently binucleated.

2. Less than 10% atypical plasma cells on marrow smears in association with large sheets of atypical plasma cells on crush preparation or sections, with plasma cells representing nearly 100% of the cell population in the sheets (Fig. 44.13B) (100, 101).

Although these morphologic features are consistent with a diagnosis of plasma-cell myeloma, additional clinical and laboratory evidence of disease also may be necessary to make a definitive diagnosis. Additional evidence may be a monoclonal gammopathy in serum or urine, characteristic bone lesions, or, rarely, suppression of other immunoglobulins in the absence of a monoclonal gammopathy.

Caution should be taken in making an unequivocal diagnosis of plasma-cell myeloma in a patient with atypical plasma cells and a monoclonal gammopathy in the absence of any other evidence of disease. A small subset of patients who have 10% to 20% atypical plasma cells on marrow smears and a monoclonal gammopathy, but who also are asymptomatic, may not pursue an aggressive course. These cases have been diagnosed as indolent or smoldering myeloma (102, 103, 104 and 105).

A significant number of patients have up to 10% atypical plasma cells in the marrow with a monoclonal gammopathy and do not have disease manifestations of plasma-cell myeloma. These cases usually pursue a benign course and are called benign monoclonal gammopathy, or alternatively, monoclonal gammopathy of undetermined significance (MGUS). Benign monoclonal gammopathy is discussed in greater detail later in this chapter.

Less than 10% atypical plasma cells or more than 10% normal-appearing plasma cells can be seen in patients with progressive myeloma; however, these findings are more consistent with a benign monoclonal gammopathy or a reactive process, respectively. When these morphologies are present, the diagnosis of plasma-cell myeloma should rest even more heavily on clinical criteria.

Because patients can have progressive plasma-cell myeloma with fewer initial morphologic changes than those described earlier,

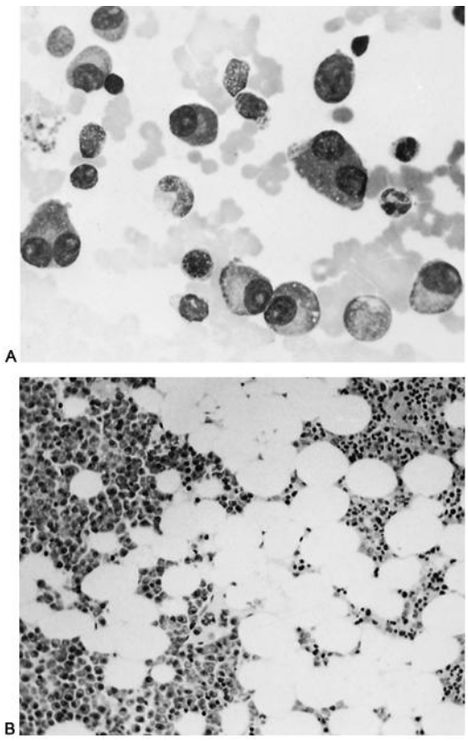

FIGURE 44.13. Plasma-cell myeloma. **A:** Marrow smear. Note immature plasma cells with a single prominent nucleolus. **B:** Bone marrow section. Note sheets of plasma cells in the upper and lower left field, and normal marrow elements to the right. Wright's stain 600X (**A**). Hematoxylin and eosin 120X (**B**). (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

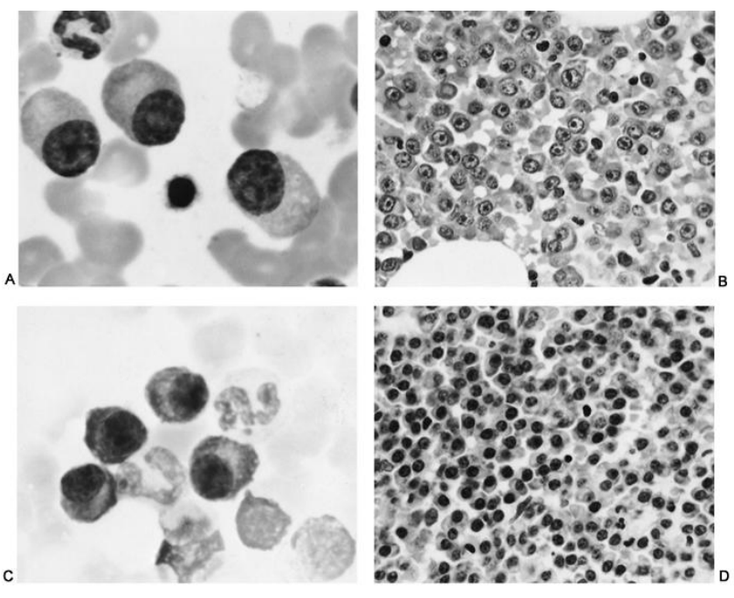

FIGURE 44.14. Plasma-cell myeloma. Marrow smears and sections. **A, B:** Myeloma with immature plasma cells having abundant eccentric basophilic cytoplasma and a prominent single nucleolus. **C, D:** Myeloma with smaller, more mature plasma cells. Chromatin is still partly dispersed but prominent nucleoli are not evident. Wright's stain 1200X (**A, C**). Hematoxylin and eosin, 600X (**B, D**). (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

or more rarely, because progressive disease may not develop when the morphologic features described above are found, several groups have developed a set of clinical pathologic criteria that serve to ensure that patients entered on protocols are diagnosed uniformly (105). A modification of one of these is illustrated in Table 44.9. Such criteria also are useful for routine diagnosis outside of protocol studies, because they emphasize the importance of using a combination of radiologic, clinical, morphologic, and laboratory features in arriving at the diagnosis of plasma-cell myeloma. These clinical-pathological features are helpful in distinguishing plasma-cell myeloma from an indolent or smoldering myeloma, and from solitary plasmacytoma and benign monoclonal gammopathy. Although these criteria may be very useful in some patients, sound judgment should be used when making the diagnosis of plasma-cell myeloma based only on these criteria. For example, if the criteria of Durie and Salmon are too rigidly adhered to, some patients with progressive plasma-cell myeloma may be excluded, or rare patients with plasmacytoma or benign monoclonal gammopathy and clinical findings caused by an unrelated disease may be included.

TABLE 44.9. CLINICAL PATHOLOGIC CRITERIA FOR INCLUSION IN STUDIES OF PLASMA-CELL MYELOMA

Major Criteria
I Plasmacytomas by biopsy
II > 30% marrow plasmacytosis
III Monoclonal gammopathy
> 3.5 g/dL of IgG
> 2.0 g/dL of IgA or
>1 gm/day κ or λ chains in urine without other significant proteinuria
Minor Criteria
A. 10%–30% marrow plasmacytosis
B. Monoclonal gammopathy with values less than in III
C. Lytic bone lesions
D. Suppressed normal immunoglobulins
< 50 mg/dL IgM,
< 100 mg/dL IgA or
< 600 mg/dL IgG
Symptomatic patient and
I plus B, C, or D
II plus B, C, or D
III
A, B, and C
A, B, and D

[From Dick FR. Chronic Lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984; 1:445–481. Modified from the criteria of Durie and Salmon (105).]

Occasional cases of reactive plasmacytosis with polyclonal gammopathy will show a significant infiltrate in the marrow with plasma cells, sometimes in sheets (101). The author of this chapter has observed two cases of reactive plasmacytosis in which there were over 50% reactive plasma cells with atypical plasma cells in a cellular bone marrow (Fig. 44.15). This emphasizes the need to identify laboratory and clinical criteria other than plasmacytosis greater than 10% or “sheets” of plasma cells in the bone marrow to establish the diagnosis of plasma-cell myeloma.

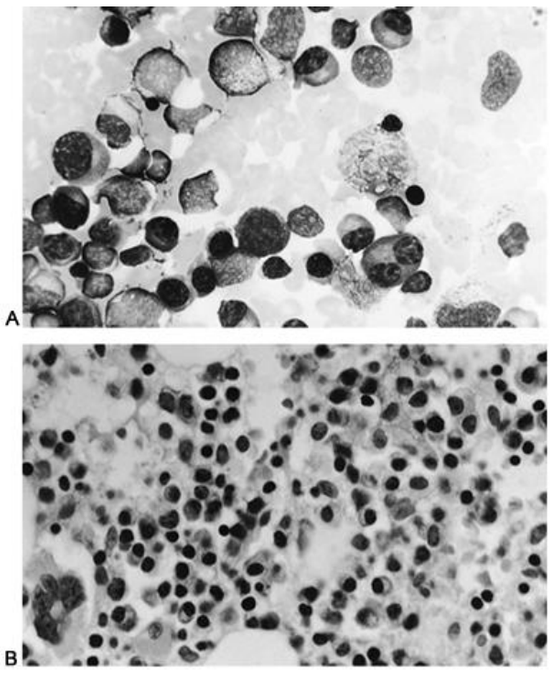

FIGURE 44.15. Bone marrow aspirate **A:** and biopsy **B:** showing a reactive plasmacytosis of greater than 50%. Note large and binucleated plasma cells. Single prominent nucleoli are not a prominent feature, however. Wright's stain 600X (**A**). Hematoxylin and eosin, 600X (**B**). (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

Morphologic Variability and Differential Diagnosis

The marrow in a classic case of plasma-cell myeloma shows a predominance of immature myeloma cells, as illustrated in Fig. 44.13 and Fig. 44.14A and Fig. 44.14B. Less commonly, smaller plasma cells with more mature nuclear features predominate (Fig. 44.14C and Fig. 44.14D). Other cases may show a spectrum of plasma cells ranging from nearly normal plasma cells to more classic myeloma cells (106).

Cytologic variability from the pattern described above occasionally occurs and should be recognized as part of the spectrum of plasma-cell myeloma (Table 44.10).

Flame cells, thesaurocytes, and inclusions can be seen in some of the plasma cells in a benign plasmacytosis; however, when they are present in plasma-cell myeloma, they usually are present in a major percentage of the plasma cells (Fig. 44.16). Flame cells and thesaurocytes (Fig. 44.16A and Fig. 44.16B) are frequently but not exclusively associated with an IgA monoclonal gammopathy (106).

A wide variety of cytoplasmic and nuclear inclusions may be seen in the cells of plasma-cell myeloma, some of which are illustrated in Figure 44.16C and Figure 44.16D (100, 107, 108, 109 and 110).

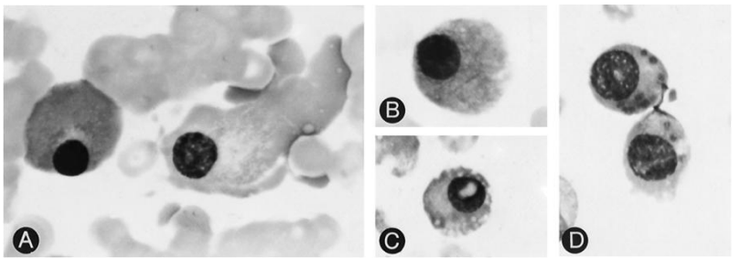

FIGURE 44.16. Variants of myeloma cells, bone marrow aspirate. **A:** Flame cells. The dark flowing cytoplasmic borders on these plasma cells are red or "flaming" on Wright's stain. **B:** Thesaurocytes are plasma cells with abundant, pale blue, foamy or reticulated cytoplasm. **C:** Dutcher bodies on smears are pale intranuclear inclusions. **D:** Russell bodies are reddish, globular, cytoplasmic inclusions. Wright's stain 1200X. (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

Occasional cases may show a pleomorphic, a plasmablastic, or anaplastic appearance, as illustrated in Fig. 44.17. A myeloma with pleomorphic morphology has marked variability in cell size with large multinucleated and bizarre forms (106). Plasmablastic, anaplastic (or immunoblastic) morphology overlap (111, 112, 113 and 114). Cases with these morphologies show poor differentiation toward plasma cells, may have less abundant cytoplasm, and may have absence of eccentric cytoplasm with paranuclear pallor (hof). They are morphologically similar to, and may be difficult to distinguish from, a large-cell lymphoma with immunoblastic or plasmacytoid features, especially if the patient also has extramarrow masses (114).

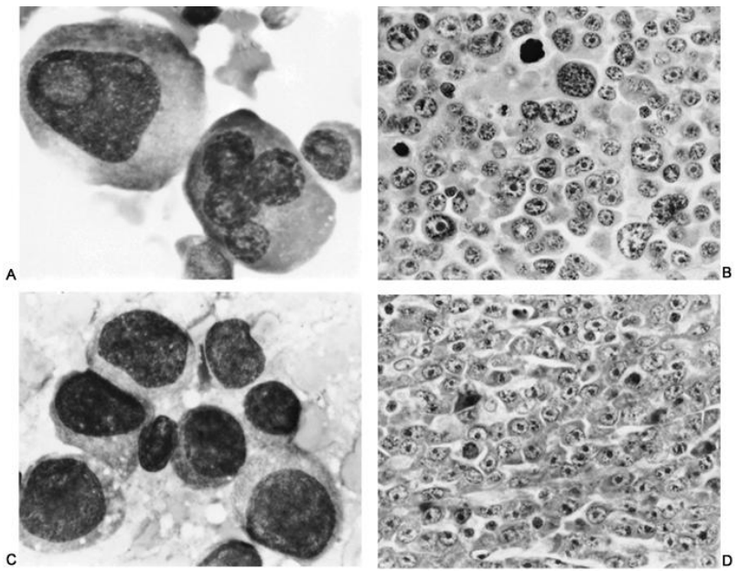

FIGURE 44.17. Variants of myeloma cells. Bone marrow aspirate and sections. **A, B:** Pleomorphic morphology in plasma-cell myeloma. Note multinucleation and large bizarre forms. **C, D:** Plasmablastic or anaplastic morphology. These plasma cells are difficult to recognize as plasma cells, and are morphologically similar to a large cell lymphoma. Wright's stain 1200X (**A, C**). Hematoxylin and eosin, 600X (**B, D**). (**A, B**, and **C**, From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

In rare cases of plasma-cell myeloma, the plasma cells in the bone marrow may have a lymphoid morphology, as illustrated in Fig. 44.18A (106, 115). These cases may be difficult to separate from lymphoma or Waldenström's macroglobulinemia if lytic lesions characteristic of plasma-cell myeloma are not present or if the patient has extra-marrow disease. Also, plasma cells, when present in the blood in typical plasma-cell myeloma, frequently have a more lymphoid appearance than in the marrow of the same patient.

Rare cases of myeloma will show considerable nuclear irregularity (multilobulated or monocytoid), as illustrated in Fig. 44.18B (116). On sections as well as on smears, these cells may be difficult to recognize as plasma cells. Rare cases of plasma-cell myeloma will slow phagocytic activity by the myeloma cells (117).

The marrow in plasma-cell myeloma usually aspirates quite freely; however, occasional cases may aspirate poorly because of increased reticulin or fibrosis; and rare cases may show osteosclerosis on radiograph and biopsy (118, 119 and 120).

Rarely, amyloidosis is present in the bone marrow in plasma-cell myeloma (121).

Plasma cells in small numbers can be seen in the peripheral blood at diagnosis in approximately 15% of cases of plasma-cell myeloma, and can be shown to be present in a much larger proportion of patients using special techniques to identify circulating plasma cells (122, 123). In about 2% of cases of plasma-cell myeloma, large numbers of plasma cells will be present in the blood (Fig. 44.19). When this occurs, the patient is said to have plasma-cell leukemia, which has been defined as having more than 2,000 plasma cells per cubic millimeter and more than 30% plasma cells in the peripheral blood (122). Plasma-cell leukemia has a younger age distribution, a greater incidence of hepatosplenomegaly, less clinical bone involvement, and a poorer prognosis than the usual case of plasma-cell myeloma. Again, plasma-cell leukemia also is more likely to show a lymphoid appearance than classic plasma-cell myeloma (106, 122).

Immunologic and Other Special Studies

A search for a monoclonal gammopathy is the single most important test that can be done in a patient suspected of having plasma-cell myeloma (Table 44.11 and Table 44.12) (124). The best procedure is to perform immunofixation electrophoresis on serum and urine as a screening test. If no monoclonal gammopathy is detected by these two procedures, it is highly unlikely that the patient has myeloma, because 1% or fewer cases of plasma-cell myeloma fail to produce at least a small monoclonal protein. Serum protein electrophoresis alone is not a good screening test for a monoclonal gammopathy because it is not as sensitive as immunofixation electrophoresis. Also, in 20% of patients

The marrow aspirates in both of these illustrations are from individuals with lytic bone lesions and IgG monoclonal gammopathy. Wright's stain 1200X. (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

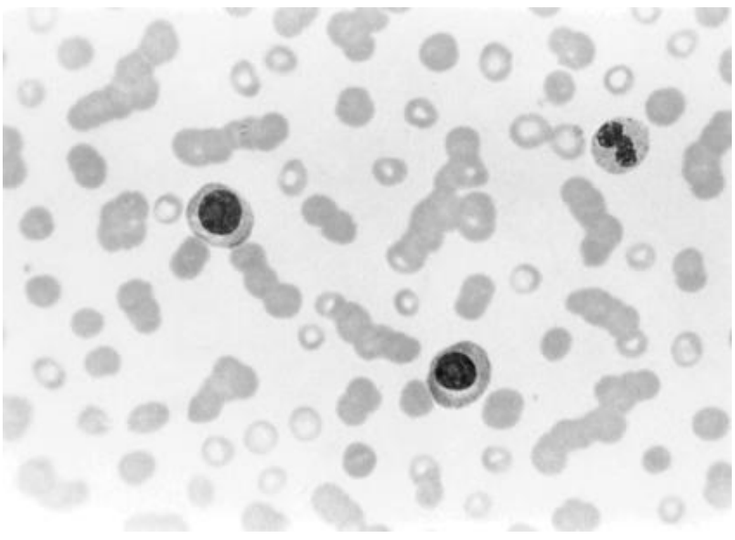

FIGURE 44.19. Plasma-cell leukemia (peripheral blood). Note the marked rouleaux and immature plasma cells. Wright's stain 600X. (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

with myeloma, the monoclonal gammopathy will be detected by urinalysis and not by serum protein electrophoresis. A serum-protein electrophoresis or quantitative immunoglobulins will, however, help detect those rare patients with myeloma who have hypogammaglobulinemia and no monoclonal gammopathy on serum immunofixation electrophoresis. As pointed out in the previous section, many patients with a monoclonal gammopathy (especially a small monoclonal gammopathy) will not have progressive plasma-cell myeloma. Thus, other features in addition to a monoclonal gammopathy are necessary to make the diagnosis of plasma-cell myeloma.

TABLE 44.11. FREQUENCY OF TYPE OF MONOCLONAL GAMMOPATHY IN PLASMA CELL MYELOMA

Monoclonal Gammopathy	Approximate Frequency of Occurrence (%)
IgG	57
IgA	20
κ or λ only	20
IgD	1
Nonsecretory	1
Biclonal	1
IgE	Rare
IgM	Rare
	100

(From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984; 1:445–481.)

TABLE 44.12. OTHER PROTEIN FINDINGS IN PLASMA-CELL MYELOMA (102)

Finding	Approximate Frequency of Occurrence in Plasma Cell Myeloma (%)
Size of monoclonal peak	
< 2 gm/dL	17
> 5 gm/dL	20
No obvious monoclonal peak on serum protein electrophoresis	20
Free light chains in urine	80
Hypoglobulinemia and no M-peak on serum electrophoresis	9
“Normal” serum protein electrophoresis	10–15
Location of monoclonal peak on protein electrophoresis	
Gamma	70
Beta	30
Alpha 2	Rare
Cryoglobulin	5
Pyroglobulin	1

(From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984; 1:445–481.)

Immunologic evaluation of the cells in myeloma is rarely needed because the morphology of the cells in myeloma usually is that of classical immature “myeloma cells,” and clonality is supported by the finding of a monoclonal gammopathy in the serum or urine. However if evaluated, the plasma cells in plasma-cell myeloma will show cytoplasmic immunoglobulin with clonally restricted light chain (125, 126 and 127). The plasma cells in plasma-cell myeloma generally are negative or SIg and B cell-associated antigens but do demonstrate plasma-cell–associated antigens.

Immunostaining of plasma cells in the bone marrow may be useful in distinguishing benign plasma cells from nonsecretory

TABLE 44.13. TRANSFORMATION AND SECONDARY TUMORS IN PLASMA-CELL MYELOMA

Acute nonlymphocytic leukemia

myeloma, but may not clearly distinguish benign monoclonal gammopathy and amyloidosis with increased plasma cells from early myeloma. This is because plasma cells in the marrow of patients with benign monoclonal gammopathy and amyloidosis may also show a restricted light chain (125, 126, 127 and 128). However, in benign monoclonal gammopathy, the κ:λ ratio usually is less altered from normal than in plasma-cell myeloma (125).

Numerous other special studies have been performed in plasma-cell myeloma, including serum β_2-microglobulin (129, 130), plasma-cell labeling indices (131, 132), chromosome analysis (133, 134), ploidy analysis (135), and growth fraction with Ki-67 (136). Some of these may have potential prognostic importance.

Change with Progression and Transformation

A small percentage of patients with plasma-cell myeloma may show some morphologic change with time. These changes are listed in Table 44.13.

About one third of patients who qualify for the diagnosis of plasma-cell leukemia have transformed from a more typical presentation of plasma-cell myeloma (122). The remainder is *de novo*, as described earlier. Transformation to plasma-cell leukemia shows many clinical features in common with *de novo* plasma-cell leukemia.

Pleomorphic, plasmablastic, or anaplastic morphologies of myeloma can be seen at diagnosis; however, they also may develop in association with aggressive disease progression and extraosseous spread (32). A variety of other terms have been applied to this aggressive transformation, including dysplastic myeloma and immunoblastic sarcoma. These forms of transformation are probably derived from the same clone as the original tumor.

CLL associated with plasma-cell myeloma usually is diagnosed simultaneously; however, rare cases of CLL developing after a diagnosis of plasma-cell myeloma have been reported (137).

The increased incidence of myelodysplastic syndrome and acute nonlymphocytic leukemia in myeloma usually is attributed to prior alkalating agent therapy; however, there are isolated reports of nonlymphocytic leukemia developing in association with plasma-cell myeloma without prior therapy (138, 139). Therapy-related myelodysplastic syndrome and acute nonlymphocytic leukemia have much poorer prognoses than *de novo* disease.

Staging, Therapy, and Prognostic Features

Prognosis in plasma-cell myeloma is based primarily on the clinical staging scheme outlined in Table 44.14(140). The features listed in the table, which determine the stage of the patient, in general correlate with the tumor burden present. About 15% of patients present as stage I disease, and most of these have a creatinine level of 2 mg/dL or less (status A). Stage II comprises 30% of patients, and only 5% to 10% of these have renal status B. More than half of the patients present with stage III disease, and half of these have a creatinine level above 2 mg/dL (status B).

TABLE 44.14. CLINICAL STAGING OF PLASMA CELL MYELOMA (119)

Stage I	All of the following:
	Hg > 10 gm/dL
	Calcium > 12 mg/dL
	Normal bone on radiograph or solitary lesion only
	Monoclonal protein
	IgG < 5 gm/dL
	IgA < 3 gm/dL
	Urine light chains < 4 g/24 h
Stage II	Fitting neither stage I nor III
Stage III	One or more of the following:
	Hg < 8.5 gm/dL
	Calcium > 12 mg/dL
	Advanced lytic bone lesions
	Monoclonal protein
	IgG > 7 gm/dL
	IgA > 5 gm/dL
	Urine light chains > 12 g/24 h
Renal Status A = creatinine < 2 mg/dL	
Renal Status B = creatinine > 2 mg/dL	

(From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984;1:445–481.)

In addition to the staging system, the following features of plasma-cell myeloma have been shown to be associated with a higher stage and worsened prognosis: elevated β_2-microglobulin (129, 130) and labeling indices (130), abnormal karyotype or DNA content (133, 134 and 135), immature or plasmablastic plasma cell morphology (111, 112, 113 and 114, 141), and pattern of marrow infiltration (142). β_2-Microglobulin appears to be the most widely used clinically.

Plasma-cell myeloma is a progressive disease that, similar to CLL, is difficult to cure. The median survival of patients with stage I disease is 6 years; with stage II, 4 years; and with stage III, 1 year. Patients with renal status A live a median of 3 years, while those with renal status B live less than 6 months (140).

Plasmacytoma

Plasmacytoma is a rare disorder characterized by a mass lesion of neoplastic plasma cells (143, 144). Although plasmacytomas usually are seen in the surgical pathology laboratory rather than the hematology laboratory, bone-marrow examination and serum and urine protein studies frequently are done subsequent to the diagnosis of plasmacytoma to rule out spread to the bone marrow. Also, as mentioned in the previous section, plasma-cell myeloma may develop extramedullary plasmacytomas late in the course of disease. Plasmacytomas can be solitary or multiple and may present in the bone (spine, pelvis, femur, etc.) or as an extramedullary lesion (upper respiratory tract, lymph nodes, spleen, skin, gastrointestinal tract, etc.). As with plasma-cell

myeloma, plasmacytomas are seen predominantly in older individuals, with a male predominance.

Immunologic Studies

When plasmacytomas are localized at presentation (solitary plasmacytoma), the presence of an associated monoclonal gammopathy is uncommon and, if present, should disappear as the solitary plasmacytoma is treated. With dissemination, the incidence of a monoclonal gammopathy increases, with IgG and κ being the predominant monoclonal gammopathies seen.

Therapy and Change with Progression

Eventual dissemination of plasmacytomas is seen in about one third to one half of patients with solitary plasmacytoma of bone. Eventual dissemination usually results in the classic picture of plasma-cell myeloma. Some cases may take up to 15 years before dissemination occurs. Extramedullary plasmacytomas have a lower incidence of eventual dissemination, and dissemination of extramedullary plasmacytoma is to lymph nodes, other extramedullary sites, and bone. Treatment for solitary plasmacytoma is radiation therapy.

Waldenström's Macroglobulinemia

Waldenström's macroglobulinemia is an uncommon disease characterized by an IgM monoclonal gammopathy and proliferation of lymphocytes in the bone marrow, which show varying degrees of differentiation into plasmacytoid lymphocytes and plasma cells (145). Waldenström's macroglobulinemia is derived from a cell that is functionally intermediate between the lymphocyte of CLL and the plasma cell of plasma-cell myeloma. The disease primarily affects the bone marrow, with frequent involvement of lymph nodes, spleen, and liver. Unlike plasma-cell myeloma, lytic bone lesions are rare. The morphology of the proliferation in Waldenström's macroglobulinemia is consistent with the diagnosis of lymphoplasmacytoid lymphoma in the REAL non-Hodgkin's lymphoma (discussed later). Thus, Waldenström's macroglobulinemia can be considered the bone marrow counterpart of lymphoplasmacytoid malignant lymphoma. In Waldenström's macroglobulinemia, as in plasma-cell myeloma, disease may be caused by the infiltrative nature of the neoplastic cells or by deleterious effects of the protein abnormality. Similar to CLL and plasma-cell myeloma, Waldenström's macroglobulinemia is a disease of older individuals and has a male predominance. Its prognosis is intermediate between CLL and plasma-cell myeloma.

Diagnostic Features

As stated above, the diagnosis of Waldenström's macroglobulinemia is made from a combination of bone-marrow findings and the presence of an IgM monoclonal gammopathy. The bone marrow frequently aspirates poorly because of increased reticulin in the marrow infiltrate. On marrow smears, there is a mild to marked lymphocytosis composed of mature lymphocytes with varying numbers of plasma cells, as illustrated in Fig. 44.20. Plasmacytoid

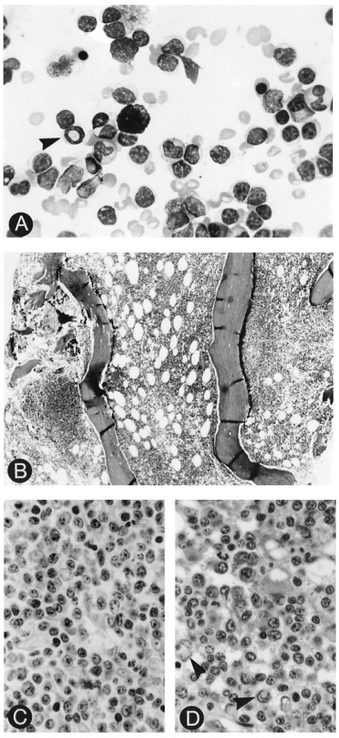

FIGURE 44.20. Waldenström's macroglobulinemia. **A:** Marrow smear. Note the numerous lymphocytes, several plasma cells, a Dutcher body (arrow), and a tissue mast cell. **B:** Trephine biopsy. In the left field, the infiltrate is focal. In the center between the two long trabeculae, it is primarily interstitial, and in the right field, it is paratrabecular. **C, D:** Note numerous lymphocytes and occasional plasma cells. In (**D**) Dutcher bodies (pale, intranuclear inclusions) are indicated with arrows. Hematoxylin and eosin, 600X (**A, C, D**), 50X (**B**). (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone, 1984;1:445–481.)

lymphocytes, which are morphologically intermediate between plasma cells and lymphocytes, may or may not be present to form a morphologic bridge between the lymphocytes and plasma cells. Tissue mast cells are increased frequently, and occasional Dutcher bodies may be observed. The peripheral blood in Waldenström's macroglobulinemia usually does not show lymphocytosis; however, there may occasionally be an elevated WBC count of up to 15,000/mm^3, with cells similar to those seen in the bone-marrow aspirate.

On bone-marrow sections, there usually are focal paratrabecular and nonparatrabecular infiltrates of mature lymphocytes with associated smaller numbers of plasma cells and plasmacytoid lymphocytes (Fig. 44.20B and Fig. 44.20C) (146, 147). The degree of involvement may range from small focal aggregates to extensive diffuse replacement, or, more rarely, there may be a diffuse interstitial infiltrate. In early marrow involvement, the marrow smears may show no increase in lymphocytes and plasma cells, and the marrow sections may show only small aggregates, which are difficult to distinguish from benign aggregates.

Morphologic Variability and Differential Diagnosis

Cases of Waldenström's macroglobulinemia may show more or less plasmacytic differentiation. This is the basis for the distinctions “lymphoplasmacytoid” and “lymphoplasmacytic” Waldenström's macroglobulinemia (146, 147). Scattered transformed cells similar to prolymphocytes of CLL, or cells with increased nuclear irregularity also may be seen in Waldenström's macroglobulinemia. Cases with increased large transformed cells (immunoblasts) have been termed “polymorphous” (146).

IgM monoclonal gammopathy can be seen in a variety of processes other than classic Waldenström's macroglobulinemia (145, 146, 149). Table 44.15 summarizes the variety of morphologies associated with monoclonal IgM. Technically, only patients with a morphology of lymphoplasmacytoid lymphoma in the bone marrow have classic Waldenström's macroglobulinemia. Patients with an IgM monoclonal gammopathy and small lymphocytic lymphoma (SLL) or CLL who have no plasmacytoid differentiation usually are not considered to have Waldenström's macroglobulinemia. The 10% lymphomas with IgM monoclonal gammopathy shown in Table 44.15 are lymphomas with more poorly differentiated morphologies such as large-cell lymphomas with plasmacytoid differentiation. These cases also should not be diagnosed as Waldenström's macroglobulinemia. It is of interest that lymphomas also can rarely have IgG monoclonal gammopathies (149).

TABLE 44.15. MORPHOLOGIC ENTITIES ASSOCIATED WITH MACROGLOBULINEMIA

Morphology	Approximate Frequency in Patients with Macroglobulinemia (%)
Lymphoplasmacytoid lymphoma	50
Small lymphocytic lymphoma or CLL	10
Other lymphomas	
diffuse	10
follicular	Rare
Other leukemias	Rare
Plasma-cell myeloma	Rare
Lymphoid aggregates in bone marrow	15
No morphologic lesion	15
	100

CLL, chronic lymphocytic leukemia (From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. *Laboratory Hematology*. New York: Churchill Livingstone 1984;1:445–481.)

Thirty percent of patients with a monoclonal IgM have no identifiable accompanying neoplastic lesion, but instead have benign-appearing lymphoid aggregates or no morphologic lesion. Such cases may be referred to as essential macroglobulinemia. These patients may have symptoms related to the protein abnormality (high serum viscosity, peripheral neuropathy cold agglutinin disease, coagulation disorders, etc.), or they may have no symptoms at all, the protein abnormality being identified incidentally on serum protein electrophoresis. This latter asymptomatic set of patients, who usually have less than 3 g/dL IgM monoclonal gammopathy would fit the category of benign monoclonal gammopathy (discussed in a later section).

Immunologic and Other Studies

As for plasma-cell myeloma, serum and urine immunofixation electrophoresis is of major diagnostic usefulness in patients suspected of having Waldenström's macroglobulinemia. Interestingly, a small percentage of patients with the classic clinical and morphologic features of Waldenström's macroglobulinemia have, instead of an IgM monoclonal gammopathy, an IgG or an IgA monoclonal gammopathy (150). Whether these patients should be included in the diagnostic category of Waldenström's macroglobulinemia is debatable.

Immunologic study of the cells on sections or smears in Waldenström's macroglobulinemia usually is not necessary because the monoclonal gammopathy serves as a clonal marker for the disease. When studied, the cells in Waldenström's macroglobulinemia will show cytoplasmic immunoglobulin of a clonally restricted light chain as well as B-cell surface markers (1, 8, 20, 151). Evaluation of bone-marrow cells using flow cytometry, immunofluorescence, and immunohistochemistry has demonstrated a light-chain restricted clone of cells in a majority of patients who have IgM monoclonal gammopathy but morphologically nondiagnostic bone marrow (151). This study concludes that patients with more than 20% “clonal” mononuclear cells in a morphologically nondiagnostic marrow without symptoms should be diagnosed as having lymphoplasmacytoid lymphoma (Waldenström's macroglobulinemia) rather than essential macroglobulinemia or a benign monoclonal gammopathy. Further investigation is necessary to confirm this conclusion.

Changes with Progression and Transformation

Occasional cases of Waldenström's macroglobulinemia show transformation to a more aggressive cell type, such as large-cell immunoblastic lymphoma (32). Like plasma-cell myeloma, rare cases also may develop acute nonlymphocytic leukemia after long-term therapy with alkylating agents (32).

About 20% of patients who present initially with an apparently benign IgM monoclonal gammopathy and no definitive

evidence of a lymphoid malignancy will develop a morphologically diagnosable hematologic malignancy. The median time for this to occur is slightly more than 4 years after the initial diagnosis (145).

Staging, Therapy, and Prognostic Features

Like CLL and plasma-cell myeloma, Waldenström's macroglobulinemia is a progressive, noncurable disease. It has a prognosis intermediate between CLL and plasma-cell myeloma, and the therapeutic approach is fairly similar to that for CLL. The bone marrow pattern and the degree of infiltration may have some prognostic significance, with a focal nodular pattern having a better prognosis than an extensive diffuse infiltrate (146, 152). Of the three morphologic variants described earlier, the lymphoplasmacytoid type has the best prognosis and the polymorphous type has the poorest (146, 147), however, another study could find no morphologic correlation with survival (147).

Heavy-Chain Disease

These rare disorders are characterized by a cellular proliferation of plasma cells and/or lymphoid cells and production of a monoclonal gammopathy composed of an incomplete heavy chain without an associated light chain (153). Thus, on immunofixation electrophoresis, the clonal protein reacts with antisera to heavy chains but not to light chains. Heavy-chain disease involving γ, μ, and α chains have been described (154, 155 and 156). The age range for heavy-chain disease is wider than that of the immunoproliferative disorders described in the preceding sections. Of the three disorders, α chain disease has the youngest age distribution, being seen primarily in the second and third decades. The organ distribution of the cellular proliferation depends on the heavy chain involved.

γ Heavy-Chain Disease

Clinical findings at presentation for this disorder, in addition to organomegaly and cytopenias, include autoimmune disease, swelling of the uvula, and neuropathy (153, 154). Approximately 70% of patients with a finding of γ heavy-chain disease have a neoplastic lesion, which may involve bone marrow, Waldeyer's ring, lymph nodes, spleen, and liver. The morphology of the lesion is characteristically a mixture of plasma cells, lymphocytes, and immunoblasts; however, more rarely, the lesion in γ heavy-chain disease may be identical to that of CLL, SLL-plasmacytoid, or large-cell immunoblastic lymphoma. The 30% of patients without a morphologic lesion associated with γ heavy-chain disease will have either atypical infiltrates in the aforementioned sites or no morphologically recognizable abnormal proliferation.

μ Heavy-Chain Disease

CLL and SLL are the most common morphologic entities associated with production of μ heavy chains (153, 155). Rare cases of large-cell lymphoma also may be seen. Plasma cells in the bone marrow in this process characteristically have cytoplasmic vacuoles (157). Most patients also have free light chains in the urine. This is the rarest of the heavy-chain diseases.

α Chain Disease

Patients with this disorder usually present with gastrointestinal symptoms (153, 156). This is the most common form of heavy-chain disease and is characteristically seen in the Mediterranean area. A morphologic lesion in α chain disease is most commonly observed in the gastrointestinal tract and abdominal lymph nodes. The cellular proliferation in the lesion can range from a dense infiltrate of plasma cells in the *lamina propria* of the bowel and nodes to a large-cell lymphoma. The bone marrow rarely may be involved (158).

"Benign" Monoclonal Gammopathy

Occasionally, a monoclonal gammopathy will be identified by serum protein electrophoresis during routine screening or workup of an elderly patient for diseases other than immunoproliferative disorders (159). A patient who has a small monoclonal gammopathy with no symptoms referable to the protein abnormality and no B-cell malignancy or amyloidosis is considered to have a benign monoclonal gammopathy, also called monoclonal gammopathy of undetermined significance (MGUS). The majority of these patients will follow a benign course, without developing plasma-cell myeloma, lymphoproliferative disorder, or complications from protein production.

Some patients with benign monoclonal gammopathy appear to have a true benign neoplastic disorder. Evidence for this includes persistence of the monoclonal gammopathy over time in an asymptomatic patient, and the presence of a mild (less than 10%) increase in atypical clonal plasma cells. Other patients appear to have a premalignant disorder. Evidence for this is the eventual development of plasma-cell myeloma or a related malignant immunoproliferative or lymphoproliferative disorder in up to 10% to 20% of cases. Currently, it is difficult to determine which patients with benign monoclonal gammopathy will experience progression to a malignant disorder. In other patients, the benign monoclonal gammopathy may represent a restricted response to some unidentified antigen. This is based on these findings: rare monoclonal gammopathies have known specificity; some benign monoclonal gammopathies are transient; and in a hospitalized setting, about 25% of benign monoclonal gammopathies are related to inflammatory, connective tissue, or neoplastic disease (159). The term essential monoclonal gammopathy has been applied to the first two sets of patients, and secondary monoclonal gammopathy to the set of patients in whom the monoclonal gammopathy may represent a restricted response (160). Although this distinction is conceptually attractive, it is not always possible to distinguish between an essential and a secondary disorder in a given patient.

Diagnostic Features

Bone-marrow examination, if performed in benign monoclonal gammopathy, usually shows less than 5% nearly normal-appearing plasma cells. However, up to 10% or more atypical plasma

cells also may be consistent with a benign course. The term smoldering myeloma, as discussed previously, has been used to describe the asymptomatic patient who has more than 10% atypical plasma cells,

TABLE 44.16. CLASSES OF SERUM IMMUNOGLOBULIN IN BENIGN MONOCLONAL GAMMOPATHY (140)

Ig Class	Frequency (%)
IgG	75
IgA	15
IgM	10

TABLE 44.18. HODGKIN'S DISEASE: CLASSIFICATION AND INCIDENCE OF BONE MARROW INVOLVEMENT

Rye Classification	Relative Frequency	Incidence of Bone Marrow Involvement
Lymphocyte predominant	14%	0%
Nodular sclerosis	41%	2–10%
Mixed cellularity	31%	5–20%
Lymphocyte depleted	14%	45–70%

has a monoclonal gammopathy above 3 g/dL, and follows a benign course (102, 103). Atypical plasma cells similar to those illustrated in Fig. 44.14 can be seen in patients with benign monoclonal gammopathy. However, markedly atypical cells should raise the possibility that the patient has significant disease at another site and will have progressive disease.

The incidence of benign monoclonal gammopathy increases with age. Screening of healthy populations using serum protein electrophoresis has shown that 1% of patients more than 25 years of age and 3% of patients more than 70 years of age will have a benign monoclonal gammopathy (161). Another study using more sensitive serum protein electrophoresis showed a 5% incidence in a healthy population less than 65 years old (162). The incidence may be even higher when using immunofixation electrophoresis.

Immunologic and Other Studies

The class of serum immunoglobulin seen in benign monoclonal gammopathy is shown in Table 44.16, and the size of the monoclonal gammopathy is shown in Table 44.17 (163). Approximately 15% of patients with benign monoclonal gammopathy will show some decrease in other immunoglobulins, and at least 10% of patients with a serum benign monoclonal gammopathy will have free light chains (usually less than 1 g per 24 hours) in the urine (159, 163). Patients with benign monoclonal gammopathy composed of free urinary light chains and no monoclonal serum protein also have been observed (159).

Immunohistochemical studies on the bone marrow in cases of benign monoclonal gammopathy have demonstrated an excess of plasma cells with a clonally restricted light chain in a majority of patients (125, 126 and 127). Thus, identification of a clonal population in this setting does not imply a malignant diagnosis.

Evaluation of $ß_2$-microglobulinemia, labeling index of bone marrow plasma cells and peripheral blood lymphocytes, cytoplasmic 5-nucleotidase, and short-term bone marrow culture have been reported in benign monoclonal gammopathy (131, 132, 159, 164, 165 and 166).

Therapy and Prognosis

Approximately 10% to 20% of patients with benign monoclonal gammopathy will eventually develop plasma-cell myeloma, Waldenström's macroglobulinemia, lymphoma, or amyloidosis (159). Although a progressive increase in the monoclonal protein level is a good indicator of the eventual development of progressive disease, a small percentage of patients who show an increase of 1 to 2 g in the monoclonal gammopathy are found not to have developed symptomatic neoplastic disease on long-term followup (159). A bone-marrow examination at the time of the discovery of benign monoclonal gammopathy may or may not be indicated, depending on other clinical and laboratory findings. There is some evidence to suggest that cases of benign monoclonal gammopathy that will progress to plasma-cell myeloma can be identified using peripheral blood labeling indices (132). $ß_2$-Microglobulin is not clearly useful in this regard (159). Benign monoclonal gammopathies should not be overinterpreted as evidence for plasma-cell myeloma; they can be seen in patients with diseases masquerading as plasma-cell myeloma, such as osteoporosis and metastatic carcinoma.

Primary Amyloidosis

Primary amyloidosis (AL amyloidosis) as opposed to secondary amyloidosis (AA amyloidosis) is associated with a clonal production of light chains with secretion in the urine (Bence-Jones protein), even when not associated with an overt malignant-cell proliferation, thus it is included under the category of immunoproliferative disorders. In addition, amyloidosis may eventually develop in about 15% of patients with plasma-cell myeloma, with an especially high propensity in patients with λ light-chain monoclonal gammopathy (121).

Amyloidosis observed on bone marrow sections usually involves vessels; however, an interstitial infiltrative pattern also may be seen, as illustrated in Fig. 44.21. The presence of amyloidosis can be confirmed on marrow sections with thioflavin-T and Congo red stains. Because amyloid can be detected in the bone marrow in only one fourth of patients with primary systemic amyloidosis; the abdominal fat aspirate is the screening method of choice in confirming the diagnosis rather than bone-marrow biopsy.

In keeping with the concept that primary amyloidosis is an immunoproliferative disorder, it has been demonstrated that, as in benign monoclonal gammopathy, there is an excess of plasma cells of restricted light chain type in almost three fourths of the bone marrows in primary amyloidosis (128). A mild atypical plasmacytosis, as seen in benign monoclonal gammopathies or smoldering myeloma, also is seen in primary amyloidosis, sometimes with plasma cells embedded in interstitial amyloid deposits. When a patient with laboratory and clinical features of primary amyloidosis has more than 10% atypical plasma cells but no other features of plasma-cell myeloma, it becomes problematic as to whether the patient also should be diagnosed as having plasma-cell myeloma.

MALIGNANT LYMPHOMA

Part of "44 - Chronic Lymphoproliferative Disorders, Immunoproliferative Disorders, and Malignant Lymphoma"

Malignant lymphomas include a diverse group of disorders ranging from morphologically mature processes with an indolent course to highly aggressive processes with morphologic immaturity. Although these processes are diagnosed primarily by tissue biopsy, they frequently have manifestations in the blood and bone marrow. Blood and bone marrow manifestations are emphasized in this chapter; more specific details of morphologic diagnosis in extramarrow sites can be found in textbooks and articles devoted to lymph-node morphology (167, 168 and 169).

Malignant lymphomas are of two major types: Hodgkin's disease and non-Hodgkin's lymphoma. There is a major difference between these two types of lymphomas. In Hodgkin's disease, the infiltrate has a minority population of a large, pleomorphic neoplastic cell (the Reed-Sternberg cell) and a major population of reactive cells including predominantly lymphocytes, with variable numbers of admixed histiocytes, eosinophils, and plasma cells. In non-Hodgkin's lymphomas, the infiltrate is composed predominantly of the neoplastic lymphoid cell.

There have been multiple classification schemes for subclassification of non-Hodgkin's lymphomas over the past several decades. In the past, non-Hodgkin's lymphomas were subclassified on the basis of infiltrative pattern and on the basis of the cell size and nuclear characteristic. Pattern and cytology are still important features in modern-day classification; however, now with the availability of monoclonal antibodies for use on paraffin section material, it is possible to subclassify the non-Hodgkin's lymphomas more precisely based on their functional cell of origin. Functional cell of origin is the major basis of the revised European-American classification of lymphoid neoplasms (REAL), which will be used in this chapter (8).

The classification of Hodgkin's disease, on the other hand, has changed only to a minor degree in the last three decades (Table 44.18). Classical Hodgkin's disease is subclassified on the basis of whether or not a nodular sclerosing pattern is present and on the basis of cellular composition, i.e., lymphocyte predominance or depletion, and number of Reed-Sternberg cells (1, 168). More recently, lymphocyte-predominant Hodgkin's lymphoma has been divided into the classical variant, which is immunophenotypically similar to other classical subtypes, and nodular lymphocyte-predominant Hodgkin's lymphoma in which the Reed-Sternberg cell has an easily identifiable B-cell phenotype, and unlike the Reed-Sternberg cell of classical Hodgkin's disease, is CD30 and CD15 negative (8, 168).

Malignant lymphomas have variable involvement of the bone marrow and peripheral blood. The relative frequency of lymphomas and their incidence in the bone marrow are shown in Table 44.18 and Table 44.19 (169, 170, 171 and 172).

Non-Hodgkin's Lymphoma

Diagnostic Features

Non-Hodgkin's lymphomas usually are initially diagnosed by examination of a tissue biopsy of a lymph node or other extra-marrow site rather than bone marrow sections. Tissue diagnosis is based on the effacement of architecture by a neoplastic lymphoid infiltrate distributed in a follicular, mantle zone, marginal zone, paracortical T-cell, or diffuse pattern. Once a diagnosis of a neoplastic lymphoid infiltrate and its pattern are identified, the cytologic subtype is assessed. Immunologic marker studies are frequently used if the specific subtype is still in question.

The details of morphologic features of the more commonly encountered types of non-Hodgkin's lymphomas are outlined in Fig. 44.22, Fig. 44.23, Fig. 44.24, Fig. 44.25 and Fig. 44.26. Small lymphocytic and lymphoplasmacytoid lymphoma are morphologically indistinguishable from CLL and Waldenström's macroglobulinemia, respectively described in Fig. 44.1, Fig. 44.2, Fig. 44.5, and Fig. 44.20.

Many lymphomas are diagnosed initially on tissue biopsy, and the marrow, if involved, is diagnosed secondarily. However, there are situations in which a primary diagnosis can be made by examination of bone-marrow sections. General principles that apply to the primary as well as secondary diagnosis of non-Hodgkin's lymphoma in the bone marrow follow.

1. Bone marrow involvement can take a variety of patterns. In the early stages of involvement, the bone marrow usually is focally involved by aggregates of lymphoma cells. These aggregates may be either nonparatrabecular or paratrabecular (171). A lymphoma with a paratrabecular pattern is illustrated in Fig. 44.27. Multiple paratrabecular aggregates may be diagnosed as lymphoma solely on the basis of their pattern, whereas nonparatrabecular aggregates, which mimic benign lymphoid aggregates,

TABLE 44.19. NON-HODGKIN'S MALIGNANT LYMPHOMAS: CLASSIFICATION AND INCIDENCE OF BONE MARROW INVOLVEMENT

REAL Classification Diagnoses	Approximate Relative Frequency	Incidence of Bone Marrow Involvement
B-cell Lymphomas		
Precursor B-lymphoblastic lymphoma	*	*
Peripheral B-cell lymphomas		
Small lymphocytic lymphoma	5%	70%
Lymphoplasmacytoid lymphoma	*	75%
Mantle-cell lymphoma	10%	65%
Follicle-center lymphoma		
Grade I (small cell)	15%	50%
Grade II (mixed small and large cell)	15%	30%
Grade III (large cell)	5%	15%
Diffuse (predominantly small cell)	*	*
Marginal zone B-cell lymphoma	10%	*
Diffuse large B-cell lymphoma	30%	10%
Burkitt's lymphoma	5%	15%
High-grade Burkitt like lymphoma	*	*
T-cell and NK-cell lymphomas		
Precursor T-lymphoblastic lymphoma	*	*
Peripheral T-cell and NK-cell lymphomas	5%	*

* Data is not readily available because of variability in the distinction between lymphoma vs. leukemia, because the diagnosis is poorly defined, or because it contains multiple subtypes.

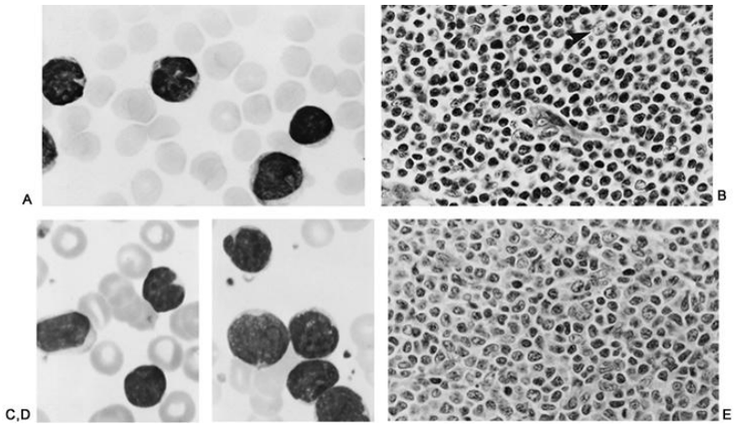

FIGURE 44.22. Lymphomas with a majority of cells the size of lymphocytes. **A, B:** Mantle-cell lymphoma. Many nearly normal appearing lymphocytes are present; however, some cells are slightly larger and there is moderate nuclear contour irregularity compared to small lymphocytic lymphoma. **C, D, E:** Small cleaved cells from a follicle-center lymphoma. On smears and sections, note the size range from small to large abnormal lymphocytes with scant cytoplasm and many sharply clefted nuclei. On sections in E, small cells predominate but scattered large cells the size of large-cell lymphoma are also seen. A normal histiocyte nucleus is present in the upper right center field of **B** (arrow) for size comparison. Wright's stain 1200X (**A, C, D**). Hematoxylin and eosin, 600X (**B, E**). (**A, C**, and **D**, From Dick FR. Chronic lymphocytic leukemia, prolymphocytic leukemia and leukemic non-Hodgkin's lymphoma. In: Koepke JA, ed. Laboratory Hematology. New York: Churchill Livingstone, 1984;1:325–357.)

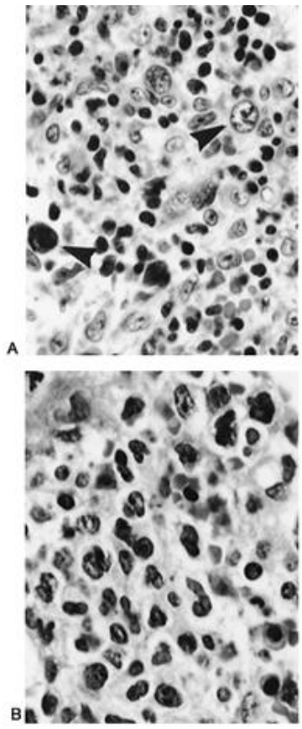

FIGURE 44.23. Large-cell lymphomas. Atypical large cells are numerous; however a mixture of cells the size of lymphocytes are also present. Note in (**A**) the hyperchromatic and convoluted large cells (arrows) and in (**B**) the numerous large clefted cells. The lymphoma in **A** immunophenotyped as a T-cell lymphoma and the lymphoma in **B** as a B-cell lymphoma. Hematoxylin and eosin, 600X.

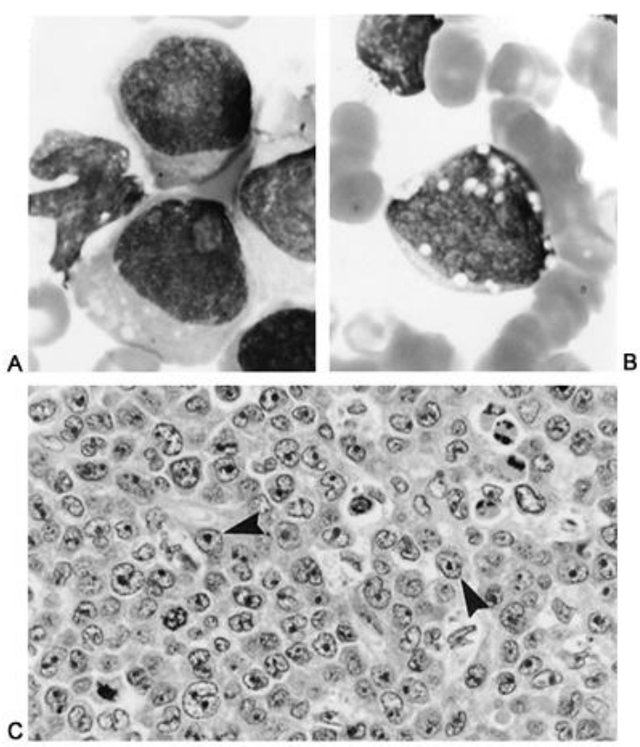

FIGURE 44.24. Large-cell lymphomas. These lymphomas have a majority of nuclei the size of a histiocyte nucleus or larger. On smears (**A, B**), there is marked variability in appearance of cells from one lymphoma to the next, (**A**) marked as a T-cell lymphoma and (**B**) as a B-cell lymphoma. **C:** This large-cell lymphoma shows many large non-clefted cells (arrows) with dispersed chromatin and nucleoli, as well as cells with nuclear pleomorphism. It immunophenotyped as a B-cell lymphoma. Wright's stain 1200X (**A, B**). Hematoxylin and eosin, 600X (**C**).

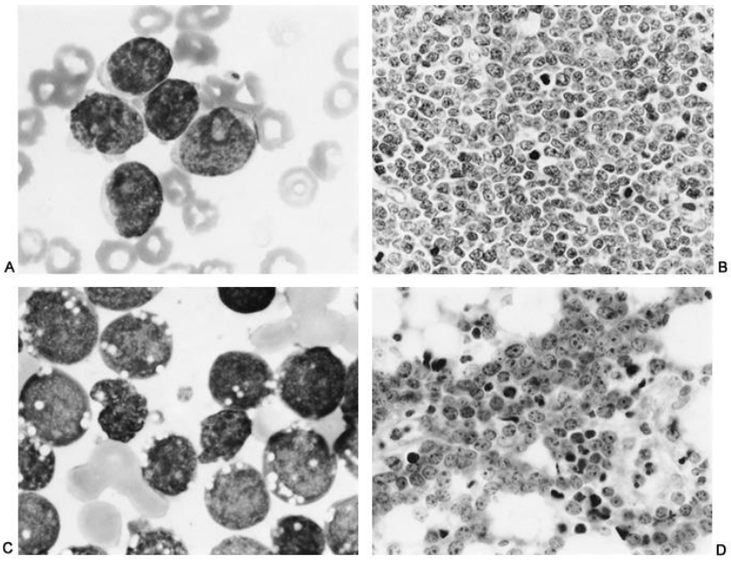

FIGURE 44.25. High-grade lymphomas with a blastlike appearance and very high mitotic activity. **A, B:** Lymphoblastic lymphoma. Lymphoma-cell nuclei are smaller than a histiocyte nucleus on sections, and on smears they are morphologically similar to blasts of acute lymphocytic leukemia of L1 and L2 type. Note the relative uniformity of cellular composition, stippled chromatin pattern, and mitotic activity on sections (**B**). Cells on smears and sections in lymphoblastic lymphomas (as in acute lymphocytic leukemia) may show a moderate degree of nuclear contour irregularity (convolution). **C, D:** Burkitt's lymphoma. Note the marked uniformity of cellular composition, hyperbasophilic cytoplasm, and crisp cytoplasmic and nuclear vacuoles. Nuclear size is slightly smaller than or about the size of a histiocyte nucleus on sections, and on smears the cells are morphologically similar to acute lymphocytic leukemia, L3 type. Note that some large-cell lymphoma cells (illustrated in Fig. 6A and Fig. 26B) may have, except for their size, some of the characteristics of Burkitt's lymphoma cells. Wright's stain 1200X (**A, C**). Hematoxylin and eosin, 600X (**B, D**).

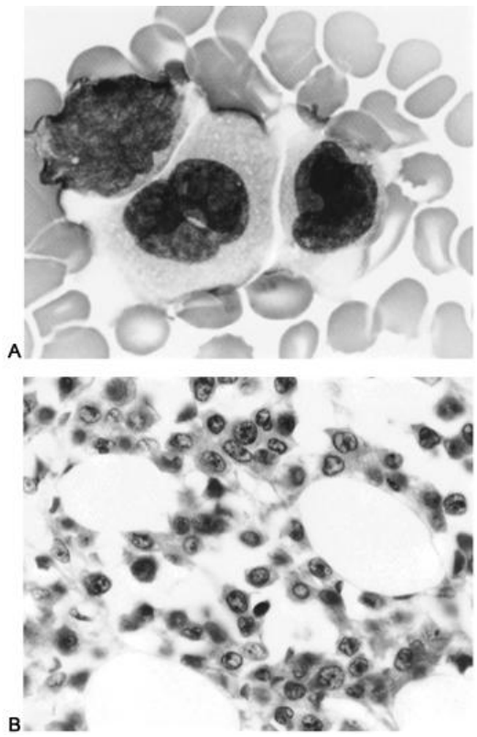

FIGURE 44.26. True histiocytic lymphoma/malignant histiocytosis, peripheral blood (A) and bone marrow section (B). Although this tumor resembles a large-cell lymphoma on sections, it is a malignancy of histiocytes. Note the resemblance of the cells on smears to large, highly pleomorphic monoblasts. The histiomonocytic nature of this process can be confirmed with a nonspecific esterase stain on smears or immunologic markers on sections or cell suspension. Wright's stain 1200X (A). Hematoxylin and eosin, 600X (B).

must be diagnosed using other features such as cytologic atypia or marker studies. As involvement increases, the marrow becomes more diffusely infiltrated and the focal pattern is obscured. Malignant lymphomas also may rarely have minimal involvement in an interstitial pattern in which lymphoma cells are diffusely admixed with normal marrow elements and don't form aggregates. When this occurs, it may be difficult to make a diagnosis from the examination of marrow sections, and the diagnosis may rest more heavily on identifying neoplastic lymphoid cells in aspirates or touch preparations, or on the use of immunologic markers.

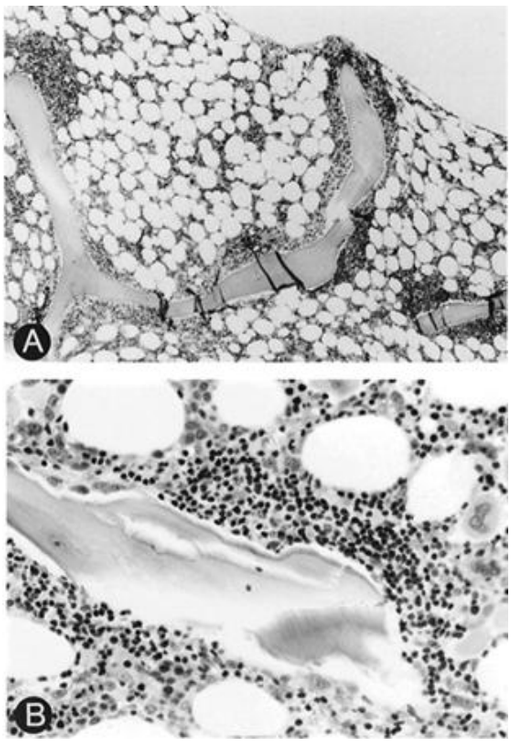

FIGURE 44.27. Paratrabecular pattern in a follicle center lymphoma. Note the “plastered on” or “piled up” appearance to most of the aggregates. The aggregate in the upper left field of (**A**) is not truly paratrabecular because its center appears to be away from the bone, and it could be touching bone by virtue of growth towards it. Note in (**B**) how the paratrabecular aggregate appears to be growing on the bone. Also note in (**B**) that the lymphocytes in this lymphoma are small and show only mild nuclear clefting, even though the lymph node biopsy showed considerable nuclear clefting. Hematoxylin and eosin, 50X (**A**), 240X (**B**).

2. Identification of the pattern of non-Hodgkin's lymphoma is rarely possible on bone-marrow examination. Focal aggregates of lymphoma can be seen in lymphomas that have a diffuse or follicular pattern on lymph-node biopsy. A focal pattern in the marrow is not equivalent to follicular lymphoma.
3. When assessing the cytology in non-Hodgkin's lymphoma, it is useful to compare the size of the nucleus of the lymphoma cells with the nucleus of a normal histiocyte on sections (or the nucleus of a myeloblast on smears). Small lymphocytic, lymphoplasmacytoid, mantle-cell, small-follicle-center cells, lymphoblastic, and small-cell variants of peripheral T-cell lymphoma have a nucleus that is definitely smaller than that of a histiocyte. Burkitt's lymphoma has a nucleus slightly smaller than or almost the size of a histiocyte nucleus, and the nuclei in large-cell lymphomas are the size of and larger than a histiocyte nucleus.
4. The bone marrow may show a lower grade subtype of lymphoma than an initial tissue biopsy (171, 172, 173, 174 and 175). For example, when a lymphoma of large-cell type is initially diagnosed in an extra-marrow site, the marrow may show a predominantly small cell type. This is particularly true of the follicle center and diffuse large-B-cell lymphomas. Thus, non-Hodgkin's lymphoma should not be definitively subtyped for purposes of therapy when a small-cell lymphoma is seen initially in the marrow, especially if an additional extra marrow site is available for biopsy. If the marrow is the only site available, then the clinician should be made aware of the potential problem of discordance. On the other hand, a primary diagnosis of large B-cell, or Burkitt's lymphoma in the marrow can be used for classification for therapy without biopsying an extra marrow site even if disease is present because discordance is not a problem with these subtypes. Although a primary diagnosis of a peripheral T-cell lymphoma can be made on bone marrow alone further subclassification T-cell lymphoma should be made with extreme caution. T-cell-rich B-cell variant of large B-cell lymphoma and Hodgkin's disease are in the differential diagnosis of T-cell lymphoma in the marrow (176, 177).
5. When faced with a lymphoma composed of small lymphocytes, and the marrow is the only site available, immunologic marker studies will be helpful in distinguishing among the small-cell types of B-cell lymphoma: small lymphocytic, lymphoplasmacytoid, mantle-cell, marginal-zone, and follicle-cell lymphomas (1, 177). These subtypes will be discussed later. Search for a monoclonal serum immunoglobulin should be performed if lymphoplasmacytoid lymphoma is a consideration.
6. Malignant lymphomas primarily represent tissue infiltration of neoplastic lymphoid cells, whereas leukemias are bone marrow and peripheral blood manifestations of neoplastic lymphoid cells. As shown in Table 44.20, for some specific cell types, the “lymphomatous” (tissue phase) and its “leukemic” or “marrow” counterpart have separate diagnostic terminology. For example, a neoplastic proliferation of the mature CD5-positive B cell with weak SIg is diagnosed as CLL when there is a peripheral blood lymphocytosis. When it involves tissues with minimal blood and marrow involvement, it is called SLL. Neoplastic proliferations of cells that comprise other types of lymphoma such as mantle-cell lymphoma; the follicle-center lymphomas; and large-cell lymphoma have no specific terminology for their leukemic phase, and thus these are simply diagnosed as the leukemic phase of malignant lymphoma. The archaic term “lymphosarcoma-cell leukemia” is no longer used.
7. In general, a trephine biopsy is superior to aspirate and particle sections in diagnosing malignant lymphoma in the marrow. This is because early bone marrow involvement is composed of small aggregates that may have increased reticulin and do not aspirate well. In addition, extensive marrow involvement may be partly fibrotic and result in a dry tap. In this latter situation, touch preparations are helpful in seeing cytologic detail. Because bone marrow involvement is frequently focal and may be minimal, bilateral bone marrow trephine biopsies of the posterior crests with five-stepped sections on each side generally are recommended (178, 179 and 180). The volume of bone marrow examined is also important because there may be focal, minimal involvement; thus, it is recommended that between the right and left biopsies a minimum total of 3 cm of trephine biopsy specimen in aggregate length be acquired, and more is preferable (181). This may require more than one pass of the trephine needle on each side. Lymphoma may rarely be seen on particle clot sections and not on trephine specimens; thus, these also should be carefully examined (178).
8. Of critical importance is the distinction between focal aggregates of lymphoma and benign lymphoid aggregates (Fig. 44.28A and Fig. 44.28B) (182). Important differential diagnostic features are listed in Table 44.21. Immunohistochemistry also may be of help as discussed in a later section.
9. Mixed cellular aggregates that are variably composed of lymphocytes, plasma cells, histiocytes, fibroblasts, endothelial cells, and immunoblasts may be seen in marrow involvement by lymphoma, especially peripheral T-cell lymphomas, Hodgkin's disease, and plasmacytoid lymphomas (Fig. 44.28C and Fig. 44.28D) (183, 184).

TABLE 44.20. TERMINOLOGY FOR "LYMPHOMATOUS" VS. "LEUKEMIC OR MARROW" MANIFESTATIONS OF LYMPHOID NEOPLASMS

"Lymphomatous" Counterpart	"Leukemic or Marrow" Counterpart
Small lymphocytic lymphoma	Chronic lymphocytic leukemia
Lymphoplasmacytoid lymphoma	Waldenström's macroglobulinemia
Burkitt's lymphoma	L3 acute lymphoblastic leukemia
Lymphoblastic lymphoma	L1 and L2 acute lymphoblastic leukemia
Mycosis fungoides	Sezary syndrome
Adult T-cell leukemia/lymphoma	Adult T-cell leukemia/lymphoma
Plasmacytoma	Plasma-cell myeloma

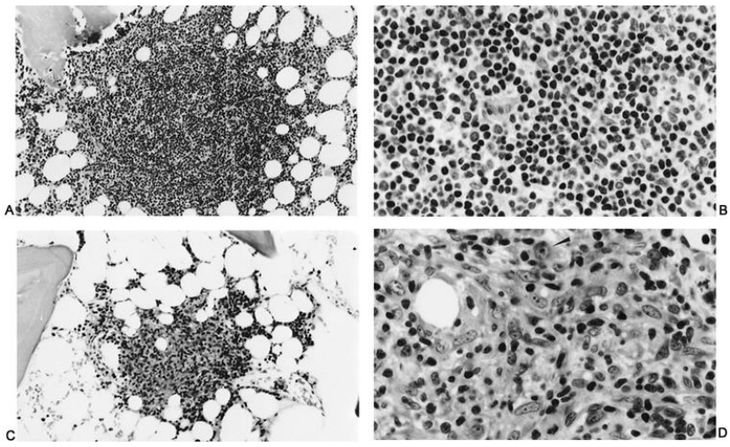

FIGURE 44.28. A, B: Large benign lymphoid aggregate. Note the mild to moderate degree of nuclear contour irregularity. **C, D:** Mixed cellular aggregate. Note the depletion of lymphocytes with admixed, histiocytes, fibroblasts, small vessels, and occasional large cells (immunoblasts) (arrow). This aggregate was seen in the marrow of a patient with a peripheral T-cell lymphoma. This aggregate is not diagnostic of marrow involvement because similar aggregates can be seen in a variety of other processes. Atypical large and small lymphoid cells similar to those seen in Fig. 44.23 or more extensive marrow infiltration would be necessary to make a definitive diagnosis of non-Hodgkin's lymphoma. Hematoxylin and eosin, 120X (**A, C**), 600X (**B, D**).

TABLE 44.21. DIFFERENTIAL DIAGNOSTIC FEATURES BETWEEN BENIGN LYMPHOID AGGREGATES AND FOCAL AGGREGATES OF LYMPHOMA

Feature of Aggregates	Benign	Lymphoma	Comment
Low Power Features			
Paratrabecular	Rare	Yes	
Nonparatrabecular	Usually	Yes	
Uniform rounded contour	Yes	Yes	
Irregular contour	Unusual	Yes	
Benign follicle center	Uncommon	Rare	Neoplastic follicles also are uncommon in bone marrow.
Poorly circumscribed spreading border	No	Yes	Especially in small lymphocytic lymphoma.
Circumscribed border	Yes	Yes	
Associated lipoid granulomas	Yes	Uncommon	
Large size	Uncommon	Yes	
Numerous	Yes	Yes	
Rare	Yes	Yes	
Small size	Yes	Yes	
Blood vessels	Yes	Uncommon	
Cytologic Features			
Minimal to mild nuclear contour irregularity	Yes	Yes	Seen in small lymphocytic, mantle-cell and follicle-center lymphoma.
Distinctly atypical cell type	No	Yes	Except for small lymphocytic, mantle-cell, and follicle-center lymphoma, which may show only mild nuclear contour irregularity.
Admixture of other elements (plasma cells, histiocytes, immunoblasts)	Yes	Sometimes	Lymphoplasmacytoid lymphoma, Hodgkin's disease, and other non-Hodgkin's lymphomas of peripheral T-cells may show a mixed cell population.

Because these mixed cellular aggregates also can be seen in infections and in autoimmune deficiency syndrome (AIDS) or angio-immunoblastic lymphadenopathy with dysproteinemia (AILD), which may be associated with or transform to lymphoma, the presence of mixed cellular aggregates in the marrow may result in very difficult differential diagnostic problems. Small mixed cellular aggregates should not be diagnosed as lymphoma unless they contain Reed-Sternberg cells morphologically and immunophenotypically consistent with a diagnosis of Hodgkin's disease, or contain atypical neoplastic lymphoid cells consistent with one of the subtypes of non-Hodgkin's lymphoma.

10. Criteria for marrow involvement vary depending on the lymphoma in question, and on whether the primary diagnosis has been made elsewhere. In general, less strict evidence is needed to secondarily diagnose marrow involvement than to make a primary diagnosis of lymphoma in the bone marrow. However, the presence of aggregates without neoplastic features should not be considered definitive evidence for secondary marrow involvement, even if the aggregates are numerous. Immunophenotyping may be of help in this situation if the aggregates contain a marked predominance of B-cells and the initial diagnosis was a B-cell lymphoma. This will be discussed in more detail later.
11. Lower-grade non-Hodgkin's lymphoma may undergo transformation to a higher-grade process, especially large-cell lymphoma. In this situation, the bone marrow may be the first site biopsied, resulting in a higher-grade marrow morphology than that seen in the original biopsy specimen (Table 44.22)(172, 173).

TABLE 44.22. MORPHOLOGIC VARIABILITY IN NHL AND HODGKIN'S DISEASE IN THE BONE MARROW, WHICH MAY LEAD TO DIAGNOSTIC DIFFICULTY

Non-Hodgkin's Lymphoma
Morphologic discordance with tissue biopsy

Posttherapy changes

NHL, non-Hodgkin's lymphoma

12. Reed-Sternberg–like cells can be seen in the marrow as well as in the lymph node in non-Hodgkin's lymphoma, especially in peripheral T-cell lymphoma, or in other lymphomas late in the course of the disease or with transformation (Fig. 44.29) (185, 186). The best way to distinguish non-Hodgkin's lymphoma from Hodgkin's disease is to identify an atypical lymphoid population in the infiltrate characteristic of a subtype of non-Hodgkin's lymphoma, in addition to the Reed-Sternberg–like cell. It is also helpful (but not always necessary) to have a tissue biopsy diagnosis of non-Hodgkin's lymphoma. Immunostaining also may be helpful if the Reed-Sternberg–like cells do not show the typical phenotype of Hodgkin's disease (187).

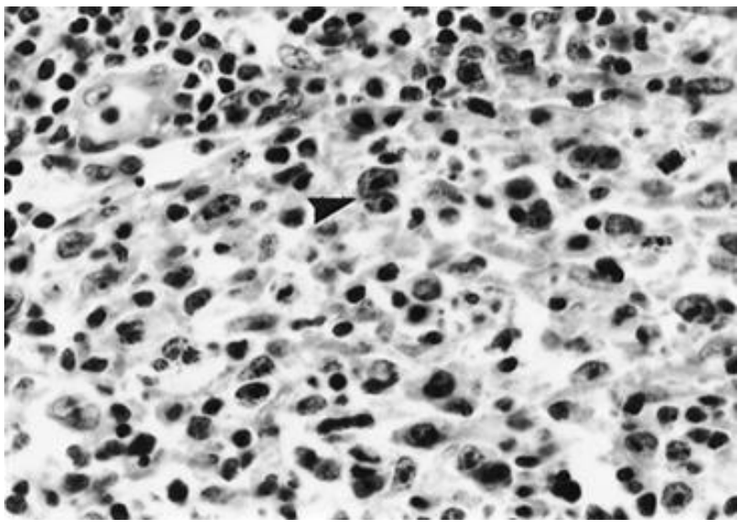

FIGURE 44.29. Follicle-center lymphoma with a Reed-Sternberg–like cell *(arrow)*. Hematoxylin and eosin, 600X.

Additional features of specific subtypes of non-Hodgkin's lymphoma and their differential diagnosis are described in the paragraphs that follow. Their characteristic marker studies are shown in Table 44.23.

Small Lymphocytic Lymphoma

SLL as diagnosed on tissue biopsy is essentially the tissue phase or the nonleukemic counterpart of CLL. Thus, to diagnose a patient as having SLL, the peripheral blood white count must be less than 5,000 lymphocytes/mm^3 (3). Otherwise, the lymph node or other tissue is diagnosed as SLL consistent with CLL, and the patient is diagnosed as having CLL. The pattern of marrow involvement

in SLL is similar to that of CLL, as illustrated in Fig. 44.1 and Fig. 44.2; however, a focal pattern is seen more commonly in SLL than is interstitial or diffuse extensive involvement (171). As in CLL, individual-cell morphology is not helpful in the diagnosis of SLL, because the tumor is made up of predominantly mature lymphocytes. The morphologic differential diagnosis of SLL includes primarily lymphoplasmacytoid lymphoma and mantle-cell lymphoma. Positivity for CD5, CD23, and CD43 with negative cyclin D1 and no IgM, monoclonal gammopathy is characteristic of SLL (16, 188, 189, 190, 191 and 192) (Table 44.23). If an aspirate is saved for flow cytometry, a clonal population of cells with weakly reacting surface immunoglobulin also will be helpful.

Lymphoplasmacytoid Lymphoma

As emphasized earlier, lymphoplasmacytoid lymphoma is morphologically the same disorder as Waldenström's macroglobulinemia, which was illustrated earlier in Fig. 44.20. The presence of a serum IgM monoclonal gammopathy and demonstration of plasmacytoid cells with clonal IgM cytoplasmic immunoglobulin if a significant monoclonal peak is not identified, are helpful in confirming the diagnosis.

Mantle-Cell Lymphoma

This subtype of lymphoma was not included in earlier classification schemes. It is now recognized as a distinct clinical pathologic entity (8, 15, 189, 191, 192, 193 and 194). It is characterized by a proliferation of small lymphocytes with a mild-to-moderate degree of nuclear irregularity (Fig. 44.22A and Fig. 44.22B) that in a lymph node may have a diffuse or a mantle-zone pattern that is characterized by nodules of lymphoma cells, some of which contain a benign-appearing germinal center. This lymphoma commonly has marrow involvement. The distribution in early bone marrow involvement usually is focal and nonparatrabecular; however, there also may be some element of a paratrabecular pattern. With extensive involvement, the pattern becomes more diffuse. On blood smears, many of the cells are fairly normal-appearing lymphocytes; however, a moderate number (10% to 20%) of cells with nuclear contour irregularity are seen (Fig. 44.22A). When the WBC is elevated, the process may be confused with CLL (15). The differential diagnosis of mantle-cell lymphoma includes primarily SLL and follicle-center lymphoma with a predominance of small cells. As indicated in Table 44.23 mantle-cell lymphoma can be distinguished on paraffin sections from these entities by its negativity for CD23 and CD10, and positivity with cyclinD-1 (16).

Marginal-Zone Lymphoma

Some cases of non-Hodgkin's lymphoma, especially the marginal-zone variant called splenic lymphoma with villous lymphocytes, may have hairy cytoplasmic borders and TRAP positivity and primarily involve the spleen (60, 177, 195). Marrow involvement is common but usually is more focal than hairy-cell leukemia. Distinction from hairy-cell leukemia may be very difficult, even with marker studies, however marker studies may be helpful if CD11c, CD25, and TRAP are negative. Because the infiltrative pattern in the spleen is different in non-Hodgkin's lymphoma (white pulp) than in hairy-cell leukemia (red pulp), splenectomy also may be useful in the differential diagnosis if the spleen is removed. As opposed to the splenic variant, nodal and extranodal variants of marginal-zone lymphoma rarely have marrow involvement.

Follicle Center Lymphomas

As indicated in Table 44.19, cells of follicle-center lymphomas, as initially described by Lukes and Collins, are composed of small and large (cleaved) cells and large (noncleaved or transformed) cells (196). On bone marrow sections, the early infiltrate of follicle-center lymphomas is characteristically focal with paratrabecular and occasional nonparatrabecular aggregates (171, 197). With more extensive involvement, the pattern becomes diffuse. To make a diagnosis of marrow involvement by follicle-center lymphoma when a diagnosis of lymphoma has previously been made on a marrow biopsy, one should see several distinctly paratrabecular lymphoid aggregates or focal infiltrates with definitely atypical cleaved lymphoid cells. The cytology on sections of follicle-center lymphoma involving the marrow may range from lymphoid cells with only mild nuclear contour irregularities (similar to mantle-cell lymphoma), to markedly clefted cells, to a mixture of large cells and small clefted cells, as illustrated in Fig. 44.22 and Fig. 44.23B. When the cytology of the cells is fairly bland and aggregates are small, the diagnosis of marrow involvement may have to be made on the basis of paratrabecular distribution of aggregates rather than on atypicality of the lymphoid cells. In follicle-center lymphomas, the cytologic atypicality and number of large cells in the bone marrow are very frequently less than in the lymph-node biopsy (171, 172).

When the marrow is extensively replaced, small clefted cells similar to those shown in Fig. 44.22C and Fig. 44.22D are seen on the aspirate. These cells are morphologically similar in appearance to the hematogones seen in the bone marrow of pediatric patients (171, 198).

The peripheral blood, similar to mantle-cell lymphoma, may be involved in follicle-center lymphomas. When the WBC is considerably increased, the peripheral blood also contains numerous small clefted cells. If the small clefted cells are not readily identified, and a lymph node biopsy has not been done, the case may be mistakenly diagnosed as CLL (198). If a previous or concurrent lymph node has not been biopsied, negativity of a SLL in the marrow to CD5, CD23, CD43, and Cyclin D1 and a positive CD10 suggests a follicle-center lymphoma.

As stated earlier, a primary diagnosis of small-cell lymphomas (SLL, mantle-cell, lymphoplasmacytoid, follicle-center, marginal-zone) should not be made on the basis of bone-marrow biopsy alone because a tissue biopsy may show a higher-grade cell type a follicular versus diffuse pattern cannot usually be determined and nuclear contour irregularity may be less pronounced in the marrow.

With minimal marrow involvement by the small cells malignant lymphomas described, it may be difficult to recognize lymphoma on bone-marrow aspirates if diagnostic aggregates are not present. Flow cytometry looking for a small clonal population may be indicated to identify minimal involvement in these cases.

Large-Cell Lymphomas

This morphologic subtype includes a heterogeneous group of lymphomas. Many cases represent the diffuse counterpart of follicle-center

lymphomas; however, others represent lymphomas derived from nonfollicular B cells or peripheral T cells (8, 167, 196). Bone-marrow involvement by large-cell lymphomas is illustrated in Fig. 44.23 and Fig. 44.24. The pattern of involvement by large cell lymphoma ranges from large focal areas of marrow replacement to interstitial infiltration by single cells that are difficult to identify on section material and may need immunohistochemistry to identify (Fig. 44.30). The differential diagnosis of large-cell lymphoma initially diagnosed in the bone marrow includes metastatic undifferentiated carcinoma, and if the marrow is completely replaced, acute leukemia. Occasionally, SLL may have numerous prolymphocytes and blastlike cells on lymph-node biopsy similar to Fig. 44.5B, and mimic a diffuse mixed lymphoma (17, 18, 199). When the bone marrow is examined in these cases, the marrow may show an infiltrate similar to SLL or CLL. This finding in the marrow should help the pathologist recognize the lymph node as a SLL with transformation as opposed to a more aggressive diffuse mixed lymphoma (199). Reed-Sternberg cells also may be seen in large-cell lymphoma in the bone marrow, and should be distinguished from Hodgkin's disease.

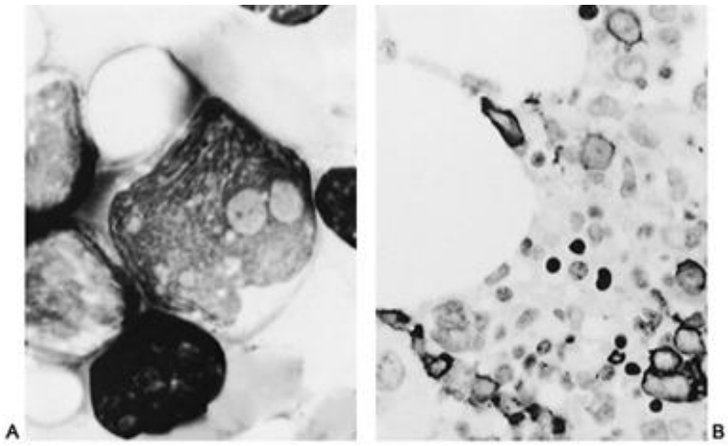

FIGURE 44.30. Large-cell lymphoma in bone marrow, diagnosed with the assistance of CD20 monoclonal antibody on paraffin section. **A:** On marrow smears in this case only, rare cells suspicious for large-cell lymphoma were seen. Sections (not shown) showed small clusters of large cells that could not be distinguished with certainty from reactive marrow elements. **B:** Immunoperoxidase staining with CD20 demonstrated small clusters and isolated positive cells (note dark staining of cytoplasmic outline), which were interpreted as B-cell, large-cell lymphoma. Wright's stain 1200X (**A**). Immunoperoxidase 600X (**B**).

Lymphoblastic Lymphoma and Burkitt's Lymphoma

As discussed previously, lymphoblastic lymphoma and acute lymphocytic leukemia (ALL) of types L1 and L2 are morphologically similar, and Burkitt's lymphoma and ALL L3 are morphologically similar. When a patient has a tissue mass diagnosed as lymphoblastic lymphoma or Burkitt's lymphoma, and the marrow shows only a small percentage of lymphoblasts with considerable marrow sparing, it is reasonable to diagnose the patient as having lymphoma. However, if the marrow is more extensively involved, then it becomes debatable whether the patient's condition should be called a malignant lymphoma with extensive marrow involvement or a leukemia with extramarrow mass(es) (see Table 44.20). In this situation, it may be advisable to diagnose the patient as having “leukemia/lymphoma” rather than struggle with deciding which came first. On the other hand, a patient presenting with a mass and blasts in the peripheral blood usually will have a bone-marrow biopsy done before a biopsy of the mass is done. At that point, a decision must be made whether to biopsy the mass, which will probably show morphology similar to the marrow.

Specific criteria for distinguishing leukemia from lymphoma for these cell types have been proposed; however, the criteria vary depending on the study group involved and thus before diagnosing an equivocal case as leukemia or lymphoma it would be prudent to consult with the hematologist/oncologist caring for the patient. Therapy for lymphoblastic lymphoma is frequently similar to aggressive therapy for ALL; thus, a firm commitment to a distinction between leukemia and lymphoma in this situation may not be necessary. Marker analysis of cells to distinguish leukemia from lymphoma is of little help. Marker analysis for ALL L3 and small, noncleaved-cell lymphoma is very similar. Lymphoblastic lymphoma is more often a precursor T-cell type (especially late thymocyte stage) than a precursor B-cell type; however, ALL also can be of precursor T-cell type. The morphologic features of the cells in ALL L1 and L2 and ALL L3 subtypes also are described in Chapter 43.

Morphologic Variability and Differential Diagnosis

As discussed in the preceding section, a characteristic of non-Hodgkin's lymphoma in the bone marrow is morphologic variability, in terms of both distribution and cytologic appearance. Some of the variability that may lead to confusion and difficulties in differential diagnosis are listed in Table 44.22. The first four of these already have been discussed in the previous section.

Fibrosis is an uncommon occurrence in the bone marrow in non-Hodgkin's lymphoma. When it does occur, however, diagnosis may be difficult unless abnormal lymphoid cells are identified in the fibrosis.

Epithelioid histiocytes, epithelioid-cell clusters, and granulomas may be admixed with non-Hodgkin's lymphoma in the bone marrow, but they also may be seen as an epiphenomenon without marrow involvement by lymphoma (200). Again, the most critical observation is to find abnormal lymphoma cells admixed with the histiocytes. Unless the histiocytes are a characteristic of the lymphoma at the previous site and lymphoma cells are admixed with histiocytes in the marrow, special stains for organisms should be performed.

Necrosis is uncommon but is very bothersome if present. This is because marrow necrosis in a patient with lymphoma is most likely from marrow involvement with lymphoma. However, a definite diagnosis cannot be made without viable tissue evident. Taking a biopsy at site may be helpful if it is crucial to know if the marrow is involved.

Following therapy for malignant lymphoma, the marrow may become altered by fibrosis or necrosis, making determination of residual disease difficult. In addition, aggregates in low-grade lymphoma may be reduced in size, so they are difficult to distinguish from benign lymphoid aggregates. When this occurs, it is best to not diagnose the lesion as lymphoma unless definite evidence of lymphoma is present. Instead, a comment should be made that lymphoma cannot be excluded.

Immunologic and Other Special Studies

A detailed description of the immunologic findings in non-Hodgkin's lymphoma is beyond the scope of this chapter. An overview of the evaluation of REAL classification of non-Hodgkin's lymphoma by marker studies can be found in the literature (8). A brief outline of the immunologic findings in non-Hodgkin's lymphoma is shown in Table 44.23. The more commonly used markers are represented. Except for lymphoblastic lymphomas, all of the non-Hodgkin's lymphomas show phenotypes similar to functionally mature/peripheral B or T-cells. Lymphoplasmacytoid lymphoma also may show cytoplasmic immunoglobulin.

Usually, marker analysis is not necessary to evaluate malignant lymphoma in the bone marrow because the diagnosis has been made on another site that may already have been immunophenotyped. Although most B-cell and T-cell lineage-specific markers can be done on paraffin section material, surface immunoglobulin to prove clonality and some lineage-specific markers such as CD11c can only reproducibly be done by flow cytometry; thus, it is suggested that a fresh aspirate for flow cytometry be saved on any patient with a suspected lymphoproliferative disorder in the bone marrow until the need for flow cytometry is determined. A fresh aspirate may be held as long as 24 hours, i.e., until after the section material has been processed and examined.

Specific situations in which immunophenotyping is useful in the evaluation of non-Hodgkin's lymphoma in the bone marrow or blood are described below.

1. The differential diagnosis of a lymphoma seen initially in the bone marrow, rests between two morphologically similar processes that have different immunophenotypes; for example, a large-cell lymphoma that is SIg negative or T-cell type can be differentiated from Burkitt's lymphoma or SLL can be distinguished from a mantle-cell lymphoma.
2. The morphology in the marrow has changed or is different from that of the tissue biopsy, and the question is whether a new tumor has developed or a transformation from the original tumor has occurred.
3. The differential diagnosis is a reactive lymphocytosis versus involvement with lymphoma. In this situation, identification of a clonally restricted light chain in B-cell process is particularly useful in confirming a lymphoid process as neoplastic. Some neoplastic T-cell processes may be identified if an abnormal T-cell phenotype characteristic of the disease in question is identified. However, with the exception of clonally restricted B-cells immunophenotyping may not help, and molecular techniques may be necessary to prove clonality.
4. Benign aggregates need to be distinguished from lymphoma. Immunohistochemistry may have some usefulness in distinguishing benign from neoplastic aggregates of low-grade lymphoma on paraffin sections if a marked predominance of B-cells possessing the immunologic characteristics of one of the low-grade lymphomas is identified (201, 202 and 203). Also lymphoplasmacytoid lymphoma may be identified by the presence of clonally restructed cytoplasmic immunoglobulin (151).
5. Identification of minimal disease. Current therapy is based on morphologic interpretation of involvement in the blood and bone marrow. New techniques, such as immunophenotypic or genotypic and clonal PCR analysis, have demonstrated that lymphoma cells may be present even when they are not seen morphologically (204, 205 and 206), especially in low-grade lymphomas. The importance of recognizing a minimal amount of marrow involvement is not yet clear. However, if autologous transplantation is a consideration, identification of residual disease in transplanted marrow or peripheral blood stem cells may assume greater importance.

A variety of other special studies have been performed on non-Hodgkin's malignant lymphomas, including chromosomal analysis (207), DNA content (27, 28), nuclear proliferation antigen Ki-67 (208, 209), and antigen receptor gene rearrangement (204, 205, 210, 211 and 212). Some of these may have applicability to lymphoma in the bone marrow and blood (185, 186).

Changes with Progression and Transformation

SLL and follicle-center lymphoma occasionally undergo morphologic transformation to lymphoma with the morphologic appearance of a more aggressive, large-cell lymphoma (32) (Table 44.24). This transformation may involve the bone marrow as well as other tissue sites; therefore, when a transformation is suspected, a bone-marrow examination may be performed before a tissue biopsy. Mantle-cell lymphoma also can undergo a blastic transformation that has a morphologic appearance of ALL in the bone marrow or blood with very blastlike cells (189). This can be distinguished from ALL with marker studies, because the blasts in transformation still retain the phenotype of the mature B-cell lymphoma. SLL may meet the criteria of CLL if the peripheral blood lymphocyte count exceeds 5,000/mm^3. Likewise, lymphoblastic lymphoma and small, noncleaved-cell lymphoma may develop bone marrow and blood involvement late in the course of the disease and become morphologically indistinguishable from acute leukemia L1, L2, or L3 subtypes. Although the marrow may become extensively involved late in the course of large-cell lymphoma, a leukemic blood picture with elevated white blood count is uncommon. Development of therapy-related myeloid leukemia similar to that seen in plasma-cell myeloma has been reported in non-Hodgkin's lymphoma(32).

Non-Hodgkin's lymphoma
Acute lymphoid leukemia
Acute myeloid leukemia
Myelodysplastic syndrome

Clinical Features

Prognosis in non-Hodgkin's lymphomas is highly dependent on the subtype of lymphoma and the extent of disease (stage). Depending

on the lymphoma type, the tumor can be seen in younger or older individuals. Low-grade lymphomas, which include peripheral B-cell lymphomas from small lymphocytic down through marginal zone on the classification list in Table 44.19, are seen almost exclusively in older individuals, whereas lymphoblastic lymphomas are seen predominantly in younger persons.

Therapy for non-Hodgkin's lymphoma is very dependent on the stage and grade of the lymphoma. Bone-marrow involvement automatically defines the patient as having widespread or stage IV disease. A few generalizations about therapy of non-Hodgkin's lymphomas follow.

Lymphomas composed of small lymphocytes usually are lumped together as low grade. Exceptions are that grade 2 follicle-center lymphoma are also considered low grade, and mantle-cell lymphoma acts more aggressively than the other low-grade lymphomas. Low-grade lymphomas are generally widespread and not curable; thus, therapy is directed at palliation as for CLL. The remaining lymphomas are frequently lumped together by clinicians as “high-grade” lymphoma. These lymphomas act aggressively if not treated but even if disseminated, long-term, disease-free survival may be achieved with intensive combination chemotherapy. Localized or bulky disease also may be treated with irradiation. Burkitt's lymphoma has the poorest prognosis of all tumors on the list. At present, autologous bone-marrow transplantation is a viable option for younger patients with a higher-grade lymphoma, widespread disease, and no marrow involvement. Autologous transplantation with purging or autologous peripheral stem-cell harvesting may have wider application in the future.

Hodgkin's Disease

Diagnostic Features

Hodgkin's disease usually is diagnosed on the basis of lymph node or other extramarrow tissue biopsy (8, 167, 168, 213). On tissue biopsy, there is effacement of architecture by an infiltrate that has as its basic component numerous mature lymphocytes and less frequent Reed-Sternberg cells. In addition, there may be varying numbers of benign histiocytes, eosinophils, and plasma cells. The subclassification of Hodgkin's disease is shown in Table 44.18.

When the bone marrow is involved by Hodgkin's disease, it is diagnosed by trephine biopsy and is almost never identified on clot sections, on smears, or in the peripheral blood (214, 215, 216, 217, 218 and 219). The marrow sections usually show focal infiltrates that are paratrabecular or nonparatrabecular. The infiltrates may be as small as lymphoid aggregates or may focally obliterate the marrow space, as in Fig. 44.31. The cellular infiltrates usually have a partly cellular and partly fibrotic appearance and are somewhat lymphocyte depleted, containing varying numbers of histiocytes and eosinophils and varying degrees of fibrosis. Reed-Sternberg cells usually are difficult to find, and numerous step sections may be necessary to identify them. With more extensive involvement, the marrow space can become completely obliterated by the infiltrate. The lymphocyte-depleted appearance of the bone marrow in Hodgkin's disease usually is present whether the lymph node shows a nodular sclerosing, mixed, or lymphocyte-depleted morphology. Thus, a subtype diagnosis of Hodgkin's disease should not be made on the basis of the bone marrow.

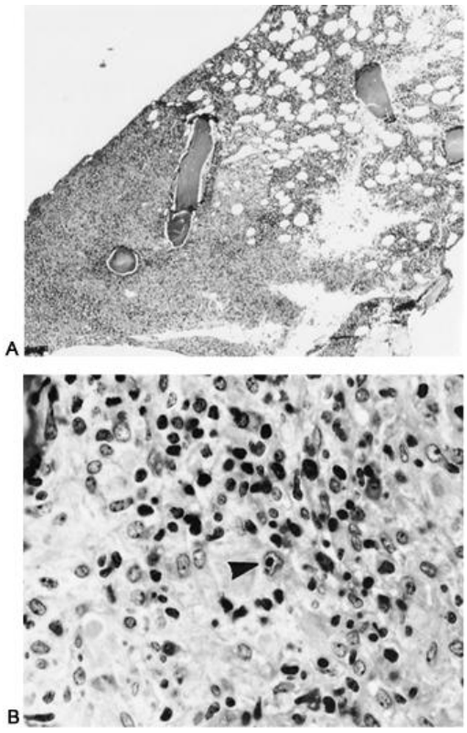

FIGURE 44.31. Hodgkin's disease, bone marrow. Note the extensive focal infiltrate in (**A**) with uninvolved normal marrow in the upper right field. Higher power (**B**) shows a mixed cellular infiltrate that is relatively lymphocyte depleted. A mononuclear Reed-Sternberg variant (half of a typical Reed-Sternberg cell) is indicated with an arrow. Hematoxylin and eosin, 25X (**A**), 600X (**B**).

Criteria for the diagnosis of Hodgkin's disease in the bone marrow are different depending on whether primary or secondary involvement is being diagnosed. When a diagnosis of Hodgkin's disease has been substantiated at another site, the requirement in the bone marrow is to see a cellular infiltrate consistent with Hodgkin's disease and at least one mononuclear variant of a Reed-Sternberg cell (Fig. 44.31B) (214, 215). To diagnose Hodgkin's disease primarily in the bone marrow, which may be necessary if the only other site of disease is in the retroperitoneum, several excellent typical Reed-Sternberg cells in addition to the typical infiltrate of Hodgkin's disease must be seen. Even then, one should be cautious, because non-Hodgkin's lymphoma can have Reed-Sternberg--like cells.

Lymphocyte-depleted Hodgkin's disease may present with marrow and retroperitoneal involvement and no easily accessible peripheral nodes on which a biopsy could be performed (218). Marker studies should be performed to confirm a primary diagnosis of Hodgkin's disease in the marrow. The background lymphocytes should predominantly express T-cell markers. The

Reed-Sternberg cells should be negative with CD45 and B- and T-cell markers, and be positive for CD30 and CD15 (8, 168, 213). Large cells associated with anaplastic large-cell non-Hodgkin's lymphomas that might mimic Reed-Sternberg cells are leukocyte common-antigen positive and should be T-cell or B-cell positive. They may also, however, be CD15 and CD30 positive, suggesting overlap between Hodgkin's disease and some anaplastic large-cell lymphomas (220).

Morphologic Variability and Differential Diagnosis

The morphologic variability that can be seen in Hodgkin's disease is listed in Table 44.22. In some cases of Hodgkin's disease, the marrow may be extensively fibrotic and mimic agnogenic myeloid metaplasia (Fig. 44.32) (219). Scattered lymphocytes within focal or diffuse areas of fibrosis should alert one to the possibility of Hodgkin's disease. When a fibrotic bone marrow infiltrate is seen in a patient with known Hodgkin's disease at another site, and an exhaustive search of adequate, stepped sectioned, bilateral trephine biopsy reveals no Reed-Sternberg cells or variants, the marrow should be considered suspicious for Hodgkin's disease. If the lesion contains an extensive, mixed cellular infiltrate that is otherwise typical of Hodgkin's disease, but no Reed-Sternberg variants, then the marrow may in consultation with the clinician be considered “consistent with, but not diagnostic of involvement” for purposes of staging.

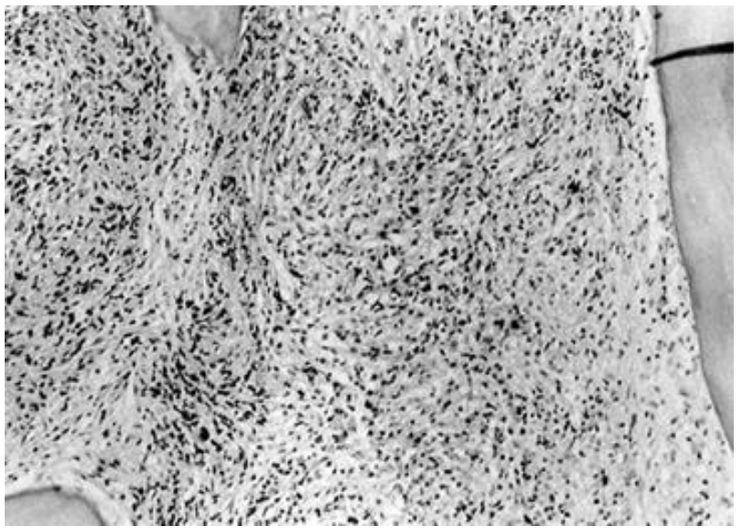

FIGURE 44.32. Hodgkin's disease showing extensive diffuse replacement of the marrow space by fibrosis. Lymphocytes admixed with the fibrosis suggested that this was Hodgkin's disease rather than agnogenic myeloid metaplasia, and Reed-Sternberg cells were identified after a careful search on multiple step sections. Hematoxylin and eosin, 120X.

Because of the mixed cellular infiltrate and the frequent presence of epithelioid histiocytes, the differential diagnosis of Hodgkin's disease in the bone marrow includes infectious disease, AIDS, and AILD. In some cases of Hodgkin's disease, granulomas may accompany Hodgkin's disease in the bone marrow; however, in other cases, nonspecific granulomas may be present in the bone marrow without marrow involvement by Hodgkin's disease (200).

Peripheral T-cell lymphomas are particularly prone to mimic Hodgkin's disease in the bone marrow (185). The critical morphologic feature to distinguish Hodgkin's disease from non-Hodgkin's lymphoma in the bone marrow, when a primary diagnosis is being considered on the marrow, is the appearance of the background lymphocytes. In Hodgkin's disease, as opposed to non-Hodgkin's lymphoma, these lymphocytes are nearly normal in appearance and do not show transitional forms to Reed-Sternberg cells. On the other hand, some variants of Hodgkin's disease may have numerous Reed-Sternberg cells and mimic an anaplastic large-cell lymphoma. This usually is more of a differential diagnostic problem with tissue biopsy than with bone-marrow biopsy.

Changes with Progression and Transformation

In general, the natural progression of Hodgkin's disease is toward the lymphocyte-depleted variant (See Table 44.24).

It is well documented that Hodgkin's disease is often associated with or develops non-Hodgkin's lymphoma (32). Cases of Hodgkin's disease that transform to large-cell lymphoma should be carefully studied to rule out the possibility of initial misdiagnosis of Hodgkin's disease or transformation of Hodgkin's disease to a syncytial or lymphocyte-depleted form of Hodgkin's disease with sheets of Reed-Sternberg cells (221, 222). Rare cases of development of ALLs also have been reported (32). Similar to other B-cell processes, myeloid leukemia can develop subsequent to therapy in Hodgkin's disease (32).

Staging, Therapy, and Prognostic Features

Survival in Hodgkin's disease is dependent on the stage of disease. Furthermore, morphologic subtypes of Hodgkin's disease correlate well with stage. Lymphocyte-predominant and nodular sclerosing forms generally correlate with a low incidence of marrow involvement, early stage of disease, and good survival, whereas mixed cellularity and lymphocyte-depleted Hodgkin's disease are correlated with a higher incidence of marrow involvement, a higher stage, and poorer survival. In general, therapy for early disease is local radiation with or without chemotherapy; for more advanced disease, therapy is combination chemotherapy with or without radiation. Transplantation is also used for younger patients with refractory disease.

Post-Transplant Lymphoproliferative Disorders

Post-transplant lymphoproliferative disorders usually develop months to years after transplantation and can be seen following solid-organ transplantation or bone-marrow transplantation (223, 224 and 225). The tumors arise secondary to severe immunocompromise, are usually of B-cell phenotype, and have been very highly associated with Epstein-Barr virus (EBV). They have many features in common with non-Hodgkin's lymphoma arising in severely immunocompromised hosts in general. They are particularly likely to develop in mismatched and T-cell–depleted bone-marrow transplant recipients.

Clinically, these disorders frequently develop as isolated extranodal disease but may present as widespread nodal disease, or they may rarely present with peripheral blood, bone marrow, or

CSF involvement (223). Morphologically, they show a spectrum, and three morphologic subsets have been described (225). One is that of a monomorphic-malignant process usually a large-cell lymphoma or less commonly plasma-cell myeloma. A second subset is described as a polymorphic lymphoproliferative disorder, containing a mixture of large cells (immunoblasts), immature plasma cells, mature plasma cells, and lymphocytes (Fig. 44.33A). Finally, a plasmacytic hyperplasia can be the tissue finding (225). When the former occurs on a tissue biopsy, and the diagnosis of malignant lymphoma is undisputed. However, when a polymorphous morphology is seen, distinction from a reactive process may be more difficult.

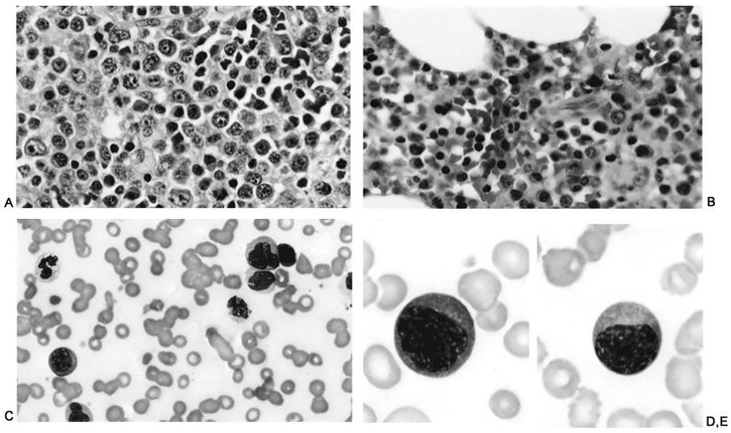

FIGURE 44.33. Post-transplant lymphoproliferative disorders. **A:** This polymorphous infiltrate is from a lymph node of a renal transplant patient. Note the spectrum of cells including lymphocytes, plasma cells, immature plasma cells, and large cells (immunoblasts). **B, C, D, E:** From a patient with a mismatched, T-cell depleted bone marrow transplant. Note the variety of large atypical plasmacytoid cells with deeply basophilic cytoplasm and dark, condensed nuclear chromatin. Hematoxylin and eosin, 600X (**A, B**). Wright's stain 600X (**C**), 1200X (**D, E**).

Post-transplantation lymphoproliferative disorders may occasionally involve the peripheral blood, bone marrow, or body fluid. The disorder should be strongly considered when large immature plasmacytoid cells are present in these sites in a patient at risk. These plasmacytoid cells are distinctly different in appearance from reactive (Downey) cells characteristic of infectious mononucleosis or cytomegolovirus (CMV) infection (Fig. 44.33B, Fig. 44.33C, Fig. 44.33D and Fig. 44.33E). This distinction is important because “Downey” cells may be associated with reactive processes in the post-transplant population. Immunophenotyping may be of some assistance in distinguishing reactive cells from cells suspicious for post-transplant lymphoproliferative disorder because Downey cells are T-cells, whereas the plasmacytoid cells of post-transplant lymphoproliferative disorders usually are B-cells, presumably transformed by EBV. Rare cases of T-cell post-transplant lymphoproliferative disorders have been described (225, 226).

The development of post-transplant lymphoproliferative disorders is thought to be a multistep process that starts in the immunocompromised host with EBV infection of B cells, followed by a polyclonal expansion of infected B cells (224). Out of this polyclonal expansion, oligoclonal B-cell proliferation can develop, presumably from lack of immune regulation. Subsequent to this, there may be eventual development of a monomorphic or dominant B-cell clone, which then behaves in a malignant fashion. If post-transplant lymphoproliferative disorders are studied for surface and cytoplasmic immunoglobulin at the polyclonal or oligoclonal stage, they are likely to express both κ and λ light chains, whereas the tumor at the monomorphic stage may show a clonally restricted light chain. An oligoclonal proliferation may be identified at an earlier stage by evaluating for clonal immunoglobulin gene rearrangement, clonal EBV incorporation, or clonal C-myc translocation (224, 225).

Therapeutic intervention in post-transplant lymphoproliferative disorders consists of removal of immunosuppression and treatment with acyclovir and interferon alpha. For more aggressive monomorphic disease combinations, chemotherapy may be

used. Prognosis for post-transplant lymphoproliferative disease is very poor; however, patients with less evidence of clonal transformation are more likely to respond to antiviral therapy and removal of immunosuppression than those with monomorphic and monoclonal proliferations (224).

Acknowledgment

The author would like to thank Barbara Ashbacher for her assistance in the preparation of this manuscript.

Chronic Myeloproliferative Disorders

Jane C. Huang

Hesham M. Amin

Serhan Alkan

Chronic myeloproliferative disorders (CMPDs) refer to a group of related primary disorders of the bone marrow that morphologically manifests as proliferations of differentiated myeloid cells. However, they are actually neoplastic, stem cell disorders, as proven by cytogenetic and molecular studies. CMPDs share overlapping features, but can be differentiated most of the time from each other by clinical, pathologic, and genetic findings. The four major categories of CMPDs consist of chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), and chronic idiopathic myelofibrosis (CIMF). A very simplistic way of distinguishing these disorders is to think of the predominant myeloid line that is manifested: granulocytes in CML, erythroid cells in PV, and megakaryocytes/platelets in ET. Other less common processes include hypereosinophilic syndrome/chronic eosinophilic leukemia and chronic neutrophilic leukemia. Chronic myelomonocytic leukemia, atypical chronic myeloid leukemia, and juvenile myelomonocytic leukemia were previously classified as CMPDs, but the new World Health Organization (WHO) classification of myeloid neoplasms has included them under a new category of myelodysplastic/myeloproliferative disorders (1).

It is important to remember the similar features that justify lumping these diseases together in the general category of CMPDs. CMPDs generally present with splenomegaly and peripheral blood cytosis. Significant dysplasia is usually not associated with CMPDs. The bone marrow frequently is fibrotic to various degrees, initially reticulin fibrosis and eventually progressing to collagen fibrosis. Megakaryocytes often are increased and characteristically clustered. The relationship between myelofibrosis and megakaryocytes has been extensively studied (see section on chronic idiopathic myelofibrosis).

These general features are useful in differentiating CMPDs from myelodysplastic syndromes. Like CMPDs, the bone marrow in myelodysplastic syndromes is hypercellular. However, myelodysplastic syndromes usually present with peripheral cytopenias and morphologic dysplasia without significant myelofibrosis or splenomegaly. Nevertheless, there remain some cases in which the distinction might be very difficult, as recognized by the WHO with the introduction of a new category, myelodysplastic/myeloproliferative disorders (1).

CHRONIC MYELOGENOUS LEUKEMIA

Part of "45 - Chronic Myeloproliferative Disorders"

CML is the best characterized and most common of all the CMPDs. This disease is defined by a molecular marker, the Philadelphia chromosome (Ph) with the breakpoint cluster region-Abelson murine leukemia virus (BCR-ABL) fusion gene that results from the translocation of chromosomes 9 and 22 [t(9;22) (q34;q11)]. Although CML is a stem cell disorder, it manifests as a predominant granulocytic proliferation. Therefore, some authorities prefer the term chronic granulocytic leukemia to refer specifically to this type of CMPD with the BCR-ABL rearrangement (2). It is important to distinguish CML from other CMPDs because the clinical course of CML is not indolent; CML patients usually progress to acute leukemia.

Etiology/Pathogenesis

The BCR-ABL hybrid protein, which is produced as a result of the characteristic translocation, is a constitutively active, cytoplasmic tyrosine kinase (3, 4). This upregulated tyrosine kinase activates multiple signal transduction pathways by phosphorylation (3, 4). Cytokines that regulate the growth of normal hematopoietic cells utilize the same signal pathways. As a result, CML cells escape normal cellular control of growth and differentiation (3).

Laboratory studies also have shown decreased adhesion of CML cells to bone marrow stromal cells (5, 6). This observation may account for the peripheral circulation of immature granulocytes and may indicate that the stromal cells have lost control of the growth of hematopoietic cells. The BCR-ABL hybrid protein has been demonstrated to transform hematopoietic cells to become independent of cytokines and growth factors (4, 5, 7). In addition, some protection from apoptosis or programmed cell death may be conferred on the CML cells by the BCR-ABL oncoprotein (5).

The underlying etiology for the development of CML is unknown. No genetic factors have been reported. Exposure to radiation has been implicated with an increased incidence of CML in atomic bomb survivors in Japan and ankylosing spondylitis patients who received spinal radiation (8, 9).

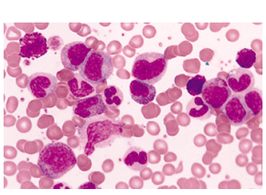

FIGURE 45.1. Characteristic peripheral blood smear of chronic myelogenous leukemia shows basophilia and granulocytosis with neutrophils and immature granulocytes.

Clinical Findings

The reported incidence of CML is about 10 to 20 cases per million people (10). The median age at diagnosis is 50 to 60 years, but CML can occur in much younger patients, including children (8). There may be a slight male predominance. Symptoms are variable and nonspecific, consisting predominantly of fatigue, anorexia, and weight loss. Up to 45% of the patients are asymptomatic at the time of diagnosis with the disease detected as a result of routine blood testing in many cases (4, 8). Some degree of splenomegaly (50% on physical examination) is usually present (4, 8). Hepatomegaly is present in about 10% to 40% of the patients (8). Lymphadenopathy is uncommon in the chronic phase of CML. In contrast to polycythemia vera and essential thrombocythemia hemorrhagic, and thrombotic complications are uncommon in the chronic phase of CML except in patients with marked thrombocytosis. Marked leukocytosis also appears to predispose patients to thromboses (8) and complications of hyperviscosity, including priapism, cerebrovascular accidents, and visual disturbances (8).

Chronic Phase

Peripheral Blood Findings

CML manifests as a primary proliferation of granulocytic elements. CML is included in the differential diagnosis whenever a granulocytosis is encountered in a complete blood count. Granulocytosis is defined as an absolute granulocyte count greater than 7.5×10^9/L. Granulocytes include not only segmented neutrophils, but also bands, metamyelocytes, myelocytes, promyelocytes and myeloblasts. Before considering the possibility of CML, reactive causes of neutrophilia must be excluded (Table 45.1). With the widespread use of colony stimulating factor (CSF) therapy, it is not uncommon to encounter a peripheral leukocytosis with a granulocytic left shift (11). A neutrophilia is expected in certain, “normal” physiologic states and responses such as infections that may be associated with a leukemoid reaction, pregnancy, neonates, stress/exercise, and acute hemorrhage/hemolysis.

TABLE 45.1. DIFFERENTIAL DIAGNOSIS OF REACTIVE NEUTROPHILIA

Infections/leukemoid reaction
Physiologic response (pregnancy, neonates, stress/exercise, acute hemorrhage/hemolysis)
Drugs/hormones (colony stimulating factor therapy, epinephrine, steroids)
Miscellaneous • Gout • Trauma • Autoimmune disorders

Peripheral blood findings in CML are rather characteristic and many times diagnostic. The white blood cell count is increased, but is variable and ranges between 20 and $1{,}000 \times 10^9$/L (median 150 to 200×10^9/L). The two most important findings are basophilia (greater than 0.2×10^9/L basophils) and granulocytosis at various stages of maturation (Fig. 45.1). Peripheral blood smear shows segmented neutrophils, bands, metamyelocytes, myelocytes, and promyelocytes without significant dysplasia. Often occasional blasts are seen, but usually no more than 1% to 2%. The presence of blasts in adults almost always indicates a hematologic malignancy, except in patients receiving CSF. Other features of peripheral blood smears in CSF therapy include very intense granulation in the granulocytes (11), but basophilia is often not present. In addition, occasional blasts in the peripheral blood smears of infants and children are not unusual, especially in tertiary medical settings.

Other peripheral blood findings in the chronic phase of CML include eosinophilia in 90% of the cases and some degree of monocytosis (9, 12). Thrombocytosis of variable degree usually is present, and levels as high as $1{,}000 \times 10^9$/L have been reached in some patients. Thrombocytopenia is extremely rare at diagnosis, and its presence would indicate an accelerated or blastic phase (8). Most patients are anemic at presentation with normal red cell morphology.

Bone Marrow Findings

Morphologic findings in the bone marrow biopsy do not add significant information for diagnostic purposes. However, a bone marrow biopsy is still recommended (13). Cytogenetic analysis for confirmation of the diagnosis of CML and for prognostic purposes is much better on bone marrow aspiration material than peripheral blood. A baseline picture of the bone marrow allows comparison with future changes, assessing initial degree of reticulin fibrosis, and looking specifically for foci of blasts in the core biopsy to indicate focal blastic transformation.

The cellularity is markedly increased, and a marked granulocytic hyperplasia is present with a myeloid to erythroid ratio of 10:1 or greater (Fig. 45.2). Megakaryocytes are increased and typically small and hypolobated (Fig. 45.3), in contrast to other CMPDs. Reticulin stain may show mildly increased reticulin fibrosis. Pseudo-Gaucher cells may be seen in 10% to 20% of the cases, representing the high release of sphingolipids from the leukemic granulocytes (9).

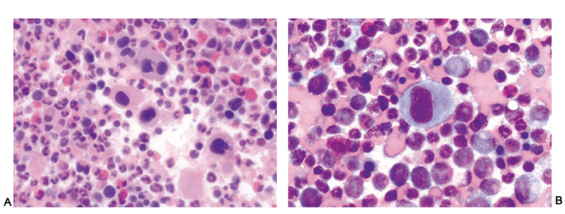

FIGURE 45.3. Typical megakaryocytes in chronic myelogenous leukemia are small and hypolobated. **A:** bone marrow clot section; **B:** bone marrow aspirate smear.

Genetic Studies

Evidence of the BCR-ABL translocation is now a diagnostic criterion. Standard cytogenetic evaluation is useful not only in confirming the diagnosis of CML, but has been useful in assessing

the efficacy of therapeutic regimens. Karyotypic analyses of bone marrow (preferably) or peripheral blood will show the t(9;22) or the Ph chromosome. The Ph chromosome is the abnormal, shortened chromosome 22 with fusion of the BCR gene in the long arm of chromosome 22 and ABL (human homologue of the Abelson murine leukemia virus) oncogene from long arm of chromosome 9 (Fig. 45.4). The breakpoints in the BCR gene of chromosome 22 involve two major areas: the major breakpoint cluster region (M-bcr) between exons 2 and 3 or between exons 3 and 4 and the minor breakpoint cluster region (m-bcr) within the first intron (upstream of M-bcr) (14). The M-bcr is associated with CML while m-bcr is seen in acute lymphoblastic leukemia cases.

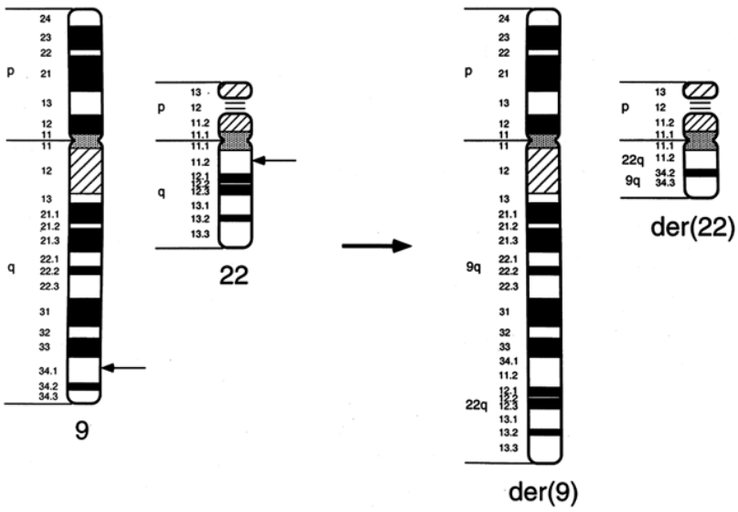

FIGURE 45.4. Schematic of the t(9;22) in chronic myelogenous leukemia. (Courtesy of V. Lindgren, PhD, Department of Pathology, Loyola University Medical Center, Maywood, IL.)

About 5% to 10% of CML cases will be negative for the t(9;22) by standard cytogenetics (15, 16). However, almost half of the Ph-negative CML cases will show evidence of the characteristic translocation by molecular studies. Because the translocation breakpoints in CML occur in a narrow 5.8 kb region of the BCR gene, Southern blot analysis following restriction enzyme digestion can be used for diagnosis (14). However, reverse transcriptase-polymerase chain reaction (RT-PCR) and fluorescence *in situ* hybridization (FISH) methods are now more commonly used in diagnostic laboratories.

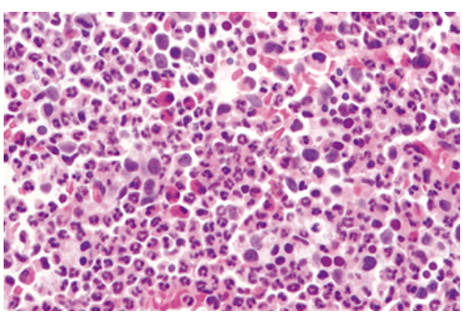

FIGURE 45.2. Bone marrow biopsy of chronic myelogenous leukemia showing marked hypercellularity and marked myeloid hyperplasia.

The breakpoint in the c-ABL gene of chromosome 9 can occur over a large region, more than 100 to 200 kb at the 5′ end upstream of exon 2 (14). As a result, PCR analysis of the BCR-ABL fusion gene is not possible, because PCR can only successfully amplify shorter DNA segments. However, RT-PCR using BCR-ABL mRNA as the template can be performed to detect the translocation. Breakpoint in the M-bcr region yields an 8.5-kb mRNA and 210-kd fusion protein that is typically found in chronic phase CML patients (14). Breakpoint in the m-bcr region produces a 7.0-kb mRNA and a 190-kd fusion protein that is seen in about half of the Ph-positive acute lymphoblastic leukemia (14). Although RT-PCR is more sensitive than standard cytogenetic analyses and southern blots, false positivity as a result of contamination is a significant concern. False negativity in RT-PCR also may occur because of different breakpoint region involvement.

Although RT-PCR analysis has been shown to be extremely sensitive in detecting the BCR-ABL rearrangement, the significance of PCR results in the monitoring of minimal residual disease after bone marrow transplantation or interferon therapy is not clear (17,18 and 19). A positive PCR analysis does not always predict impending relapse, and a negative result does not mean cure. In fact, there have been two studies demonstrating the detection of BCR-ABL transcripts by RT-PCR in normal, healthy individuals (20, 21). Therefore, using PCR results for CML patients in clinical therapeutic decision making are not recommended until more prospective studies are performed (22).

Cytogeneticists have been using FISH more frequently to detect the Ph chromosome. Directly conjugated fluorescent probes against the BCR and c-ABL genes are commercially available. Assuming the ABL probe is attached to a red/rhodamine fluorochrome, and the BCR probe has a green/FITC fluorochrome, normal cells will show two red and two green signals. In contrast, cells with the translocation will show one red signal, one green signal, and one yellow signal due to the fusion of the red and green signals, indicative of the BCR-ABL translocation (Fig. 45.5). Studies have shown the efficacy of FISH in the detection of the translocation at the time of diagnosis (23) and that FISH is a viable alternative to karyotyping and Southern blot analysis (24). FISH is fast and simple; results can be available in 24 hours. If

fresh material is not available for karyotyping or molecular studies, old peripheral blood or bone marrow smears may be used. Another advantage of FISH over standard cytogenetics is the capability to evaluate nuclei in interphase; therefore, the FISH method is not restricted by the quality and quantity of metaphases. However, there are limitations to FISH. No interlaboratory reproducibility and consistency have been established as specific regulations and guidelines are not available. The cutoff point for determining positive or negative results has to be determined by each individual laboratory. Therefore, the use of FISH in monitoring minimal residual disease would be difficult (23).

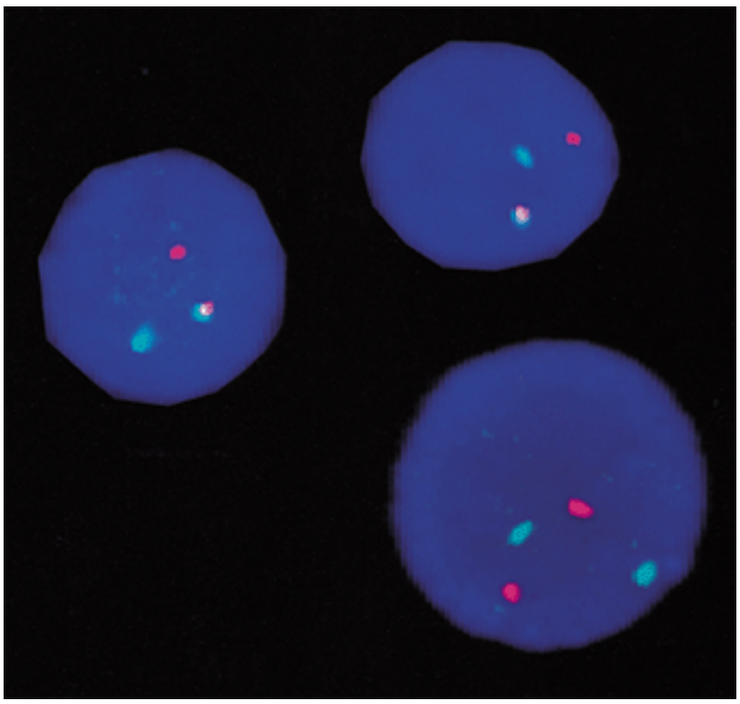

FIGURE 45.5. FISH (fluorescence *in situ* hybridization) analysis of the t(9;22) in chronic myelogenous leukemia. The normal cell shows two red signals of ABL gene and two green signals of the BCR gene. The two abnormal cells show one red signal, one green signal, and one yellow signal of the translocation due to the fusion of the red and green signals. (Courtesy of V. Lindgren, PhD, Department of Pathology, Loyola University Medical Center, Maywood, IL.)

There are other disorders with the t(9;22) besides CML (13). A small percentage of acute lymphoblastic leukemias also has a t(9;22), about 5% of pediatric and 20% to 25% of adult acute lymphoblastic leukemia. About half of acute lymphoblastic leukemia with the t(9;22) involve identical breakpoints in the BCR gene as CML (M-bcr), resulting in the 210-kD BCR-ABL protein. About half involve the breakpoint in the m-bcr (first intron) that produces the 190-kD fusion protein (14). The presence of t(9;22) in acute lymphoblastic leukemia is a poor prognostic indicator; patients in this particular group usually are older, present with a high white blood cell count, and are resistant to chemotherapy (25, 26). The Ph chromosome is also detected in a few cases of acute myelogenous leukemias (<1%). It has been reported in acute basophilic leukemia (27) and acute biphenotypic or mixed lineage leukemia (28).

Flow Cytometry

Flow cytometric analysis is not indicated for the chronic phase of CML. However, if blastic transformation occurs, immunophenotyping is critical in the characterization of the blasts to determine myeloid or lymphoid lineage.

Leukocyte Alkaline Phosphatase (LAP) Score

An additional study that may be useful in the workup of a possible CML case is the LAP score (29). The LAP score test is performed on fresh, heparinized peripheral blood. A cytochemical stain detecting the level of enzyme activity is analyzed by examining 100 neutrophils or bands for individual intensity of cytoplasmic reaction on a scale of 0 to 4. The individual scores of 100 cells are summed to obtain the total score. A wide normal range of the total score (30 to 150) has been reported. Because of the variability of observers and dyes among different laboratories, each laboratory should establish its own normal range. A low LAP score less than the established normal range is strong supportive evidence of CML. Paroxysmal nocturnal hemoglobinuria is an example of other rare conditions that may cause a low LAP score. However, a normal or high LAP score does not exclude the possibility of CML because superimposed infections/leukemoid reactions, pregnancy, drugs, and other inflammatory disorders can elevate the LAP score. Because of the analytical uncertainty of the LAP score, interpretation should be made with great caution (30).

Differential Diagnosis of CML

Leukemoid Reaction

The marked, polyclonal increase in neutrophils and bands secondary to inflammation, infection, cancer, and drugs is known as leukemoid reaction (31). The distinction between CML and leukemoid reaction is generally straightforward. While the total leukocyte count in leukemoid reaction is increased to more than 50×10^9/L, peripheral blood smear shows mostly mature neutrophils and bands with absence of basophilia. Furthermore, leukemoid reaction is associated with a normal cytogenetic analysis and high, or less commonly normal, LAP scores.

Chronic Myelomonocytic Leukemia and Atypical Chronic Myeloid Leukemia

As stated above, about 5% of CML lack cytogenetic (Ph-negative) and molecular evidence of the BCR-ABL fusion. The differential diagnosis for most of the remaining 5% of the cases includes chronic myelomonocytic leukemia (CMML) and atypical chronic myeloid leukemia (aCML) (32). Diagnostic criteria for CMML and aCML are not straightforward, but guidelines have been proposed (32,33 and 34). Most of the differentiating features are based on peripheral blood findings with emphasis on the degree of monocytosis, basophilia, immature granulocytosis, and dysplasia. The presence of peripheral basophilia has been found to be the best morphologic discriminator for Ph-positive CML (35). The presence of granulocytic dysplasia and monocytosis raises the possibility of CMML and aCML (34). The bone marrow findings in CMML and aCML are similar with hypercellular marrows except for the percentage of erythroid precursors (34).

CMML is a disease primarily seen in the elderly. Patients typically present with anemia and thrombocytopenia as well as splenomegaly and leukocytosis resulting from neutrophilia and monocytosis. The monocytosis is generally greater than 10% (33) and exceeds 1×10^9/L. However, basophilia usually is absent (less than 2% and less than 0.2×10^9/L), and immature granulocytes (metamyelocytes, myelocytes, and promyelocytes) are less than or equal to 10% (33). Granulocytic dysplasia is mild to absent. In summary, the peripheral blood smear of CMML shows basically a mixture of increased numbers of mature neutrophils and monocytes with only occasional myelocyte or metamyelocyte (32). The bone marrow contains more erythroid precursors than aCML or Ph-positive CML (usually greater than or equal to 15%) (34, 36).

CMML has been a difficult disorder to classify with some cases better classified as a myelodysplastic disorder and others better classified as a myeloproliferative disorder. The distinction between the two phases had been based primarily on the presenting leukocyte count and the presence or absence of splenomegaly. A recent study divided CMML into a myelodysplastic type and a myeloproliferative type based on the leukocyte count, using 13×10^9/L as the cutoff. The study found no significant difference in the 2-year survival or overall prognosis between the two types of CMML (37).

The new WHO classification of acute leukemia and myelodysplastic syndromes removes the CMML category from the myelodysplastic disorders and places it in a new “myelodysplastic/myeloproliferative disorders” category, recognizing that there is a group of disorders that have both myelodysplastic and myeloproliferative features. This mixed category also includes aCML and juvenile myelomonocytic leukemia (formerly known as juvenile chronic myeloid leukemia) (1).

aCML, similar to CML, shows a neutrophilia with shift to immaturity (immature granulocytes between 10% and 20%), but lacks basophilia and shows minimal to mild monocytosis (between 3% and 10%). Another distinguishing feature of aCML is the presence of trilineage dysplasia with hypogranular and hypo/hypersegmented granulocytes, dyserythropoiesis, and dysmegakaryopoiesis (32). Erythroid precursors in the bone marrow are rare.

Recognition of Ph-negative and BCR-ABL negative CML cases has prognostic significance. aCML appears to be clinically aggressive with a reported median survival of less than 2 years (34). Prognosis for CMML is variable because of the heterogeneity in cases reported as CMML. In general, CMML is thought to behave more poorly than the BCR-ABL positive CML (chronic granulocytic leukemia) (34).

Juvenile Chronic Myelogenous Leukemia

Chronic myeloproliferative disorders in children are uncommon and overlap with myelodysplastic syndromes of childhood, as recognized by the new WHO classification (1). Juvenile chronic myelogenous leukemia (JCML) represents the most common form of myeloproliferative/myelodysplastic disorders in children

under the age of four. JCML has also been described under different names such as chronic myelomonocytic leukemia in children, monosomy 7 syndrome, and juvenile myelomonocytic leukemia (JMML). The latter designation of JMML was proposed by the recently established International Juvenile Myelomonocytic Leukemia Working Group (38, 39).

This group of disorders is distinctly different from the Ph-positive adult CML. JCML or JMML lacks the Ph chromosome and molecular evidence of the BCR-ABL rearrangement. Additional criteria for this diagnosis, as proposed by the International Working Group (38), include absolute peripheral monocytosis of greater than 1×10^9/L [usually > 5×10^9/L (39)], and bone marrow blasts less than 20%. Two additional criteria from the following list must also be met: elevated hemoglobin F for age [greater than 10%, but seen in only one half to two thirds of the patients (39, 40)], granulocytic left shift in the peripheral blood, peripheral leukocytosis over 10×10^9/L, cytogenetic abnormality [about two thirds with normal karyotype, but monosomy 7 in one quarter of the patients analyzed (41)], or *in vitro* cell culture studies demonstrating hypersensitivity of myeloid progenitor cells to granulocyte/macrophage colony stimulating factor (42).

Most patients present before the age of four, and median age at presentation in one series was 1.8 years (41). Characteristic clinical features of this disorder consist of hepatosplenomegaly, lymphadenopathy, skin rashes, and bleeding in the form of purpura, ecchymoses, petechiae, and epistaxis secondary to thrombocytopenia (43, 44). Skin manifestations include erythematous maculopapular rashes of the face and lesions associated with neurofibromatosis (e.g., xanthomas, café-au-lait spots and neurofibromas) (43).

About 10% to 25% of the cases are associated with neurofibromatosis, type 1 (44). In fact, the risk for JMML in children with neurofibromatosis is increased by more than 300-fold (41, 45). The association with neurofibromatosis has shed some light on the pathogenesis of JMML/JCML (39). Loss of the normal NF1 allele results in decreased downregulation of Ras-GTP. The increased Ras-GTP level causes constitutive activation of its signal transduction pathway. In addition, 30% of the cases have mutations in the RAS gene that also result in increased levels of Ras bound to GTP.

The prognosis, in general, is poor, and some patients do develop blastic transformation (40, 43). Chemotherapy is of very limited usefulness, and bone marrow transplantation (BMT) provides the only chance of prolonging survival (39, 41). Poor prognostic factors include age at presentation over 2 years, elevated hemoglobin F greater than 10%, and low platelet count (40, 41). High blast and normoblast counts in peripheral blood were also found to be predictive of short survival (43).

Chronic Neutrophilic Leukemia

This disorder is very rare and remains a controversial entity. The pathologic findings closely mimic leukemoid reaction (9, 46), characterized by a persistent, unexplained, predominantly mature neutrophilia without basophilia. There is a slight left shift in the granulocytes, including occasional myeloblasts. Toxic granulation and Dohle bodies are often seen in the neutrophils. Despite the reactive changes seen in the neutrophils, these patients do not have any evidence of an underlying infection. Instead, these patients are usually elderly with prolonged splenomegaly accompanying the neutrophilia. Cytogenetics is helpful, as these patients do not have the Ph chromosome, but occasionally may show other clonal abnormalities (47). Blastic transformation has been reported (48).

Clinical Course and Progression of CML

The chronic phase of CML usually lasts 3 years and often progresses to an accelerated phase and ultimately, blastic transformation and death. About 20% to 25% of the patients progress directly to the blastic phase without evidence of the accelerated phase (8). Median survival after patient reaches the accelerated phase is 6 to 18 months, and survival is less than 6 months with blastic transformation. Common causes of death are leukemic transformation and bone marrow failure/fibrosis.

Accelerated phase

The diagnostic criteria for the accelerated phase are vague and include both morphologic and clinical findings (49). Clinically, the patient may be refractory to therapy with increasing splenomegaly or may require higher doses of drugs to control the disease. In the peripheral blood, the white cell count may increase or decrease with increasing blasts, but blasts constitute less than 30%. Peripheral blasts greater than or equal to 15% (but less than 30%) or peripheral blasts and promyelocytes greater than or equal to 30% (but blasts less than 30%) have been used as criteria for the accelerated phase (49). Increasing basophilia greater than or equal to 20% and morphologic evidence of dysplasia are indicative of disease progression (9). Hemoglobin levels and platelet counts may drop with platelet counts less than 100×10^9/L found to be a poor, independent prognostic factor (49). In the bone marrow, increasing numbers of blasts (but less than 30%) and increasing basophilia may be seen. A reticulin stain to evaluate for increasing myelofibrosis is useful. Clonal cytogenetic evolution with additional cytogenetic abnormalities is indicative of progression of CML. Common additional abnormalities include a second Ph chromosome, trisomy 8 (+8), and isochromosome 17q.

Blastic Transformation

A diagnosis of blastic transformation of CML can be made if any of the following three criteria are met (50). First, there are 30% or more blasts in the peripheral blood or bone marrow (Fig. 45.6). The development of an extramedullary myeloid tumor or lymphoblastic lymphoma also indicates a blast crisis. The extramedullary disease may be the first and only evidence of blastic transformation with no increased blasts in the bone marrow and peripheral blood (9, 51). Finally, blastic transformation has occurred if blasts in the peripheral blood and bone marrow are less than 30%, but the bone marrow core biopsy shows large intramedullary foci of blasts. This latter finding is usually referred to as focal blast transformation.

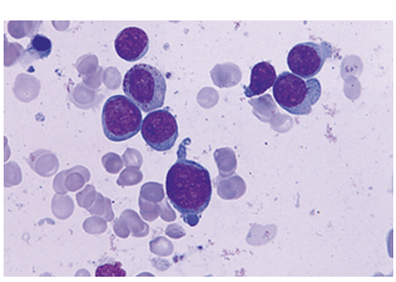

FIGURE 45.6. Numerous blasts in the bone marrow aspirate smear from a patient with chronic myelogenous leukemia in blastic transformation.

Analysis of 242 patients with CML in blast crisis was performed

by Kantarjian et al (52). Three independent, poor prognostic factors were identified: myeloid or undifferentiated blasts, evidence of clonal evolution, and thrombocytopenia less than 50 × 10^9/L (indicative of low marrow reserve). These factors affected overall survival and response to therapy. The morphologic findings of myeloid, lymphoid, or undifferentiated blast crises are similar to their respective counterparts in *de novo* acute leukemia. Appropriate workup includes immunophenotypic characterization of blasts by flow cytometry and fresh aspirate material sent for cytogenetic evaluation because many patients [up to 60% in one study (52)] demonstrate clonal evolution. Clonal evolution most frequently involves the development of a second Ph chromosome and trisomy 8 (Fig. 45.7). The presence of isochromosome 17q is also considered as evidence of clonal evolution (52, 53).

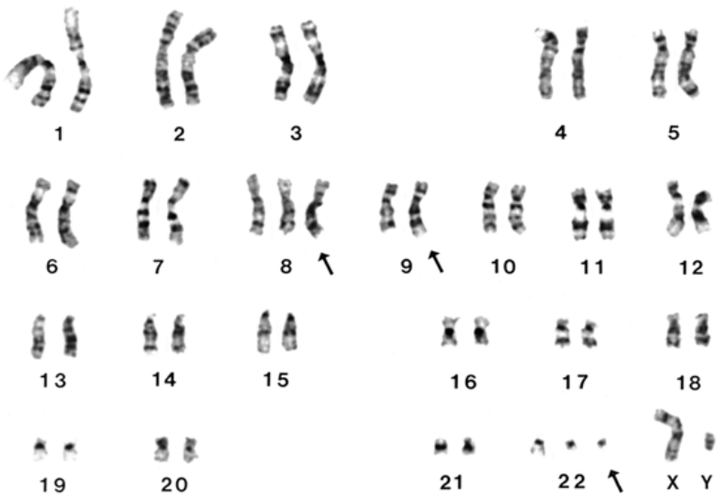

FIGURE 45.7. Karyotype of a man with chronic myelogenous leukemia in blastic transformation demonstrating several chromosomal abnormalities. The abnormalities include Philadelphia chromosome (abnormally shortened chromosome 22), a second Philadelphia chromosome, and trisomy 8. (Courtesy of V. Lindgren, PhD, Department of Pathology, Loyola University Medical Center, Maywood, IL.)

About two thirds of the blast crises are myeloid in origin and one third is lymphoid in origin. It is clinically and prognostically important to determine lineage of these blast crises. Although blast crises of CML in general are clinically very aggressive with survival usually less than 6 months, several studies have found that the lymphoid blast crisis in CML is associated with longer median survival and better response to therapy when compared with the myeloid blast crisis (54,55 and 56). The lymphoid blast crisis appears to respond to acute lymphoblastic leukemia therapeutic regimens containing vincristine and prednisone. Although the prognosis is better with the lymphoid blast crisis, the overall survival advantage is of short duration with median survival of 9 to 12 months for a lymphoid blast crisis versus 3 to 4 months for a nonlymphoid blast crisis. As a result, allogeneic BMT is recommended for patients with a lymphoid blast crisis after induction of a second chronic phase (54).

Other characteristics associated with the lymphoid blast crisis in CML include abrupt transformation without a preceding accelerated phase, less frequent organomegaly, lower white blood cell count with lower blast percentage, fewer peripheral basophils, lesser degree of anemia, more extensive involvement of bone marrow by blasts, and more frequent extramedullary involvement (54,55 and 56). The overwhelming majority of the lymphoid blast crisis show a B-lineage with only rare cases of T-cell blast crisis (57). Aberrant expression of myeloid antigens in these lymphoid blast crises appears to be relatively common (55, 56).

Extramedullary blast transformation can occur anywhere, but common locations include lymph nodes, skin, spleen, and soft tissues. A leukemic tumor in extramedullary sites usually consists of a proliferation of relatively uniform, medium to large mononuclear cells (Fig. 45.8). Differentiation from large-cell lymphoma and other large, poorly differentiated neoplasms is difficult based on morphology alone. Sometimes an eosinophilic infiltrate may accompany the tumor cells and provide a clue to the leukemic nature of the neoplasm.

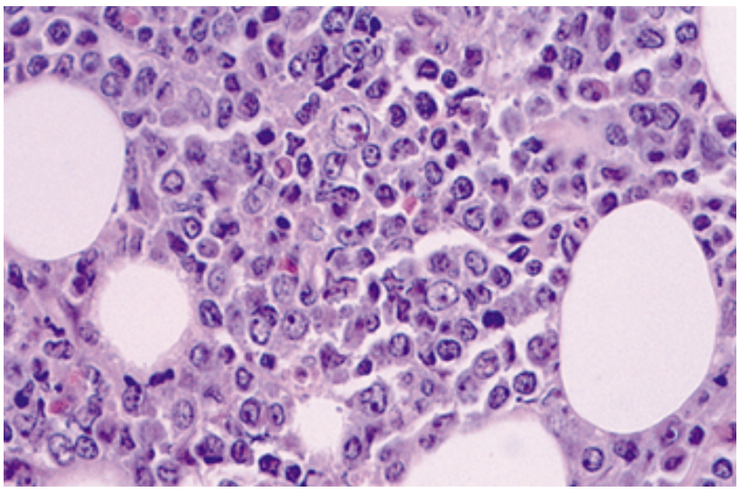

FIGURE 45.8. Extramedullary myeloid tumor (granulocytic sarcoma) in retroperitoneal tissue from a patient with chronic myelogenous leukemia. The tumor cells are relatively uniform, medium to large, mononuclear with high nuclear/cytoplasmic ratio.

Immunohistochemical analysis should be performed (58). For an extramedullary myeloid tumor (also known as granulocytic sarcoma), myeloperoxidase and lysozyme are good myeloid markers (Fig. 45.9). For lymphoblastic lymphoma, TdT is probably the most useful in confirming the diagnosis. For purposes of determining lineage, CD79a and CD10-immunopositivity indicate B-cell lineage. CD20 is not as useful, given that most

precursor B-acute lymphoblastic leukemias are negative for CD20. For T-cell lineage, antibody against CD3 can be used to detect both surface and cytoplasmic CD3 expression. Although CD43 is a nonspecific T-cell marker, it also marks myeloid cells, and many times it may be the only marker initially positive if an extramedullary myeloid tumor was not considered in the differential diagnosis. CD34 is a marker of progenitor, hematopoietic cells, and its expression is consistent with acute leukemia, but it does not indicate myeloid or lymphoid origin.

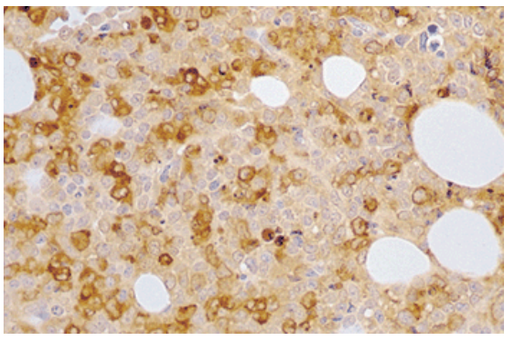

FIGURE 45.9. Myeloperoxidase positivity in extramedullary myeloid tumor (granulocytic sarcoma). This tumor is the same case presented in Fig. 8.

Therapy

Most patients with favorable clinical findings are treated with hydroxyurea, busulfan, or recombinant interferon-α. Allogeneic BMT is the preferred first-line therapy if the patient is young (preferably less than 50 years of age) and if an HLA-matched related donor is available. Transplantation in the early stages is advocated because better survival has been seen in patients transplanted in the chronic phase than in the accelerated or blastic phase. In addition, patients have better chances of survival if they are transplanted within the first year after diagnosis rather than later in the chronic phase (4). However, the benefits of BMT should be weighed against potential morbidity and mortality associated with transplantation (59).

For patients in whom BMT is not possible, interferon-α alone or in combination with other agents is the preferred optimal therapy (59). Interferon-α has been shown to induce hematologic and cytogenetic remissions that are not long-lasting. One of the important assays for clinical response to interferon-α is FISH detection of the Ph chromosome. Other experimental therapies include anti-BCR-ABL antisense oligonucleotides, BCR-ABL–specific tyrosine kinase inhibitors, and intensive chemotherapy with purged auto stem cell transplantation.

The role of autologous transplantation in CML as primary or salvage therapy has not been clearly defined and is still experimental. Investigators have attempted to improve methods for purging the graft by *ex vivo* and *in vivo* means (60). *Ex vivo* purging includes longterm liquid cultures, antisense oligonucleotides, tyrosine kinase inhibitors, and selection of CD34-positive, HLA-DR negative progenitor cells. *In vivo* purging primarily involves decreasing the tumor burden by intensive chemotherapy prior to harvesting of the bone marrow or peripheral blood.

POLYCYTHEMIA VERA

Part of "45 - Chronic Myeloproliferative Disorders"

PV is distinguishable from the other chronic myeloproliferative disorders by its predominant proliferation of the erythroid cell line. However, it is actually a stem cell disorder that causes proliferation of all the myeloid components. The increased red cell mass is the hallmark of this disorder, but the white blood cell count is often mildly increased, and quite significant thrombocytosis is generally present. In addition, the bone marrow often shows panhyperplasia, not just erythroid hyperplasia.

Etiology/Pathogenesis

PV is a clonal disorder, as confirmed by cytogenetic and clonality analyses. About 17% of untreated patients with PV have karyotypic abnormalities (61,62,63,64 and 65). The most common abnormalities found at the time of diagnosis include deletion of the long arm of chromosomes 20 and 13 (20q- and 13q-), trisomy 8 (+8), and trisomy 9 (+9). With progression of disease to myelofibrosis or acute leukemia, the frequency of chromosomal anomalies increases to 50% to 80% (65). Overall 65% of patients who were treated with myelosuppressive agents showed cytogenetic abnormalities, most commonly involving chromosomes 5 and 7 (61,62,63,64,65 and 66).

Clonality assays looking at glucose-6-phosphate dehydrogenase isoenzymes and allelic patterns of X-linked genes have demonstrated monoclonality with a monoallelic pattern (67,68 and 69). A skewed pattern of X-inactivation in granulocytes together with a balanced pattern in lymphocytes generally indicates clonality. However, similar findings have been found in 25% to 50% of normal, elderly women (70). This increased skewing with age seems to indicate that analysis of X-chromosome inactivation patterns cannot be used as a diagnostic test for clonality of chronic myeloproliferative disorders in elderly women (71).

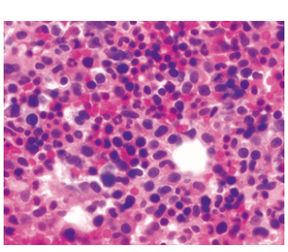

FIGURE 45.10. Bone marrow clot section of polycythemia vera in the proliferative stage showing hypercellular marrow with marked erythroid hyperplasia.

Another interesting observation is spontaneous *in vitro* erythroid colony formation without the addition of exogenous

erythropoietin (72). Supporting this observation is the generally low levels of serum erythropoietin in PV patients (73). Subsequent studies have actually found that the erythroid precursors in PV are hypersensitive to several different growth factors (e.g., stem-cell factor, interleukin-3, and granulocyte macrophage-colony stimulating factor), suggesting possible defects in the signal transduction pathway (65).

Proliferative Stage

Clinical Findings

About 5 to 10 cases of PV occur per million people per year, about half the incidence of CML. PV most commonly occurs in older people in their seventh decade. No sexual predilection is seen. About 20% of the patients with PV present with an acute thrombotic episode, and an additional 30% develop thromboses later on (74). Both arterial and venous thromboses occur with equal frequency. Arterial thrombi can involve cerebral, coronary, and peripheral blood vessels. The risk of thromboses increases with higher hematocrit levels from the increased red cell mass and the associated increased whole blood viscosity (74, 75). Other risk factors for thrombotic complications include older age over 70 years, previous history of thrombi, and history of frequent phlebotomy (most likely related to increased severity of the disease that requires more phlebotomies to maintain stable hematocrit levels) (76).

PV patients also experience microvascular, occlusive symptoms in the form of erythromelalgia and transient neurologic and ocular defects (75). Erythromelalgia presents as burning, painful, swollen toes and fingers. The neurologic and visual disturbances include attacks of aphasia, unstable gait, temporary interruption of ongoing activities, transient blindness, flashing lights, and blurred vision. These microvascular complications are attributed to increased platelet counts and are common in essential thrombocythemia and PV associated with thrombocytosis (76).

In additon, intractable pruritus is a frequent and bothersome symptom in PV (75, 77). About two thirds of the patients have a plethoric complexion. Splenomegaly is present in 70% of the patients, and a palpable liver is appreciated in 40% (77).

Peripheral Blood Findings

The key abnormalities in the peripheral blood are an elevated red cell count (usually greater than 6×10^{12}/L), increased hemoglobin level, and elevated hematocrit. No significant poikilocytosis usually is seen in the peripheral blood smear. The hemoglobin, not uncommonly, may be within normal range because oftentimes the patient is also iron deficient with decreased mean corpuscular volume. The red cell parameters in the complete blood count may indicate PV, but increased total red cell mass must be documented by radioisotopic studies for definitive diagnosis (see “Diagnostic Criteria and Other Studies,” below). Before considering PV as the underlying cause for the erythrocytosis, relative and secondary erythrocytosis need to be excluded. Relative erythrocytosis refers to spurious erythrocytosis as a result of plasma volume contraction from vomiting, dehydration or diarrhea. Secondary erythrocytosis is discussed below in “Diagnostic Criteria and Other Studies.”

The white cell counts generally range from 10 to 20 × 10^9/L with a slight shift to immaturity. Modest absolute basophilia is seen in about 70% of the patients (46). The platelet counts usually are increased, ranging from 400 to 800 × 10^9/L with counts greater than 1,000 × 10^9/L not uncommon (77). In fact, thromobocytosis and leukocytosis in the absence of fever and infection are cited as B criteria in the initial diagnostic criteria for PV (77).

Bone Marrow Findings

The morphologic findings in the bone marrow core biopsy are not specific or diagnostic for PV. The marrow is hypercellular for age with panmyelosis or trilineal hyperplasia, particularly of the erythroid (Fig. 45.10) and megakaryocytic series. Erythroid precursors do not show evidence of dysplasia. Megakaryocytes may cluster and may be large and hyperlobulated, resembling the megakaryocytes in essential thrombocythemia. The granulocytic elements are unremarkable with no increase in blasts. An iron stain is important, as iron stores are almost always absent. A reticulin stain shows normal reticulin content in most patients, but up to one third may have some degree of increased reticulin fibrosis. This finding at the proliferative stage does not appear to have prognostic significance (78).

Diagnostic Criteria and Other Studies

PV is a clinicopathologic diagnosis. In the 1970s, the Polycythemia Vera Study Group (PVSG) proposed a set of criteria for the diagnosis of PV (77). Table 45.2 lists the PVSG criteria. A diagnosis of PV was considered acceptable if the red cell mass exceeded 36 mL/kg in men or 32 mL/kg in women, arterial oxygen saturation was normal, and splenomegaly was present. If splenomegaly was not present, then two additional B criteria must be met.

TABLE 45.2. PVSG CRITERIA FOR POLYCYTHEMIA VERA

A Criteria (Major)		B Criteria (Minor)	
A1	Increased red cell mass Male ≥ 36 mL/kg Female ≥ 32 mL/kg	B1	Thrombocytosis (> 400 × 10^9/L)
A2	Normal arterial oxygen saturation ≥ 92%	B2	Leukocytosis (> 12 × 10^9/L) in absence of fever or infection
A3	Splenomegaly	B3	Increased neutrophil alkaline phosphatase score in absence of fever or infection
		B4	Increased B_{12} (≥ 900 mg/L) or increased unsaturated B_{12} binding capacity (>2200 mg/L)

Diagnosis of PV if A1 + A2 + A3 or A1 + A2 + 2B criteria

(From Berlin NI. Diagnosis and classification of the polycythemias. *Semin Hematol* 1975;12:339–351, reprinted with permission.)

With the development of new techniques and new scientific findings in PV, revised diagnostic criteria have been proposed (79) (Table 45.3). Total red-cell mass determined by radioisotopic studies involves *in vitro* labeling of patient's erythrocytes

with 51-chromium, reinjecting the labeled red cells into the patient, and measuring the radioactivity after adequate equilibration. It is felt that the measurement of red-cell mass in milliliters per kilogram was insufficient, but that the red cell mass should be compared to the normal predicted value (80).

TABLE 45.3. PROPOSED REVISED DIAGNOSTIC CRITERIA FOR POLYCYTHEMIA VERA (PV)

A Criteria		B Criteria	
A1	Increased red-cell mass (> 25% above mean normal predicted value)	B1	Thrombocytosis (> 400 × 10^9/L)
		B2	Neutrophilia (> 10 × 10^9/L)
		B3	Splenomegaly by isotope/ultrasound scan
A2	Secondary polycythemia excluded	B4	Spontaneous BFU-E growth or decreased serum erythropoietin
A3	Palpable splenomegaly		
A4	Evidence of clonality		

Diagnosis of PV if A1 + A2 + (A3 or A4) or A1 + A2 + 2B criteria

(From Pearson TC, Messinezy M. The diagnostic criteria of polycythaemia rubra vera. *Leuk Lymphoma* 1996;22:87–93, reprinted with permission.)

The initial PVSG criterion of normal arterial oxygen saturation was replaced by “absence of cause of secondary polycythemia” to be more encompassing and to include causes of inappropriate erythropoietin production by certain neoplasms. The differential diagnosis for secondary polycythemia is a long list (Table 45.4) (77). A major category is increased erythropoietin as a physiologic response to hypoxia of various causes, including living at high altitudes, smokers, congenital heart disease, chronic obstructive pulmonary disease, and high oxygen affinity hemoglobinopathy. In the latter entity, the abnormal hemoglobin binds tightly to the oxygen molecules, and oxygen delivery to tissue sites is decreased. The second major category is inappropriate erythropoietin production, as seen in some renal-cell carcinomas, hepatocellular carcinomas, and cerebellar hemangioblastomas.

TABLE 45.4. DIFFERENTIAL DIAGNOSIS OF SECONDARY POLYCYTHEMIA

Response to Hypoxia
High altitude
Congenital heart disease
Chronic obstructive pulmonary disease
Smoking
High oxygen affinity hemoglobinopathy
Inappropriate erythropoietin production
Tumors (renal-cell carcinoma, hepatocellular carcinoma, hemangioblastoma)
Benign renal lesions (cysts, hydronephrosis)

An additional primary criterion of cytogenetic abnormality was included, as discussed in “Pathogenesis.” The importance of splenomegaly was again emphasized with palpable splenomegaly a major criterion and splenomegaly by radiologic studies a minor criterion. A new minor criterion was added: the spontaneous growth of erythroid colonies without the addition of erythropoietin (81) or decreased serum erythropoietin level, in contrast to increased erythropoietin level in secondary erythrocytosis.

Progression of PV

In 7 to 8 years after diagnosis (78), about 10% of PV cases will progress to the stage known as postpolycythemic myeloid metaplasia or the “spent phase” (82). From the pathologic standpoint, the morphologic findings are essentially identical to chronic idiopathic myelofibrosis with marked fibrosis in the bone marrow and presence of teardrop red cells in the peripheral blood. Histologic examination of spleens at this stage shows extramedullary hematopoiesis as the cause for the increasing splenomegaly, whereas splenomegaly in the proliferative phase is secondary to marked congestion (83).

Progression to acute leukemia is considered part of the natural history with an incidence of 1% to 2% in untreated patients who received phlebotomy only (82). Patients who were treated with alkylating agents or radioactive phosphorus had an increased incidence of 10% to 15%. The leukemogenic effect of hydroxyurea is still an issue that needs to be resolved (84). In addition, an antecedent postpolycythemic myeloid metaplasia also causes an increased risk for the development of acute leukemia (82). The onset of blastic transformation is usually abrupt without a previous myelodysplastic stage. The blastic progression is mostly myeloid in origin with occasional cases of acute lymphoblastic leukemia (82). Acute leukemia generally shows a poor clinical response to chemotherapy.

Therapy/Prognosis

PV is a progressive disease, and patients need to be treated, in contrast to essential thrombocythemia. If untreated, patients have a 50% chance of dying within 18 months after the onset of first symptom (85). To control the vascular complications in PV, therapy is aimed at maintaining hematocrit levels below 45% and platelet counts below 400 × 10^9/L (76, 86). Phlebotomy alone does not prevent the microcirculatory complications of erythromelalgia and the transient ischemia of cerebral and ocular blood vessels because the thrombocytosis persists.

In the 1970s, treatment primarily consisted of radiophosphorus and alkylating agents such as busulfan, melphalan, and chlorambucil. The increased risk of developing therapy-related malignancies from alkylating agents was recognized, and hydroxyurea became first-line therapy in 1980. Hydroxyurea has been effective in controlling thrombocytosis and elevated hematocrit; thereby, decreasing the risk of thrombosis (84). However, it causes side effects, including myelosuppression and possibly

acute leukemia. Long-term safety of hydroxyurea is still not known.

Newer treatment modalities have evolved. Low-dose aspirin is currently recommended for the treatment of erythromelalgia and other microvascular circulatory problems (76, 87). Possible contraindications to the use of aspirin are history of gastrointestinal bleeding or peptic ulcer disease and extremely high platelet counts. Interferon-α has been tried in a limited number of patients and has been found to be effective in controlling the disease by reducing the degree of splenomegaly, platelet counts, and requirements for phlebotomy (88). In particular, this drug has been especially effective in the treatment of PV-associated pruritus, but side effects remain a limiting factor in up to one-third of the patients treated (88). Allogeneic bone marrow transplantation for PV patients who progress to myelofibrosis has only been attempted in very few patients (89).

Median survival is about 10 years, and a common cause of death in treated and untreated patients is thrombosis in the coronary or cerebral vessels (74). Other causes of death include acute leukemia and marrow failure from fibrosis.

ESSENTIAL THROMBOCYTHEMIA

Part of "45 - Chronic Myeloproliferative Disorders"

ET is characterized by marked thrombocytosis in the peripheral blood; however, thrombocytosis is often present in other CMPDs. ET is primarily a diagnosis of exclusion because it lacks a diagnostic genetic marker. In addition, its clinical, laboratory, and pathologic features significantly overlap with other CMPDs.

Etiology/Pathogenesis

ET is generally thought to be a clonal stem cell disorder. However, only about 5% of the cases analyzed by cytogenetics show clonal abnormalities, and no consistent karyotypic anomalies have been found (66, 90). Other ways to determine clonality have been attempted, and Fialkow in 1981 demonstrated clonality by glucose-6-phosphate dehydrogenase isoenzyme analysis in three ET patients (91).

Studies based on the human androgen receptor gene (HUMARA) showed conflicting results. While El-Kassar et al. demonstrated clonality in 27 of 48 patients (92), Harrison et al. (93) demonstrated clonality in only 10 of 46 female patients. Evaluation of clonality may be useful in determining which patients are at a higher risk for progression to acute leukemia or at greater risk for thrombotic or hemorrhagic complications (94).

A few cases of familial ET have been reported with generally an autosomal-dominant mode of inheritance (95,96 and 97). A molecular abnormality in the thrombopoietin gene was discovered in one family (97). A one-base deletion in the 5′ end of the thrombopoietin gene resulted in increased levels of thrombopoietin in affected family members. However, sporadic cases of ET do not display increased thrombopoietin levels (98), but one study found decreased expression of the thrombopoietin receptor (c-Mpl) in ET platelets (99). Therefore, it has been proposed that the underlying molecular mechanisms for familial and sporadic cases of ET are most likely different (97).

Clinical Findings

ET is less common than CML or PV with less than five new cases per million people per year. In fact, one study found ET in only 4% of 280 patients with a platelet count greater than 1,000 × 10^9/L (100). The age at diagnosis is variable with a median age of about 60 years and a range of 21 to 85 years of age in the group of 91 patients with ET followed by the PVSG (101). About 10% to 25% of the patients present under the age of 40 (74). No sexual predilection is noted.

Presenting clinical symptoms are variable, ranging from asymptomatic to unexplained thrombotic/hemorrhagic episodes, as seen in PV. Up to one third of the patients are discovered incidentally (74). Twenty-five percent to 75% of ET patients present with a thrombotic event, most commonly affecting the microcirculation in the form of erythromelalgia, characterized by painful, swollen, burning toes and fingers (75, 102). Erythromelalgia is caused by platelet microthrombi in the arterial vasculature of the extremities (102). Venous thrombosis is less common than arterial thrombosis in ET. Arterial thrombosis mainly involve the cerebral vasculature, peripheral vessels, and coronary arteries (103). Many ET patients experience neurologic symptoms such as headaches, dizziness, or visual problems as a result of cerebrovascular ischemia (103). Bleeding events at the time of presentation are apparently less common [4% in one study (104)]. Hemorrhage occurs with excessively high platelet counts (75, 104).

The overall risk for thrombosis in ET patients is around 10%. Major thrombotic events occur in about 20% to 30% of the patients (74, 105). Significant risk factors for the development of thrombotic episodes as determined in a study by Cortelazzo et al. (106) included age (over 60 years old), previous thrombotic event and long duration of thrombocytosis. Smoking, hypertension, diabetes mellitus, and hyperlipidemia apparently did not affect the risk for thrombosis. It generally is accepted that neither the degree of thrombocytosis nor qualitative abnormalities of the platelets correlate well with the risk of bleeding or thrombosis in ET (103).

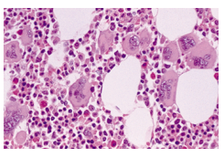

FIGURE 45.11. Bone marrow biopsy of essential thrombocythemia with megakaryocytic hyperplasia. The megakaryocytes are clustering and show characteristic morphology: large size and hyperlobated nuclei.

Peripheral Blood Findings

ET is a diagnostic possibility whenever a significant thrombocytosis is seen in a complete blood count. It is important to remember that ET is a diagnosis of exclusion. What is a significant thrombocytosis? A platelet count greater than 600 × 10^9/L has been cited in the past as a diagnostic criterion for ET; however, that has been questioned (107). The differential diagnosis for thrombocytosis falls into two major categories (Table 45.5): reactive versus malignant (ET or other types of CMPD). Reactive thrombocytosis includes postsplenectomy, chronic iron deficiency (platelet count as high as 1,000 × 10^9/L has been reported), hemorrhage, chronic inflammatory states such as systemic lupus erythematosus and other collagen vascular disorders, chronic infections, nonhematopoietic malignancies, and drug effects such as vincristine and high dose erythropoietin. Other types of CMPD need to be excluded before a diagnosis of ET can be rendered. In particular, CML and PV often present with some degree of thrombocytosis. Peripheral basophilia is expected in

CML, and the morphology of the megakaryocytes in CML is different from that seen in ET. Ultimately, the presence or absence of the Ph chromosome will provide the definitive answer. PV can often masquerade as ET with concomitant iron deficiency and apparently normal hemoglobin levels. A trial of iron therapy may be necessary before such a distinction can be made.

TABLE 45.5. DIFFERENTIAL DIAGNOSIS OF THROMBOCYTOSIS

Hemorrhage
Chronic iron deficiency
Postsplenectomy
Drugs
Chronic inflammation/infection
Neoplastic
Essential thrombocythemia
Other CMPDs (CML, PV, CIMF)

CIMF, chronic idiopathic myelofibrosis
CML, chronic myelogenous leukemia
CMPD, chronic myeloproliferative disorders
PV, polycythemia vera

The peripheral blood smear is often unremarkable, except for confirming the thrombocytosis. Morphology of the platelets is variable, ranging from normal to highly atypical forms. The white blood cell count is in general modestly increased without basophilia, and the hemoglobin level is normally or mildly decreased.

Bone Marrow Findings

The marrow is usually hypercellular with megakaryocytic hyperplasia (Fig. 45.11). The megakaryocytes may or may not cluster and are preferentially located close to bony trabeculae. They are characteristically very large with hyperlobulated nuclei, in contrast to the small, hypolobulated megakaryocytes of CML. There may be erythroid and granulocytic hyperplasia.

Diagnostic Criteria and Other Studies

Similar to PV, the PVSG proposed a set of criteria for the diagnosis of ET (108) (Table 45.6). These criteria primarily excluded other major types of CMPDs that can present with thromobocytosis as well as any causes of reactive thromobocytosis. A normal red-cell mass and the presence of stainable iron exclude PV. The absence of Ph chromosome eliminates the possibility of CML. Absence of significant fibrosis makes chronic idiopathic myelofibrosis (agnogenic myeloid metaplasia) very unlikely. Therefore, in addition to clinical correlation, an appropriate pathologic workup on a potential ET patient includes cytogenetic analysis, iron stain on bone marrow aspirate, and reticulin or trichrome stain to assess degree of marrow fibrosis. Morphologic findings of ET and proliferative phase of PV are very similar and sometimes can be indistinguishable.

TABLE 45.6. PVSG CRITERIA FOR ESSENTIAL THROMBOCYTHEMIA

1.	Platelet count > 600 × 10^9/L
2.	Hemoglobin ≤ 13 gm/dL or normal red cell mass (males < 36 mL/kg, females < 32 mL/kg)
3.	Stainable iron in marrow
4.	No Philadelphia chromosome
5.	Collagen fibrosis of bone marrow
	absent or
	< 1/3 biopsy area, no splenomegaly, no leukoerythroblastosis
6.	Reactive thrombocytosis excluded

(From Murphy S, Iland H, Rosental D, et al. Essential thrombocythemia: an interim report from the Polycythemia Vera Study Group. *Semin Hematol* 23:177–182, reprinted with permission.)

Like PV, revised diagnostic criteria for ET have been proposed, with the advent of new scientific techniques and findings. Table 45.7 lists the revised diagnostic criteria (109). In addition to the retention of some “old” criteria, characteristic bone marrow findings, as described above, are now part of the diagnostic criteria. Although prominent splenomegaly generally is not characteristic of ET, splenomegaly detected on scan or ultrasound favors ET over reactive thrombocytosis. Spontaneous erythroid and/or megakaryocytic colony formation without addition of cytokines also supports ET (110, 111), provided the red cell mass is normal.

Therapy

Although ET generally is considered to have an excellent prognosis with regards to overall survival, it can cause a certain degree of morbidity. Therefore, the decision whether or not to treat must be carefully evaluated, comparing the risks and benefits of treatment and no treatment. In general, a conservative approach of just observation is advocated for younger (under 40 years of

age), asymptomatic patients (105). Treatment is recommended for patients at high risk for thrombosis.

TABLE 45.7. PROPOSED REVISED DIAGNOSTIC CRITERIA FOR ESSENTIAL THROMBOCYTHEMIA

A Criteria		B Criteria	
A1	Platelet count > 600 × 10^9/L	B1	Splenomegaly on isotopic scan or echogram
A2	No increase in red cell mass		
A3	No Philadelphia chromosome	B2	Spontaneous growth of BFU-E and/or CFU-Meg
A4	Characteristic bone marrow	B3	Normal ESR/fibrinogen findings (increased numbers of large megakaryocytes with no collagen fibrosis)

Diagnosis of ET if A1 + A2 + A3 + A4 + or A1 + A2 + A3 + 2B criteria

ET, essential thrombocythemia

(Kutti J, Wadenvik H. Diagnostic and differential criteria of essential thrombocythemia and reactive thrombocytosis. *Leuk Lymphoma* 1996;22(Suppl 1):41–45, reprinted with permission.)

In the 1970s, patients were treated with radioactive phosphorus and alkylating agents such as melphalan and chlorambucil. Because of the increased risk of blastic transformation from these agents, hydroxyurea was introduced in the late 1970s. Hydroxyurea has been shown to be effective and is currently recommended for older patients at risk for thromboses (84).

The PVSG did not find hydroxyurea to be leukemogenic if used alone, after more than 8 years of follow-up of hydroxyurea-treated patients (101). However, there was a high incidence of acute leukemia (five of seven patients) in patients initially treated with hydroxyurea, but then switched to radioactive phosphorus or alkylating agents. A different study found an association between the development of acute myelogenous leukemia and myelodysplastic syndrome in hydroxyurea-treated ET patients and deletion of the short arm of chromosome 17 (112). The typical morphologic characteristics of the 17p- syndrome (dysgranulopoiesis in the form of pseudo Pelger-Huet changes and vacuolation in neutrophils) also were seen.

Other therapeutic agents have been tried, including low-dose aspirin, anegrelide, and interferon-α. Low-dose aspirin has been shown to be effective in ameliorating the microvascular symptoms of erythromelalgia and neurological and visual symptoms (84). Anegrelide is a platelet-lowering drug that has only recently been approved by the Food and Drug Administration. Clinical studies have found 80% to 90% response rate in controlling thrombocytosis (113,114 and 115). Anagrelide currently is recommended for younger, symptomatic patients or as an alternative to other forms of therapy. Because of the high degree of intolerance and cost, interferon-α usually is reserved for high-risk pregnant women or women of childbearing age and for those patients who have failed other forms of therapy (84, 116). The major advantage of interferon-α is its lack of teratogenicity and mutagenicity.

Prognosis/Clinical Course

In general, ET has an excellent prognosis with median survival of more than 10 years. It is important to distinguish ET from reactive thrombocytosis because a patient with ET is more likely to experience thrombohemorrhagic complications. Because most patients with ET can expect to have near normal life expectancy (117), it is important to distinguish ET from other CMPDs.

Transformation to polycythemia vera or myelofibrosis has been documented (74). Blastic transformation of ET occurs in a very small percentage of patients (less than 5%) (90). Usually the blasts are of myeloid origin, but lymphoblastic transformation has been described. Untreated patients are at very low risk for leukemic transformation. However, therapeutic agents such as radioactive phosphorus, and alklyating agents (118) increase the risk of development of acute leukemia.

CHRONIC IDIOPATHIC MYELOFIBROSIS

Part of "45 - Chronic Myeloproliferative Disorders"

This uncommon CMPD, first reported in 1879, has been described under at least 37 different names (119). The more common names include “myelosclerosis or myelofibrosis with myeloid metaplasia (MMM), agnogenic myeloid metaplasia, chronic idiopathic or primary myelofibrosis (CIMF), and megakaryocytic myelosis with osteosclerosis.” Bone marrow fibrosis, extramedullary hematopoiesis as evidenced by massive splenomegaly, leukoerythroblastic blood picture, and osteosclerosis characterize this disorder.

Etiology/Pathogenesis

The exact etiology of CIMF is unknown; however, it is a clonal stem cell disorder. Glucose-6-phosphate dehydrogenase isoenzyme analyses have demonstrated the same isoenzyme in erythrocytes, granulocytes, and platelets in a heterozygous female patient with CIMF (120). Studies using X-linked restriction fragment length polymorphism found clonality in all bone-marrow cells at various stages of disease in heterogzygous female patients (121). Cytogenetic abnormalities have been detected in 30% to 50% of the cases with deletions of the long arm of chromosome 13 and 20 being the most common (122,123,124 and 125).

In contrast, cytogenetic studies of the fibroblasts do not show clonality (126, 127). The marked myelofibrosis that is so characteristic of this disease is believed to be secondary to the stimulation of the nonclonal fibroblasts by several cytokines produced by the clonal, abnormal megakaryocytes (122, 128). The major cytokines or growth factors include platelet-derived growth factor (PDGF), transforming growth factor-ß (TGF-ß), epidermal growth factor (EGF), calmodulin, and basic fibroblast growth factor (bFBF) (122). PDGF as well as EGF, calmodulin, and bFBF are strong fibroblast mitogens. TGF-ß, synthesized by megakaryocytes and stored in the alpha granules of the platelets, upregulates extracellular matrix synthesis, including collagen type I, III, and IV, and hinders degradation of stromal matrix by inhibiting metalloproteinases that are collagenase-like proteases (122, 128). In addition, TGF-ß also promotes angiogenesis.

Extramedullary hematopoiesis that is so characteristic of this disorder is thought to be secondary to the marrow fibrosis that alters and distorts the marrow sinusoids (9, 129). Hematopoietic elements enter the sinusoids, morphologically manifested as intrasinusoidal hematopoiesis. They are transported to the peripheral blood, as evidenced by the leukoerythroblastic blood picture; and then become lodged in extramedullary sites such as the spleen and liver, resulting in organomegaly and extramedullary hematopoiesis.

Clinical Findings

CIMF is less common than CML and PV; roughly three new cases per million people are diagnosed each year. CIMF generally affects older patients in their seventh decade of life without sexual predilection. Not infrequently the patient is asymptomatic at the time of diagnosis with splenomegaly detected incidentally during a routine examination. However, some patients may present with constitutional symptoms (fever, night sweats, and weight loss), fatigue from anemia, hemorrhage secondary to thrombocytopenia or functional defects in platelets, or variceal bleeding from portal hypertension.

The most important clinical finding is the presence of splenomegaly secondary to extramedullary hematopoiesis (Fig. 45.12). A diagnosis of CIMF should be made with great caution

if splenomegaly is absent. The spleens in CIMF are among the largest, comparable to kala-azar, Gaucher's disease, and schistosomiasis. Hepatomegaly is seen in about two thirds of the patients (130). In addition, a significant number of patients (one third to one half) exhibit osteosclerosis, which can be detected in radiographic studies as symmetrically increased bone density (119, 130).

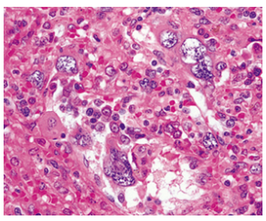

FIGURE 45.12. Extramedullary hematopoiesis in the spleen of a patient with chronic idiopathic myelofibrosis showing large, pleomorphic megakaryocytes in the red pulp (the case is courtesy of the College of American Pathologists, Chicago, IL; Performance Improvement Program, case 98-80).

Peripheral Blood Findings

A diagnosis of CIMF is usually considered when the bone marrow shows prominent myelofibrosis. Supporting morphologic findings in the peripheral blood for this diagnosis include the following: (i) anisopoikilocytosis with numerous teardrop red blood cells, (ii) a leukoerythroblastic blood picture with circulating nucleated red cells and immature granulocytes (Fig. 45.13), and (iii) atypical platelets with circulating micromegakaryocytes. A mild degree of dysplasia may be seen.

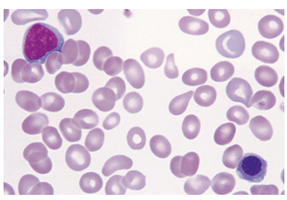

FIGURE 45.13. Typical peripheral blood smear of chronic idiopathic myelofibrosis with leukoerythroblastosis and teardrop red blood cells.

Patients may be anemic (normochromic, normocytic) as a result of ineffective erythropoiesis and splenic sequestration. The white cell count is usually mildly increased, between 10 to 20 × 10^9/L, and circulating myeloblasts may be seen. Up to 10% blasts may be present, but they do not necessarily indicate progression of disease (119, 131). About 20% of CIMF patients are leukopenic, particularly with disease progression (130). A mild basophilia and eosinophilia may be seen in a small proportion of the patients (10% to 30% of the cases) (119). Platelet counts are variable with about half of the patients with thrombocytosis early in the course of the disease. The degree of thrombocytosis may reach the levels seen in ET (131). Thrombocytopenia often results with increasing splenomegaly.

Bone Marrow Findings

Aspiration is generally not successful secondary to the marked myelofibrosis. There are two basic stages in CIMF with a cellular and fibrotic phase. In the cellular or early phase, the bone marrow core biopsy is variably hypercellular with panmyelosis and atypical megakaryocytic hyperplasia accompanied by marked reticulin fibrosis. Hematopoietic elements may show a characteristic streaming pattern with increasing fibrosis (Fig. 45.14). Sinusoids are dilated with intrasinusoidal hematopoiesis. Osteosclerosis characterized by thickened bony trabeculae is often present.

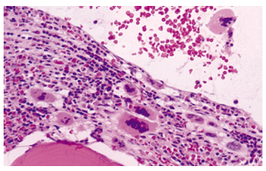

FIGURE 45.14. Bone marrow biopsy from a patient with chronic idiopathic myelofibrosis showing the characteristic streaming pattern secondary to marrow fibrosis.

Megakaryocytes are large, atypical, pleomorphic and often cluster. Megakaryocytic hyperplasia is often seen in CMPDs, but they assume different morphology. Fig. 45.15 compares the variable morphology with small megakaryocytes in CML; relatively normal megakaryocytes in PV; very large, hyperlobulated ones in ET; and large, pleomorphic forms in CIMF. Granulocytic and erythroid series generally are unremarkable, although occasional granulocytic hyperplasia and rare erythroid hypoplasia are seen.

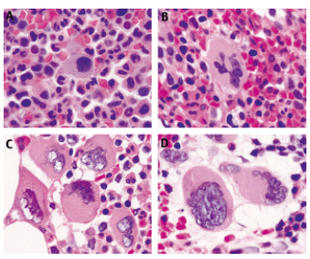

FIGURE 45.15. Composite photomicrograph comparing megakaryocytic morphology in: (**A**) chronic myelogenous leukemia (small, hypolobated); (**B**) polycythemia vera (relatively normal); (**C**) essential thrombocythemia (large, hyperlobated); (**D**) chronic idiopathic myelofibrosis (large, pleomorphic).

In the advanced, fibrotic stage, the bone marrow shows increasing fibrosis with collagen deposition and progressive loss of hematopoietic elements with only clusters of megakaryocytes remaining.

Diagnostic Criteria

In 1975, Laszlo, under the auspices of the Polycythemia Vera Study Group, defined CIMF by the following criteria: splenomegaly, fibrosis involving greater than one third of the

bone marrow biopsy, leukoerythroblastic blood picture, no evidence of an increased red-cell mass, absence of Ph chromosome, and exclusion of causes of secondary myelofibrosis (131).

In 1995, an Italian Cooperative Study Group was formed because of the lack of consistent, standardized criteria for the diagnosis of CIMF (132). Based on the consensus of 12 experts, the preferred name for this disease was myelofibrosis with myeloid metaplasia (MMM). A set of necessary and optional criteria was proposed with the realization that the criteria were limited by the lack of a specific genetic marker that defines this disorder (132). Table 45.8 lists the proposed diagnostic criteria. For a diagnosis of CIMF or MMM, all patients must demonstrate diffuse fibrosis in the bone marrow core biopsy, and the genetic marker for CML must be absent (no evidence of the BCR-ABL rearrangement). Depending on the presence or absence of splenomegaly, two or four of the optional criteria also must be met before such a diagnosis can be rendered.

TABLE 45.8. ITALIAN COOPERATIVE STUDY GROUP PROPOSED CRITERIA FOR MYELOFIBROSIS WITH MYELOID METAPLASIA (CIMF)

Necessary Criteria

1. Diffuse bone marrow fibrosis
2. No Philadelphia chromosome and no evidence of BCR-ABL rearrangement

Optional Criteria

1. Splenomegaly
2. Anisopoikilocytosis with dacrocytes
3. Immature myeloid cells in peripheral blood
4. Erythroblasts in peripheral blood
5. Clustering of megakaryoblasts and anomalous megakaryocytes in bone marrow
6. Myeloid metaplasia

Diagnosis of CIMF if

2 necessary criteria + 2 optional criteria (splenomegaly present)

2 necessary criteria + 4 optional criteria (splenomegaly absent)

From Barosi G, Ambrosetti A, Finelli C, et al. The Italian Consensus Conference on diagnostic criteria for myelofibrosis with myeloid metaplasia. *Br J Haematol* 1999;104:730–737. Reprinted with permission.

Differential Diagnosis

Normal bone marrow has an underlying, delicate reticulin framework with more reticulin around blood vessels and lymphoid aggregates. Marrow fibrosis is initially reticulin fibrosis with collagen fibrosis occurring later. Reticulin is detected by silver stains (Fig. 45.16), and bone marrow contains cells that produce both type III and type I collagen (133). To detect collagen fibrosis, a trichrome stain is required to detect the predominant type I collagen. To determine the degree of reticulin fibrosis, the

number and thickness of reticulin fibers need to be examined, whereas any degree of collagen deposition is considered pathologic and is usually associated with marked reticulin fibrosis and paucity of hematopoiesis (134).

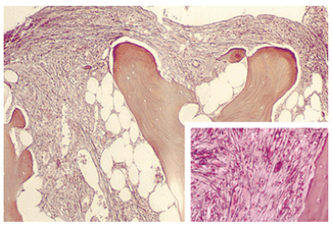

FIGURE 45.16. Silver stain of bone marrow biopsy in chronic idiopathic myelofibrosis showing marked reticulin fibrosis. Bone trabeculae are significantly thickened. The insert illustrates higher magnification.

The differential diagnosis of myelofibrosis is a long list (Table 45.9). Nonneoplastic causes of myelofibrosis include drugs, toxins, radiation, certain chronic infections (such as tuberculosis), Paget's disease or hyperparathyroidism. The neoplastic causes can be separated into hematopoietic and nonhematopoietic malignancies. Metastatic carcinoma should be excluded, including a cytokeratin immunostain, especially in a patient with a history of carcinoma.

TABLE 45.9. DIFFERENTIAL DIAGNOSIS OF MARROW FIBROSIS

Nonneoplastic
– Drugs/toxins
– Infections
– Granulomas
– Miscellaneous
Nonhematopoietic neoplasms (metastatic carcinoma)
Hematopoietic neoplasms
– Chronic lymphoproliferative disorders (hairy cell leukemia, lymphoma)
– Hodgkin's disease
– Mast cell disease
– Myeloproliferative disorders
• Acute myelofibrosis
• Acute myelogenous leukemia (AML-M7)
• Myelodysplastic syndrome
• CIMF
• Other chronic myeloproliferative disorders (PV in spent phase)

CIMF, chronic ideopathic myelofibrosis

PV, polycythemia vera

Hematopoietic neoplasms inciting marrow fibrosis can be classified into four major categories, including marrow involvement by Hodgkin's disease, systemic mast cell disease, chronic lymphoproliferative disorders (e.g., hairy cell leukemia and marrow involvement by non-Hodgkin's lymphoma) and myeloproliferative disorders of the bone marrow. Myeloproliferative disorders include acute myelofibrosis and acute myelogenous leukemia with fibrosis (AML-M7), myelodysplastic syndrome with fibrosis, and CMPDs.

Some degree of marrow fibrosis is usually seen in all CMPDs, but to a much lesser degree than CIMF. The only exception is the postpolycythemic myeloid metaplasia or spent phase of PV, which morphologically can be indistinguishable from CIMF. To differentiate from CML, peripheral blood smears from CML patients in accelerated phase usually do not display teardrop red blood cells. The bone marrow biopsy in CML shows predominant granulocytic hyperplasia with smaller megakaryocytes that are different from the large, pleomorphic, and bizarre megakaryocytes in CIMF. Ultimately, the presence of the Ph chromosome by cytogenetics or evidence of the BCR-ABL rearrangement by molecular methods confirms the diagnosis of CML.

Thrombocytosis above 1,000 × 10^9/L in CIMF may mimic ET. Again, ET does not show the characteristic peripheral blood findings of leukoerythroblastosis and teardrop red blood cells. The morphology of megakaryocytes in ET is different with much less pleomorphism and atypia. In occasional cases, only the clinical course will determine the type of disease. The proliferative stage of PV may be hard to distinguish from the cellular phase of CIMF in occasional cases. Again, PV will not demonstrate teardrop red blood cells, and determination of the red cell mass will oftentimes differentiate between the two, except in PV with iron deficiency (9).

Acute myelofibrosis is a rare disease that behaves in a clinically aggressive manner like acute leukemia, but this disorder is incompletely understood and somewhat controversial (135,136 and 137). However, clinically these patients do not present with splenomegaly, and the characteristic red blood cell changes of CIMF are lacking. The bone marrow in acute myelofibrosis is hypercellular with trilineage hyperplasia accompanied by marked reticulin fibrosis, mimicking CIMF in the cellular phase.

Acute myeloid leukemia with fibrosis, particularly AML-M7, may enter the differential diagnosis. Acute megakaryoblastic leukemia may show a spectrum of undifferentiated blasts to immature or mature megakaryocytes and may appear as marked megakaryocytic hyperplasia with marked reticulin fibrosis on the bone marrow core biopsy (137, 138). The erythroid and granulocytic elements may comprise a small component of the marrow. AML-M7 is favored over CIMF if a predominant blast population is seen at the time of initial disease presentation. Mediastinal germ cell tumors in young men are associated with AML-M7, and the incidence of AML-M7 is also increased in Down's syndrome patients (139).

CIMF does not usually show significant dysplasia. Some cases of myelodysplasia with fibrosis may show significant myelofibrosis and mimic CIMF. However, myelodysplasia with fibrosis is characterized by trilineal dysplasia and pancytopenia, and lacks organomegaly (140).

Clinical Course/Prognosis

The clinical course of CIMF is variable with reported survivals ranging from 1 year to greater than 30 years, but median survival is 5 years after diagnosis. Common causes of death are infection, thrombohemorrhagic episodes, cardiac failure (exacerbated by anemia and hemorrhage), or blastic transformation (141,142 and 143).

Overall, 5% to 10% of patients (9) will undergo blast crisis. Progression to acute leukemia is part of the natural history of this disease and is not limited to patients who received prior alkylating agents (9).

Various prognostic indicators have been implicated in different studies. Poor prognostic indices that have been reported include severe anemia, especially if accompanied by reticulocytopenia; thrombocytopenia; increased numbers of circulating, immature granulocytes; marked marrow fibrosis; constitutional symptoms of fever, night sweats, and weight loss; increased age; and clonal karyotypic abnormalities (141,142,143 and 144). Spleen size has not been shown to significantly affect prognosis (141).

Therapy

Standard therapy is primarily palliative with blood transfusions for the cytopenias; androgen therapy for erythropoiesis; hydroxyurea to improve hepatosplenomegaly and to provide relief of the constitutional symptoms; and splenectomy for refractory cytopenias, symptomatic splenomegaly, and portal hypertension from massive splenomegaly. Allogeneic bone marrow transplantation offers the possibility of a cure, particularly in young patients under the age of 40 (145, 146). Experimental therapeutic agents such as vitamin D, α- and γ-interferons, and erythropoietin have been tried, but show conflicting results (122).

HYPEREOSINOPHILIC SYNDROME/CHRONIC EOSINOPHILIC LEUKEMIA

Part of "45 - Chronic Myeloproliferative Disorders"

Eosinophilia is defined as abnormal accumulation of eosinophils in peripheral blood or tissue. Blood eosinophilia often is associated with tissue eosinophilia that can cause end organ damage. Peripheral blood eosinophilia is present when the absolute eosinophil count exceeds 0.4×10^9/L, and it has been classified into mild (less than 1.5×10^9/L), moderate (greater than 1.5×10^9/L, but less than 5×10^9/L), and severe (greater than 5×10^9/L) (147).

Differential Diagnosis of Eosinophilia

The differential diagnosis of peripheral blood eosinophilia (147,148 and 149) comprises a long and varied list that may be broadly classified into two major categories of reactive, nonclonal causes and neoplastic etiologies. The most common causes of reactive eosinophilia are allergies/atopic diseases (including asthma, rhinitis, eczema, atopic dermatitis), parasitic infections (predominantly helminthic parasites), and drug reactions. Connective tissue diseases such as rheumatoid arthritis and polyarteritis nodosa, cutaneous disorders, and certain neoplasms (e.g., breast and ovarian cancer, Hodgkin's disease) also can cause reactive eosinophilia.

The neoplastic or reactive nature of the eosinophilia in hematopoietic neoplasms may sometimes be difficult to determine. Tumor-associated tissue eosinophilia is seen in extramedullary myeloid tumors (granulocytic sarcoma), peripheral T-cell lymphomas, Hodgkin's disease, and mast cell disease. Primary leukemic and marrow disorders associated with eosinophilia include chronic myelogenous leukemia, chronic eosinophilic leukemia (Fig. 45.17), acute myelogenous leukemia-M4 with increased eosinophils (AML-M4 EO) associated with chromosome 16 abnormalities, and acute lymphoblastic leukemia with eosinophilia. In most cases of AML with eosinophilia, the eosinophils are thought to be part of the malignant clone (150). In contrast, the eosinophilia associated with acute lymphoblastic leukemia is generally reactive (150,151 and 152).

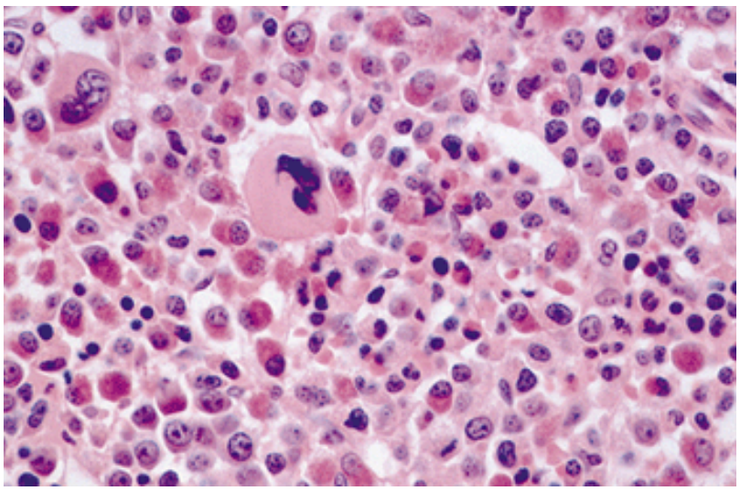

FIGURE 45.17. Bone marrow biopsy of chronic eosinophilic leukemia showing myeloid hypercellularity with marked eosinophilic hyperplasia.

In addition, some diseases are associated with accumulation of eosinophils limited to specific organs (149). Examples include Well's syndrome (eosinophilic cellulitis), Loffler's syndrome (eosinophilic pneumonia), and Shulman's syndrome (eosinophilic fasciitis).

Hypereosinophilic Syndrome (HES)

This diagnosis is reserved for patients with unexplained, persistent blood eosinophilia causing organ damage. This disorder is seen predominantly in men and will progress if not adequately treated. The diagnostic criteria for this disorder include persistent blood eosinophilia of greater than 1.5×10^9/L for longer than 6 months, exclusion of all known causes of eosinophilia, and evidence of organ/tissue damage presumably from the eosinophilia (153, 154). HES is difficult to differentiate from chronic eosinophilic leukemia, as a recent study found clonal eosinophils in a HES patient using clonality assays directed to the human androgen receptor gene (HUMARA) (155). However, such clonality studies require a larger cohort of HES patients.

Organ damage secondary to eosinophilia can occur, regardless of the reactive or clonal nature of the eosinophilia. The heart is the most commonly involved organ and may manifest as constrictive pericarditis, myocarditis, cardiomyopathy, endomyocardial fibrosis, intramural thrombi, and valve regurgitation (147, 156). Neurologic, cutaneous, gastrointestinal, pulmonary, ocular, renal, and articular involvements also have been reported. The tissue damage is believed to be secondary to the released contents of the eosinophil granules together with thrombosis and eosinophilic infiltration of the tissue (147). Eosinophils contain several proteins that can damage endothelium

and cause thrombosis (157). The eosinophil major basic protein and cationic protein can also cause significant tissue damage (158).

Chronic Eosinophilic Leukemia (CEL)

Diagnostic criteria for CEL have been proposed by Weide et al. (159) and Oliver et al. (160). First, the blood eosinophil count is greater than 1.5×10^9/L. All other causes of eosinophilia are excluded. There is no evidence of the Ph chromosome or BCR/ABL translocation to exclude the possibility of eosinophilic variant of CML (159). In addition, there is no evidence of inv (16), t(16;16), or CBFβ/MYH11 rearrangement to exclude AML-M4 EO (159). Finally, eosinophils demonstrate clonal chromosomal abnormalities or two of the following criteria have to be met: (i) immature eosinophil precursors account for greater than 25% of the bone marrow or periperal blood differential count, (ii) myeloblasts comprise greater than 5%, but less than 30% of the bone marrow or peripheral blood differential count, or (iii) eosinophils demonstrate positivity for chloroacetate esterase (160).

Some cases of CEL are diagnosed later on with follow-up, as the patient develops granulocytic sarcoma or blastic transformation, or subsequent studies show evidence of clonality. Morphologic features of the eosinophils usually are not reliable in distinguishing between reactive and neoplastic disorders (150). Hypogranularity/agranularity, cytoplasmic vacuolation, and nuclear abnormalities (hyperlobation, hypolobation, and ring forms) of the eosinophils have been described in CEL (147, 150, 159).

Clonality can only be reliably resolved by cytogenetic and molecular studies. Although most cases have normal karyotype, numerous cytogenetic abnormalities have been reported in CEL (150, 159, 160). Among the more common chromosomal anomalies are trisomy 8, isochromosome 17, monosomy 7, translocations involving the long arm of chromosome 5, and loss of the Y chromosome. Fluorescence *in situ* hybridization also has been used to demonstrate cytogenetic abnormalities in the eosinophils (161). Clonality assays utilizing glucose-6-phosphate dehydrogenase isoenzyme analysis or X-linked gene inactivation patterns in heterozygous females have been used (147, 150). Some chromosomal abnormalities have been associated with specific clinical presentations. For example, t(5;12) has been associated with a chronic myeloproliferative disorder with marrow eosinophilia (150, 162). These patients are mostly men with hepatosplenomegaly, neutrophilia, and low neutrophil alkaline phosphatase score. In addition, an association between t(8;13), T-lineage lymphoblastic lymphoma and myeloid hyperplasia/malignancy in the bone marrow with eosinophilia has been described (163, 164).

It has been proposed that CEL, similar to CML, has a chronic phase, but blastic transformation can occur (147, 159, 160). Some patients, however, die soon after diagnosis without an increase in blasts in their bone marrow. The early death is thought to be primarily from HES (150). Treatment options for CEL include hydroxyurea, interferon, aggressive chemotherapy, or allogeneic bone marrow transplantation (159).

46 Overview of Hemostasis

47 Laboratory Evaluation of Platelet Disorders

48 Coagulation Abnormalities

49 Thrombophilia

Our understanding of hemostatic process has increased greatly over the past decade. With the introduction of sophisticated biochemical and molecular biology techniques, the components of this process have been characterized in great detail. This section is designed to provide an overview of the hemostatic process and of disorders resulting from abnormalities of this system. In Chapter 46, the normal mechanisms of hemostasis are reviewed, including primary hemostasis (platelet plug formation), secondary hemostasis (fibrin clot formation), and regulation of hemostasis. Included in this chapter is an introduction to the evaluation of patients with hemostatic problems.

Disorders of primary hemostasis are discussed in Chapter 47. Congenital and acquired disorders of platelet function, including heparin-induced thrombocytopenia and thrombotic thrombocytopenic purpura, are summarized in this chapter. The characteristic laboratory findings in these disorders are reviewed.

Disorders of fibrin clot formation are discussed in Chapter 48. These include the common congenital disorders hemo-philia A and B as well as acquired abnormalities such as factor inhibitors and lupus anticoagulants. Laboratory techniques for diagnosis of these various disorders are reviewed in detail.

Chapter 49 is devoted to problems associated with an increased risk of thrombosis. Emphasis is placed on congenital disorders associated with thrombosis (thrombophilia) and the role of the laboratory in the diagnosis of these conditions. The potential for utilizing markets of hemostasis activation is also reviewed.

46
Overview of Hemostasis

John T. Brandt

Hemostasis may be defined as the process that maintains flowing blood in a fluid state and prevents loss of blood from sites of vascular disruption. This definition implies two major components: first, a potent procoagulant mechanism that is capable of forming stable hemostatic plugs at sites of vascular disruption; and second, regulatory systems that confine normal hemostatic plug formation to sites of vascular disruption. Active components in this system include circulating platelets, procoagulant and regulatory plasma proteins, and endothelial cells lining the vascular wall. Normal hemostasis is a dynamically modulated process in which a delicate balance between the procoagulant and regulatory components of hemostasis is maintained.

The procoagulant mechanism normally is initiated by vascular damage or disruption. This leads to deposition of platelets at the damaged site, a process that is sometimes referred to as primary hemostasis. The platelet plug is reinforced and anchored by the fibrin clot, which is composed of a meshwork of fibrin strands. The formation of the fibrin clot is sometimes referred to as secondary hemostasis. Formation of the hemostatic plug normally is halted as it extends into areas of the vessel lined by intact endothelial cells (Fig. 46.1). The mechanisms involved in turning off the process comprise the regulatory systems of hemostasis. This chapter reviews the major mechanisms involved in primary hemostasis, secondary hemostasis, and regulation of hemostasis. It also outlines an approach to the evaluation of patients with hemostatic disorders. Specific disorders affecting hemostasis are discussed in subsequent chapters in this section.

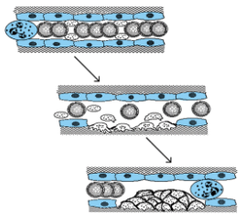

FIGURE 46.1. The formation of a hemostatic plug usually begins when the vessel wall is damaged, exposing the thrombogenic subendothelial tissue to blood. The initial response is platelet adhesion, with the responding platelets forming a monolayer over the exposed subendothelial tissue (**B**). During this response the platelets are activated and additional platelets are recruited to form the platelet plug. This phase of platelet-platelet interaction is known as platelet aggregation. Fibrin formation begins as the responding platelets are activated, resulting in deposition of a fibrin meshwork, which envelops the platelet plug (**C**). Hemostatic plug formation is normally limited to sites of vascular disruption by an active regulatory mechanism that is dependent upon intact endothelial cells.

PRIMARY HEMOSTASIS

Part of "46 - Overview of Hemostasis"

Platelet Production and Morphology

Platelets, an essential component of hemostasis, are anucleate cytoplasmic fragments derived from bone marrow megakaryocytes that are themselves derived from the pluripotent hematopoietic stem cell (1,2,3,4,5 and 6). At least two sequential stages of megakaryocyte progenitors have been demonstrated by *in vitro* culture techniques; the burst-forming unit-megakaryocyte and the more mature colony-forming unit-megakaryocyte. Each of these stages appears to be sensitive to a different set of cytokines and hematopoietic growth factors that may up- or down-regulate megakaryopoiesis. The major growth factor that drives megakaryocyte development is thrombopoietin (TPO), a 332 amino-acid glycoprotein. Thrombopoietin has the capacity to affect both stages of megarkaryocyte development; it can induce production of burst-forming unit-megakaryocytes from pluripotent stem cells and drive maturation and differentiation of colony-forming unit-megakaryocytes. The effect of TPO is mediated by interaction with a specific receptor, cMpl, on progenitor cells. The importance of this ligand-receptor interaction is demonstrated by the severe thrombocytopenia that occurs in experimental animals in which the gene for cMpl is inactivated by homologous recombination. Other cytokines and growth factors, such as IL3, IL6, IL11, erythropoietin and CSF-GM also appear to actively modulate the effect of TPO on megakaryocyte development.

Maturation of the colony-forming unit-megakaryocyte leads to formation of recognizable megakaryocytes. Megakaryocytes are large cells with multilobated nuclei derived from a process of endomitosis. Normal megakaryocytes are usually 8N-32N, but ploidy can vary depending on the rate of platelet production and consumption. Maturation of megakaryocytes is associated with development of platelet specific proteins both within cytoplasmic granules and on the membrane surface. Platelets are formed and released from megakaryocytes by a process of cytoplasmic fragmentation along lines of demarcation formed by infolding of the cytoplasmic membrane. Platelet size thus depends on the size of the zone of demarcation. When platelet production is increased, the zones of demarcation are typically larger, resulting in an increase in the mean platelet volume (MPV), a common feature of thrombocytopenia secondary to increased consumption.

The nonactivated platelet normally has a discoid shape that is maintained by a circumferential band of microtubules (Fig. 46.2). The platelet membrane is physically and biochemically complex. There are numerous infoldings of the external plasma membrane to form the surface-connected open canalicular system. The membrane contains a variety of receptors and functional proteins, some of which are linked to membrane-associated cytoplasmic enzyme systems such as phospholipase A2, phospholipase C, and adenylate cyclase (Table 46.1). Beneath the cytoplasmic membrane is a sol-gel zone rich in actin and myosin. These proteins are involved in the shape change and contraction characteristic of platelet activation and aggregation.

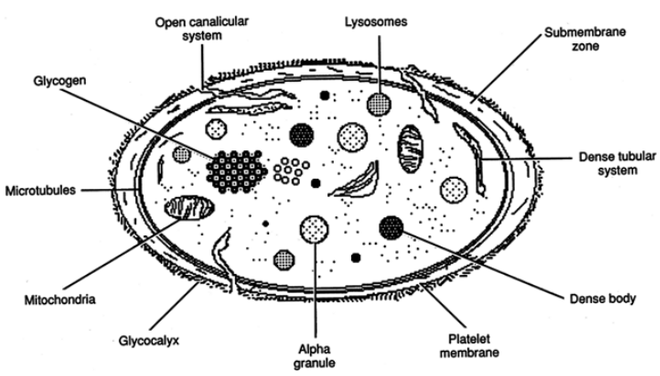

FIGURE 46.2. Key structural features of normal resting platelets are depicted. The open canalicular system is formed by invaginations of the plasma membrane. This system becomes dilated upon platelet activation and serves as a route for platelet secretion. Closely juxtaposed to the open canalicular system is the dense tubular system, which serves as a storage site for calcium. Platelet α-granules contain a variety of proteins, while the major functional constituents of the dense granules are small organic compounds such as ADP, ATP, and serotonin. The discoid shape of the resting platelet is maintained by a circumferential band of microtubules.

Juxtaposed to the surface-connected open canalicular system is a series of membrane-bound tubules referred to as the dense tubular system. The dense tubular system corresponds to the endoplasmic reticulum of smooth muscle cells and functions as a storage site for calcium. Within the cytoplasm are several

organelles, including mitochondria, peroxisomes, α-granules, dense granules and lysosomes; storage pools of glycogen also are frequently present in resting platelets. The α granules contain a variety of proteins, many of which are homologues of plasma proteins (Table 46.2). A long-standing question has been whether or not such proteins are derived from endocytosis by the platelets or active synthesis by the megakaryocyte. Evidence to date suggests that both mechanisms are involved. Platelet IgG, albumin, and fibrinogen concentrations are directly proportional to the plasma concentration of these proteins, suggesting that their presence in the α-granule represents endocytosis from plasma rather than endogenous platelet synthesis. Other proteins, including platelet factor 4, ß-thromboglobulin, and von Willebrand factor (vWF), are clearly synthesized by megakaryocytes.

TABLE 46.1. PLATELET SURFACE PROTEINS AND RECEPTORS

	Protein/Receptor	Alternate Designation	Function
Expressed on nonactivated platelets	GP Ia/IIa	CD49b/CD29	Collagen receptor
	GP Ic/IIa	CD49e/CD29	Fibronectin receptor
	GP Ib/IX/V	CD42b/CD42c/CD42a/CD42d	von Willebrand factor receptor
	GP IIb/IIIa	CD41/CD61	Fibrinogen receptor
	GP IV	CD36	Thrombospondin receptor
	GP Ic'/IIa	CD49f/CD29	Laminin receptor
	Vn Rα/IIIa (α_v $ß_3$)	CD51/CD61	Vitronectin receptor
	GP VI		Collagen receptor
	Thrombin receptor (Protease-activated receptor)		Mediates thrombin activation of platelets
	P2Y1 ADP receptors		ADP stimulation of calcium mobilization
	P2X1 ADP receptors		ADP stimulation of cation influx
	$P2T_{AC}$ ADP receptors		ADP-mediated macroscopic aggregation
	α_2-adrenergic receptors		Mediate epinephrine-induced platelet aggregation
	PECAM-1	CD31	Adhesion molecule (Platelet-endothelial cell adhesion molecule)
	FcγRIIa	CD32	Receptor for immune-complex IgG
	Membrane cofactor protein	CD46	Cofactor for factor I-mediated cleavage of C3b/C4b
	Decay accelerating factor	CD55	Glycosylphosphatidylinositol linked protein that accelerates decay of C3 and C5 convertase
	Membrane inhibitor of reactive lysis (MIRL)	CD59	Glycosylphosphatidylinositol linked inhibitor of complement-mediated cell lysis
	Apolipoprotein E		Binding of ApoE stimulates nitric oxide synthetase
	Receptor 2		
Expression limited to activated platelets	P-Selectin	CD62P	Mediates interaction with leukocytes
	CD40 Ligand	CD154	Induces endothelial-cell activation
	Thrombospondin		Stablizes fibrinogen-GP IIb/IIIa interaction
	Multimerin		Function of surface expression unknown
	GP53	CD63	Lysosomal protein
	LAMP-1		Lysosomal protein

Some α-granule proteins are specific for platelets. Activation of platelets *in vivo* can lead to secretion of these proteins into plasma. As these proteins have a relatively short half-life in circulating blood, the plasma level of proteins such as platelet factor 4 and ß-thromboglobulin can serve as an indicator of *in vivo* platelet activation. Thrombospondin, a major constituent of α-granules, has a limited tissue distribution and has also been used as a marker of platelet activation. Some granule-associated proteins (Table 46.1) redistribute to the platelet surface after platelet activation; measurement of platelet surface expression of such proteins also can be used as an indicator of *in vivo* platelet activation.

The platelet-dense granules contain a variety of small organic compounds, including ADP, ATP, calcium, and serotonin. Perhaps the most important component of the dense granules is ADP, an essential platelet agonist. Patients who have platelets that are deficient in dense granules have a bleeding disorder related to abnormal platelet function. As circulating platelets are anucleate, their ability to synthesize new proteins is relatively limited. Thus, once a platelet has undergone release of its granule contents or inactivation of one or more of its enzymes (e.g., aspirin effect), it remains functionally impaired until it is removed from the circulation.

The Platelet Response to Vascular Injury

The typical platelet response to vascular injury can be divided into three major phases. These are: *platelet adhesion*, the interaction of platelets with nonplatelet surfaces; *platelet activation*, a phase during which biochemical pathways are activated, cytoplasmic calcium concentration increases, and platelets undergo

shape change and secrete granule constituents, including ADP; and *platelet aggregation*, the interaction of platelets with each other to form platelet aggregates.

TABLE 46.2. PLATELET α-GRANULE PROTEINS

Homologues of Plasma Proteins	Platelet-Specific Proteins	Platelet-Associated Proteins
Fibrinogen	Platelet factor 4	Thrombospondin
Factor V, VIII	ß-Thromboglobulin	Multimerin
von Willebrand factor		P-Selectin
High molecular weight Kininogen		Platelet-derived growth factor
Protein S		Endothelial-cell growth factor
Plasminogen		
Plasminogen activator inhibitor-1		
α_2-Antiplasmin		
α_1-Antiprotease		
α_2-Macroglobulin		
Fibronectin		
Vitronectin		
Osteonectin		
Albumin		
Factor D		
ß-1H-Globulin		

Platelet Adhesion

The adhesion of platelets to exposed subendothelial structures is mediated primarily by the interaction between vWF and its cellular receptor, glycoprotein Ib/IX/V (GP Ib/IX/V) (Fig. 46.3)(7,8,9,10,11 and 12). vWF is a very large glycoprotein that is normally released into the circulation as an unbranched polymer consisting of a variable number of homodimeric subunits (Fig. 46.4). vWF is synthesized by both endothelial cells and megakaryocytes; plasma vWF is primarily a product of endothelial cell synthesis and release, whereas platelet α-granule vWF is primarily a product of megakaryocyte synthesis. In addition, endothelial cells secrete vWF into the subendothelial cell space so that vWF is present in the subendothelial matrix itself. All three sources of vWF are necessary for an adequate platelet response to vascular injury.

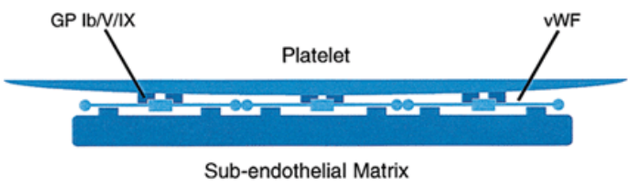

FIGURE 46.3. Platelet adhesion is a "molecular gluing" process mediated by von Willebrand factor (vWF) interaction with the platelet glycoprotein Ib/IX/V receptor complex (GP Ib/IX/V) and the subendothelial matrix. HMW multimers of vWF are necessary for effective platelet adhesion, perhaps because this maximizes the contact between platelet surfaces and the tissues to which the platelets adhere. Under normal flow conditions, vWF does not bind to GP Ib/IX/V. Apparently, binding of vWF to matrix materials such as collagen induces a conformational change in vWF that allows it to bind to GP Ib/IX/V.

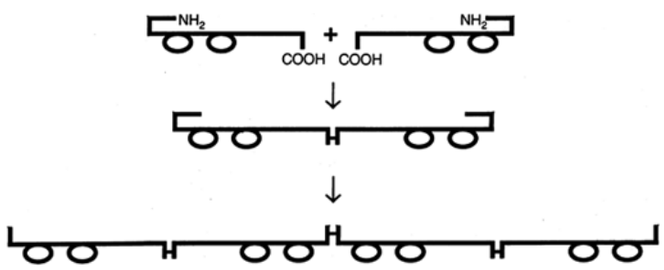

FIGURE 46.4. The synthesis of von Willebrand factor (vWF) is a complex, multi-step process in which 275 kd monomeric subunits are assembled into long, unbranched polymers. Monomeric subunits initially form dimers through the formation of disulfide linkages between the carboxyl terminal ends of monomers. The amino-terminal ends of dimers are then linked together by disulfide bonds. During the later stages of processing, a large peptide is removed from the amino-terminal end of the subunits; this fragment has been designated vWF antigen II. Only the large polymers (HMW multimers) are effective in mediating platelet adhesion.

The GP Ib/IX/V receptor complex is composed of four proteins: Ibα, Ibß, V and IX, each coded for by a distinct gene. Expression of the receptor complex on the platelet surface is dependent on coordinated synthesis of these protein components, as defects in either the Ibα, Ibß, or IX gene may lead to decreased expression of the receptor (Bernard-Soulier syndrome, see Chapter 47). The binding site for vWF is present in the N-terminal extracellular domain of GP Ibα. Intracellular domains of the receptor complex are associated with the platelet cytoskeleton and phospholipase A2. Consequently, ligand binding to the receptor is able to initiate biochemical signaling pathways.

Under normal conditions, vWF multimers do not bind to the platelet GP Ib/IX/V receptor. Current evidence suggests that a conformational change in vWF and/or GP Ib/IX/V is necessary for binding. Such a conformational change may be induced by interaction between vWF and subendothelial components such as collagen, high sheer stress associated with blood flow, or various exogenous agents such as ristocetin or certain venoms. Only the longer polymers [high-molecular-weight (HMW) multimers] of vWF are capable of effectively mediating platelet adhesion, perhaps because the larger forms maximize surface contact between the platelet and vessel wall. In addition, the HMW multimers of vWF may enhance clustering of GP Ib/IX/V receptors on the platelet surface, a step which may be critical for transmitting a ligand binding signal into the cytoplasm of the responding platelets.

Platelet Activation

Platelet activation is associated with a change in platelet shape, marked by extension of pseudopodia, secretion of dense and α-granule contents, activation of the ligand-binding site on GP IIb/IIIa, and translocation of negatively charged aminophospholipids to the external surface of the platelet(13,14,15,16,17 and 18). The cascade of these events is driven by a rapid increase in cytoplasmic calcium concentration. The rise in calcium is triggered by activation of biochemical response pathways resulting from interaction of platelet agonists such as thrombin, ADP, thromboxane A_2, collagen, epinephrine, and vWF with specific membrane receptors. Some of the membrane receptors, such as the thrombin receptor, are coupled to a G protein response mechanism that directly activates phospholipase Cγ while other receptors interact with the cytoskeleton or other response mechanisms that trigger

activation of other phospholipase C isoforms. For example, the GP Ib/IX/V receptor complex is linked to the platelet cytoskeleton and vWF binding induces clustering of these receptors, transmitting a signal to the cytoplasm and activating the biochemical response pathways.

Activation of phospholipase C by any one of a number of membrane signals leads to cleavage of phosphatidylinositol-bisphosphate (PIP_2) and release of two critical intracytoplasmic mediators, diacylglycerol (DG) and inositol trisphosphate (IP_3) (Fig. 46.5). Inositol trisphosphate causes a rapid release of calcium from its storage sites into the platelet cytoplasm, leading to the increase in cytoplasmic calcium. This activates calmodulin-dependent phosphokinases and leads directly to phosphorylation of myosin light chain. Diacylglycerol binds to and activates protein kinase C, which then phosphorylates a number of proteins, including pleckstrin, a 47-kd protein essential for propagating the activation signal. In addition, DG can lead to activation of the phospholipase A2 pathway, further amplifying the activation signal.

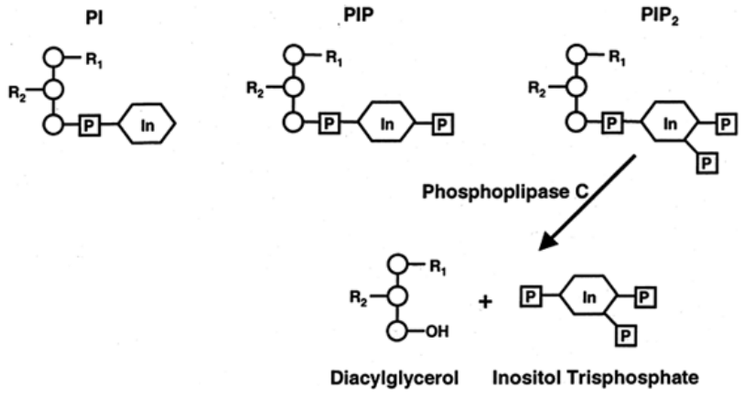

FIGURE 46.5. Platelet activation involves a number of biosynthetic pathways in the platelet. The phospholipase C (PL C) pathway is responsible for production of diacylglycerol (DG) and inositol trisphosphate (IP_3) from phosphatidylinositol bisphosphate (PIP_2). Diacylglycerol activates protein kinase C (PK C), leading to phosphorylation of pleckstrin and activation of a number of downstream pathways. IP_3 releases calcium from storage sites, leading to a sudden increase in cytoplasmic calcium concentration and activation of calmodulin-dependent protein kinases. This pathway leads to myosin light chain phosphorylation and platelet contraction.

Phospholipase A2 releases arachidonic acid from membrane phospholipids, particularly phosphatidylcholine (Fig. 46.6). Arachidonic acid can be converted into cyclic endoperoxides by cyclo-oxygenase or metabolized by 12-lipoxygenase. In the platelet, the cyclo-oxygenase pathway leads to formation of thromboxane A_2, another potent stimulator of phospholipase C. Aspirin and other nonsteroidal antiinflammatory agents have an antiplatelet effect because of their ability to inhibit cyclo-oxygenase and block formation of thromboxane A_2.

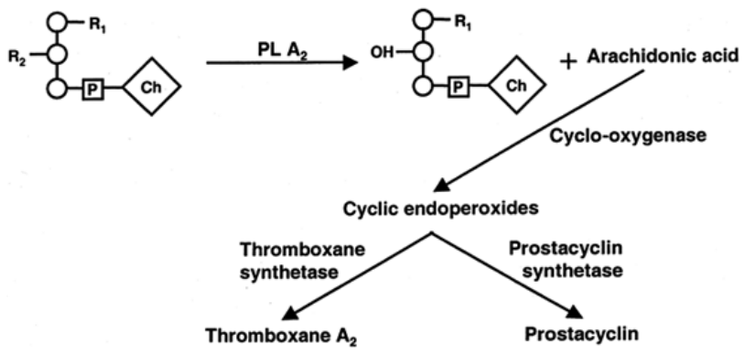

FIGURE 46.6. The phospholipase A2 (PL A2) pathway releases arachidonic acid (AA) from membrane phospholipids, particularly phosphatidylcholine. Arachidonic acid is then converted into cyclic endoperoxides by cyclo-oxygenase. In the platelets these cyclic endoperoxides are converted into thromboxane A_2 (TxA_2), a potent platelet agonist. In the vessel wall, the cyclic endoperoxides are converted into prostacyclin, a potent inhibitor of platelet function.

TABLE 46.3. CONTACT SYSTEM ENZYMES

Protein	Molecular Weight (kd)	Biological Half-Life (hr)	Activated By	Function
Factor XII (Hageman factor)	80	50	Kallikrein	Activates prekallikrein, factor XI
Prekallikrein (Fletcher factor)	85	50	Factor XIIa	Activates factor XI, Prourokinase, HMW Kininogen→bradykinin
Factor XI	160 (dimer)	40	Factor XIIa	Activates factor IX

The phosphatidylinositol-3 kinase (PI3-K) pathway leads to synthesis of intracellular lipid messengers, including phosphatidylinositol-3,4 bisphosphate and phosphatidylinositol-3,4,5 triphosphate (Fig. 46.7). These mediators interact with a variety of proteins bearing pleckstrinlike domains, initiating downstream activities, including exposure of the ligand-binding site on GP IIb/IIIa. Inhibition of the PI3-K pathway by specific inhibitors blocks a normal platelet aggregation response to many platelet agonists, indicating that this pathway plays an important role in modulating the signal pathways in platelets.

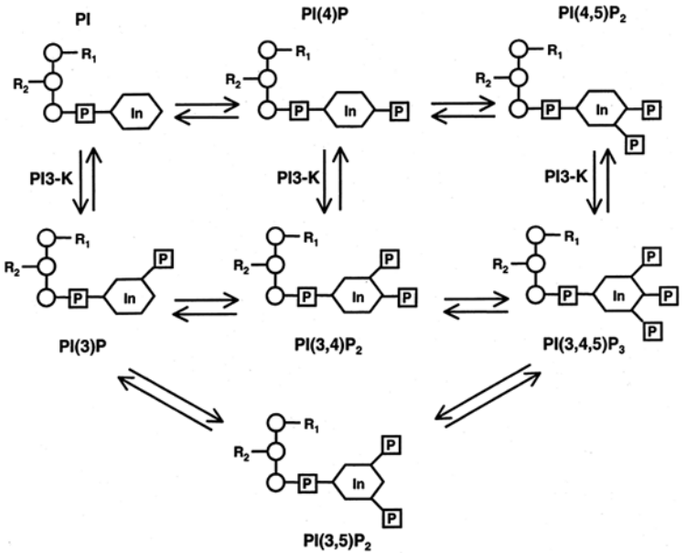

FIGURE 46.7. The phosphatidylinositol-3-kinase (PI3-K) pathway generates important intermediate messengers in the platelet activation pathway. The various phosphatidylinositol-3-PO4 species [PI(3,X)Px] bind to pleckstrinlike domains on responder molecules, modulating their activity. The PI3-K pathway is essential for platelet aggregation, as inhibition of PI3-K by specific inhibitors can block the aggregation response to certain platelet agonists.

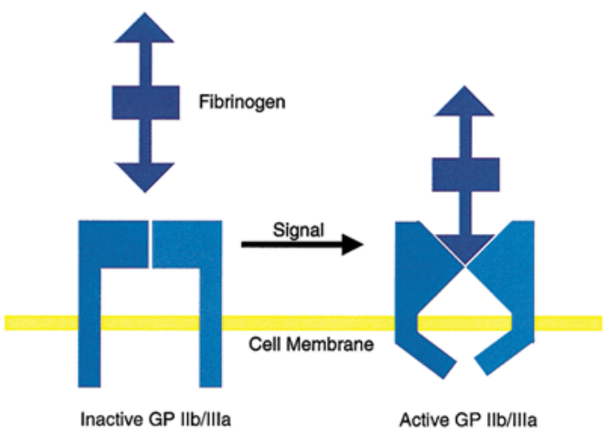

FIGURE 46.8. Platelet aggregation is mediated by the cross-linking of glycoprotein IIb/IIIa (GP IIb/IIIa) on adjacent platelet membranes. A number of adhesive proteins may mediate this process, but fibrinogen is the major mediator of this process *in vivo*. The structural symmetry of fibrinogen makes it an excellent molecule for this process. Under resting conditions, the binding site on GP IIb/IIIa for adhesive proteins is not exposed. Upon platelet activation, GP IIb/IIIa undergoes a conformational change, allowing binding of fibrinogen or other adhesive proteins. The conformational change in GP IIb/IIIa may be initiated by changes in the intracytoplasmic domains of IIb and/or IIIa (inside-out signaling) or by extracellular factors. Binding of fibrinogen to GP IIb/IIIa also induces a change in the cytoplasmic domain of the molecules, so that extracellular activation of the receptor and subsequent ligand binding can also be a signaling process (outside-in signaling).

One of the principal results of activation of these various biochemical pathways is exposure of the ligand-binding site on GP IIb/IIIa, the receptor that mediates the final stage of the platelet response, platelet aggregation. In its nonactivated form, GP IIb/IIIa cannot bind to its ligands and thus cannot participate in cross-linking of platelets. However, platelet activation is associated with a conformational change in GP IIb/IIIa that permits ligand binding. Activation of the ligand binding sites on GP IIb/IIIa may occur through biochemical modification of the cytoplasmic component of the complex (inside-out-signaling) or interaction of GP IIb/IIIa with extracelllular factors. As with platelet adhesion, ligand binding to the activated GP IIb/IIIa receptor can also activate other platelet response pathways (outside-in-signaling).

Platelet activation also leads to secretion of the contents of the dense and α-granules. The secreted substances propagate the platelet aggregation response and accelerate thrombin formation by the coagulation cascade. Another critical event associated with platelet activation is the translocation of phosphatidylserine from the inner surface of the platelet membrane to the exterior surface. This process is dependent on a “scramblase” enzyme that is activated by the increase in cytoplasmic calcium concentration. Expression of phosphatidylserine on the external surface facilitates the formation of coagulation activation complexes that mediate thrombin formation. Translocation of phosphatidylserine also is necessary for the formation of platelet microparticles associated with platelet activation.

Platelet Aggregation

Platelet aggregation is another example of “molecular gluing.” The activated form of GP IIb/IIIa can be cross-linked by a variety of adhesive proteins bearing the amino-acid sequence RGD (19). However, the major protein involved in cross-linking platelets *in vivo* is fibrinogen. Intact fibrinogen is a dimeric molecule that allows reciprocal interaction of its terminal ends (D domains) with GP IIb/IIIa receptors on adjacent platelets once the receptor has been activated (Fig. 46.8). Thrombospondin, a major component of platelet α-granules, appears to stabilize and augment the platelet-platelet interaction mediated by fibrinogen. Ligand binding to GP IIb/IIIa activates biochemical response pathways within the platelet cytoplasm, a process referred to as “outside-in signaling.” Under conditions of high shear stress, vWF also can bind directly to the GP IIb/IIIa complex, initiating a platelet aggregation response through the response pathways.

In summary, the primary hemostatic response consists of three major stages. Platelet adhesion is the first step and is mediated by vWF interaction with GP Ib/IX/V and subendothelial receptors. The subsequent shape change and secretion are dependent on activation of multiple biochemical pathways within the platelet resulting in a rapid increase in cytoplasmic calcium. Activation of the platelet leads to expression of the ligand binding site on GP IIb/IIIa and cross-linking by intact fibrinogen. Defects in various platelet and plasma components of this response mechanism have been described and constitute many of the platelet disorders described in Chapter 47. In addition, components of these response pathways have been the target of antithrombotic drugs aimed at inhibiting the platelet component of the hemostatic response.

SECONDARY HEMOSTASIS

Part of "46 - Overview of Hemostasis"

Secondary hemostasis is marked by the conversion of a soluble protein, fibrinogen, into an insoluble gel. Formation of the fibrin meshwork results in reinforcement and stabilization of the platelet plug at sites of vascular disruption. The process of fibrin clot formation can be divided into two major phases; the first phase consists of formation of the potent procoagulant enzyme thrombin; the second phase consists of the conversion of fibrinogen into fibrin with subsequent polymerization and stabilization. The first phase takes place on negatively charged phospholipid surfaces while the second phase occurs in the fluid phase.

Thrombin is formed as a result of multiple enzymatic steps, collectively known as the coagulation cascade. Most of the enzymatic steps involve formation of an “enzyme activation complex” composed of an active enzyme, a proenzyme/substrate protein, a catalytic cofactor, and a negatively charged phospholipid surface (activated platelet with translocated phosphatidylserine) that serves to localize the process and concentrate the reactants (Fig. 46.9). The coagulation cascade can be viewed as the formation of a series of these key activation complexes. As each enzyme activates many substrate proenzymes, each activation complex represents an important amplification step. The result of this amplification is that a small initiating signal can be transformed into a high concentration of thrombin at the site of clot formation.

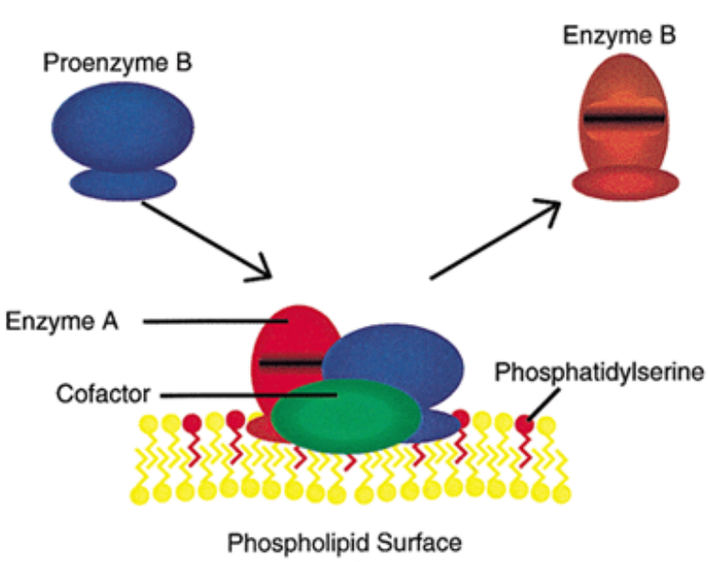

FIGURE 46.9. The basis for most reactions involving the coagulation cascade is the formation of an enzyme activation complex composed of an active enzyme (serine protease); a substrate that is usually the zymogen (proenzyme) of another active enzyme; a catalytic cofactor protein that serves to localize the enzyme and substrate to a phospholipid surface; and a negatively charged phospholipid surface. Thrombin is formed by such a complex in which the active enzyme is factor Xa, the substrate is prothrombin, the cofactor is factor Va, and the phospholipid is provided by a cell surface (e.g., activated platelet). As each enzyme/cofactor is capable of activating many substrate/proenzyme molecules, the formation of these activation complexes allows rapid amplification of the original activation signal.

Coagulation Proteins

The enzymes of the coagulation cascade are serine proteases; that is, they are enzymes that split specific peptide bonds in selected

proteins through formation of unstable intermediate bonds between the target peptide bond and the reactive serine at the enzyme's active site (20,21). Coagulation serine proteases can be divided into two families, the contact system enzymes and the vitamin K-dependent proteases (Table 46.3 and Table 46.4). The contact system serine proteases share several characteristics: the molecular weight of each monomeric unit is 80 to 85 kd; (*b*) they do not require vitamin K for complete synthesis; (*c*) they are not adsorbed by $BaSO_4$ or $Al(OH)_3$; (*d*) they are not dependent on ionic calcium for activation and (*e*) they are not completely consumed during *in vitro* coagulation of blood. Factor XI is unique among these serine proteases in that it circulates as a homodimer linked by disulfide bonds and it is the only protein of this family that is associated with a bleeding tendency when the factor is absent.

TABLE 46.4. VITAMIN K DEPENDENT PROTEINS

Protein	Molecular Weight (kd)	Gla Residues	Biological Half-Life (h)	Activated By	Function
Factor II (prothrombin)	72	10	60	Factor Xa	Cleaves fibrinogen, activates V, VIII, XIII, protein C, platelets
Factor VII	48	10	4-6	Factors IIa, Xa	Activates factors IX, X
Factor IX	57	12	25	Factors XIa, VIIa	Activates factor X
Factor X	55	11	24	Factors VIIa, IXa	Activates factor II
Protein C	62	9	6	Thrombin	Inactivates factors Va and VIIIa
Protein S	69	10	60	Not activated	No enzymatic activity; cofactor for activated protein C

The vitamin K dependent factors are all characterized by the presence of 9-12 γ carboxyglutamic acid residues near the amino terminal end of the protein. Vitamin K is necessary for the post-transcriptional carboxylation of these glutamic acid residues (Fig. 46.10). In the absence of γ-carboxylation, these proteins do not bind calcium and do not interact with phospholipid surfaces. Such descarboxy forms, which are found in vitamin K deficiency, oral anticoagulant therapy and liver disease, are ineffective at mediating secondary hemostasis. Vitamin K dependent proteins are heat stable and, with the exception of prothrombin, are not entirely consumed during coagulation *in vitro*. Some of the proteins (protein C, protein S, factor IX, and factor X) are characterized by an additional post-transcriptional modification, the hydroxylation of an aspartic acid or asparagine in epidermal growth factorlike domains to form ß-hydroxyaspartic acid or ß-hydroxyasparagine. This hydroxylation step creates additional calcium binding sites, which are necessary for normal function of the proteins. The catalytic domain necessary for trypsinlike enzyme activity is found at the carboxyl-terminal end of the vitamin K dependent proteases. Protein S differs from the other vitamin K dependent coagulation proteins in that it has no catalytic domain at the carboxyl terminus. In contrast to the proteolytic activity of the other vitamin K dependent factors, protein S functions as a cofactor, accelerating the activity of activated protein C (APC).

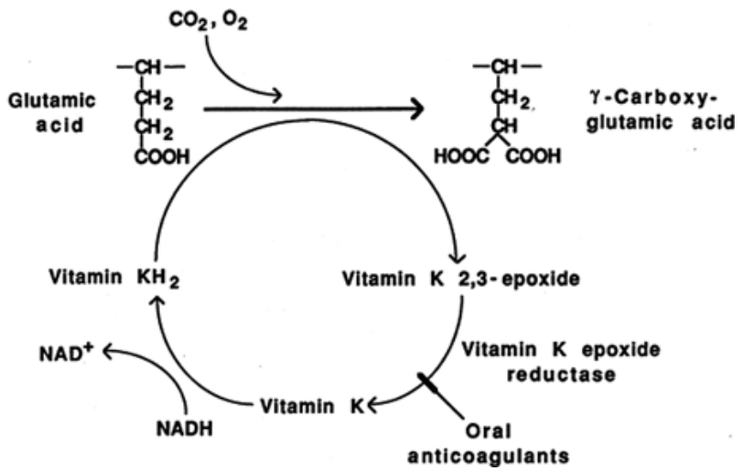

FIGURE 46.10. Vitamin K is necessary for the post-translational modification of glutamic acid residues located near the amino terminal end of the vitamin K dependent proteins. In the presence of reduced vitamin K, these residues are converted to the γ-carboxyglutamic acid residues necessary for calcium binding and interaction with negatively charged phospholipid surfaces. The vitamin K epoxide formed in this process is then metabolized to regenerate the reduced form of vitamin K. Oral anticoagulants inhibit the regeneration of reduced vitamin K, trapping it in the inactive epoxide form.

The remaining coagulation proteins can be grouped into a family designated as thrombin-sensitive proteins and cofactors (Table 46.5). These proteins are all large, with molecular weights greater than 110 kd. Factor V, factor VIII, and HMW kininogen function as catalytic cofactors in enzyme activation complexes, while fibrin functions as a cofactor for the activation of plasminogen by tissue plasminogen activator (tPA). Factor XIII is the only enzyme in this family; it differs from other coagulation enzymes in that it is a transpeptidase and is responsible for cross-linking and stabilizing the fibrin clot. HMW kininogen is the only one of these proteins that is not activated by thrombin.

TABLE 46.5. THROMBIN-SENSITIVE PROTEINS AND COFACTORS

Protein	Molecular Weight (kd)	Biological Half-Life	Activated By	Function
Fibrinogen	340	4-5 days	Thrombin	Fibrin clot, cofactor for activation of plasmin
Factor V	330	12-36 h	Thrombin	Cofactor for activation of prothrombin
Factor VIII	240	12 h	Thrombin	Cofactor for activation of factor X
High molecular kininogen (Fitzgerald factor)	110	6-7 days	Not activated	Cofactor for activation of factor XI, prekallikrein; source of bradykinin
Factor XIII	320	3-5 days	Thrombin	Transpeptidase that stabilizes fibrin clot

Thrombin Formation

There are at least two mechanisms for initiating thrombin formation; these have been designated the intrinsic and extrinsic pathways (22,23,24 and 25). Their names derive from the fact that all components of the intrinsic system are found in circulating blood, while the extrinsic pathway requires the presence of tissue factor, a component that is normally extrinsic to circulating blood. The extrinsic pathway is the major physiological mechanism for initiating the coagulation cascade and generating thrombin for fibrin clot formation. Activation of the intrinsic pathway is not necessary for generation of fibrin clots, but may play a role in fibrinolysis and inflammatory response mechanisms and may be involved in pathological activation of the coagulation cascade. The two pathways correspond to two commonly used tests to screen the coagulation system, the prothrombin time (PT), which measures the extrinsic pathway,

and the activated partial thromboplastin time (APTT), which measures the intrinsic pathway.

Extrinsic Coagulation Pathway

The extrinsic pathway begins with exposure of blood to tissue factor (Fig. 46.11). In the presence of tissue factor and calcium, VIIa activates both factor IX and factor X. Just where the initial factor VIIa comes from is a matter of continuing debate. However, it appears that the coagulation system is dynamically modulated with a constant low level of activation. It is likely that there is always a small amount of factor VIIa around, but in the absence of tissue factor it is incapable of initiating an effective response. Factor IXa, in the presence of factor VIIIa and phospholipid, also converts factor X to Xa. Factor Xa then converts prothrombin to thrombin in the presence of factor Va and phospholipid. The prothrombinase complex (Xa/Va/II/phospholipid) is often designated the “final common pathway” as it is common to both the intrinsic and extrinsic pathways.

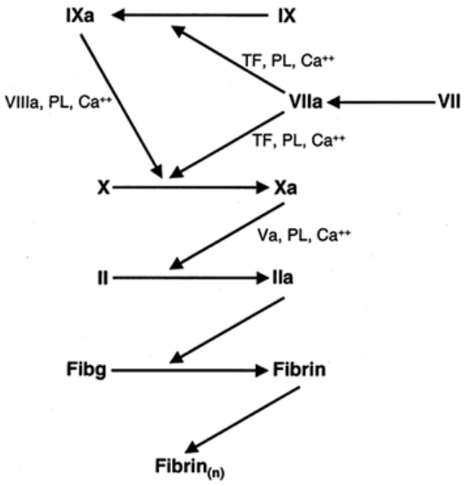

FIGURE 46.11. The coagulation cascade may be initiated by one of two mechanisms; the contact system, that activates the intrinsic system, and the tissue factor pathway (shown here), which initiates the extrinsic system. The extrinsic pathway is activated whenever blood is exposed to tissue factor (TF), an ubiquitous membrane protein found on most cells except circulating blood cells and quiescent endothelial cells. Factor VIIa binds to TF to form an “enzyme activation complex” that converts factor IX to IXa and factor X to Xa. Factor IXa interacts with factor VIIIa to form an additional activation complex that converts factor X to Xa. Factor Xa then interacts with factor Va to form the prothrombinase complex that converts prothrombin into thrombin. Thrombin then converts fibrinogen into fibrin, which spontaneously polymerizes if the concentration of monomers is sufficiently high. Both factors V and VIII must be activated by thrombin before they express effective procoagulant activity (Fig. 46.12). Therefore, initial thrombin generation is slow until there is sufficient thrombin formed to activate these cofactors.

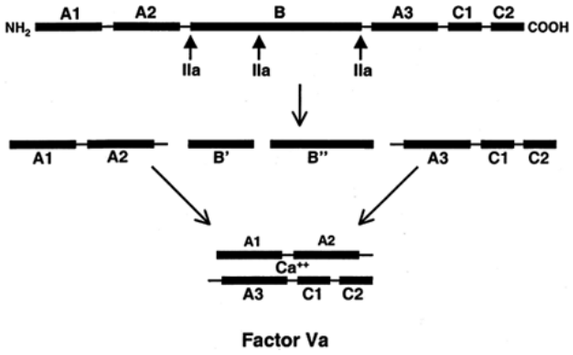

FIGURE 46.12. Factors V and VIII are critical cofactors for the generation of thrombin. These two factors are quite similar in structure, with each composed of 3 homologous “A” domains, a large, heavily glycosylated “B” domain and two homologous “C” domains. These domains are organized into the sequence A1·A2·B·A3·C1·C2. Thrombin activates factors V (shown) and VIII by splitting peptide bonds that remove the large B domain. The A1·A2 fragment (heavy chain) and the A3·C1·C2 fragment form a noncovalently linked, calcium dependent complex that functions as the catalytic cofactor. Factors Va and VIIIa are degraded by activated protein C-mediated cleavage of peptide bonds in the A1·A2 domain.

The role of factors VIIIa and Va is to accelerate the interaction between active enzymes and their target proenzymes. Both factors V and VIII must be activated by thrombin for expression of catalytic cofactor activity (Fig. 46.12). Therefore, the rate of thrombin generation is initially very slow until sufficient thrombin to activate factors V and VIII is formed. The rate of thrombin formation rises exponentially once these cofactors are activated, leading to explosive generation of thrombin at the site of clot formation. The rate of thrombin formation is significantly reduced in the absence of these critical cofactors.

Intrinsic Coagulation Pathway

Classically, activation of the intrinsic system is thought to occur when factor XII binds to negatively charged surfaces, resulting in a conformational change in the molecule and expression of factor XIIa enzymatic activity (Fig. 46.13). Factor XIIa can activate both prekallikrein and factor XI; HMW kininogen serves as a cofactor for both of these activation steps. Indeed, prekallikrein and factor XI each bind to HMW kininogen in circulating plasma. The kallikrein formed by surface-activated XIIa is a potent activator of factor XII and thus the activation of prekallikrein initiates a positive feedback loop, permitting generation of large quantities of factor XIIa and increasing concentrations of factor XIa. Calcium is not required during these initial steps involving vitamin K independent proteins.

More recently, it has been shown that prekallikrein/HMW kininogen complex can bind to specific multi-protein receptors on cell surfaces, including endothelial cells. Cell-associated prekallikrein can be converted to kallikrein independent of factor XII. The kallikrein thus formed can generate bradykinin and activate factor XII and single chain prourokinase. Activation of factor XII can then lead to amplification of the pathway (Fig. 46.13). In addition, alternate mechanisms for the activation of factor XI have been described. Factor XI and XIa can bind avidly to the surface of activated platelets. This binding may be augmented in the presence of low concentrations of thrombin. On the activated platelet surface both thrombin and factor XIa can directly activate factor XI to factor XIa. These cell surface-based mechanisms for activation of the contact system of coagulation bypass the classic factor XII-mediated mechanism proposed for activation of the intrinsic pathway.

Once formed, factor XIa activates factor IX in the presence of calcium and a negatively charged phospholipid surface, particularly activated platelet membranes (Fig. 46.13). This is the only enzymatic step in thrombin formation for which there is no known protein cofactor. Factor IXa activates factor X in the presence of VIIIa, calcium, and phospholipid. Factor Xa then converts prothrombin to thrombin in the presence of factor Va, calcium, and phospholipid. Intrinsic coagulation thus involves two enzyme activation complexes — the factor IXa/VIIIa/X/phospholipid complex and the factor Xa/Va/prothrombin/phospholipid complex — that also are involved in the extrinsic pathway.

The key product of these pathways is thrombin, a potent enzyme that serves several key roles in hemostasis. These include conversion of fibrinogen to fibrin, activation of factors V and VIII, activation of factor XIII, activation of protein C, and activation of platelets. In addition, thrombin can interact and stimulate a variety of other cells, including endothelial cells. For example, interaction of thrombin with endothelial cells can lead to fundamental changes in the endothelial cell surface that increase

procoagulant activity and promote thrombosis. Critical to these functions of thrombin is the fact that conversion of prothrombin is accompanied by separation of the amino terminal, phospholipid-binding portion of the protein from its catalytic (enzymatic) domain. The large amino terminal fragment that is released is referred to as prothrombin fragment 1.2 ($F_{1.2}$). With release of $F_{1.2}$, thrombin becomes a soluble enzyme in contrast to the other vitamin K-dependent enzymes, which are only effective when associated with phospholipid surfaces.

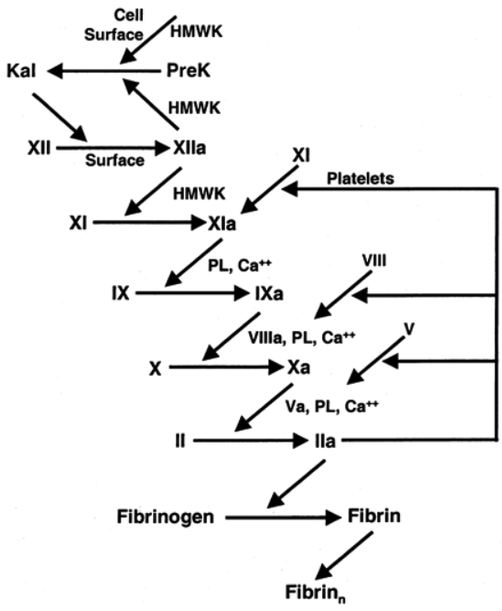

FIGURE 46.13. Classically, the intrinsic system is thought to begin when factor XII is activated by contact with appropriate negatively charged surfaces. Activated factor XII (XIIa) then activates prekallikrein (PreK) and factor XI, initiating the enzymatic cascade resulting in thrombin formation. Kallikrein (Kal), in turn, activates factor XII, resulting in a positive feedback loop in which a high concentration of factor XIIa and XIa can be generated. Factor XIa converts factor IX to IXa and the pathway then follows the reactions of the extrinsic pathway. More recently, it has been shown that there are at least two other mechanisms for initiating the intrinsic system. First, the HMW kininogen (HMWK)/prekallikrein complex that is present in plasma can bind to specific multimolecular cell receptors where prekallikrein is converted to kallikrein. Kallikrein then can activate factor XII, initiating the positive feedback loop of contact activation. Second, thrombin can directly activate factor XI on platelet surfaces, bypassing the need for factor XII and kallikrein. As with the extrinsic pathway, thrombin must activate factors V and VIII before they are effective cofactors.

Fibrin Formation

Fibrinogen is a large homodimeric protein having a molecular weight of 340 kd. It is composed of six peptide chains: two Aα, two Bß, and two γ chains (26). Each half of the fibrinogen molecule is composed of one Aα, one Bß, and one γ chain linked together by extensive disulfide bonds that are concentrated in the amino and carboxyl-terminal ends. The extensive cross-linking gives these regions of the molecule a globular structure, while the intervening sequences are arranged in a long helical structure. The two halves are linked together by reciprocal disulfide bonds between the amino terminal ends of each γ chain (Fig. 46.14).

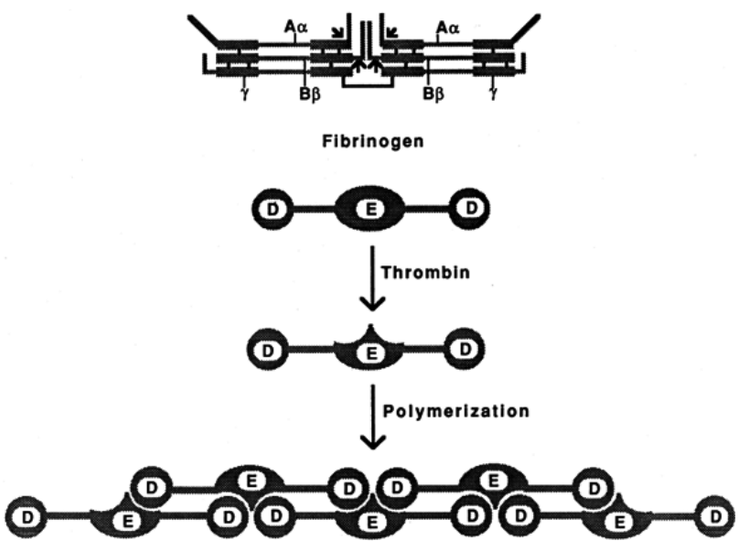

FIGURE 46.14. Fibrinogen is a large dimeric protein composed of six peptide chains. Each half of the dimer is composed of an Aα, a Bß, and a γ chain. There are extensive interchain disulfide bonds near the amino termini, resulting in a central nodular region known as the E domain. Interchain disulfide bonds at the carboxyl termini also result in nodular regions, known as the D domains. A fibrinogen molecule thus consists of a central E domain linked by helical segments to two D domains. Thrombin removes a short peptide from each Aα and Bß chain (fibrinopeptides A and B), altering the conformation of the central E domain. This exposes binding sites for D domains within the central E domain and permits polymerization of the fibrin monomers to form the fibrin gel.

Thrombin cleaves a 16 amino-acid peptide (fibrinopeptide A) from the amino terminal end of each Aα chain and a 14 amino acid peptide (fibrinopeptide B) from each amino terminal end of the Bß chains. Loss of these peptides from the central (E) domain of the fibrinogen molecule alters the charge distribution and exposes binding sites for the carboxyl-terminal ends of fibrin, known as the D domains. As each E domain binds two D domains, the fibrin monomers polymerize in a staggered overlap, with D domains of adjacent fibrin monomers interacting with a central E domain of a third fibrin monomer (Fig. 46.14). Lateral association then leads to gelation of the fibrin. Formation of the fibrin gel is dependent on having a high concentration of fibrin monomers; the gel does not form if the fibrin monomers are present in low concentration. As the gel forms, a large number of proteins are entrapped in the gel matrix, including thrombin, factor XIII, plasminogen, tPA, plasminogen activator inhibitor-

1 (PAI-1) and α_2-antiplasmin. The relative activity of these incorporated proteins ultimately determines the fate of the fibrin clot.

The fibrin gel is stabilized by factor XIIIa, which covalently cross-links fibrin monomers. Plasma factor XIII is a large tetrameric molecule composed of two A and two B subunits. The A and B subunits are under separate genetic control. The B subunit serves as a plasma carrier protein for the A subunit, which contains the catalytic domain. Factor XIII is activated by thrombin, but full enzyme activity is expressed only after the A subunit

separates from the B subunit, a process that occurs within the fibrin matrix. Thrombin activation of factor XIII is accelerated by the presence of non–cross-linked fibrin but is inhibited by fully cross-linked fibrin. This autoregulation serves to help limit factor XIIIa activity to sites of fibrin clot formation. Factor XIIIa covalently links glutamine to lysine amino acids. The principal sites of cross-linkage are between D domains of adjacent fibrin monomers and between the carboxyl-terminal ends of the α chains of distant fibrin monomers (Fig 46.15). Covalent cross-linkage greatly stabilizes the fibrin clot and makes it resistant to fibrinolysis. In addition to cross-linking and stabilizing the fibrin clot, factor XIIIa can also catalyze the formation of covalent bonds between fibrin and other proteins incorporated in the clot matrix, including α_2-antiplasmin.

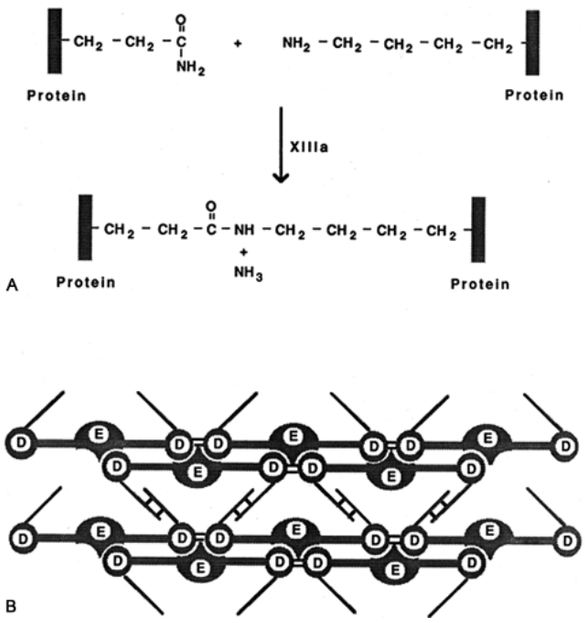

FIGURE 46.15. Factor XIIIa is a transpeptidase that cross-links peptide chains by inducing covalent linkage between glutamine and lysine amino acids (**A**). There are multiple cross-linkage sites in fibrin monomers; some are located near the carboxyl termini of γ chains and result in cross-linkage of adjacent D domains, while others are located in the carboxyl termini of γ chains and result in cross-linkage of distant fibrin monomers. The net effect is an extensively cross-linked fibrin gel that is resistant to fibrinolysis.

REGULATION OF HEMOSTASIS

Part of "46 - Overview of Hemostasis"

The procoagulant mechanisms described in the previous sections lead to rapid formation of hemostatic plugs at sites of vascular damage. Under normal circumstances, coagulation is limited to sites of vascular disruption and is not propagated throughout the vessel. However, if the procoagulant mechanisms are not held in check, thrombus formation can propagate within the vessel, leading to clinically significant occlusive thrombi. There are multiple systems that work in a synergistic manner to regulate the extent of clot formation. An underlying theme to these various systems is the critical role of intact endothelium. Although the endothelium was once thought of as a relatively inert barrier between the circulating blood and the procoagulant extravascular tissues, it is now clear that endothelial cells play an active role in the hemostatic response. Furthermore, it is becoming apparent that endothelial cell function can vary in important ways between different tissues and in response to various inflammatory mediators. Thus the relative importance of the various regulatory systems described below may differ depending on the tissue in which hemostatic activation occurs or the underlying disease process (27,28 and 29).

TABLE 46.6. REGULATION OF PLATELET RESPONSE

Component	Action	Effect
Prostacyclin	Increases cyclic AMP	Inhibits aggregation
Nitric oxide	Increases cyclic GMP	Inhibits aggregation and adhesion
ADPase	Metabolizes ADP	Inhibits aggregation
Endothelial glyocalyx	Electrostatic repulsion	Inhibits platelet adhesion

Regulation of the Platelet Response in Hemostasis

A number of factors that contribute to the regulation of the platelet response have been identified and most are related to intact endothelial cells (Table 46.6) (30,31). One of the most important inhibitors of the platelet response is prostacyclin, which is formed by metabolism of arachidonic acid through the prostaglandin pathway in endothelial and vascular wall cells (Fig. 46.6). Prostacyclin is a short-lived, but potent inhibitor of platelet aggregation. It stimulates platelet adenylate cyclase, which leads to an increase in platelet cytoplasmic cyclic AMP concentration. Cyclic AMP activates Protein Kinase A, which in turn phosphorylates target proteins, leading to inhibition of the phospholipase C pathway and inhibition of the release of calcium from cytoplasmic storage sites.

TABLE 46.7. REGULATION OF FIBRIN CLOT FORMATION

Component	Action	Effect
Tissue factor pathway inhibitor	Inhibits tissue factor/VIIa	Inhibits thrombin formation
Serine protease inhibitors	Neutralize thrombin, factor Xa	Inhibit thrombin formation and activity
Protein C system	Degradation of factors Va and VIIIa	Inhibits thrombin formation
Fibrinolytic system	Degradation of fibrin	Removes excess fibrin clot

Nitric oxide (NO), also known as endothelial-derived relaxing factor, is a short-lived metabolite that has profound effects on platelet responsiveness to vascular injury. NO is a potent vasodilator that causes an increase in platelet cytoplasmic cyclic GMP levels. The increase in cyclic GMP activates Protein Kinase G, which in turn phosphorylates target proteins resulting in inhibition of both platelet adhesion and aggregation. Increased levels of cyclic GMP also lead to inhibition of the phosphodiesterase that degrades cyclic AMP. Consequently, the NO-induced increase in cyclic GMP leads to increased levels of cyclic AMP. In a reciprocal fashion, increased levels of cyclic AMP lead to inhibition of the phosphodiesterase that degrades cyclic GMP. This reciprocal effect on the concentration of these cyclic nucleotides leads to a synergism between the effects of NO and prostacyclin; thus, the low basal levels of these two factors may be sufficient to minimize platelet activation under resting conditions.

There are multiple forms of NO synthetase, including constitutive and inducible isoenzymes. The activity of the constitutive enzyme usually is regulated by calcium concentration and thus is limited to periods of cellular stimulation associated with transient increases in cytoplasmic calcium. The inducible isoform of the enzyme is not dependent on increased calcium concentration for activity and thus can provide a more persistent supply of NO. A number of inflammatory mediators can stimulate production of the inducible NO synthetase and thus NO is an important inflammatory mediator in the sepsis syndrome. Platelets contain a constitutive NO synthetase that can generate low levels of NO. This may be an important mechanism of modulating platelet responsiveness in the circulation. Endogenous platelet NO synthesis can be modulated by the interaction between apolipoprotein E and the apolipoprotein E receptor 2, a transmembrane signaling receptor found on platelet surfaces.

Endothelial cells also express an ADPase (apyrase) (CD39) on their cell surface. The function of ADPase is to convert ADP into inactive metabolites. ADP is essential for platelet aggregation and exposure of the GP IIb/IIIa ligand binding site. Degradation of ADP thus down-regulates propagation of platelet aggregation. Another barrier to platelet activation is the glycocalyx on the surface of intact endothelial cells. The glycocalyx has a negative charge and tends to repulse platelets under resting conditions. In addition, intact endothelial cells serve as a barrier between circulating platelets and subendothelial vWF. Thus, platelet adhesion is prevented in areas where the endothelium remains intact. Under normal circumstances, these components work in concert to limit platelet activation to sites of endothelial disruption.

TABLE 46.8. SERINE PROTEASE INHIBITORS (SERPINS)

Serpin	Target Enzymes
Antithrombin	Factor Xa, thrombin
Heparin cofactor II	Thrombin, chymotrypsin
α_2-Antiplasmin	Plasmin
Protein C inhibitor	Activated protein C, tissue plasminogen activator
Plasminogen activator inhibitor-1	Tissue plasminogen activator, urokinase, activated protein C
C-1-Esterase inhibitor	C-1-Esterase, factor XIIa, kallikrein
α_1-Antiprotease	Neutrophil elastase, trypsin

Regulation of Fibrin Clot Formation

At least four systems have been identified as having a role in the regulation of fibrin clot formation (Table 46.7). Each of these

component mechanisms appears to be critical for effective regulation of hemostasis, and isolated deficiency of components of these systems has been associated with clinical manifestations. These four systems work synergistically to regulate fibrin formation and stabilization.

Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor (TFPI) is a 40-kd glycoprotein that has also been called lipid-associated coagulation inhibitor (LACI) and extrinsic pathway inhibitor (EPI) (32). Tissue factor pathway inhibitor is a Kunitz-type inhibitor with three Kunitz inhibitor domains. It rapidly combines with free factor Xa to form a heterodimeric complex; this interaction is further accelerated in the presence of heparin. In the process, TFPI Kunitz domain 2 binds to the active site of factor Xa, inhibiting its enzymatic activity. The TFPI/Xa complex then binds to the phospholipid membrane-associated tissue factor/factor VIIa complex. The Kunitz domain 1 on TFPI binds to the active site of factor VIIa, inhibiting VIIa enzymatic activity (Fig. 46.16). The γ-carboxyglutamic acid domain of factor Xa is necessary for the TFPI/Xa complex to bind to the phospholipid surface. The TFPI/Xa complex thus is responsible for inhibition of the major physiological initiator of hemostasis, the tissue factor/VIIa complex.

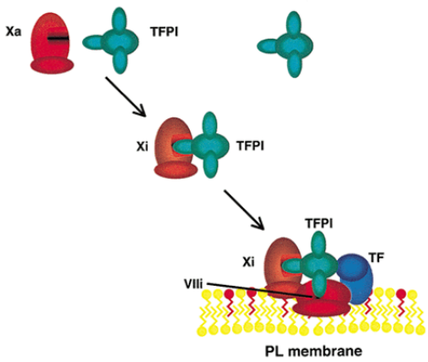

FIGURE 46.16. Tissue factor pathway inhibitor (TFPI) is a Kunitz-type inhibitor that initially forms a 1:1 complex with factor Xa (Xa). Binding of TFPI to Xa converts Xa into an inactive enzyme (Xi). The TFPI-Xi complex then binds to the tissue factor (TF)/factor VIIa(VIIa)-phospholipid complex, inhibiting the activity of TF/VIIa. This provides a mechanism for turning off the tissue factor pathway of initiating the coagulation cascade.

The vascular distribution of TFPI is complex. The majority (75% to 90%) of TFPI is bound to endothelial cells. It can be reversibly displaced into plasma by administration of exogenous heparin. Indeed, one of the potential antithrombotic mechanisms of heparin is its ability to increase the plasma level of TFPI and accelerate its interaction with factor Xa. Most of the circulating TFPI is found bound to plasma lipoproteins; this interaction is mediated by Kunitz domain 3 on TFPI. Only a small portion of total vascular TFPI (1% to 3%) actually is present in plasma as free TFPI. The distribution of TFPI into these various compartments has made accurate assessment of TFPI levels in clinical samples difficult.

Serine Protease Inhibitors

The **se**rine **p**rotease **in**hibitors (serpins) are substrates for specific serine proteases that form stable complexes with the enzymes following cleavage of a target peptide bond (33,34,35,36,37 and 38). In contrast to usual substrate proteins, cleavage of the target peptide bond results in a refolding of the serpin into a stable conformation, trapping the serine protease in the complex (Fig. 46.17). The enzyme-inhibitor complex is removed from the circulation after binding to specific receptors in the liver. Some serpins have a “latent” or inactive conformation in which the target site is not expressed. These serpins need to be “activated” (e.g., by binding to heparin in the case on antithrombin) before they can effectively inhibit their target serine protease. Cleavage of the reactive loop at other sites by nontarget proteases can induce a conformational change without trapping the protease. The conformational change stabilizes the serpin so that is no longer capable of exposing the reactive loop and inhibiting its target serine protease. The serpin family includes a large number of proteins that regulate several key response pathways (Table 46.8). A characteristic of the serpins is that, while they can inhibit many different serine proteases, they usually show a preference for only one or a few select enzymes.

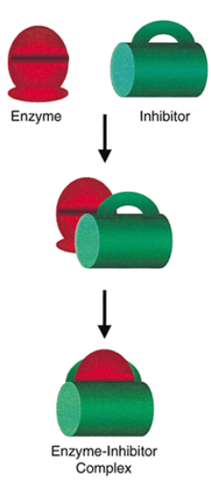

FIGURE 46.17. The general mechanism of action of serine protease inhibitors (serpins) is shown schematically. The inhibitors function as pseudosubstrates for the enzyme, which attacks a susceptible peptide bond in a reactive loop of the inhibitor. In a typical proteolytic reaction, the target protein separates from the enzyme following cleavage of the susceptible peptide bond. In the case of a serpin, cleavage of the susceptible bond in the reactive loop allows the serpin to refold into a stable conformation that traps the serine protease in a stable complex. The enzyme-inhibitor complexes then are rapidly removed from the circulation following interaction with a specific receptor in the liver. The reactive loop of some serpins is exposed under normal conditions; such inhibitors are able to rapidly inhibit their target serine protease. The reactive loop of other serine proteases appears to be in a latent conformation under resting conditions. For example, antithrombin requires interaction with heparin to expose the reactive loop before it can effectively interact with its target enzymes, factor Xa and thrombin. Cleavage of the serpin at sites away from the target peptide may alter the conformation of the reactive loop so that the serpin is no longer capable of inhibiting its target proteases. Such proteolytic cleavage basically inactivates the serpin.

The major serpins involved in the regulation of thrombin formation are antithrombin (AT) and heparin cofactor II. Antithrombin appears to be the most important of these, as heterozygous deficiency of AT is clearly associated with an increased risk of thrombosis (Chapter 48). Antithrombin is capable of neutralizing purified thrombin and factor Xa in the absence of a catalyst, but the rate of this reaction is too slow to account for its ability to regulate these coagulation enzymes *in vivo*. The interaction between AT and its target enzymes is greatly accelerated by heparinlike molecules. Heparin binds to AT, inducing a conformational change that results in exposure of the reactive loop. In addition, heparin simultaneously binds to thrombin and AT, resulting in approximation of the inhibitor to its target enzyme. Relatively long chains of heparin (≥ 18 saccharide units) are necessary to mediate this function. In contrast, only the heparin-induced conformational change is necessary for the inhibition of factor Xa. Accordingly, inhibition of factor Xa can be accelerated

by both short (e.g., low-molecular-weight) and long heparin chains (e.g., unfractionated heparin). Heparin is not normally found in circulating plasma; however, heparinlike glycosaminoglycans are present on the surface of endothelial cells. Thus, endothelial cells are probably the site of heparin-mediated neutralization of factor Xa and thrombin *in vivo*.

In contrast to AT, heparin cofactor II inhibits only thrombin among the coagulation enzymes. Like AT, it also requires a cofactor, dermatan sulfate, to accelerate the rate of inhibition. As the name implies, heparin also can accelerate the activity of heparin cofactor II, but high concentrations (greater than 1.0 U/mL) are necessary for effective activity. The precise physiologic role of heparin cofactor II is uncertain. As dermatan sulfate usually is found in tissues outside the vessel wall, it may be involved in extravascular regulation of thrombin. Levels of heparin cofactor II are decreased in patients with acute consumptive coagulopathies, suggesting that it does contribute to the normal regulation of hemostasis.

The Protein C System

The protein C system is necessary for regulating the major cofactors of the coagulation cascade, factors Va and VIIIa (39,40 and 41). The protein C system involves multiple protein components and can be divided into three phases: activation, functional, and regulatory (Table 46.9). Thrombin is the major activator of protein C. As with many of the reactions in the hemostatic system, the activation of protein C by thrombin is a slow process unless a catalytic cofactor, thrombomodulin, is present. Thrombomodulin is a membrane-associated protein that is found on the surface of most, but not all endothelial cells. Thrombin binds with high affinity to thrombomodulin and undergoes an important conformational change; thrombin associated with thrombomodulin loses its procoagulant activity and no longer converts fibrinogen to fibrin nor activates factors V, VIII, XIII, or platelets. Thus, binding of thrombin by thrombomodulin is itself an anticoagulant step, as it converts thrombin from a procoagulant enzyme into an anticoagulant enzyme. The altered thrombin, however, readily activates protein C and can still be inhibited by AT (Fig. 46.18). A receptor for protein C and APC is present on endothelial cells and appears to facilitate the activation of protein C by thrombomodulin.

TABLE 46.9. PROTEIN C SYSTEM

Phase	Component	Function
Activation	Thrombin	Activates protein C
	Thrombomodulin	Cofactor for thrombin activation of protein C
	Protein C	Substrate for thrombin-thrombomodulin
	Endothelial PC receptor	Facilitate protein C activation, endothelial signaling
Functional	Activated protein C	Proteolytic degradation of factors Va and VIIIa, endothelial signaling when bound to endothelial PC receptor
	Protein S	Cofactor for activated protein C
	Factors Va and VIIIa	Substrates for activated protein C
	Factor V	Cofactor for degradation of factor VIIIa by activated protein C and PS
Regulation	Protein C inhibitor	Neutralizes activated protein C
	Plasminogen activator inhibitor-1	Neutralizes activated protein C
	α_1-Antiprotease	Neutralizes activated protein C

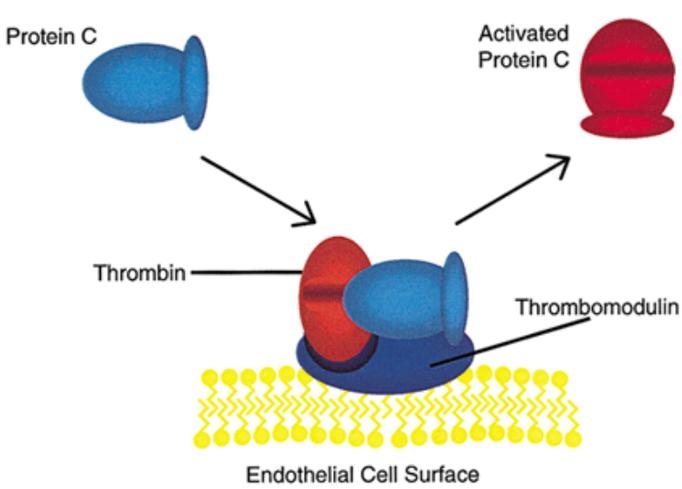

FIGURE 46.18. Protein C (PC) is activated by an endothelial cell (EC)-dependent process. Thrombin (IIa) binds to thrombomodulin (TM), a constituent membrane protein present on most ECs and undergoes a conformational change. Thrombin bound to TM loses its procoagulant activity but becomes an effective activator of protein C, releasing a short peptide from the heavy chain of PC. Activated protein C (APC) is then available to carry out its functions.

Activated protein C degrades factors Va and VIIIa by cleaving selected peptide bonds in the heavy chain of each cofactor. This step requires a phospholipid surface and a protein cofactor, protein S (Fig. 46.19). Protein S is produced by a variety of cells, including hepatocytes, endothelial cells, and megakaryocytes. The complement related protein, C4b binding protein (C4b BP), avidly binds protein S in plasma and thus the plasma pool of protein S is divided into C4b BP-bound and free protein S fractions. Protein S bound to C4b BP is unable to function as an active cofactor for APC and thus only the free protein S fraction is functionally active. Any stimulus that causes an increase in C4b BP without also increasing the total protein S concentration can lead to a functional deficiency of free protein S; this pattern may be observed in some inflammatory reactions.

The degradation of factor VIIIa by APC/protein S is accelerated in the presence of native, nonactivated factor V. A common mutation in factor V (Arg506→Gln, factor V_{Leiden}) does not affect the procoagulant activity of factor Va but does affect both

the ability of APC to inactivate factor Va_{Leiden} and the APC cofactor activity of nonactivated factor V_{Leiden}. This results in “resistance” to APC and a thrombophilic phenotype.

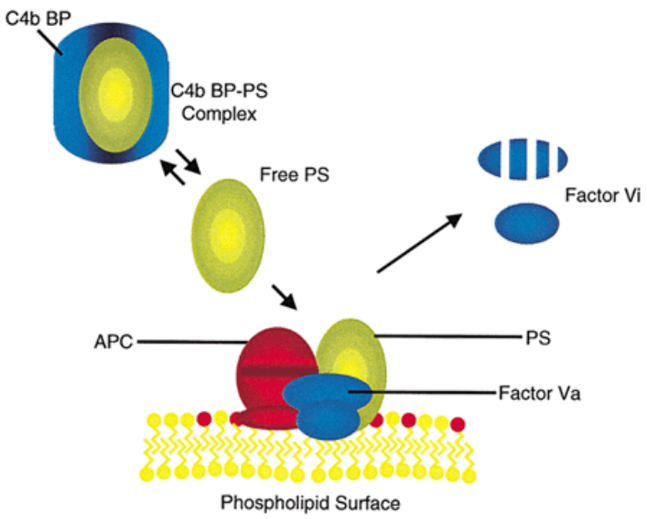

FIGURE 46.19. Activated protein C (APC) degrades the major cofactors of the coagulation cascade, factors Va and VIIIa by cleaving the heavy chains of Va and VIIIa. Protein S (PS) serves as a catalytic cofactor for this phospholipid-dependent process. Protein S binds to C4b binding protein (C4b BP) in plasma and the bound PS is not able to participate in the activity of APC. Only free protein S is capable of functioning as an effective cofactor.

The ability of APC to degrade factor Va is inhibited by prothrombin and thus a change in the balance between the concentration of prothrombin and APC may alter the effectiveness of the protein C system. For example, during the early phases of oral anticoagulant therapy, the concentration of protein C drops more rapidly than prothrombin. In this setting, prothrombin would be in relative excess to the APC formed, leading to relative inhibition of the protein C system. This may be one of the underlying mechanisms of warfarin-induced skin necrosis. Another setting in which this may be important is the relatively common prothrombin mutation at nucleotide 20210, which results in an increased plasma concentration of prothrombin and a thrombophilic phenotype.

Activated protein C is inhibited by several serpins, including protein C inhibitor (which is identical to plasminogen activator inhibitor-3), plasminogen activator inhibitor-1 (PAI-1) and α_1-antiprotease. Experimental evidence suggests that APC has profibrinolytic activity in addition to its effect on factors Va and VIIIa. There are at least two potential mechanisms for this profibrinolytic activity. First, there is competition between APC and tPA for protein C inhibitor and PAI-1. In the presence of increased amounts of APC, the inhibitors are utilized to neutralize APC, leaving tPA free to activate plasminogen. Second, activation of procarboxypeptidase B is dependent on thrombin activation. Inhibition of thrombin generation by degradation of factors Va and VIIIa decreases formation of carboxypeptidase B. As discussed below, carboxypeptidase B (also known as thrombin activatable fibrinolysis inhibitor, TAFI) inhibits the fibrinolytic pathway at multiple stages.

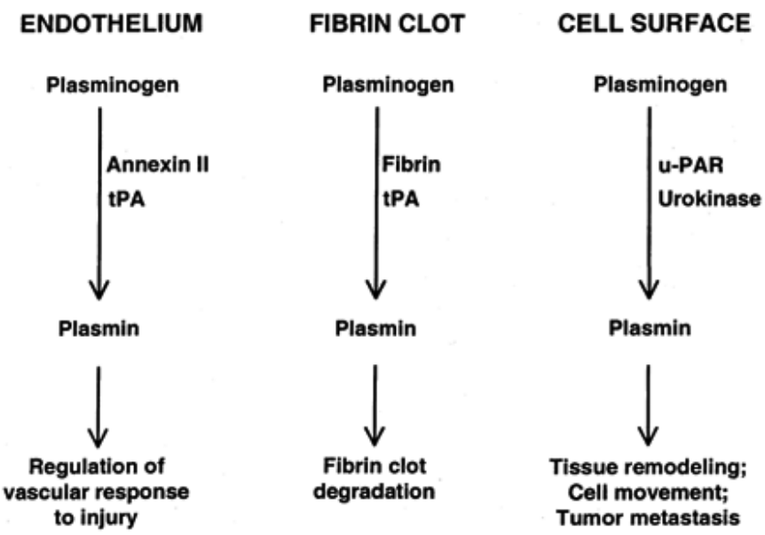

FIGURE 46.20. The key enzyme of the fibrinolytic system is plasmin, which serves a number of functions. Plasmin can be activated in a number of environments, with its functional role dependent on the site of activation. Plasmin can be activated on the surface of endothelial cells by tissue plasminogen activator (tPA) in the presence of annexin II. This pathway appears to play an important role in regulating the vascular response to injury. Plasminogen also is activated by tPA within the matrix of the fibrin clot, where it is capable of digesting excess clot. A third important site of plasmin activity is on the surface of cells. The plasminogen activator urokinase binds to a specific cell receptor, urokinaselike plasminogen activator receptor (u-PAR), where it converts plasminogen to plasmin. The cell-associated plasmin is then able to digest matrix constituents and facilitate tissue remodeling, cell movement through extracellular matrices, and tumor-cell invasion.

The Fibrinolytic System

The fibrinolytic system is also a complex, multicomponent system that can be divided into activation, functional, and regulatory phases (Table 46.10) (42,43,44,45,46,47,48 and 49). The key component of the fibrinolytic system is plasminogen, a 92-kd zymogen of a serine protease. The amino terminal portion of plasminogen contains multiple kringle domains with lysine binding sites that mediate the binding of plasminogen to other proteins. The catalytic domain is in the carboxyl-terminal domain of the molecule and is activated by limited proteolytic cleavage. Several mechanisms for the activation of plasminogen have been described, including clot-based activation, endothelial-mediated activation, cell-based activation and fluid phase activation (Fig. 46.20).

TABLE 46.10. THE FIBRINOLYTIC SYSTEM

Phase	Component	Function
Activation	Plasminogen	Substrate for plasminogen activators
	Tissue plasminogen activator (tPA)	Major physiological activator of plasminogen
	Fibrin	Cofactor for activation of plasminogen by tPA
	Annexin II	Cell surface receptor for plasminogen and tPA that mediates plasminogen activation
	Kallikrein	Converts prourokinase to urokinase
	Urokinase	Direct activator of plasminogen
	Prourokinase	Precursor of urokinase
	Urokinase-type Plasminogen Activator Receptor	Cellular receptor for urokinase
Functional	Plasmin	Potent proteolytic enzyme
	Fibrin	Major substrate for plasmin
	Fibrinogen	Substrate for free plasmin
	Factors V and VIII	Substrates for free plasmin
	Platelet membrane glycoproteins	Substrates for free plasmin
	Extracellular matrix	Substrate for cell-associated and free plasmin
Regulation	Plasminogen activator inhibitor-1	Inhibits tPA, urokinase and activated protein C
	Protein C inhibitor	Inhibits tPA and activated protein C
	α_2-Antiplasmin	Inhibits plasmin
	Carboxypeptidase B (Thrombin activated inhibitor of fibrinolysis - TAFI)	Inhibits fibrinolysis by cleavage of carboxyl-terminal lysine and arginine residues

Plasmin is a potent proteolytic enzyme that is capable of degrading fibrin clots. However, the ability of plasmin to cleave fibrin is impaired by factor XIIIa-mediated cross-linking of fibrin monomers. The more extensively the monomers are cross-linked, the more resistant they are to plasmin activity whereas clots formed in the absence of factor XIIIa are very susceptible to lysis by plasmin. Plasmin digestion of fibrinogen and fibrin monomers occurs in a relatively ordered pattern (Fig. 46.21). The initial sites of attack include the carboxyl end of the α chain and the amino terminal end of the ß chain. Cleavage at these sites generates a large residual molecule known as fragment X. Plasmin can then cleave bonds in a helical region, releasing a D domain; the remaining D/E component is known as fragment Y. Cleavage of the remaining helical region releases another D domain and the central E domain. If adjacent D domains have been cross-linked by factor XIIIa, then plasmin cleavage will generate fragments known as D-dimers, which can be measured as an indicator of *in vivo* fibrinolysis. Under normal circumstances, plasmin remains bound to the fibrin clot through interaction of its lysine binding sites with the fibrin matrix. As the clot is lysed and plasmin is released, the free plasmin is inhibited by α_2-antiplasmin. Thus plasmin activity is normally limited to the clot itself. However, if plasmin breaks free of the fibrin clot and is not inhibited, it is capable of digesting fibrinogen, factors V and VIII, as well as platelet membrane glycoproteins.

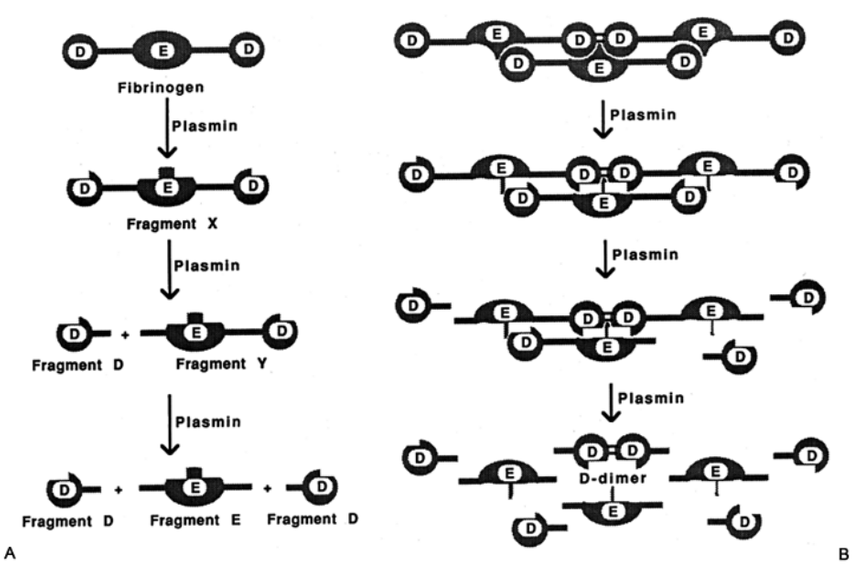

FIGURE 46.21. Plasmin can degrade either fibrinogen (**A**) or fibrin (**B**) in a stepwise fashion. Plasmin initially attacks the carboxyl terminus of the Aα chain and the amino terminus of the Bß chain, resulting in the formation of the large degradation product designated fragment X. Cleavage of an interconnecting helical segment releases a D domain from the residual fragment (fragment Y). Further proteolysis results in the release of fragments D and E. Analogous fragments are released from the degradation of fibrin. However, adjacent D domains covalently cross-linked by factor XIIIa remain cross-linked, forming D-dimers. These D-dimers are thus unique products of plasmin degradation of cross-linked fibrin gels.

Clot-based activation of plasminogen is mediated by tPA, a serine protease that is secreted by endothelial cells. Free tPA is capable of activating plasminogen in solution but the rate of acti

vation is very slow. However, activation of plasminogen by tPA is greatly accelerated in the presence of fibrin (but not intact fibrinogen). As both tPA and plasminogen have a relatively high affinity for fibrin, both proteins are incorporated into the matrix of the fibrin gel. The dependence on fibrin as a cofactor essentially limits this mechanism of plasminogen activation to sites of fibrin clot formation.

Plasminogen and tPA also bind avidly to intact endothelial cells. The receptor for both proteins is annexin II, which is expressed both within the cytoplasm and on the surface of endothelial cells (48). Binding of plasminogen to surface annexin II appears to be dependent on cleavage of the bond between lysine 307 and arginine 308 of annexin II, which exposes a carboxyl-terminal lysine residue for interaction with the lysine binding site on plasminogen. Lipoprotein (a) is a low-density lipoprotein particle that has a variable number of kringle domains that are structurally similar to the kringle domains of plasminogen. Lipoprotein (a) can successfully compete with plasminogen for binding to annexin II at lysine 307. Thus, the higher the concentration of lipoprotein (a), the less plasminogen will bind to endothelial cells and be activated by tPA. Of note, high levels of lipoprotein (a) are associated with an increased risk of cardiovascular disease. The ability of annexin II to bind plasminogen can also be destroyed by carboxypeptidase B, an enzyme that removes carboxyl-terminal lysine and arginine residues.

The binding of tPA to annexin II is dependent on a free cysteine found near the amino terminal end of annexin II. Site-directed mutagenesis of this cysteine significantly impairs the ability of tPA to bind to the modified annexin II. Homocysteine can also interact with this cysteine residue to form a disulfide-linked derivative of annexin II that lacks the ability to bind tPA. Formation of this modified form of annexin II increases as the concentration of homocysteine increases and tPA binding is significantly impaired at homocysteine levels commonly encountered in clinical practice and that have been associated with an increased risk of atherothrombotic disease. The association between increased levels of homocysteine or lipoprotein (a) with vascular disease suggests that this mechanism of plasminogen activation may play a critical role in regulating the hemostatic system and the response to vascular injury.

TABLE 46.11. COMMON PATTERNS ASSOCIATED WITH BLEEDING DISORDERS

	Platelet Disorders	Coagulation Disorders	Fibrinolytic Disorders
Clinical history	Mucocutaneous bleeding	Soft-tissue bleeding	Delayed bleeding
Screening laboratory tests	Long bleeding time and/or low platelet count	Long PT and/or APTT	Normal

APTT, activated partial thromboplastin time

PT, prothrombin time

Urokinase is another serine protease that can convert plasminogen into plasmin. In contrast to tPA, free urokinase readily activates plasminogen and thus urokinase can mediate fluid phase plasminogen activation. Additionally, urokinase is a key mediator of cell-associated plasminogen activation. A variety of cells express a glycosylphosphatidylinositol-linked membrane receptor known as urokinase-type plasminogen activator receptor (u-PAR, CD87). When urokinase binds to u-PAR it is capable of activating plasminogen in association with the cell surface. Such localized plasmin formation plays an essential role in a variety of cellular

processes, including tissue remodeling, cell migration, and tumor metastasis. This mechanism also appears to contribute to the bleeding tendency of patients with acute promyelocytic leukemia (AML-M3). The leukemic cells in this disorder frequently express u-PAR, leading to inappropriate plasmin activation and an enhanced risk of bleeding. Treatment with trans-retinoic acid induces maturation of the leukemic cells, down regulation of u-PAR expression and reversal of the bleeding tendency. Formation of the u-PAR/urokinase complex also initiates intracellular signaling that is probably mediated by proteins such as integrins that are juxtaposed to u-PAR on the cell surface. A linkage to a transmembrane signaling protein is needed because, as a glycosylphosphotidylinositol-linked surface protein, u-PAR has no intracytoplasmic signaling domain. Plasminogen-activator inhibitor-1 binds to and inhibits both tPA and urokinase. When PAI-1 binds to urokinase associated with u-PAR, the entire complex is internalized into the cell where the PAI-1/urokinase complex is degraded and u-PAR is recycled to the cell surface.

Regulation of the fibrinolytic system occurs on at least three levels. First, the major activators of plasmin are inhibited by serpins. Tissue plasminogen activator is inhibited by both PAI-1 and protein C inhibitor, whereas urokinase is inhibited by PAI-1. As discussed in the section on protein C, these inhibitors also inhibit APC, and their availability for regulation of tPA is dependent on the amount of APC in the environment. That is, the higher the concentration of APC, the less PAI-1 and protein C inhibitor will be available to regulate tPA. The second level of regulation involves the serpin α_2-antiplasmin. In the fluid phase, α_2-antiplasmin rapidly inhibits free plasmin. However, within the clot matrix it competes with fibrin for the same lysine binding sites on plasmin (Fig. 46.22). Thus, as long as plasmin is bound to the fibrin clot matrix (or cell surface) it is not inhibited by α_2-antiplasmin, but once plasmin breaks free of the fibrin clot, it is instantaneously inhibited by α_2-antiplasmin. Because of this mechanism, it is uncommon to encounter free plasmin in the circulation. When this does happen, it is often associated with a significant coagulopathy related to the nonspecific proteolytic activity of plasmin. For example, this is one of the key pathological changes underlying disseminated intravascular coagulation. One of the reasons that such pathological fibrinolysis can even occur is that there is normally twice as much plasminogen as α_2-antiplasmin on a molar basis. With marked activation of the fibrinolytic system, α_2-antiplasmin is consumed and this regulatory mechanism is overwhelmed.

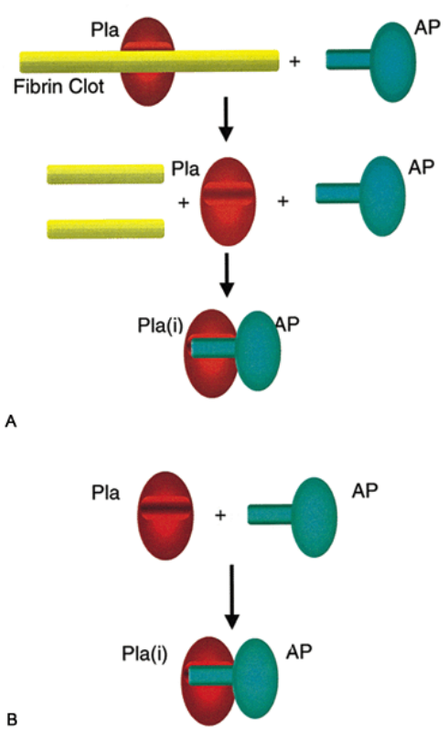

FIGURE 46.22. Plasmin (Pla) activity is regulated by the serine protease inhibitor α_2-antiplasmin (AP). Plasmin associated with a fibrin gel is relatively protected from inhibition because fibrin and AP compete for the same lysine binding sites on plasmin (**A**). As the fibrin gel is lysed, the released plasmin is neutralized by AP, effectively limiting plasmin action to the fibrin matrix. In contrast, plasmin formed in plasma or released from cell surfaces or dissolving clot is very rapidly neutralized by AP (**B**). The rapid inhibition of plasmin normally limits the sites where it can function. However, depletion of AP, as might occur with overwhelming activation of plasmin, can lead to free plasmin in the circulation.

A third mechanism of regulating fibrinolysis involves the enzyme carboxypeptidase B, also known as TAFI. Procarboxypeptidase B circulates as an inactive zymogen that is converted to its active form by thrombin or factor XIa. Thrombin-mediated activation of TAFI is accelerated by thrombomodulin on endothelial surfaces. Factor XIa appears to play a critical role in the activation of TAFI, either through generation of sufficient thrombin to mediate TAFI activation or direct activation of TAFI by platelet-associated factor XIa. Impaired activation of TAFI may account for many of the bleeding manifestations associated with congenital deficiency of factor XI.

TAFI removes carboxyl-terminal lysine and arginine amino-acid residues from a number of proteins. As lysine is often involved in the interaction between the lysine binding sites on plasmin(ogen) and other proteins, cleavage of such lysine residues impairs plasmin(ogen) binding to target proteins. In addition, removal of the carboxyl-terminal lysine from modified plasminogen or plasmin impairs the potential activity of the enzyme. Thus TAFI can induce changes in both plasmin(ogen) and related proteins that impair clot-based and endothelial-mediated fibrinolysis.

Summary of the Regulation of the Coagulation Cascade

These four systems interact in a synergistic manner to regulate activity of the coagulation cascade. As indicated in Fig. 46.23, virtually every step of the cascade is controlled by one or more of these systems. Combined with the factors regulating primary hemostasis, these systems are normally successful in limiting hemostatic plug formation to sites of vascular disruption. A

number of hereditary and acquired defects of the regulatory system have now been described. Alterations that result in a decrease in the effectiveness of any one of these regulatory components can lead to increased clot formation *in vivo*, giving rise to a thrombotic tendency.

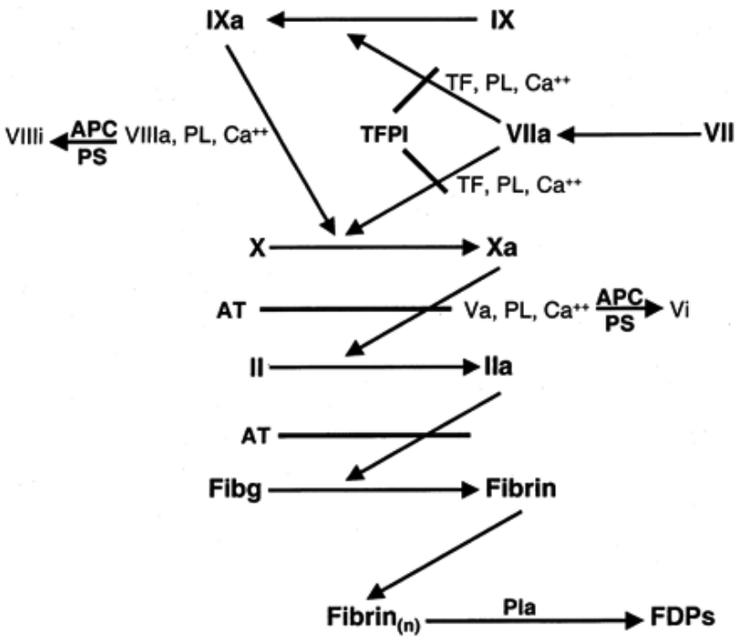

FIGURE 46.23. The four systems involved in the regulation of the coagulation cascade, tissue factor pathway inhibitor (TFPI), antithrombin (AT), activated protein C (APC) and plasmin (Pla) function in a synergistic way to control thrombin formation. The points of regulation of the extrinsic (tissue factor) pathway of coagulation are depicted in this figure. As can be seen, these four systems control almost every step of the extrinsic pathway of coagulation.

AN APPROACH TO HEMOSTATIC DISORDERS

Part of "46 - Overview of Hemostasis"

There are a number of reasons why the hemostatic system may be evaluated during the clinical management of patients. Common reasons include therapeutic drug monitoring, presurgical evaluation of hemostasis, evaluation of a possible bleeding tendency, evaluation of a possible thrombotic tendency, evaluation for the possibility of a circulating lupus anticoagulant, evaluation for the possibility of disseminated intravascular coagulation, and evaluation for other specific disorders. The hemostasis laboratory plays a key role in monitoring oral anticoagulant and unfractionated heparin therapy. In contrast, the laboratory has only a minor role in monitoring fibrinolytic therapy (e.g., tPA therapy) or antiplatelet therapy. In general, laboratory parameters measured during these latter therapeutic regimens provide little useful information, at least currently.

Routine presurgical evaluation of hemostasis remains a controversial topic. In general, routine preoperative bleeding times, prothrombin times (PTs) and activated partial thromboplastin times (APTTs) do not accurately predict the risk of bleeding during surgery. In fact, a thorough clinical history is probably more sensitive and specific for the identification of patients with a bleeding disorder. In the absence of a clinical history or medical disorder that suggests a compromised hemostatic system, routine preoperative hemostasis testing is probably not indicated.

Laboratory evaluation of hemostasis is indicated whenever the clinical and/or medical history suggests the possibility of altered hemostasis. As hemostasis is a balanced system with potent procoagulant and regulatory mechanisms, bleeding or thrombotic disorders can arise whenever this balance is disturbed. Two general mechanisms may lead to an increase in bleeding: any alteration that decreases procoagulant activity or any defect that increases regulatory activity. Von Willebrand's disease and hemophilia A provide examples of the first mechanism, whereas heparin therapy and fibrinolytic therapy provide examples of the second mechanism. Similarly, thrombosis may occur because of decreased regulatory activity, as with antithrombin deficiency, or increased procoagulant activity, as may occur during the course of metastatic carcinoma.

Evaluation of a Potential Bleeding Disorder

The clinical history of a patient with a potential bleeding disorder is used to determine whether the patient truly does have a bleeding problem, whether the problem is likely to be congenital or acquired, and whether the defect is related to altered primary hemostasis, secondary hemostasis, or regulation of hemostasis (50,51,52,53,54 and 55). As perceptions of the seriousness of a bleeding problem vary significantly from patient to patient, the clinician must establish the frequency of bleeding, sites of bleeding, and severity of bleeding to determine the actual presence of a significant bleeding diathesis. Age of onset and family history are very helpful in distinguishing between congenital and acquired disorders. An early age of onset is suggestive of a congenital bleeding disorder, whereas the sudden appearance of bleeding in a previously healthy adult suggests an acquired problem. Family history can help establish a pattern of hereditary transmission. Some disorders are characterized by sex-linked recessive inheritance while other disorders are characterized by either autosomal-dominant or autosomal-recessive inheritance.

The pattern of bleeding is very helpful in constructing a differential diagnosis. Mucocutaneous bleeding, characterized by epistaxis, ecchymosis, and genitourinary bleeding, is suggestive of a platelet disorder. Soft-tissue bleeding, including hemarthrosis, hematomas, and retroperitoneal bleeding, is more suggestive of a coagulation disorder such as hemophilia A. Delayed bleeding is a classic manifestation of fibrinolytic-type bleeding. The clinical history should include a thorough medical history to document any other medical problems that may predispose to a bleeding diathesis. In addition, a careful medication history, including over-the-counter medications, should be obtained. It is helpful to remember that the most common cause of abnormal platelet function is drug effect, particularly aspirin therapy.

Following the clinical history, routine screening tests are commonly performed. These include the platelet count and bleeding time to assess platelet function and the PT and APTT to assess fibrin clot formation. Note that these screening tests do not assess fibrin stabilization or fibrinolysis. The bleeding time is a commonly performed test to assess primary hemostasis. A number of techniques for determining the bleeding time have been described, but the most commonly performed method is the template bleeding time using a disposable device. Although this test appears to be simple and straightforward, a number of

technical variables can confound results. Therefore a standardized technique should be used when performing this procedure. Newer technologies for assessing platelet function, such as the PFA 100 (Dade Behring, Deerfield, Illinois), are emerging and may replace the bleeding time as a screening test of platelet function.

The PT and APTT are tests of fibrin clot formation. The PT evaluates the extrinsic system of coagulation, beginning with activation of coagulation by tissue factor/VIIa (Fig. 46.8), and is sensitive to defects in fibrinogen, prothrombin, factor V, factor X, and factor VII. Of interest, the tissue factor/VIIa activation of factor IX is not evident with the PT unless the PT reagent is first diluted. This is because the lack of dependence of the PT on factors VIII and IX is related to the concentration of tissue factor and phospholipid used in the assay rather than the biological importance of this part of the pathway. The APTT evaluates the intrinsic system of coagulation and is sensitive to defects in fibrinogen, prothrombin, factor V, factor X, factor VIII, factor IX, factor XI, factor XII, prekallikrein, and HMW kininogen. A number of technical variables can affect performance of the PT and APTT. Among these specimen acquisition, sample processing, and choice of reagent are key components. Care should be taken to obtain a clean venipuncture sample and to anticoagulate it promptly with an appropriate amount of citrate. The concentration of citrate used is important, particularly for monitoring anticoagulant therapy. It is now recommended that 0.109 M (3.2%) citrate be used to collect coagulation samples. The sample should be processed as soon as possible to yield platelet-poor plasma. PT and APTT reagents vary significantly in their sensitivity and responsiveness to various hemostatic disorders. Therefore, the laboratory should be aware of the performance characteristics of their reagents and should carefully construct their own reference ranges to adequately distinguish normal from abnormal.

Based on the results of the clinical history and screening laboratory tests, a limited number of patterns emerge (Table 46.11). Platelet disorders usually are characterized by mucocutaneous bleeding and a long bleeding time and/or a low platelet count. In contrast, coagulation disorders usually are characterized by a history of soft tissue bleeding and an abnormality of the APTT and/or PT. Fibrinolytic disorders are classically characterized by a history of delayed bleeding, often following trauma, and normal screening tests of hemostasis. Based on these initial results, further evaluation for a specific disorder can be undertaken. It is helpful to keep in mind the relative frequency of congenital disorders associated with bleeding when pursuing such an evaluation (Table 46.12). The three most common disorders are von Willebrand's disease, hemophilia A, and hemophilia B. Specific platelet disorders are reviewed in Chapter 47 and specific coagulation disorders are presented in Chapter 48.

TABLE 46.12. APPROXIMATE FREQUENCY OF CONGENITAL BLEEDING DISORDERS

Disorder or Deficiency	Frequency per 10^6 Population
Fibrinogen	1
Prothrombin	< 0.5
Factor V	< 0.5
Factor VII	< 0.5
Factor VIII	60-100
Factor IX	10-20
Factor X	< 0.5
Factor XI	1
Factor XIII	< 0.5
α_2-antiplasmin	< 0.5
von Willebrand's disease	> 100
Bernard-Soulier syndrome	< 0.5
Glanzmann's thrombasthenia	< 0.5
Hermansky-Pudlak syndrome	< 0.5

Evaluation of a Potential Thrombotic Tendency

As with the evaluation of bleeding disorders, the evaluation of a potential thrombotic tendency begins with a thorough medical history (56,57,58 and 59). One of the primary goals of the history is to determine the likelihood of a congenital defect. In this regard, it is important to note the age of onset of symptoms and any family history of thrombosis. Most congenital defects are associated with onset of symptoms prior to the age of 45, and the family history for most of these disorders also is positive. Congenital thrombophilia usually is associated with recurrent deep venous thrombosis but can, on occasion, be associated with arterial thrombosis. A complete medical history must be obtained to determine if there is an underlying medical illness that may predispose to thrombosis (metastatic tumor, autoimmune disorder, etc.). A thorough medication history is also important.

There are no screening assays that assess the overall function of the regulatory system of coagulation or the degree of activation of the procoagulant systems. Therefore, the laboratory approach to potential thrombotic disorders involves measuring selected individual components of the regulatory systems. In general, assays that reflect the biological activity of the protein in question should be used for screening purposes. In practice, such functional assays have been difficult to develop for some components of the system, notably protein S. In addition, assays for lupus anticoagulant activity and antiphospholipid antibodies may be helpful in the initial screening of a patient for a thrombotic tendency. A variety of markers of the level of activation of the hemostatic system have been described. These include sensitive D-

dimer, fibrinopeptide A, $F_{1.2}$, thrombin-antithrombin complex, protein C activation peptide, and plasminogen-antiplasmin complex assays. The usefulness of these markers in determining the risk of thrombosis, however, remains undetermined. Disorders associated with thrombosis are discussed in detail in Chapter 49.

Laboratory Evaluation of Platelet Disorders

John T. Brandt

Platelet disorders are a common clinical cause of excessive bleeding. These disorders most commonly represent acquired problems and the etiology is often apparent from a thorough clinical history and performance of a few straightforward laboratory procedures. Congenital disorders of platelet function comprise an interesting group of disorders that teach much about the key mechanisms of the platelet response in hemostasis. While identification of abnormal platelet function may be relatively straightforward in patients with congenital disorders, pinpointing the actual biochemical defect may involve very specialized studies and is often beyond the scope of the clinical laboratory. The congenital disorders are usually evident early in life, although clinical manifestations may be delayed until adulthood. In contrast, the acquired abnormalities of primary hemostasis are common causes of clinical bleeding problems at any age. This chapter presents a diagnostic approach to congenital and acquired disorders affecting platelet function, starting with an overview of the laboratory procedures that are used in the evaluation of these disorders. The pathogenesis and evaluation of thrombocytopenia, as well as the therapeutic options for various platelet disorders, are briefly reviewed.

LABORATORY METHODS FOR EVALUATION OF PLATELET FUNCTION

Part of "47 - Laboratory Evaluation of Platelet Disorders"

A variety of laboratory techniques may be used to assess platelet function, but a limited number of techniques are necessary for most clinical situations (Table 47.1). Procedures for the evaluation of von Willebrand factor (vWF) are among the most important because von Willebrand disease (vWD) is the most common congenital disorder of platelet function. Other procedures may be used to assess the platelet response to selected agonists, the ability of platelets to secrete the contents of their granules or the activation state of circulating platelets. Selection of which assays to use for a specific patient should be based on clinical history, results of screening assays and a review of platelet morphology on the peripheral blood smear.

TABLE 47.1. LABORATORY TECHNIQUES FOR EVALUATION OF PLATELET FUNCTION

Procedure	Property Evaluated	Clinical Uses
Platelet count	Platelet number in peripheral blood	Platelet production
Mean platelet volume	Average platelet size	Assessing platelet mass, platelet production
Bleeding time	Global platelet function	Screen for platelet function
PFA 100®	Platelet function	Screen for platelet function
Platelet aggregation studies	Platelet function	Delineate type of platelet dysfunction; detection of variant vWD, HIT
vWF antigen (vWF:ag)	Quantity of vWF protein in blood	Evaluation of possible vWD
vWF:Rcof	Measurement of vWF functional activity	Evaluation of possible vWD
Collagen binding of vWF	Measurement of vWF interaction with collagen	Screen for variant vWD
GP Ibα binding of vWF	Measurement of vWF function	Screen for vWD
Factor VIII binding to vWF	Evaluation of factor VIII binding site on vWF	Screen for Type 2N vWD
vWF multimeric analysis	Measure of vWF polymerization	Evaluation of variant vWD
Electron microscopy	Platelet morphology, platelet granules	Evaluation of congenital platelet disorders
Bone marrow exam	Assessment of platelet production	Evaluation of thrombocytopenia, thrombocytosis
Platelet antibody	Detection of antiplatelet antibodies	Evaluation of possible ITP
Platelet survival	Rate of platelet turnover	Mechanism of thrombocytopenia
PF4, βTG	In vivo platelet release	Detection of platelet activation
Flow cytometry	Expression of membrane proteins	Evaluation of platelet activation, function and diagnosis of HIT
Flow cytometry	Measurement of platelet RNA	Assessment of platelet production

Abbreviations used: vWD, von Willebrand disease; vWF, von Willebrand factor; vWF: Rcof, ristocetin cofactor activity of vWF; HIT, heparin-induced thrombocytopenia; ITP, idiopathic/immune thrombocytopenic purpura; PF4, platelet factor 4; βTG, β-thromboglobulin

The Bleeding Time

The bleeding time is a commonly performed test to assess global function of primary hemostasis (1,2 and 3). A number of techniques for determining the bleeding time have been described, but the most commonly performed method is the template bleeding time using a disposable device. Although this test appears to be simple and straightforward, a number of technical variables can confound results. Therefore, each laboratory should attempt to standardize the procedure as completely as possible. Key variables include the accuracy of the pressure in the blood pressure cuff, the pressure with which the template device is applied to the volar surface of the forearm, the time of stasis and the direction of the incision. Following completion of the bleeding time the wound should be closed with a butterfly-type bandage and covered with a bandage as performance of the bleeding time can be associated with significant scar formation in some individuals. The bleeding time is prolonged in conditions associated with significant impairment of platelet function, including thrombocytopenia. However, the bleeding time is not very sensitive to mild platelet disorders and may be normal in patients with significant clinical defects. Therefore, if a patient has a history of significant mucocutaneous bleeding, further workup is indicated even if the bleeding time is normal. The bleeding time is not predictive of the risk of bleeding during surgical procedures and thus there is no role for the bleeding time as a routine preoperative screening procedure. Because of the technical and diagnostic limitations of the bleeding time, other procedures have been developed to assess primary hemostasis.

Analysis of Von Willebrand Factor

Commonly used procedures to evaluate vWF include vWF antigen concentration (vWF:ag), ristocetin cofactor activity (vWF:Rcof), vWF binding to collagen or recombinant glycoprotein Ibα (GP Ibα), the platelet aggregation response to ristocetin, and vWF multimeric analysis (4,5 and 6). Immunoelectrophoresis was once the only practical method available for determination of vWF:ag, but enzyme-linked immunosorbant assays (ELISAs) and automated immunoassays are now available. Quantitation of vWF:ag provides a measure of the total plasma concentration of vWF that is independent of the multimeric composition and function of vWF. In general, the plasma concentration of vWF:ag parallels that of functional assays for vWF, such as factor VIII activity and vWF:Rcof, when the result of each of assay is expressed as a percent of pooled normal plasma.

An alteration in the ratio of vWF:ag to one or more functional assays may indicate the presence of a dysfunctional vWF.

vWF has two major functions in hemostasis; first it mediates platelet adhesion and second, it is an obligate carrier of factor VIII in plasma. Therefore, an assessment of the functional capacity of vWF involves an assessment of both platelet-associated vWF function and factor VIII-vWF interaction. The aggregation response of formalin-fixed platelets to ristocetin and a limiting concentration of plasma as a source of vWF is the classic technique for assessing the platelet-associated activity of vWF; the activity measured by this type of assay is designated vWF:Rcof. Limiting factors of the vWF:Rcof assay include the technical difficulty of the assay, the observation that vWF:Rcof activity does not always correlate with *in vivo* activity in patients with variant (type 2) forms of vWD and the lack of precision in the assay. This has led to the development of alternative assays for assessment of platelet-associated vWF function. The collagen-binding assay provides a measure of the ability of vWF to bind to collagen immobilized in microtiter plate wells. As such binding is dependent on the multimeric composition of vWF, this assay can be used to screen for Type 2 vWD associated with a decrease in HMW multimers. Another assay measures the ability of patient vWF to bind to an immobilized recombinant GP 1bα peptide in the presence of ristocetin. The recombinant peptide includes the binding site for vWF and thus this assay, which measures the interaction between vWF and its platelet receptor, is an alternative to the ristocetin-induced aggregation assay.

A functional assay for factor VIII activity is used to screen for the interaction between vWF and factor VIII. The specific ability of patient vWF to bind normal factor VIII can be determined using a binding assay in which patient vWF is captured on a microtiter plate by an anti-vWF monoclonal antibody. This assay may be useful for identification of Type 2N vWD, which is characterized by an abnormality in vWF that diminishes its ability to bind and carry factor VIII in plasma. Such patients may present with a hemophilialike clinical phenotype.

The multimeric composition of vWF, which is helpful in differentiating type 2 vWD, is most accurately assessed by SDS-agarose gel electrophoresis with immunoblotting. High-resolution electrophoresis and blotting may permit identification of specific abnormalities characteristic of certain sub-types of type 2 vWD. Performance of multimeric analysis is technically complex and subject to a number of analytical variables. This procedure should be performed by experienced, expert laboratories that use appropriate internal controls to verify the adequacy of the procedure. The major goal of multimeric analysis is to determine whether or not the normal high molecular weight multimers of vWF are present.

Platelet Response to Agonists

Platelet aggregation studies are used to assess the response of platelets to a variety of agonists (5, 7,8,9,10,11,12,13,14,15 and 16). Platelet aggregation is most commonly performed by a turbidimetric method using platelet-rich plasma but also can be performed by an impedance method that utilizes either whole blood or platelet-rich plasma. Commonly used platelet agonists for *in vitro* studies include ADP, collagen, epinephrine, arachidonic acid, and ristocetin. The basic principle of turbidimetric aggregometry is that light transmittance increases as platelet aggregates form (Fig. 47.1). ADP and epinephrine at the appropriate concentration characteristically induce a biphasic wave of aggregation in normal individuals. The initial (primary) wave is because of formation of small aggregates in direct response to agonist interaction with the platelet surface. The second wave is caused by the formation of large aggregates and is dependent on the release/secretion of endogenous platelet products. Patients may show a normal biphasic response to these agonists, a primary wave followed by disag

gregation (designated a secondary wave defect) or a total lack of response (designated a primary wave defect). The responses to arachidonic acid and collagen are typically monophasic; abnormalities of response to these agonists may include a partial, delayed, or absent response. Secretion of ATP from the responding platelets, a marker of dense granule release, can be simultaneously measured in some aggregometers using a chemiluminescent procedure.

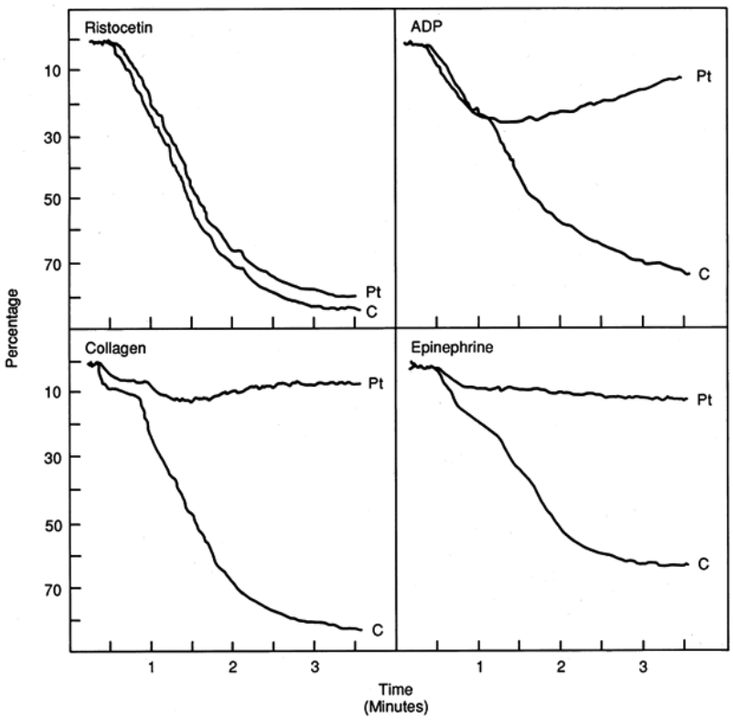

FIGURE 47.1. Normal (C) and abnormal (Pt) aggregation responses for ADP, collagen, epinephrine, and ristocetin. The normal response to ADP at optimal concentrations is a biphasic wave, with the secondary wave dependent on an intact release response by the responding platelets. An inability to undergo release results in a primary wave of aggregation, followed by disaggregation (Pt); this pattern is designated a secondary wave defect. A total lack of response to ADP would be designated a primary wave defect. Abnormal responses to collagen include a delay in onset of aggregation or, as in this case, a decreased response to collagen. Epinephrine usually results in a biphasic wave of aggregation; abnormalities to this agonist vary from total lack of response to a primary wave followed by disaggregation. Diminished response to ristocetin (not shown) is characteristic of abnormalities of platelet adhesion.

Normal platelets tend to aggregate to ristocetin in a monophasic pattern when the ristocetin concentration is greater than 1.0 mg/mL. Patients with vWD or Bernard-Soulier syndrome may show a lack of response at these concentrations. Normal platelets do not aggregate at ristocetin concentrations less than 0.8 mg/mL. However, platelet aggregation may be seen at concentrations less than 0.8 mg/mL in samples from patients with platelet-type vWD and type 2B vWD. Thus, it is important to test with both high (>1.0 mg/mL) and low (<0.8 mg/mL) concentrations of ristocetin when performing ristocetin-induced platelet aggregation assays.

Although thrombin is a key platelet agonist *in vivo*, it is not commonly used in the clinical laboratory. One of the limiting factors is the propensity of platelet-rich plasma to clot upon addition of activating concentrations of thrombin. This can be circumvented by using washed platelets or adding agents that block fibrin polymerization. The development of a peptide agonist that binds to and activates the thrombin receptor, protease activated receptor-1 (PAR-1), has provided a mechanism for evaluation of the thrombin-activated pathways in platelet-rich plasma. However, it is unclear whether the PAR-1 pathway is the only pathway activated by thrombin and thus use of the peptide may not reflect all of thrombin's platelet stimulating activities.

An alternative to turbidometric aggregometry is impedance aggregometry. The principle of impedance aggregation is that formation of platelet aggregates on the surface of a sensitive electrode effectively “insulates” the electrode, altering the resistance to an electric current. The change in resistance over time is used as a measure of the platelet aggregation response. As with turbidometric techniques, a variety of agonists may be used. An

advantage of impedance aggregometry is that it can be performed in whole blood, which is thought to be a more natural environment. However, as the aggregation response is affected by the concentration of red cells, the whole blood sample usually is diluted to give a constant red cell concentration and thus it does not actually represent a completely natural environment.

The PFA 100 (Dade Behring, Deerfield, Illinois) measures the platelet aggregation response in a flow chamber. Whole blood, anticoagulated with citrate, is passed through an aperture coated with collagen and either ADP or epinephrine. As platelets pass through the orifice, they adhere and become activated to form platelet aggregates that eventually occlude the aperture and block flow. The time that it takes for closure of the aperture is dependent on platelet function and relatively independent of fibrin formation. This procedure appears to be very sensitive to a variety of platelet function abnormalities, including vWD, platelet storage pool defects and platelet inhibitors such as aspirin and GP IIb/IIIa inhibitors.

Flow cytometry has emerged as a powerful tool for the analysis of platelet function. Platelet activation is associated with surface expression of proteins not found on quiescent platelets. Analysis of these proteins has been used to evaluate *in vivo* platelet activation, which occurs in a variety of clinical settings. A similar approach can be taken to follow the response of platelets to agonists added *in vitro*. For example, methods have been developed for the diagnosis of heparin-induced thrombocytopenia (HIT) using flow cytometry. Advantages of this type of approach include the ability to study platelets in whole blood and the requirement for only small amounts of blood. Flow cytometry also can be used to evaluate the formation of platelet microparticles *in vivo* or *in vitro*. Activation of platelets is associated with shedding of membrane-rich particles in which procoagulant phospholipids are readily available to support the coagulation cascade. Formation of such procoagulant microparticles is a significant component of the pathogenesis of some platelet disorders, including HIT.

Another use of flow cytometry is quantitation of platelet RNA content. As platelets are shed from megakaryocytes they contain a moderate amount of RNA that is lost over time in the circulation, analogous to reticulocytes. Measurement of platelet RNA content may indicate whether there has been a shift to younger platelets (higher RNA content); this may help differentiate a thrombocytopenia resulting from increased consumption from a thrombocytopenia from decreased production.

Evaluation of vWF and platelet function plays a major role in assessing the possibility of congenital platelet disorders, congenital vWD and acquired vWD. In contrast, these studies have a limited role in the evaluation of most acquired platelet disorders. Thus the laboratory evaluation should be guided by whether the clinical history suggests a congenital or acquired disorder. Congenital disorders of platelet function usually present with a history of mucocutaneous bleeding starting during childhood. Consequently, this is the population that will be evaluated most frequently. Congenital platelet disorders can be classified according to the aspect of platelet function (adhesion, activation or aggregation) that is abnormal. The laboratory features of disorders of adhesion, activation, and aggregation are sufficiently distinct to permit construction of a flow diagram for their laboratory evaluation and diagnosis (Fig. 47.2).

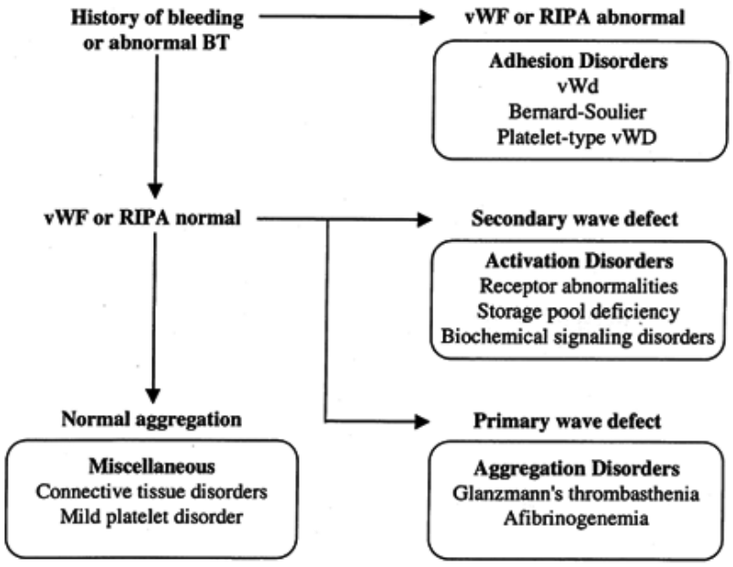

FIGURE 47.2. Flow diagram for diagnosis of abnormalities of platelet function. Abnormalities of platelet adhesion are characterized by an abnormal aggregation response to ristocetin and/or abnormalities of von Willebrand factor. Abnormalities of platelet activation usually are characterized by a secondary wave-type defect with ADP, while abnormalities of platelet aggregation are characterized by a primary wave defect. Occasional patients with mild platelet dysfunction may show a normal response to all the agonists used in routine studies.

CONGENITAL DISORDERS OF PLATELET FUNCTION

Part of "47 - Laboratory Evaluation of Platelet Disorders"

Abnormalities of Platelet Adhesion

A number of congenital disorders affecting platelet adhesion have been described, the most common of which is vWD. The other disorders in this group, although rare, are important for what they teach about the normal process of platelet adhesion and because a correct diagnosis is necessary in order to provide appropriate therapy.

von Willebrand Disease

vWD is the most common congenital bleeding disorder known, but its actual frequency still has not yet been accurately defined (4,5,13,17,18,19 and 20). Some have estimated the frequency to be as high as 1:100, but clinical experience would suggest a lower incidence. It is typically inherited as an autosomal-dominant trait; that is, heterozygous patients are clinically symptomatic. Compound heterozygous and homozygous forms of the disease also have been described. Patients with vWD have clinical manifestations characteristic of platelet disorders, with the most common complaints related to increased bruising, epistaxis, menorrhagia, and bleeding following surgical procedures. Indeed, the development of iron deficiency anemia in a pubescent female may be an indication of an underlying platelet disorder such as vWD. The family history usually is positive, with male and female relatives being affected with equal frequency.

The bleeding in vWD tends to be mild to moderate, and symptoms often spontaneously improve after adolescence. This disorder is relatively well tolerated, unless the hemostatic system is challenged by trauma or surgery, at which time bleeding may

be serious. During childhood, this may occur with oral surgery such as tooth extractions or tonsillectomy. The post-partum period is another high-risk time for bleeding in women with vWD, despite the pregnancy-associated rise in the level of vWF. The level of vWF drops precipitously in the post-partum period, and the patient may begin to bleed seriously at that time. Occasionally, a diagnosis is not established during childhood and the patient remains asymptomatic until later in life (usually after age 50), when recurrent gastrointestinal bleeding may be the initial manifestation of vWD. An extensive evaluation of the gastrointestinal tract is usually unrevealing or demonstrates only angiodysplasia.

Homozygous (type 3) vWD usually is associated with a more severe hemorrhagic diathesis. The clinical manifestations may mimic those of hemophilia A because of the very low or absent factor VIII. These patients may be misdiagnosed as having hemophilia A if appropriate laboratory studies are not performed. It is important to discriminate between type 3 vWD and hemophilia A because the therapy of these two disorders is different.

vWD is caused by a deficiency or structural abnormality of vWF. vWF is synthesized by endothelial cells and megakaryocytes and is found in subendothelial spaces, plasma, and platelet α-granules. Platelet α-granule vWF appears to make a significant contribution to platelet adhesion, as reflected by the relatively shorter bleeding times in those vWD patients who have a low plasma vWF concentration but a normal platelet vWF concentration. vWF has two major functions; first, it mediates platelet adhesion and second, it is an obligate carrier for factor VIII in plasma. The platelet-associated function of vWF is dependent on production of high-molecular-weight multimers (see Chapter 46) whereas the binding of factor VIII is less dependent on polymerization of vWF. This dichotomy leads to dissociation between vWF-mediated platelet function and vWF-dependent factor VIII concentration in some subtypes of vWD.

Many of the functional domains of vWF have now been mapped to structural areas of the molecule (Fig. 47.3). The factor VIII binding site is located in the amino-terminal portion of the monomer, which also contains a heparin binding site. The A1 domain, which is bounded by a disulfide-bonded loop, contains the site that binds to platelet GP Ib/IX/V. The A2 domain contains a protease-sensitive domain that is involved in plasma processing of vWF. The vWF that is secreted from endothelial cells is normally larger than that found in plasma. A plasma protease cleaves the secreted vWF, resulting in removal of the largest multimers. This is an important regulatory step, as such very large multimers have an intrinsic propensity to bind to GP Ib/IX/V and initiate a platelet aggregation response. A collagen-binding domain is located in the A3 domain of the molecule, another loop structure delimited by disulfide bonds. The RGD sequence that binds to GP IIb/IIIa under conditions of high-shear stress is located in the carboxyl-terminal end of the molecule.

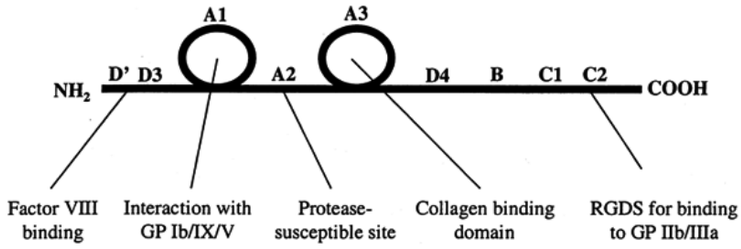

FIGURE 47.3. The domain structure for monomeric von Willbrand factor (vWF) is depicted in this figure. The binding site for factor VIII is located in domains D′ and D3 near the amino terminal end of the monomer. The binding site for platelet GP Ib/IX/V is located in the A1 domain, which is delineated by a disulfide-linked loop. There is a critical protease susceptible region located in the A2 domain. This is the site of extracellular processing that removes the very large multimers secreted by endothelial cells. Mutations that lead to excessive proteolysis cause Type 2A von Willebrand's disease while a deficiency of the protease is associated with thrombotic thrombocytopenic purpura. The A3 domain contains a collagen binding site that is probably involved in vWF interaction with extracellular matrix. There is an RGDS sequence near the carboxyl terminal end of the molecule that mediates the binding of vWF to platelet GP IIb/IIIa.

A number of genetic defects may give rise to vWD. The syndrome is divided into three major types, based on whether the defect results in a simple quantitative deficiency of vWF or a qualitative defect in vWF (Table 47.2). Type 1 vWD is the most common type of vWD and is characterized by a moderate quantitative deficiency of vWF, with vWF:ag usually in the range of 30% to 50% of normal. The vWF that is present has a normal multimeric structure and normal function in terms of mediating platelet adhesion and binding factor VIII. Type 2 vWD is characterized by qualitative abnormalities in vWF. These abnormalities may be associated with loss of high-molecular-weight multimers (type 2A), enhanced affinity for GP Ib/IX/V (type 2B), decreased affinity for GP Ib/IX/V without loss of high-molecular-weight-multimers (type 2M) or loss of affinity for factor VIII (type 2N). Type 3 vWD is characterized by a severe deficiency of vWF and, consequently, a deficiency of factor VIII.

Analysis of the molecular biology of vWD has indicated that mutations in certain regions of the molecule are associated with distinct phenotypes. Type 2A vWD is the second most common type of vWD and represents a heterogeneous group of defects. In some patients, the disorder is associated with missense mutations that result in amino acid substitutions in the A2 domain. Apparently these mutations make this region of the molecule more susceptible to the plasma protease that normally processes vWF. The enhanced degradation of vWF leads to a loss of the high-molecular-weight multimers and diminished vWF-mediated platelet function. In other patients, there appears to be a mutation that affects endothelial cell processing and secretion of vWF such that the high-molecular-weight multimers are not appropriately formed and secreted. Patients with type 2A vWD show a significant loss of high-molecular-weight multimers of vWF.

Type 2B vWD is the third most common type of vWD and is associated with point mutations in or near the A1 domain that result in amino-acid substitutions that increase the affinity of vWF for GP Ib/IX/V so that vWF can bind to GP Ib/IX/V under normal flow conditions. The bound abnormal vWF is re

moved from the circulation, resulting in a mild deficiency of the high-molecular-weight multimers. The enhanced affinity of the abnormal vWF for GP Ib/IX/V also accounts for the enhanced platelet aggregation response seen at low concentrations of ristocetin. A clinical correlate of the interaction between the abnormal vWF and GP Ib/IX/V is the propensity of these patients to develop mild to moderate thrombocytopenia.

TABLE 47.2. CLASSIFICATION OF VON WILLEBRAND DISEASE

VWD Sub-Type	Defect	Inheritance
Type 1	Decreased quantity of all vWF multimers High-molecular-weight multimers present Concordance between vWF:ag and vWF:Rcof	Autosomal dominant
Type 2A	High molecular weight multimers absent Abnormal platelet dependent vWF function Discordance between vWF:ag and vWF:Rcof	Autosomal dominant
Type 2B	Loss of some high-molecular-weight multimers Increased affinity of vWF for GP Ib/IX/V Association with thrombocytopenia	Autosomal dominant
Type 2M	Abnormal platelet-dependent vWF function Discordance between vWF:ag and vWF:Rcof High-molecular-weight multimers present	Autosomal dominant
Type 2N	Decreased affinity for factor VIII Normal platelet-dependent vWF function Decreased factor VIII, prolonged APTT	Autosomal recessive
Type 3	Severe deficiency of vWF Multimeric analysis cannot be performed Factor VIII also markedly decreased	Autosomal recessive
Platelet-Type	Abnormal GPIb/V/IX (Ibα) Increased affinity for normal vWF Association with thrombocytopenia	Autosomal dominant

Type 2M vWD is an uncommon type of vWD and also has been associated with missense mutations in the A1 domain of vWF. In contrast to type 2B vWD, the mutations in the GP Ib/IX/V-binding domain of vWF associated with type 2M result in a loss of affinity for GP Ib/IX/V. Thus, the abnormal vWF is not able to adequately bind to GP Ib/IX/V and mediate platelet adhesion. The vWF multimeric structure usually is normal in such patients. Type 2N vWD is a rare type of vWD and is characterized by mutations in the amino-terminal end of the molecule that affect the affinity of vWF for factor VIII. The relative impact of the mutation on affinity for factor VIII depends on the precise site of the mutation. Consequently, the plasma level of factor VIII can range from very low (˜1%) to moderately low (10% to 15%) in affected patients.

The molecular pathology of type 1 and type 3 vWD is more complex. Although it might seem that type 3 vWD would simply represent a homozygous form of type 1 vWD, this does not appear to be the case. Most heterozygous carriers of mutations that result in type 3 vWD are asymptomatic. The mutations associated with type 1 vWD appear to be distinct from those associated with type 3 vWD, and, in many cases, are still not defined. A variety of defects, including point mutations and gene deletions may give rise to a quantitative deficiency of vWF. The synthesis of vWF is a complicated process and it is possible that defects in other components of the synthetic pathway may affect the plasma level of vWF, giving rise to a type 1 vWD phenotype. In a mouse model of vWD, the plasma deficiency is from abnormal glycosylation of vWF that results in a shorter half-life for vWF. The finding of normal levels of platelet vWF (which would be protected from enhanced clearance) and reduced plasma vWF in some patients with type 1 vWD suggests that a similar mechanism may be operative in humans.

Given the complex nature of the pathogenesis of vWD, it should not be surprising that the laboratory phenotype is quite variable. Therefore, a number of procedures must be utilized to evaluate the possibility of vWD whenever a patient presents with a history of mucocutaneous bleeding of unknown etiology. The bleeding time is often used as a screening test and is typically mildly to moderately prolonged in vWD. However, the bleeding time may fluctuate significantly over time and may be within the normal range at any given point. In particular, patients with normal levels of platelet vWF may have only a modest, if any, prolongation of the bleeding time. Therefore, a normal bleeding time in a patient with a history of mucocutaneous bleeding does not rule out vWD, and further laboratory studies are indicated in such patients. The aspirin tolerance test, in which the bleeding time is repeated 2 to 8 hours after a challenge with aspirin (650 mg), may be helpful; patients with mild vWD (or other mild platelet function disorders) usually show a marked prolongation of the bleeding time after such an aspirin challenge. The PFA 100 analyzer also appears to be a very sensitive procedure for the detection of abnormal vWF-mediated platelet function and is less invasive than the bleeding time.

Factor VIII activity and vWF:ag assays are used to measure the concentration of the components of the vWF-factor VIII complex in plasma. Patients with type 1 vWD also usually show reduced, but concordant results whereas the results in samples from patients with type 2 vWD may show discordance between these parameters; indeed, such a finding should raise the possibility of type 2 vWD. Blood type has a significant impact on the plasma concentration of vWF, with lower levels of vWF associated with blood type O. Of note, the ABO carbohydrate group is present on vWF and it is possible that the blood type O phe

notype is associated with enhanced clearance of vWF. As a consequence, the patient's blood type should be taken into consideration when assessing the possibility of vWD. The platelet-associated function of vWF may be assessed using ristocetin-induced platelet aggregation at low (<0.8 mg/mL) and high (>1.0 mg/mL) concentrations, the ristocetin cofactor assay, the collagen binding assay or the recombinant GP Ibα binding assay. Of these assays, the platelet aggregation assay is perhaps the least sensitive for the diagnosis of type 1 vWD. The multimeric composition of vWF is best assessed using SDS-agarose electrophoresis. This procedure may provide pivotal information because the only abnormalities that may be found in some patients with type 2 vWD are an abnormal screening test (e.g., bleeding time) and an abnormal vWF multimeric composition.

The diagnosis of vWD depends on the combination of an appropriate clinical history, laboratory abnormalities involving vWF and evidence of hereditary transmission (Table 47.3). Patients with type 1 vWD typically have a prolonged bleeding time, a concordant decrease in vWF:ag, vWF:Rcof and factor VIII, a decreased aggregation response to ristocetin (at concentrations >1.0 mg/mL), and a normal multimeric composition. Patients with type 2A vWD tend to have a low to normal vWF:ag concentration, with vWF:Rcof activity even lower than the antigen concentration; multimeric analysis demonstrates the characteristic loss of high-molecular-weight multimers. The results in patients with type 2B are quite variable. Perhaps the most useful parameter for identification of these patients is the increased platelet aggregation at low concentrations (<0.8 mg/mL) of ristocetin. High-molecular-weight multimers also are decreased, but not usually to the extent of the decrease associated with type 2A vWD. Type 2M vWD is associated with a low to normal vWF:ag and a significantly reduced vWF:Rcof activity. Multimeric analysis is normal in patients with type 2M vWD. Type 2N vWD may be easily misdiagnosed as hemophilia unless the ability of patient vWF to bind factor VIII is assessed. All other parameters of vWF may be normal. Type 3 vWD is characterized by very long bleeding times, absent vWF, very low or undetectable factor VIII activity, and absent vWF:Rcof. Multimeric analysis cannot be performed in these patients because of the lack of antigen.

TABLE 47.3. TYPICAL LABORATORY PARAMETERS IN VON WILLEBRAND DISEASE AND RELATED DISORDERS

Parameter	Type 1	Type 2A	Type 2B	Type 2M	Type 2N	Type 3	Platelet-Type	Bernard-Soulier Syndrome
Bleeding time	↑ or N	↑	↑	↑	N	↑	↑	↑
Platelet count	N	N	↓ or N	N	N	N	↓ or N	↓
APTT	↑	↑ or N	N or ↑	N or ↑	↑	↑	N or ↑	N
vWF:Ag	↓	↓ or N	N or ↓	↓ or N	N or slight ↓	↓↓	N or ↓	N
vWF:Rcof	↓	↓	↓, N or ↑	↓	N or slight ↓	↓↓	↓ or N	N
VIII	↓	N or ↓	N or ↓	N or ↓	↓↓	↓↓	N or ↓	N
RIPA	↓	↓	↑	↓	N	↓↓	↑	↓↓
Multimers	N	Abn	Abn	Abn	N	ND	Abn	N

Abbreviations used: APTT, activated partial thromboplastin time; vWF:ag, von Willebrand factor antigen; vWF:Rcof, ristocetin cofactor activity; VIII, factor VIII coagulant activity; N, normal; ND, not done (antigen too low); RIPA, ristocetin-induced platelet aggregation.

Many of the bleeding episodes with type 1 vWD can be treated effectively with desmopressin (1-deamino-8-D-arginine vassopressin, Aventis, Bridgewater, NJ). This agent induces a twofold to tenfold increase in the plasma level of vWF, a response that is often adequate to maintain hemostasis during dental procedures or other minor surgical procedures. The fibrinolytic inhibitor, ε-aminocaproic acid [Amicar (Immunex Corp., Seattle, Washington)], may be a useful adjunct, particularly in procedures involving the oral mucosa. vWF can be replaced using cryoprecipitate, an excellent source of fully functional vWF, but this is no longer recommended as a first line of therapy because of the potential for transmission of viral diseases. Certain highly purified factor VIII concentrates contain high concentrations of vWF and are effective in the therapy of vWD. An advantage of the factor VIII concentrates is that they have undergone one or more viral inactivation steps. Such products are now recommended as a first line of therapy for patients needing replacement of vWF. Generally, this would include patients with type 2 or 3 vWD. In particular, patients with type 2B vWD must be treated with care. Treatment of these patients with desmopressin may induce thrombocytopenia, presumably resulting from release of the abnormal vWF from endothelial cells. The therapy of choice in these patients is a factor VIII concentrate with sufficient concentrations of vWF.

Platelet-Type von Willebrand Disease (Pseudo-vWD)

Platelet-type vWD is a rare disorder that presents with a clinical history and laboratory profile consistent with a diagnosis of type 2B vWD (5,21,22,23,24 and 25). These patients have a history of mucocutaneous bleeding, prolonged bleeding time, intermittent thrombocytopenia, and decreased concentration of the high-molecular-weight multimers of vWF. In contrast to patients with Type 2B vWD, the defect in these patients lies in platelet GP Ib/IX/V rather than vWF. The abnormal GP Ib/IX/V complex has an increased affinity for normal vWF. Normal high-molecular-weight multimers of vWF bind to the abnormal receptor and are cleared from the circulation. The inappropriate interaction between the abnormal platelets and normal vWF also can lead to removal of the platelets from the circulation, causing the thrombocytopenia. Thus the pathogenesis of platelet-type vWD is similar to the pathogenesis of type 2B vWD in that a mutation leads to an inappropriate interaction between vWF and GP Ib/IX/V. Molecular analysis of patients with platelet-type vWD has revealed missense mutations in the gene for GP Ibα that result in amino-acid substitutions in the vWF binding domain of the molecule. Peptide fragments of GP Ibα with these mutations expressed by recombinant technology show increased affinity for vWF in the

presence of low concentrations of ristocetin, consistent with the presumed mechanism for loss of vWF multimers associated with this disorder.

The laboratory picture in these patients resembles type 2B vWD (Table 47.3). The bleeding time usually is prolonged, the concentration of vWF:ag is variable, but often reduced and patient platelets show an enhanced aggregation response to low concentrations of ristocetin. The clearance of high-molecular-weight vWF multimers by the abnormal platelets results in a decrease in plasma high-molecular-weight multimers evident on multimeric analysis. Platelet-type vWD can be distinguished from type 2B vWD by demonstrating that the defect lies in the patient's platelets and not in vWF. Platelets from patients with platelet-type vWD have been shown to bind increased amounts of normal vWF at low concentrations of ristocetin. This allows separation of these two disorders, as platelets from patients with type 2B bind normal amounts of vWF. In addition, plasma from patients with type 2B vWD may support aggregation of normal platelets at low ristocetin concentrations. The clinical management of patients with platelet-type vWD differs from those with type 2B vWD; patients with platelet-type vWD should be treated with platelets for control of bleeding episodes.

Bernard-Soulier Syndrome

The Bernard-Soulier syndrome is a rare, autosomal-recessive disorder characterized by the onset of mucocutaneous bleeding at an early age, a prolonged bleeding time, and thrombocytopenia with giant platelets (5,21,27 and 27). The Bernard-Soulier syndrome is caused by a deficiency or functional abnormality of the GP Ib/IX/V complex, resulting in abnormal platelet adhesion. However, thrombin also binds to the GP Ib/IX/V receptor and thus thrombin-mediated aggregation is abnormal in patients with Bernard-Soulier syndrome. This effect is distinct from the major thrombin receptor, as platelet aggregation induced by peptides capable of activating PAR-1 is normal in platelets from patients with Bernard-Soulier syndrome.

The GP Ib/IX/V complex is composed of at least four proteins — GP Ibα, GP Ibß, GP IX and GP V in a stoichiometry of 2:2:2:1 (Fig. 47.4). Each protein is coded for by a distinct gene, but all belong to the leucine-rich motif superfamily of proteins. GP Ibα and GP Ibß are covalently linked by a disulfide bond in the extracellular region near the transmembrane domains; failure to form this linkage impairs expression and function of the receptor. Mutations in the genes for GP Ibα, GP Ibß and GP IX all have been associated with the Bernard-Soulier syndrome. In most patients, the mutations result in the inability to express the receptor complex on the cell surface. In a few patients, a mutation in GP Ibα results in a loss of affinity for vWF and impaired function even though the receptor is expressed on the cell surface.

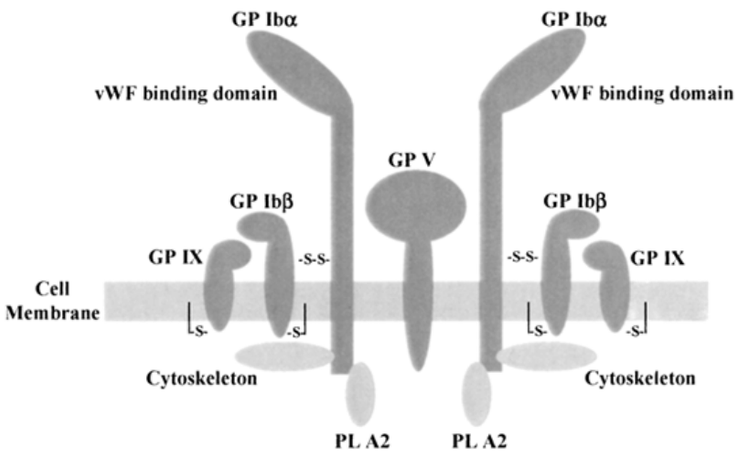

FIGURE 47.4. The GP Ib/IX/V receptor mediates platelet adhesion through interaction with von Willebrand factor (vWF). The receptor complex is composed of four distinct proteins, GP Ibα, GP Ibß, GP IX and GP V in a stoichiometry of 2:2:2:1. All four proteins appear to be necessary for normal expression and function of the receptor. The binding site for vWF is in an acidic extracellular domain of GP Ibα near the amino terminal end of the molecule. The extracellular region of GP Ibα nearest the cell membrane contains a mucinlike domain that is rich in O-linked carbohydrates. The intracellular domain of GP Ibα interacts with elements of the cytoskeleton, including actin binding protein, and with phospholipase A2 (PL A2). Ligand binding initiates the biochemical signaling pathways through these protein-protein interactions. GP Ibß is covalently linked to GP Ibα through a disulfide bond (-S-S-) in the extracellular domain. The short intracellular domain contains a free cysteine (-S), which can be linked to membrane lipids. GP IX is not covalently linked to the complex, but interacts with GP Ibß. The intracytoplasmic tail of GP IX also includes a free cysteine that can bind to membrane lipids. As with each of the proteins in the complex, GP V contains leucine-rich repeats. Glycoprotein V contains a thrombin susceptible site and the molecule may be cleaved by thrombin during platelet activation, releasing a 69 kDa fragment that includes most of the extracellular domain.

Initial laboratory evaluation of patients with the Bernard-Soulier syndrome usually demonstrates a mild to moderate thrombocytopenia with giant platelets, a prolonged bleeding time and a normal prothrombin time (PT) and activated partial thromboplastin time (APTT). The aggregation response to agonists such as ADP, epinephrine, collagen, and arachidonic acid is normal. However, platelets from patients do not aggregate in response to ristocetin. Addition of normal plasma or a source of vWF does not correct the ristocetin-induced aggregation defect, as it does in a patient with vWD. Analysis of vWF shows normal levels of vWF:ag and normal vWF:Rcof activity. The multimeric composition of vWF in plasma from patients with Bernard-Soulier syndrome also is normal (Table 47.3). The absence of the GP Ib/IX/V complex on the patient's platelets can be documented with flow cytometry using monoclonal antibodies directed at the receptor complex. Therapy of patients with Bernard-Soulier syndrome revolves around transfusion of platelets to control bleeding episodes. Alloimmunization is a problem in those patients requiring frequent transfusions.

Collagen Receptor Deficiency

Congenital deficiency of platelet membrane receptors for collagen results in impaired platelet adhesion and aggregation (5,28). Platelet adhesion to collagen appears to augment the process initiated by vWF binding to GP Ib/IX/V and is necessary for adequate function *in vivo*. At least two membrane proteins appear to be involved in collagen binding. The initial interaction appears to be between collagen and glycoprotein Ia/IIa, with subsequent binding to GP VI. Patients with abnormalities of collagen binding usually have a prolonged bleeding time, mild to moderate mucocutaneous bleeding, and defects in the platelet aggregation response to collagen. The platelet response to ristocetin and vWF concentration and function are normal.

Connective Tissue Disorders

Patients who have congenital disorders of connective tissue, such as the Ehlers-Danlos syndrome, may have problems with mucocutaneous bleeding (5,29). Bleeding times in such patients are often mildly prolonged. *In vitro* assessment of platelet function usually shows normal results and normal levels of vWF. The defect in such patients appears to be in the vessel wall components that mediate platelet adhesion.

Disorders of Platelet Activation

A number of congenital disorders that affect platelet activation have been described (5,14,15,30,31,32,33,34,35,36,37 and 38). These patients typically present with a clinical history characteristic of platelet dysfunction, with the onset of mucocutaneous bleeding early in life. The family history is often positive, suggesting an autosomal-dominant pattern of inheritance. However, the precise inheritance pattern for some of these disorders is still poorly defined because only a few kindred have been studied. The bleeding time is typically prolonged, but, as in vWD, it may be within the upper range of normal. The aspirin tolerance test can be used to unmask an underlying platelet defect in this group of patients. The PFA 100 appears to be an alternate, sensitive method for detecting abnormal platelet function in this group of disorders.

Laboratory studies characteristically show normal vWF concentration and function and a normal platelet aggregation response to ristocetin. Platelet aggregation with ADP and epinephrine typically shows a secondary wave defect, characterized by an initial wave of aggregation followed by dissociation of the platelets (Figure 47.1). The response to arachidonic acid and collagen may be blunted or delayed as well. A number of specific disorders, as briefly described below, have been delineated, but platelet transfusion therapy for bleeding episodes is the common therapy for all of these disorders. Although the mechanism is unknown, desmopressin has been shown to be effective in some patients and may be a useful adjunctive therapy.

Disorders of platelet activation can be divided into platelet membrane receptor disorders, storage pool disorders, and biochemical signaling disorders (Table 47.4). Deficiency of GP Ia, a collagen receptor, is associated with an abnormal aggregation response to collagen and defective platelet adhesion. Deficiency of α_2-adrenergic receptors (epinephrine receptors) has been associated with a mild bleeding tendency and failure of platelets to aggregate in response to epinephrine *in vitro*. In many of these patients, the aggregation response to ADP, collagen, and arachidonic acid has been normal. Patients with an abnormality of the ADP receptors show decreased binding of ADP, a decreased aggregation response to ADP and functional changes that mimic the defect seen with platelets exposed to the platelet inhibitor clopidogrel. Abnormal platelet function because of mutations in the receptor for TxA_2 also has been described. As one would expect, the aggregation response to arachidonic acid is abnormal in such patients.

TABLE 47.4. CONGENITAL PLATELET DISORDERS ASSOCIATED WITH ABNORMAL PLATELET ACTIVATION

Membrane Receptor Disorders	Storage Pool Disorders	Biochemical Signaling Disorders
Collagen receptor deficiency	Hermansky-Pudlak syndrome	Cyclooxygenase deficiency
α_2-Adrenergic receptor deficiency	Wiscott-Aldrich syndrome	Thromboxane synthetase deficiency
ADP receptor deficiency	Chediak-Higashi syndrome	Decreased arachidonic-acid release
TxA_2 receptor abnormality	Idiopathic dense granule deficiency	Phospholipase C disorders
	Gray platelet syndrome	G-protein disorders
	Quebec platelet disorder	Abnormal phosphatidylinositol metabolism Idiopathic

Abnormalities of platelet α and dense granules result in what are known as the storage pool disorders. This is a heterogeneous group of disorders that have been associated with clinically significant platelet dysfunction. The abnormalities may affect dense granules, α-granules, or both types of granules. Deficiency of dense granules has been associated with congenital disorders such as the Hemansky-Pudlak syndrome and the Wiskott-Aldrich syndrome, but may occur independent of such disorders (Table 47.5). The Hermansky-Pudlak syndrome is an autosomal-recessive disorder characterized by tyrosinase-positive ocular-cutaneous albinism, mucocutaneous bleeding as a result of absent dense granules and lysosomal accumulation and storage of ceroid-lipofuscin. The clinical course often is complicated by granulomatous colitis and/or progressive pulmonary fibrosis. The disorder is related to genetic abnormalities affecting the formation and function of melanosomes, platelet dense gran-ules and lysosomes. While mutations at distinct genetic loci

have been associated with the syndrome, the mechanism for the organelle abnormalities has not been elucidated. Platelet aggregation studies from patients with Hermansky-Pudlak syndrome characteristically show a secondary wave defect and lack of secretion of serotonin and ATP in response to ADP and epinephrine.

TABLE 47.5. ACQUIRED ABNORMALITIES OF PLATELET FUNCTION

Medications	Multiple myeloma
Antiplatelet antibodies	Monoclonal proteins
Uremia	Macromolecules
Cardiopulmonary bypass	Hypothyroidism
Consumptive coagulopathies	Liver disease
Acquired von Willebrand disease	

The Wiskott-Aldrich syndrome is an X-linked recessive disorder characterized by immunodeficiency, platelet abnormalities, eczema, and an increased risk of autoimmune disorders and malignancy. Platelet abnormalities include thrombocytopenia, small platelets, a decreased number of platelet granules and an abnormal platelet aggregation response to ADP, epinephrine and collagen. Megakaryocytes are present in normal or mildly increased numbers and platelet turnover is decreased, consistent with ineffective thrombopoiesis. The pathogenesis of the Wiskott-Aldrich syndrome has been linked to abnormalities of a protein (WASP) that is involved in transmitting signals from the cell membrane to the actin cytoskeleton.

The Chediak-Higashi syndrome is an autosomal recessive disorder characterized by partial oculocutaneous albinism, predisposition to infection, an immunodeficiency that predisposes to the development of lymphoproliferative disorders and abnormal granules in a variety of cell types, including platelets. Chediak-Higashi syndrome is caused by a defect in the lysosomal trafficking regulator protein (LYST). The precise mechanisms by which defects in this protein lead to the clinical manifestations of the disorder are still unknown.

The gray-platelet syndrome is a rare, autosomal-recessive disorder characterized by mild to moderate thrombocytopenia and pale-appearing platelets on a Wright-Giemsa–stained peripheral blood film. The abnormal platelet morphology is caused by an inability to store soluble proteins in the α-granules. In contrast, platelet α-granule membrane proteins such as P-selectin (CD62) are present in relatively normal concentration and translocate to the surface of the platelets following platelet activation. The aggregation response of platelets from patients with the gray-platelet syndrome usually show a normal response to epinephrine and arachidonic acid but a decreased response to thrombin and low concentrations of collagen. The aggregation response to ADP and ristocetin is variable. A common finding among patients with the gray-platelet syndrome is the early onset of myelofibrosis, perhaps resulting from an inability of megakaryocytes to normally store platelet-derived growth factors.

The Quebec platelet disorder is a rare, autosomal-dominant disorder characterized by moderate to severe mucocutaneous bleeding that is not responsive to platelet transfusion. The platelet count in patients has varied from normal to moderately reduced. Platelet aggregation in response to epinephrine is abnormal, but the response to ADP and collagen may be normal or mildly reduced. There is a deficiency of multimerin, a normal α-granule protein, and proteolysis of many, but not all α-granule proteins. Platelet factor V, fibrinogen, vWF, thrombospondin, P-selectin, osteonectin, and fibronectin are all abnormally degraded. The degraded fibrinogen can be detected by assays for fibrin degradation products if whole blood is allowed to clot before the serum is separated. However, the degraded fibrinogen is not detected with assays for D-dimer or if platelet-poor plasma is allowed to clot and used for the assay, suggesting that the abnormal platelets are able to secrete the degraded fibrinogen *in vitro*. The therapy of choice for bleeding episodes in patients with the Quebec platelet disorder appears to be fibrinolytic inhibitors, such as ε-aminocaproic acid.

The biochemical signaling abnormalities represent a heterogeneous group of disorders that share a common clinical phenotype characterized by mucocutaneous bleeding, a normal platelet count and abnormalities in the platelet aggregation response to one or more agonists. Deficiency of either cyclooxygenase or thromboxane synthetase in the phospholipase A_2 pathway results in deficient synthesis of thromboxane A_2. Such patients typically show no aggregation response to arachidonic acid and a secondary wave-type defect in response to ADP. Defects in the phospholipase C pathway may lead to decreased formation of inositol trisphosphate and diacylglycerol, leading to decreased mobilization of calcium from storage sites. Defects in this pathway include abnormalities of specific isotypes of phospholipase C and abnormalities of the G-proteins that couple receptor activation to the signaling pathway. Abnormalities in downstream signaling pathways also may lead to an abnormal platelet response.

The biochemical signaling disorders can be differentiated from storage pool disorders with specialized studies such as electron microscopic evaluation of platelet granules, measurement of serotonin uptake and release, measurement of α-granule proteins and measurement of ATP release in response to strong agonists such as thrombin or thrombin receptor agonists. Typically, patients with dense granule deficiency show a decreased uptake of radiolabeled serotonin, a decreased number of granules on electron microscopy, and decreased release of ATP in response to thrombin. Distinction between these types of disorders generally does not affect the clinical management of these patients, which, in most situations, involves transfusion of platelets to control significant bleeding episodes.

Disorders of Platelet Aggregation

Glanzmann's thrombasthenia is the major disorder affecting platelet-platelet interaction (5,14,39,40). Glanzmann's thrombasthenia is a rare, autosomal-recessive disorder characterized by a prolonged bleeding time, recurrent mucocutaneous bleeding, and an absent aggregation response to ADP, epinephrine, collagen, and arachidonic acid (primary wave defect). The aggregation response to ristocetin often is normal in these patients. Glanzmann's thrombasthenia is caused by a deficiency or functional abnormality of the GP IIb/IIIa receptor. Because of the defect, the platelets cannot bind fibrinogen or other adhesive proteins and thus cannot be cross-linked to form platelet aggregates. The diagnosis is established by the clinical history, a long

bleeding time, and the characteristic lack of platelet aggregation with normal fibrinogen levels. The platelet surface concentration of GP IIb/IIIa measured by flow cytometry is significantly reduced in most patients. The concentration of the receptor may be normal in a few patients, but it is unable to function normally.

Clot retraction usually is diminished in samples from patients with Glanzmann's thrombasthenia because of the interaction of GP IIb/IIIa with the platelet cytoskeleton. The α-granules of patients with Glanzmann's thrombasthenia are deficient in fibrinogen, indicating that the GP IIb/IIIa receptor is involved in the normal uptake of fibrinogen from plasma. As the human platelet antigens PL^{A1}, Bak^{a}, and Lek^{a} are located on the glycoprotein IIb/IIIa complex, patients with Glanzmann's thrombasthenia usually are negative for these antigens and are thus susceptible to alloimmunization. Alloimmunization can be a major clinical problem in the management of patients requiring frequent transfusions.

A variety of mutations involving the genes for GP IIb and IIIa have been identified in patients with Glanzmann's thrombasthenia. Affected patients may be homozygous for a single type of mutation or a compound heterozygote for two mutations. Although the incidence of Glanzmann's thrombasthenia is rare in the general population, there are selected populations in which it may occur as commonly as hemophilia, including French gypsies, Iraqi Jews, Jordanian nomads and South Indian Hindus. A relatively high prevalence of a characteristic mutation is found in each of these populations.

Patients with afibrinogenemia also may have problems with mucocutaneous bleeding and may lack a response to agonists such as ADP, collagen, arachidonic acid, and epinephrine. The defect in platelet aggregation in these cases is from the absence of the fibrinogen as a cross-linking material. The clinical picture in such patients usually is dominated by the major defect in fibrin clot formation. As one would expect, the PT and APTT are basically not measurable in such patients.

Disorders Affecting Platelet Procoagulant Activity

Activation of the platelet by its various physiologic agonists leads to calcium dependent, transient expression of negatively charged aminophospholipids, particularly phosphatidylserine, on the external platelet surface (5,14,41). The aminophospholipids provide the requisite surface for many of the coagulation activation complexes described in Chapter 48. Scott syndrome is a rare, autosomal-recessive disorder characterized by impaired formation of factor Xa and thrombin in the presence of platelets. The defect is related to a lack of expression of aminophospholipids on the platelet surface following platelet activation. A similar defect is present in red cells and lymphocytes from patients with Scott syndrome. The pathogenesis of the disorder is still uncertain, as the cells from patients with Scott syndrome have a normal, functional concentration of the “scramblase” enzyme that mediates the translocation of the phospholipid. Other parameters of platelet function, such as platelet aggregation to ADP and collagen, dense and α-granule content and platelet secretion are normal in patients with Scott syndrome. However, platelets from patients with Scott syndrome do not shed microparticles following activation. The binding of annexin V to platelets is dependent on phospholipid translocation and thus annexin V does not bind to platelets from patients with Scott syndrome following platelet activation. This provides a method for screening for the disorder using flow cytometry and measurement of the binding of annexin V labeled with fluorescent dye following *in vitro* platelet activation.

Constitutive expression of phosphatidylserine on nonactivated platelets has been described in three members of a family (Stormorken syndrome). As one would expect, platelets from these patients bound annexin V without platelet activation. In addition, circulating platelet microparticles were increased. Platelet aggregation in response to collagen was abnormal and borderline in response to ADP. Other findings in the affected family members included asplenia, reduced platelet survival, miosis, dyslexia, muscle fatigue, and icthyosis. Because of the continuous expression of procoagulant phospholipids, one might expect these patients to suffer from thromboembolic problems. However, the principal hemostatic problem has been recurrent bleeding. Despite the continuous expression of procoagulant phospholipids, the defects in platelet function appear to dominate the clinical picture.

ACQUIRED DISORDERS OF PLATELET FUNCTION

Part of "47 - Laboratory Evaluation of Platelet Disorders"

Acquired abnormalities of platelet function are a more common cause of clinical bleeding than congenital disorders. A number of conditions have been associated with abnormal platelet function (Table 47.5). Among these, drug-induced abnormalities are the most common cause of abnormal platelet function. Indeed, intentional inhibition of platelet function has become an important component in the management of patients with cardiovascular disease. In contrast to congenital disorders, in which platelet aggregation studies play a pivotal role in delineating the nature of the platelet defect, platelet aggregation studies have only a minor role in evaluating acquired platelet dysfunction. In most patients, the combination of the clinical history and a prolonged bleeding time or other screening test of platelet function are sufficient to establish the platelet abnormality; platelet aggregation studies do not add any specific or clinically predictive information in most patients.

Medications That May Affect Platelet Function

Numerous drugs and foods have been found to have an inhibitory effect on platelet function either *in vivo* or *in vitro* (Table 47.6) (10,42,43,44,45,46,47,48,49,50,51,52 and 53). Major groups of drugs that affect platelet function include nonsteroidal antiinflammatory agents, of which aspirin is the most common offender; ß-lactam-containing antibiotics; a variety of cardiovascular drugs, particularly ß-blockers; psychotropic drugs; anesthetics; antihistamines; and some chemotherapeutic agents. Aspirin is taken by many patients on a routine basis and is also a common ingredient in many over-the-counter medications. Therefore, a history of aspirin ingestion may be difficult to elicit unless detailed questioning is performed. Antibiotics are often an overlooked source of

impaired platelet function in hospitalized patients and can have an adverse effect on *in vivo* bleeding tendencies.

TABLE 47.6. SUBSTANCES ASSOCIATED WITH ABNORMAL PLATELET FUNCTION IN VIVO OR IN VITRO

Antiinflammatory agents	*ß-Blockers*	*Platelet Inhibitors*
Aspirin	Propranolol	Ticlopidine
Indomethacin	Labetalol	Clopidogrel
Ibuprofen		Dipyridamole
Phenylbutazone	*Calcium-channel blockers*	Abciximab
Sulfinpyrazone	Verapamil	Tirofiban
Naproxen	Nifedipine	Eptifibatide
Diclofenac	Diltiazem	
Zompirac		*Miscellaneous*
Tolmetin	*Lipid-lowering drugs*	Ethanol
	Clofibrate	Sodium valproate
Antibiotics	Halofenate	Hydralazine
Ampicillin	Cyproheptadine	Dextran
Penicillin		Papaverine
Carbenicillin	*Antihistamines*	Suloctidil
Ticarcillin	Theophylline	Furosemide
Mezlocillin	Aminophylline	Ethacrynic acid
Piperacillin	Chlorpheniramine	Acetazolamide
Cephalosporins	Diphenhydramine	Hydroxychloroquine
		Hydrocortisone
Tricyclic antidepressants	*Foods*	Methylprednisolone
Imipramine	Garlic	Daunorubicin
Desipramine	N-3 fatty acids	Mithramycin
Amitriptyline	Ginger	Chlorpromazine
Nortriptyline	Onion	Triprolidine
	Cumin	Reserpine
	Turmeric	Nitrofurantoin
		Heparin

In contrast to the “inadvertent” and generally undesirable effect of these drugs on platelet function, inhibitors of platelet function now are used frequently as part of the therapy of patients with cardiovascular disease. This group of drugs includes aspirin, an inhibitor of cyclooxygenase; ticlopidine, and clopidogrel, ADP receptor antagonists; dipyridamole, a phosphodiesterase inhibitor; and abciximab, eptifibatide and tirofiban, inhibitors of GP IIb/IIIa. The most potent of these agents are the GP IIb/IIIa inhibitors, which block the “final common pathway” of platelet aggregation.

Ticlopidine has been associated with a variety of toxic side effects, including gastrointestinal disturbance, skin rash, severe neutropenia, aplastic anemia, and thrombotic thrombocytopenic purpura (TTP). In view of the seriousness of the side effects, therapy with ticlopidine must be monitored closely. Clopidogrel has a safer profile in terms of bone marrow toxicity but it also has been associated with the development of TTP in a few patients.

Inhibition of greater than 80% of the platelet GP IIb/IIIa receptors is necessary for the GP IIb/IIIa inhibitors to have a significant clinical effect while inhibition of 100% of the receptors may be associated with clinical bleeding. Thus, there is a relatively narrow therapeutic window with the GP IIb/IIIa inhibitors. Flow cytometric assays have been developed to determine the percent of receptors inhibited, but it is unclear whether these assays provide a significant benefit in the management of patients being treated with these agents. Eptifibatide and tirofiban have a short half-life, both in terms of plasma concentration and inhibitor activity. Consequently, their antiplatelet effect is short-lived and essentially limited to the period of infusion. In contrast, abciximab, which is a chimeric monoclonal antibody fragment, has a short plasma half-life but a prolonged platelet-associated half-life. This appears to be from persistent binding of the antibody fragment to platelet GP IIb/IIIa. Thus, the antiplatelet effect of abciximab persists well beyond the period of active infusion. An uncommon, but clinically significant, side effect of the GP IIb/IIIa inhibitors is the sudden onset of severe thrombocytopenia, with platelet counts decreasing to less than 20×10^9/l. The mechanism of thrombocytopenia is uncertain but may be related to naturally occurring antibodies directed at neoepitopes on GP IIb/IIIa exposed when the drug binds to the receptor.

Uremia

Uremia is associated with a complex coagulopathy dominated by abnormal platelet function (46, 54, 55). A number of biochemical changes in platelets have been described in patients with uremia, but the precise lesion(s) responsible for the clinical manifestations is still unclear. Anemia contributes significantly to the bleeding tendency associated with uremia, particularly when the hemoglobin is less than 90 to 100 g/L. Studies have documented that the bleeding time and bleeding tendency both decrease if the hemoglobin concentration is raised by transfusion of red blood cells or administration of erythropoietin. Other defects that have been reported in uremia include: decreased adhesion of platelets to subendothelium, decreased availability of platelet factor 3 (platelet procoagulant activity), increased cytoplasmic c-AMP

levels, alterations in cytoplasmic calcium and a diminished rise in calcium following stimulation by a variety of platelet agonists, decreased storage products in both dense and α-granules, and alterations in vessel wall prostacyclin synthesis. Platelet aggregation studies in patients with uremia have been variable, with some groups reporting essentially normal aggregation responses and others reporting markedly impaired aggregation responses. In most studies, the aggregation responses observed *in vitro* have not correlated with clinical manifestations.

In addition to the platelet abnormalities listed above, there is evidence of ongoing activation of the coagulation cascade and fibrinolysis in patients with renal failure, even in the absence of hemodialysis. For example, the levels of thrombin-antithrombin complexes and prothrombin fragment F1.2 are increased, consistent with activation of the coagulation cascade. Fibrin degradation products and plasmin-antiplasmin complexes are also increased, consistent with ongoing activation of fibrinolysis. Thus, there may be a component of a low-grade consumptive coagulopathy in patients with uremia. The low-grade hemostatic activation could lead to platelet secretion without consumption or removal from the circulation and to modification of membrane receptors by plasmin. Such “exhausted” platelets would be expected to be functionally impaired.

Dialysis improves platelet function in patients with uremia and is an important part of the therapeutic approach to these patients. In addition to dialysis and correction of the anemia, a number of other therapeutic options for managing clinical bleeding in these patients have been developed. Cryoprecipitate has been reported to decrease the bleeding time and bleeding severity. The mechanism of action of cryoprecipitate is unclear, but it is relatively rich in vWF, which could promote platelet adhesion. Desmopressin has also been associated with a decrease in the bleeding time and correction of the bleeding tendency in patients with uremia. More recently, conjugated estrogens have been used in these patients with a beneficial effect.

Antiplatelet Antibodies

The most common clinical manifestation of antiplatelet antibodies is thrombocytopenia (56,57 and 58). However, antibodies that bind to the platelet surface also can cause abnormalities of platelet function. Decreased platelet function resulting from antiplatelet antibodies is most commonly associated with chronic autoimmune thrombocytopenic purpura (chronic ITP). The precise mechanism of abnormal platelet function in these patients is still unclear, but probably is related to interaction of the antibody with platelet surface membrane glycoproteins, as GP Ib/IX/V and IIb/IIIa are frequent epitopes for antibodies in chronic ITP. It has been suggested that antibody binding to these critical membrane receptors may impair their physiological function.

Binding of platelet antibodies to the surface of the platelet also may lead to platelet activation and thrombosis. This has been most commonly associated with HIT, but has also been noted with heparin-independent antiplatelet antibodies. The platelet activation is often a result of binding of immune complexes to the platelet receptor for IgG, FcγRIIa. Binding of immune complexes clusters the FcγRIIa receptors, initiating an intracytoplasmic signaling cascade that leads to platelet aggregation and secretion. Complement activation on the platelet surface can also lead to platelet activation and aggregation.

Myeloproliferative Disorders

A variety of platelet defects have been described in patients with underlying acute or chronic myeloproliferative disorders (46, 59). In some patients, there is evidence of increased platelet reactivity, as indicated by an increase in circulating platelet aggregates, plasma platelet factor 4, β-thromboglobulin and increased *in vitro* aggregation responses to platelet agonists. In other patients, platelet function appears to be impaired. A variety of changes in platelet structure and function may be observed in platelets from patients with myeloproliferative disorders, including a decrease in the α and dense granules; abnormalities of granule morphology; a decrease in platelet vWF and fibrinogen; an alteration in platelet membrane glycoproteins; decreased uptake and release of serotonin; decreased aggregation in response to a variety of agonists; and decreased procoagulant activity. Impaired platelet function may also be suggested by a discrepancy between the platelet count and the bleeding time.

Clinical manifestations of abnormal platelet function in these patients have included both thromboembolic and hemorrhagic complications. Unfortunately, there are no laboratory tests that can determine with accuracy which patient is likely to have thromboembolic or hemorrhagic complications. Therefore, there is little use for platelet aggregation studies in evaluating these patients. The one setting in which platelet aggregation studies may be helpful is in assessing a patient with marked thrombocytosis. Many patients with essential thrombocythemia have an abnormal *in vitro* aggregation response, particularly when epinephrine is used as the agonist, whereas patients with reactive thrombocytosis often have normal aggregation studies, unless there is a medication or other medical condition that could affect platelet function.

Fibrinolysis

Enhanced fibrinolysis can impair platelet function through a variety of mechanisms, including fibrin degradation products (FDPs) inhibiting fibrinogen binding to GP IIb/IIIa and plasmin-mediated degradation of membrane GP Ib/IX/V and GP IIb/IIIa (46). Abnormal platelet function resulting from enhanced fibrinolysis is perhaps most commonly seen in patients undergoing cardiopulmonary bypass procedures. The resulting impairment in platelet function probably plays a significant role in post-operative bleeding in such patients. A similar defect may be seen in patients treated with a systemic fibrinolytic agents such as streptokinase or tissue plasminogen activator and in patients with disseminated intravascular coagulation (DIC).

Acquired von Willebrand Disease

Acquired vWD is an uncommon clinical disorder characterized by the sudden onset of a bleeding diathesis in a previously asymptomatic patient (60, 61). As with other platelet disorders, the bleeding tends to be mucocutaneous in nature, with gas

trointestinal bleeding a frequent manifestation in this disorder. Acquired vWD has been seen in patients with severe congenital vWD following replacement therapy, lymphoproliferative disorders, myeloproliferative disorders, nonhematologic malignancies, autoimmune disorders, hypothyroidism, certain medications and spontaneously in the elderly. The pathogenesis of acquired vWD may involve one or more of several mechanisms. A common mechanism is the development of an antibody to vWF that may lead to increased clearance of vWF from the circulation and/or inhibition of vWF function. Another mechanism is adsorption of circulating vWF by binding of vWF to tumor cells. In some cases, this abnormal adsorption of vWF has been linked to aberrant expression of GP Ibα on the tumor cells. Other mechanisms that have been proposed include enhanced proteolysis of vWF and decreased synthesis of vWF.

The laboratory findings in acquired vWD are quite variable and somewhat dependent on the pathogenesis; most commonly the bleeding time is prolonged, and vWF, as measured by vWF:ag and vWF:Rcof, is decreased. The factor VIII level is usually concordant with the vWF:ag level in these patients. Some patients with acquired vWD may show a type 2 pattern of vWD; in these patients there may be a discordance between vWF:ag and vWF:Rcof. Multimeric analysis of such patients demonstrates the characteristic decrease in high-molecular-weight multimers of vWF. An inhibitor of vWF function can be demonstrated in some patients with immune-mediated acquired vWD. However, inhibitor activity cannot be demonstrated in patients with acquired vWD from nonimmune mechanisms or nonneutralizing antibodies.

In patients with an underlying malignancy, therapy of the tumor often is associated with regression of the acquired vWD. In those who have a documented inhibitor of vWF, immunosuppression forms the cornerstone of therapy. Various agents have been used to achieve this, including steroids, cytotoxic drugs, and intravenous immunoglobulin. Replacement of vWF with cryoprecipitate is occasionally helpful in such patients during periods of bleeding.

Other Disorders

Abnormal platelet function has been associated with macromolecules, including high concentrations of monoclonal IgM and high-molecular-weight dextrans used for volume expansion. Patients with myeloma and high concentrations of monoclonal IgG occasionally have abnormalities of platelet function as well. On occasion, patients with hypothyroidism or end-stage liver disease may have impaired platelet function.

QUANTITATIVE PLATELET DISORDERS

Part of "47 - Laboratory Evaluation of Platelet Disorders"

Evaluation of Quantitative Platelet Disorders

Thrombocytopenia and thrombocytosis are common clinical findings. Thrombocytopenia generally is of greater clinical concern because of its association with an increased risk of bleeding. The major concern with thrombocytosis is distinguishing reactive thrombocytosis from thrombocytosis secondary to a myeloproliferative disorder (thrombocythemia), which may be associated with either bleeding or thromboembolic manifestations. Thrombocytopenia usually is classified by the underlying mechanism, whereas thrombocytosis usually is divided into reactive processes and hematologic malignancies.

Thrombocytopenia may be from increased destruction, decreased production, spurious platelet counting, or splenic sequestration (Table 47.7). Thrombocytopenia is most commonly an acquired problem, but there are congenital disorders associated with either decreased production or increased clearance of platelets. Patients with congenital thrombocytopenia may be misdiagnosed (and mistreated) as having autoimmune thrombocytopenic purpura (ITP).

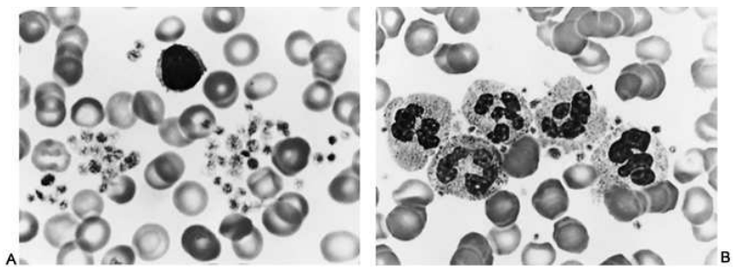

FIGURE 47.5. Pseudothrombocytopenia may be caused by *in vitro* agglutination of platelets (**A**) or platelet satellitosis (**B**). *In vitro* platelet agglutination may be EDTA dependent or independent. Both platelet agglutination and platelet satellitosis may affect the accuracy of the white blood cell count as well as the platelet count (original magnification × 500). It is thought that these findings are related to antibodies to platelet epitopes exposed by chelation of calcium by EDTA.

TABLE 47.7. MECHANISMS OF THROMBOCYTOPENIA

Increased Destruction	**Decreased Production**
Immune-mediated destruction	*Congenital disorders*
Autoimmune	Amegakaryocytic thrombocytopenia
Alloimmune (posttransfusion purpura, neonatal)	Fanconi's anemia
Drug-dependent antiplatelet antibodies	Wiskott-Aldrich
Immune complex disease	Alport syndrome and variants
	May-Hegglin anomaly
Microangiopathic processes	Familial thrombocytopenia
Thrombotic thrombocytopenic purpura	Bernard-Soulier syndrome
Hemolytic-uremic syndrome	Gray platelet syndrome
Disseminated intravascular coagulation	Quebec platelet syndrome
Sepsis	Neonatal rubella
Preeclampsia/eclampsia	
Metastatic carcinoma	*Bone marrow replacement*
Malignant hypertension	Metastatic tumor
Vascular tumors and lesions (including artificial valves)	Leukemia
	Myeloma
Cardiopulmonary bypass	Storage disorders (e.g., Gaucher's)
	Granulomatous disease
Major burns	
	Bone marrow failure
Massive transfusion	Aplastic anemia
	Radiation
Abnormalities of von Willebrand factor or GPIba	Chemotherapy
	Drugs
Hypersplenism	Immune suppression
	Viral infections
Spurious thrombocytopenia	
EDTA-dependent antibodies	*Ineffective thrombopoiesis*
Temperature-dependent platelet agglutinins	Megaloblastic anemia
Platelet satellitosis	Alcoholism
	Myeloproliferative syndromes
	Myelodysplastic syndromes

The laboratory approach to the evaluation of alterations in the platelet count begins with a careful review of the clinical history and the peripheral blood morphology, with particular emphasis on platelet morphology. Analysis of the mean platelet volume (MPV), platelet volume distribution, and examination of the bone marrow are additional useful steps (Table 47.1). Measurement of platelet RNA content by flow cytometry may be helpful in identifying a shift to “younger” platelets with a higher RNA concentration.

The initial goal in the evaluation of thrombocytopenia is to determine if the cause is related to increased peripheral destruction or decreased bone marrow production. The peripheral blood film should be carefully reviewed for evidence of platelet clumps or platelet satellitosis, giant platelets, and the presence of abnormal, hypogranular platelets (Fig. 47.5). Morphologic evidence of other hematologic abnormalities such as myelodysplasia, acute leukemia, megaloblastic anemia, autoimmune hemolytic anemia, TTP, or the May-Hegglin anomaly, should also be sought.

The MPV is another parameter that can provide useful information in the initial evaluation of thrombocytopenia. The normal bone marrow response to thrombocytopenia is an increase in megakaryocyte cytoplasmic size, associated with an increase in the size of zones of demarcation, resulting in the production of larger platelets. Accordingly, an increase in the MPV is often a hallmark of active thrombopoiesis and may be used as an indicator of the marrow response to thrombocytopenia associated with increased peripheral destruction. On the other hand, thrombocytopenia associated with a low MPV suggests a decreased marrow response to the thrombocytopenia (decreased production). Often the review of the smear combined with the clinical history and MPV will suggest a specific etiology.

If the etiology of the altered platelet count is not evident from the clinical history and peripheral blood findings, a bone marrow aspirate and biopsy should be examined to evaluate hematopoiesis in general and megakaryocyte number and morphology in detail. Megakaryocyte number and growth pattern are assessed most accurately by bone-marrow biopsy. In reactive conditions associated with an increase in megakaryocytes, the megakaryocytes tend to be randomly spaced throughout the marrow and do not form tight clusters or colonies. In contrast, clusters of megakaryocytes that may have a normal or strikingly abnormal morphology are commonly seen in bone marrow samples from patients with myeloproliferative disorders and abnormal megakaryopoiesis (Fig. 47.6). Both the bone marrow biopsy and the bone marrow aspirate can yield useful information re

garding megakaryocyte morphology, particularly if a myeloproliferative disorder is suspected. The bone marrow aspirate is particularly useful for assessing whether megakaryocytes are normally shedding platelets. Finally, the bone marrow aspirate and biopsy should be reviewed carefully for evidence of other diseases that may affect platelet production.

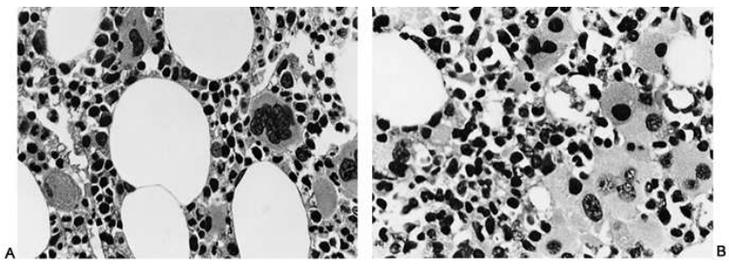

FIGURE 47.6. Megakaryocytic hyperplasia in reactive conditions is usually characterized by an increase in megakaryocytes throughout the marrow without formation of large clusters (**A**). In contrast, megakaryocytic hyperplasia associated with myeloproliferative disorders is often characterized by formation of clusters of closely approximated megakaryocytes (**B**). In addition, megakaryocyte morphology is frequently abnormal in patients with myeloproliferative disorders.

Detection of platelet-associated antibodies has been frequently used to assess the possibility of immune-mediated platelet destruction. However, a consensus panel of experts has indicated that measurement of platelet-associated IgG is not helpful in the routine evaluation of adult patients with autoimmune thrombocytopenic purpura (ITP). This recommendation was based on the lack of sensitivity and specificity of assays for measurement of platelet-associated antibody. Informative assays, such as those that measure surface-bound immunoglobulin through detection of the “free” Fc component of the antibody and those that measure an interaction with a specific platelet membrane protein, may be helpful in selected cases.

Additional procedures may be helpful on occasion, depending on the suspected underlying disorder. Such procedures may include electron-microscopy, cytogenetics, bone-marrow culture assays, and enzyme assays (e.g., Gaucher's disease) to evaluate platelet production and hematopoietic clonality. Other specialized assays may be used to confirm the diagnosis of disorders such as HIT, TTP, or paroxysmal nocturnal hemoglobinuria.

Thrombocytopenia Due to Increased Destruction

A number of disease processes may lead to increased platelet destruction (Table 47.7). In clinical practice, antibody-mediated thrombocytopenia is one of the more common mechanisms. Antibodies may induce thrombocytopenia through one or more of several mechanisms, including autoimmune, drug-dependent, alloimmune, and immune complex pathways. Microangiopathic processes, including TTP, the hemolytic-uremic syndrome (HUS) and disseminated intravascular coagulation (DIC) are characterized by accelerated platelet consumption, microvascular thrombosis and red cell fragmentation (schistocytes). A major side effect of cardiopulmonary bypass is transient thrombocytopenia resulting from both hemodilution and consumption.

Autoimmune Thrombocytopenia

ITP is the prototypic example of immune-mediated destruction of platelets (57, 62,63,64,65 and 66). Clinically, ITP is often divided into two forms, acute/childhood and chronic/adult (Table 47.8). Acute ITP often is associated with an antecedent viral infection and it has been suggested that the platelet is an innocent casualty of a cross-reacting antibody that recognizes both the pathogen and platelet membrane. In contrast, chronic ITP appears to be more of a classic autoimmune disorder and is often associated with other immunologic disorders such as systemic lupus erythematosus, rheumatoid arthritis, and autoimmune thyroid disease. As indicated in Table 47.8, the clinical course of these two forms of ITP is quite different, with acute ITP having an excellent prognosis and a high rate of spontaneous remission. In contrast, chronic ITP tends to be long-lasting, often requiring long-term immunosuppressive therapy.

TABLE 47.8. COMPARISON OF ACUTE AND CHRONIC AUTOIMMUNE THROMBOCYTOPENIA

Parameter	Acute ITP	Chronic ITP
Age	All ages; most frequent in childhood	All ages; most frequent in young adults
Gender	F = M	F > M
Onset	Abrupt	Gradual
Platelet count	Often <50 × 10^9/L	Often >50 × 10^9/L
Other autoimmune disorders	Usually absent	Often present
Clinical remission	Frequent	Infrequent

In recent years, the target antigens for the antiplatelet antibodies have been identified in many patients with ITP. The most frequent target antigens are GP Ib/IX/V and GP IIb/IIIa. In some patients the antibodies react with only one of these recep

tor complexes, while in other patients the antibodies react with both complexes. Although antibodies commonly bind to these proteins, they only occasionally cause a clinical picture of acquired Bernard-Soulier (GP 1b/V/IX) or acquired Glanzmann's thrombasthenia (GP IIb/IIIa).

Typical laboratory features of ITP include moderate to marked thrombocytopenia with a normal to increased MPV. Platelet morphology on peripheral blood smear tends to be normal, except for the shift to slightly larger platelets. Bone marrow examination usually demonstrates normal to increased numbers of megakaryocytes, which have a normal morphology. Bone marrow examination is most useful in patients who are greater than 60 years of age, in whom there is a higher incidence of myeloproliferative disorders, or in patients who are being considered for splenectomy. The bleeding time in patients with acute ITP is often proportional to the decrease in platelet count or is even shorter than expected. In contrast, in patients with chronic ITP, the bleeding time may be more prolonged than predicted by the decrease in platelet count, reflecting interference with platelet function by the platelet-associated antibody. However, changes in the bleeding time are not diagnostic for ITP, nor predictive of the clinical manifestations of the disorder. Therefore, performance of the bleeding time is not recommended as part of the evaluation of patients for ITP. Assays for platelet-associated IgG are not sufficiently sensitive or specific to aid in the diagnosis of ITP. The most important diagnostic step is to rule out other causes of thrombocytopenia. This may include specific evaluation for other disorders that may present with thrombocytopenia, such as human immunodeficiency virus (HIV) infection or Type 2B vWD. The diagnosis of ITP is thus based on the clinical history, physical examination, complete blood count and careful review of the peripheral blood film. In the absence of atypical findings or results that suggest another diagnosis, no further evaluation is usually needed.

Alloimmune Thrombocytopenia

Immune-mediated platelet destruction also is found in post-transfusion purpura, neonatal thrombocytopenia, and thrombocytopenia refractory to random platelet transfusions (57, 67). Post-transfusion purpura is an uncommon disorder characterized by the sudden onset of thrombocytopenia 7 to 10 days following a blood transfusion. The thrombocytopenia is from immune-mediated destruction of the patient's own platelets. The disorder usually occurs in patients with the PLA2 (HPA-1b) phenotype who receive blood products from PLA1 (HPA-1a) positive donors. The affected patients frequently have antibodies to PLA1, as well as antibodies to other platelet membrane proteins. Development of HLA-related antibodies and specific antiplatelet antibodies underlies the development of refractoriness to platelet transfusion. Therapeutic options in such patients include utilization of HLA-matched platelets and actual cross-matching of potential donor platelets with patient serum. Neonatal thrombocytopenia is usually a consequence of a maternal antibody that crosses the placenta and recognizes the neonatal platelets as foreign. Neonatal thrombocytopenia also may occur in the setting of maternal chronic ITP. Nonimmune neonatal thrombocytopenia is commonly seen in patients with hemolytic disease of the newborn and should be differentiated from these disorders.

Drug Induced Thrombocytopenia

Over 100 drugs have been implicated in the development of thrombocytopenia (58, 68,69,70, 71 and 72). In most cases, the platelet destruction is a result of the development of a drug-dependent antibody. At least three potential mechanisms for immunologic destruction in this setting have been described. Quinidine-related thrombocytopenia is an example of the mechanism in which drug binds to and alters platelet surface glycoproteins (GP Ib/IX/V), leading to immunologic destruction. Penicillin is an example of a second mechanism, in which the drug serves as a hapten that binds to the platelet surface. The hapten induces an antibody response and the IgG then binds to the membrane-associated hapten, leading to premature removal of the platelet from the circulation. A third mechanism is through immune complex interaction with the Fc receptor on the platelet surface (FcγRIIa); HIT is an example of this third mechanism.

Heparin-induced thrombocytopenia is one of the major side effects of heparin therapy. Two forms of heparin-related thrombocytopenia have been identified; the first is characterized by a mild drop in the platelet count (rarely less than 100×10^9/L), while the second is associated with more severe thrombocytopenia. The drop in the platelet count in the mild form usually occurs shortly after heparin therapy is instituted and the platelet count returns to normal whenever heparin therapy is discontinued. The platelet count may even rise toward the preheparin platelet count even if heparin therapy is continued. The mechanism for this form of heparin-related thrombocytopenia is unclear, but no immunologic component has been identified. Patients with this form of heparin-related thrombocytopenia do not appear to be at increased risk of either bleeding or thromboembolic complications.

The more severe type of heparin-related thrombocytopenia, known as HIT, is caused by an antibody that binds to a complex composed of heparin and a protein, usually PF4. When heparin binds to soluble PF4 a neoepitope is exposed on PF4. Antibodies, usually IgG, form to this eiptope and bind to the complex when heparin and PF4 are in the correct relative concentration. The heparin/PF4/IgG immune complex binds to platelet FcγRIIa receptors, clustering the receptors by the multivalent binding of the immune complex. The FcγRIIa cytoplasmic domain has a signaling motif that is activated when the receptor is clustered. This triggers activation of biochemical signaling pathways, platelet activation and platelet aggregation. In addition, the activated platelets shed membrane phosphoplipid particles (platelet microparticles) that support thrombin generation. Consequently, platelet activation in HIT also is associated with enhanced thrombin formation. These pathways are thought to account for the thromboembolic complications that commonly occur with this syndrome. Alternate terms that have been used to describe HIT include heparin-induced thrombocytopenia-thrombosis (HITT), white clot syndrome, and heparin-associated thrombocytopenia (HAT). The diagnostic and therapeutic approaches to this disorder are discussed in detail in Chapter 48.

Thrombocytopenia Associated with Human Immunodeficiency Virus

Thrombocytopenia is a common complication in patients with HIV infection (65). The mechanism of thrombocytopenia in these patients appears to be multifactorial. In many patients antiplatelet antibodies form, and the thrombocytopenia in these patients is similar to the chronic form of ITP. It has been hypothesized that formation of immune complexes, particularly between viral proteins and antibodies, also may promote thrombocytopenia in these patients. Finally, there is some evidence that the virus may infect megakaryocytes and that thrombopoiesis may be decreased in patients with HIV infection. Substantiating this viewpoint is the increase in platelet count that occurs in many patients following the introduction of antiviral therapy.

Thrombotic Thrombocytopenic Purpura and Hemolytic-Uremic Syndrome

Thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (HUS) are distinct but related disorders characterized by thrombocytopenia, microangiopathic hemolytic anemia with frequent schistocytes on the peripheral blood smear, and microvascular thrombosis (43, 73,74,75,76,77,78,79 and 80). The pathogenesis of TTP has been linked to abnormalities of the protease that normally modifies plasma vWF, whereas development of HUS has been commonly linked to certain infections, particularly specific serotypes of *Escherichia coli*. A TTP/HUS-like syndrome also may be seen with certain drugs, including mitomycin, cisplatin, cyclosporin, ticlopidine, and clopidogrel. A similar microangiopathic hemolytic anemia with microvascular thrombosis also has been associated with HIV infection.

The pathogenesis of TTP appears to be related to the presence of abnormally large vWF multimers. Plasma vWF is derived from endothelial cells, where it is stored in Weibel-Palade bodies. Newly secreted vWF includes very large multimers that can mediate platelet adhesion, activation and aggregation, particularly in areas of high shear. A plasma protease normally cleaves these very large multimers into smaller forms once the vWF is released into the circulation. Acquired TTP appears to be related to the development of an IgG that inhibits the function of this protease, permitting persistence of the abnormally large vWF multimers. A familial form of TTP has been described and it is associated with a congenital deficiency of the plasma protease. Thus, congenital or acquired loss of protease function appears to result in TTP.

In contrast to TTP, the plasma activity of the vWF-cleaving protease is normal in patients with HUS. Hemolytic-uremic syndrome is seen most commonly in the pediatric age range and usually is preceded by a phase of diarrhea, which is often bloody. The prodromal gastroenteritis usually is caused by a verocytotoxin-producing strain of *E. coli* (VTEC), most commonly strain O157:H7. Verocytotoxin produced by the VTEC in the gastrointestinal track can enter the systemic circulation and bind to endothelial cells, especially after the endothelial cells have been activated by inflammatory mediators, such as tumor necrosis factor-α, that increase the expression of a binding site for verocytotoxin. The bound verocytotoxin can damage endothelial cells, initiating the procoagulant response mechanisms. Thus, microvascular endothelial-cell injury is thought to be an underlying mechanism for HUS.

The classic pentad of clinical findings in TTP consists of fever, fluctuating neurological deficits, thrombocytopenia, red-cell fragmentation, and renal failure. One of the major clinical differences between HUS and TTP is that neurological symptoms tend to be absent and renal failure more pronounced in HUS. Laboratory parameters typical of both HUS and TTP include marked thrombocytopenia, often with giant platelets, frequent schistocytes and nucleated red blood cells in the peripheral blood, increased reticulocyte count and lactate dehydrogenase (LD), particularly LD1, and a normal PT, APTT, fibrinogen, and antithrombin. Assays for fibrin degradation products often are negative but may show a mild increase. Bone marrow examination, when performed, shows normal to increased numbers of megakaryocytes. Marrow vessels occasionally show the characteristic microthrombi, however, this does not occur frequently enough to warrant performing a bone marrow biopsy for the purpose of identifying microthrombi. As the disease progresses, evidence of a consumptive coagulopathy may emerge. The LD level is useful in monitoring the response to therapy, with a decreasing LD being a favorable sign. A rebound increase in the LD may signify an early relapse of the disorder.

Plasma exchange (apheresis) with fresh frozen plasma appears to be the therapy of choice in these patients. In the absence of prompt therapeutic intervention, the mortality rate for TTP approaches 80%; with prompt institution of plasma exchange, the mortality rate probably is less than 20%. Vincristine has been used as an adjunct in some patients who have not responded promptly to plasma exchange. In small series of patients, this appears to be an effective additional agent. Steroids, aspirin therapy, and splenectomy remain controversial in these disorders. Relapses occur in up to 25% to 30% of patients who respond to the initial therapy, necessitating continued monitoring of these patients. Relapses in TTP correspond to a persistent lack or inhibition of vWF-cleaving protease activity.

Other Mechanisms of Increased Platelet Destruction

Increased platelet destruction may be seen in association with a number of other clinical disorders. Sepsis, particularly with Gram-negative bacteria, is one of the more common causes of increased platelet destruction in hospitalized patients. Many of these patients also have a component of acute DIC as well. Diagnosis in these patients depends on recognition of the infectious or consumptive process and the characteristic signs and symptoms of the systemic inflammatory response syndrome.

Cardiopulmonary bypass is associated with an acute drop in the platelet count during the procedure. The post-cardiopulmonary bypass platelet count is often 50% to 60% of the baseline count because of the combination of hemodilution and consumption. The platelet count tends to return to the preoperative level over the first 1 to 2 days following surgery. In most patients, the platelet count following bypass is sufficient to support hemostasis; platelet-type bleeding in these patients usually is a result of a qualitative defect rather than a lack of platelets. However, for patients who start the procedure with borderline platelet

counts, the decrease in platelet count may compromise hemostatic plug formation in the immediate post-operative period.

A number of snake venoms and other biological toxins may lead to a decrease in the platelet count. In these clinical settings, there is often a component of a DIC associated with the envenomation. This may be assessed by measuring fibrinogen, fibrin degradation products, prothrombin time, activated partial thromboplastin time, as well as the platelet count.

A variety of vascular malformations and tumors have been associated with increased platelet consumption due to the abnormal blood flow through the deformed vessels. A classic example of this is the Kasabach-Merritt syndrome, which usually presents in the pediatric age range. Cardiac valve disease and artificial cardiac valves also may lead to a shortened platelet half-life and overt thrombocytopenia in some patients.

Functional hypersplenism also is commonly associated with low peripheral platelet count. The problem in these patients is one of sequestration rather than true thrombocytopenia. Administration of epinephrine or other vasoactive compounds can lead to splenic contraction and release of platelets from the spleen. When this is done, the platelet count may transiently rise into the normal range. Therefore, the total peripheral platelet mass tends to be normal but with an abnormal distribution.

Thrombocytopenia Due to Decreased Production

Decreased platelet production occurs in a variety of clinical settings (Table 47.7). The characteristic findings in these patients are thrombocytopenia with a normal to decreased MPV and abnormal bone marrow findings. Additional abnormalities evident on the peripheral blood smear may indicate the nature of the underlying disorder.

Congenital Disorders Associated With Decreased Platelet Production

Thrombocytopenia has been associated with a number of congenital disorders, some of which also demonstrate abnormal platelet function (Table 47.9) (5, 26, 36, 38, 81,82,83,84,85,86,87,88 and 89). In some patients, the accompanying clinical manifestations suggest the diagnosis while in other patients the congenital nature of the thrombocytopenia may be missed. Such patients are often misdiagnosed as having ITP and may receive inappropriate immunosuppressive therapy. Therefore, the possibility of a congenital cause of thrombocytopenia should be considered before establishing the diagnosis of ITP.

Amegakaryocytic thrombocytopenia is an autosomal-recessive disorder characterized by nearly total absence of megakaryocytes from the marrow. Amegakaryocytic thrombocytopenia may be associated with frequent episodes of leukemoid reactions and skeletal abnormalities, particularly involving the radii. This later form is designated thrombocytopenia with absent radii or TAR syndrome. Platelet size (MPV) tends to be normal to mildly increased; platelet survival is normal; and the bleeding time is proportional to the platelet count. There may be multiple genetic defects that give rise to amegakaryocytic thrombocytopenia; the TAR syndrome has not been associated with any abnormalities of the receptor for thrombopoietin (c-Mpl) whereas amegakaryocytic thrombocytopenia without skeletal malformations has been associated with mutation of the c-Mpl gene.

Fanconi's anemia (congenital aplastic anemia) is an autosomal-recessive disorder characterized by severe marrow hypoplasia. Thrombocytopenia may dominate the clinical picture, and death from hemorrhage is a frequent complication of this disorder. The platelets in Fanconi's anemia have a normal MPV and half-life; the bleeding time is proportional to the platelet count. Megakaryocytes and other hematopoietic elements in the bone marrow are markedly decreased. Fanconi's anemia has been associated with a variety of cytogenetic abnormalities and may terminate as a hematopoietic neoplasm. Thrombocytopenia can also be a component of other congenital hematopoietic stem-cell defects.

Congenital thrombocytopenia has been described in several families with familial nephritis and high-frequency deafness (Alport syndrome). The clinical manifestations have varied between families, some showing the classic association between nephritis and deafness, and others showing only thrombocytopenia and nephritis. This syndrome is inherited as an autosomal-dominant trait and usually has been associated with macrothrombocytes (increased MPV). The bone marrow usually shows a normal numbers of megakaryocytes. There is little information concerning platelet survival in these patients. Platelet function is quite variable between families. Some have a bleeding time proportional to the thrombocytopenia, while others have a relative prolongation of the bleeding time for the degree of thrombocytopenia. Variants of Alport syndrome include Epstein syndrome, characterized by severe thrombocytopenia in addition to the other features of Alport syndrome; Fechtner syndrome, characterized by neutrophil inclusions resembling Dohle bodies (and the May-Hegglin anomaly) in addition to other features of Alport syndrome; and Sebastian syndrome, characterized by thrombocytopenia, neutrophil inclusions, and lack of the other features of Alport syndrome.

The May-Hegglin anomaly is an autosomal-dominant trait characterized by macrothrombocytes (increased MPV) and the presence of Döhle body-like inclusions within neutrophils. The bone marrow in patients with the May-Hegglin anomaly shows a normal number of megakaryocytes, and platelet survival in these patients is also normal. The bleeding time is variable and may be disproportionately prolonged for the degree of thrombocytopenia, suggesting additional qualitative platelet defects in some patients. It has been suggested that the total circulating platelet mass is normal in patients with May-Hegglin anomaly from the increase in the MPV.

Familial thrombocytopenia is an autosomal-dominant trait that has been occasionally reported in the literature. The clinical and laboratory features in these families have been quite variable. Platelet size has varied from normal to increased. Bone marrow examination has shown normal to decreased numbers of megakaryocytes. Platelet survival, when examined, has been quite variable. Usually the bleeding time in affected patients is proportional to the platelet count, suggesting that this is primarily a problem of platelet production. These cases usually have an

isolated thrombocytopenia without other significant clinical or laboratory findings.

TABLE 47.9. CONGENITAL THROMBOCYTOPENIAS

Disorder	MPV	Inheritance	Platelet Function	Other Laboratory Findings	Other Clinical Findings
Bernard-Soulier syndrome	↑	Autosomal dominant	Abnormal	Decreased GP Ib/IX/V, Decreased RIPA	Mucocutaneous bleeding
Type 2B vWD	N or ↑	Autosomal dominant	Abnormal	Decreased HMW vWF multimers, increased RIPA	Mucocutaneous bleeding
Platelet-type vWD	N or ↑	Autosomal dominant	Abnormal	Decreased HMW vWF multimers, increased RIPA, abnormal GP Ibα	Mucocutaneous bleeding
Gray platelet syndrome	↑	Autosomal dominant	Abnormal	Decreased platelet α-granule proteins	Mucocutaneous bleeding
Quebec platelet disorder	N or ↑	Autosomal dominant	Abnormal	Decreased aggregation to epinephrine, proteolysis of α-granule proteins	Mucocutaneous bleeding
May-Hegglin anomaly	↑	Autosomal dominant	Normal	Neutrophil inclusions (Dohle bodies)	Nephritis, familial spastic paralysis
Alport syndrome	↑	Autosomal dominant	Normal or abnormal	Abnormal secondary wave aggregation	Nephritis, high-frequency hearing loss
Epstein syndrome	↑	Autosomal dominant	Normal or abnormal	Alport syndrome with severe thrombocytopenia	Nephritis, high-frequency hearing loss
Sebastian syndrome	↑	Autosomal dominant	Normal	Neutrophil inclusions	Variant of Alport syndrome
Fechtner syndrome	↑	Autosomal dominant	Normal	Neutrophil inclusions	Nephritis, high-frequency hearing loss
Montreal platelet syndrome	↑	Autosomal dominant	Abnormal	Spontaneous aggregation, decreased aggregation response to thrombin, decreased calpain activity	Mucocutaneous bleeding
Wiskott-Aldrich syndrome	↓	X-linked recessive	Abnormal	Decreased aggregation to ADP, epinephrine, collagen; abnormal B and T cell function	Immunodeficiency, eczema, autoimmune diseases, malignancies
X-linked micro-thrombocytopenia	↓	X-linked recessive	Abnormal	Mild storage pool defect	Variant of Wiskott-Aldrich, without nonplatelet manifestations
Paris-Trousseau platelet disorder		Autosomal dominant	Abnormal	Megakaryocytes increased, micromegakaryocytes, giant α-granules in some platelets, partial deletion of chromosome 11 (del(11)q23.3→qter)	Mild bleeding tendency
Fanconi's anemia	N	Autosomal recessive		Decrease megakaryocytes, bone marrow aplasia	Propensity to develop hematologic malignancies, mucocutaneous bleeding

Abbreviations used: MPV, mean platelet volume; RIPA, ristocetin-induced platelet aggregation; N, normal; HWM, high-molecular-weight

Drug Induced Suppression of Platelet Production

Perhaps the most common cause of decreased platelet production among hospitalized patients today is chemotherapy. Transient thrombocytopenia is a common complication of intensive chemotherapy. Thrombocytopenia also is commonly seen in alcoholics. The etiology of the decreased platelet count in this setting is often multi-factorial, including splenic sequestration, folate deficiency, and a direct toxic effect of ethanol on thrombopoiesis. Ionizing radiation can also affect platelet production as well as overall hematopoiesis production. A number of nonchemotherapeutic drugs, including tetracycline, ganciclovir, and chloramphenicol, may affect the marrow, leading to hematopoietic hypoplasia and thrombocytopenia.

Other Disorders Associated With Decreased Platelet Production

A number of viral illnesses have been associated with thrombocytopenia, including hepatitis, parvovirus, and HIV. It has long been suspected that decreased platelet production can be caused by autoimmune mechanisms, either humoral or cellular. However, documentation of the mechanism in such patients has proven to be quite difficult. The bone marrow in these patients usually shows a marked decrease in megakaryocytes, similar to congenital amegakaryocytic thrombocytopenia. Nutritional deficiencies such as folate or vitamin B12 deficiency also may be as

sociated with significant thrombocytopenia. Infiltrative processes in the bone marrow may result in replacement of normal hematopoietic elements and thrombocytopenia. Such infiltrative processes may be non-neoplastic, (e.g., Gaucher's disease, granulomatous disease), or neoplastic (e.g., acute leukemia). Metastatic tumor also may replace hematopoietic bone marrow, leading to thrombocytopenia; common tumors associated with this problem include breast and prostate carcinoma.

Thrombocytosis

An increase in the peripheral platelet count may occur in a variety of clinical settings (Table 47.10). The mechanism of thrombocytosis in many of these cases is not known. In some cases (e.g., alcohol abuse) the thrombocytosis appears to be a rebound phenomenon following recovery from toxic suppression of thrombopoiesis. The clinical and laboratory evaluation of thrombocytosis revolves around the determination of the associated condition and separation of a reactive thrombocytosis from a neoplastic thrombocythemia.

TABLE 47.10. CONDITIONS ASSOCIATED WITH THROMBOCYTOSIS

Reactive Thrombocytosis
Acute inflammatory disorders
Chronic inflammation or infections
Hemolytic anemia
Acute hemorrhage
Rebound following suppression (e.g., ethanol chemotherapy, etc.)
Postsplenectomy
Exercise
Iron deficiency
Trauma
Drugs (vincristine, epinephrine)
Malignancy
Neoplastic Thrombocytosis (thrombocythemia)
Essential thrombocythemia
Chronic myelogenous leukemia
Polycythemia vera
Myelofibrosis with myeloid metaplasia

Thrombocytosis is a common finding in myeloproliferative disorders. If a myeloproliferative disorder is suspected, a bone marrow examination, cytogenetics, and red blood cell mass determination may be helpful in delineating the specific disorder. The presence of the Philadelphia chromosome is indicative of chronic myelogenous leukemia, even though the peripheral blood may have the appearance of essential thrombocythemia. Platelet function may be abnormal in association with myeloproliferative disorders, leading to either bleeding or thromboembolic complications.

Coagulation Abnormalities

Douglas A. Triplett

Abnormalities of secondary hemostasis (i.e., coagulation proteins) typically present with a different clinical picture than abnormalities of primary hemostasis. In classical severe hemophilia the pattern of bleeding will be musculoskeletal and often “spontaneous.” However, in acquired disorders of secondary hemostasis, the pattern of bleeding may often present as mucocutaneous bleeding. A mixed pattern of bleeding reflects the complex pathophysiology of many acquired coagulopathies.

This chapter will address both hereditary and acquired disorders of coagulation proteins. The hereditary abnormalities will be discussed initially followed by the acquired disorders. The laboratory tests used to evaluate secondary hemostasis will be reviewed with special emphasis on interpretation.

HEREDITARY DISORDERS OF COAGULATION PROTEINS

Part of "48 - Coagulation Abnormalities"

Hemophilia A (Factor VIII Deficiency)

Hemophilia A is an X-linked inherited disorder of factor VIII (Antihemophiliac Globulin) (1). The incidence is approximately 1:5,000 males (1). As previously discussed, factor VIII is a critical cofactor in the intrinsic coagulation pathway at the level of factor X activation.

There are variable degrees of factor VIII deficiency that have arbitrarily been divided into severe, moderate, and mild (Table 48.1). Severe hemophilia A is characterized by “spontaneous” musculoskeletal bleeding. This pattern of bleeding is often first evident when the child begins to walk at 9 to 12 months of age. These patients also may present with bleeding following circumcision; however, it is not uncommon for a severely affected child to have minimal bleeding with this procedure. Mild and moderately affected patients may not present until much later in life. Mild hemophilia is often diagnosed when a patient presents with unexplained bleeding following surgery or in association with trauma. Occasionally, very mild hemophilia A patients may only complain of easy bruising or small superficial hematomata.

With the advent of molecular biological techniques, the genetics of hemophilia A have been extensively studied. In 1984, investigators first reported the successful cloning of the human factor VIII gene. The entire gene spans 186 Kb (103 base-pairs), which comprises approximately 0.1% of the X chromosome. There are a total of 26 exons and 25 introns. The coding DNA is 9 Kb, which codes for 2,351 amino acids. The first 19 amino acids are the secretory leader peptide of the nascent factor VIII. The complete amino-acid sequence now is established and the calculated molecular weight is 267,039 daltons. There are three homologous A domains, and two C domains as well as an intervening B domain, which is rich in carbohydrate (Fig. 48.1). Factor VIII is represented by the following formula: Al-A2-B-A3-Cl-C2. The A domains show significant homology with similar domains in ceruloplasmin.

Both deletions and point mutations have been found in patients with hemophilia A. Prior to the availability of molecular biology procedures, it was evident that a significant number of cases of hemophilia A occurred in families with a negative history. Consequently, it was anticipated that “hotspots” would be identified to account for *de novo* mutations. The “hotspots” appear to be related to CpG dinucleotides. The C can be methylated in the 5′ position of the pyrimidine ring and then deaminated to thymine. This leads to the CG → TG and CG → CA mutations. All of these mutations are recognized by TaqI recognition sites.

With the introduction of polymerase chain reaction (PCR), investigators were able to significantly increase their efforts to characterize the factor VIII gene in hemophilia patients. In 1992, Naylor et al. found factor VIII mRNA of all patients with hemophilia A had mutations of the factor VIII gene (2, 3). However, 45% of the patients with severe disease had an unusual mRNA defect. This defect prevented amplification of any segment that crossed the boundary between exons 22 and 23. This mutation results in inversions which affect patient mRNA. Both “proximal” and “distal” inversions have been described.

The laboratory diagnosis of hemophilia A is relatively straightforward. In the majority of cases, the activated partial thromboplastin time (APTT) will be prolonged while the prothrombin time (PT) and bleeding time (BT) will be within normal limits (Table 48.2). Factor VIII:C assays are necessary to establish the diagnosis. Patients with severe hemophilia A will have factor VIII:C levels, which are less than 1% (0.01 unit/mL). Factor assays are relatively easy to perform. However, the laboratory must have a strict quality assurance program to ensure accuracy and precision.

The treatment of hemophilia A has undergone rather dramatic changes in the last 30 years. Prior to the use of cryoprecipitate, the hemorrhaging patient was transfused with either whole blood or fresh frozen plasma. Following the introduction of cryoprecipitate, commercially prepared factor VIII concentrates

were introduced in the early 1970s. These concentrates were processed from large pools of plasma, which were obtained from thousands of donors. As a complication of replacement therapy, many hemophiliacs were found to have chronic persistent or chronic active hepatitis. In some cases frank cirrhosis was also diagnosed. With the introduction of specific testing for hepatitis B surface antigen and subsequently surrogate and specific testing for non-A non-B hepatitis virus (hepatitis C) the incidence of post-transfusion hepatitis decreased. Unfortunately, coincident with the advances of hepatitis screening, transfusion associated human immunodeficiency virus (HIV) was recognized in the early 1980s. This was a particularly devastating finding to all hemophilia A patients who had found greater social and employment opportunities with the use of self-administered factor VIII concentrates.

TABLE 48.1. CLINICAL CLASSIFICATION OF HEMOPHILIA A

Severity	Factor VIII Activity	Clinical Picture	Activated Partial Thromboplastin Time	Incidence
Severe	<1%	Severe hemarthrosis and spontaneous bleeding	Prolonged	48%
Moderate	2% to 15%	Spontaneous bleeding uncommon; serious bleeding from minimal trauma	Prolonged	31%
Mild	>15% to <30%	Spontaneous bleeding rare; unsuspected bleeding after surgical intervention or trauma	Variable	21%
Subclinical	>30% to <50%	Often asymptomatic, will bleed with trauma or surgery	Prolonged/Normal

APTT, activated partial thromboplastin time.
PT, prothrombin time
The APTT may be borderline or within the reference interval in patients with mild or moderate hemophilia A. This variability is from both choice of APTT reagent and biological patient variables. For instance, during times of stress, the factor VIII levels may increase, resulting in a normal APTT.

The late 1980s and early 1990s were characterized by greater emphasis on increased purity of factor VIII concentrates with enhanced viral attenuation or inactivation. A variety of viral attenuation techniques were used including: dry heat pasteurization, solvent/detergent treatment, steam treatment and heating in an organic solvent. Also attempts to increase factor VIII purity were introduced using monoclonal murine antibodies to either human VIII or human von Willebrand factor (vWF). The monoclonal antibodies were used with immunoaffinity chromatography.

In 1984, successful cloning and expression of factor VIII was reported. Recombinant factor VIII products are prepared by transfecting cDNA encoding human factor VIII into either baby hamster kidney or Chinese hamster ovary cell lines (4). Also, recombinant factor VIII that lacks the B domain has been manufactured. The availability of recombinant factor VIII eliminates problems of virally transmitted diseases associated with earlier factor VIII concentrates. Recently, transgenic animals (cows and goats) have been used to produce human proteins, which can be harvested from their milk. Transgenic pigs that produce human factor VIII also have been reported.

Recombinant factor VIII concentrates should be used to treat an acute bleeding episode or to prepare the patient for surgery. One unit of factor VIII/Kg of body weight will raise the factor VIII level approximately 2% (0.02 u/mL). The half-life of infused factor VIII is approximately 12 hours. Typically, a bleeding episode is treated with 40 to 50 u/Kg with subsequent infusion of 3 to 4 u/Kg/hr. In order to monitor response, factor VIII:C assays are recommended on a daily basis. Prophylactic use of factor VIII concentrates may be indicated following a CNS hemorrhage.

In mild/moderate hemophilia A patients, the initial treatment of choice is DDAVP (1-deamino-8-D arginine vasopressin) (Stimate, Ferning Pharmaceuticals, Malmo, Sweden). This synthetic analogue of vasopressin will cause a two- to 10-fold increase in factor VIII:C following an IV infusion of 0.3 to 0.4 ug/Kg of body weight. The postulated mechanism of action is release of vWF from endothelial storage sites (Weibel Palade Bodies). Repeated doses may lead to diminished response of factor VIII. Side effects of DDAVP include: facial flushing, fluid retention resulting from the antidiuretic effect and recent reports of thrombosis. The latter complication has been most often

identified in older individuals with significant atherosclerotic vascular disease.

One of the most common complications of hemophilia A is the appearance of an alloantibody to factor VIII:C (factor VIII:C inhibitors) (5). Factor VIII:C inhibitors are most commonly seen in severe hemophilia A patients. In the majority of cases they appear prior to the age of 20 years. As part of the annual evaluation of hemophilia A patients it is necessary to screen each patient for factor VIII: C inhibitors. These inhibitors are quantitated utilizing the Bethesda Assay system. Because most factor VIII:C inhibitors are time and temperature dependent, the Bethesda assay involves mixing patient plasma and a source of normal plasma. The mixture is incubated at 37°C for 2 hours. APTTs are performed at 30, 60, and 120 minutes. By definition one Bethesda Unit (BU) is defined as the amount of inhibitor that destroys half the factor VIII:C activity in an equal mixture of patient and normal plasma utilizing the above conditions. It is imperative to quantitate a factor VIII:C inhibitor so proper therapy can be instituted. Patients with high titer inhibitors (e.g., >30 BU) frequently are very difficult to manage. In addition to the Bethesda titer, it is also necessary to obtain a clinical history regarding the patient's anamnestic response. Arbitrarily, the patients have been divided into “low” and “high” responders. “High” responders will demonstrate a marked increase in factor VIII:C inhibitor titer upon exposure to factor VIII concentrates.

A variety of modalities have been used to treat factor VIII:C inhibitors (Table 48.3). Porcine factor VIII is of value particularly in patients whose factor VIII inhibitor has little cross reactivity with porcine VIII. Both “activated” and “nonactivated” prothrombin complex concentrates (PCC) (II, VII, IX, X) have been successfully used to treat acute hemorrhage. Protein A columns have been used to remove IgG from factor VIII:C inhibitor patients. In most cases factor VIII:C inhibitors are IgG (4). Consequently, the protein A will remove the majority of the intravascular inhibitor.

Recombinant factor VII (NovoSeven, Novo Nordisk, Copenhagen, Denmark) has been used effectively to treat patients with factor VIII inhibitors (6). Recombinant factor VIIa results in increased thrombin generation and more effective hemostasis. Recombinant factor VIIa has also been used in other clinical states including severe liver disease.

Also, experimental efforts are ongoing to develop gene therapy to “cure” hemophilia. Unfortunately, there have been many technical barriers that have delayed introduction of gene therapy. Selecting the appropriate vector to carry normal genes for either factor VIII or factor IX has been an issue particularly with respect to factor VIII. The factor VIII gene is very large; consequently, viral vectors with a large DNA component are required. Currently, experimental studies using the gene for factor IX have shown promise in animal models (dogs and mice).

Hemophilia B (Factor IX Deficiency)

Hemophilia B is also a sex-linked disorder. Christmas disease and factor IX deficiency are frequently used synonyms. The incidence of hemophilia B is approximately 1:40,000 to 1:50,000 population. However, in certain groups such as the Amish and East Indians, hemophilia B occurs as often as hemophilia A. Varying degrees of hemophilia B have been recognized with severe <1% (0.01 u/mL), moderate <5% (0.01 to 0.05 u/mL) and mild >5% (>0.05 u/mL) phenotypes analogous to factor VIII deficiency. The clinical presentation and genetics of hemophilia B are similar to hemophilia A. Consequently, to establish the diagnosis a specific factor IX assay is necessary.

With severe and moderate factors IX deficiency the APTT will be prolonged. However, there is marked variability among the commercial APTT reagents with respect: to factor IX sensitivity. Consequently, mild and moderate hemophilia B patients may have a normal screening APTT. In this situation, the family and personal history are extremely important in identifying a bleeding disorder. Typically, the PT is normal, however, there is a variant (hemophilia B_m) in which the PT is prolonged if bovine brain thromboplastin is used (Table 48.4). Tests of primary hemostasis (BT and platelet count) typically are normal.

TABLE 48.4. LABORATORY RESULTS IN HEMOPHILIA B

PT	Normal*
APTT	Abnormal*
Bleeding Time	Normal
Platelet Count	Normal
Factor IX Assay	Abnormal

APTT, activated partial thromboplastin time
PT, prothrombin time
In some instances, the prothrombin time may be prolonged if a bovine brain thromboplastin is used. This has been referred to as the Hemophilia B_m variant. The APTT is variable and may be normal in mild hemophilia B patients. This is due to the varying sensitivities of commercial APTT reagents.

Factor IX is a vitamin-K–dependent protein that is produced in the liver. The existence of a second coagulation protein, a deficiency of which was associated with hemophilia A, was first identified by Pavlovsky. He demonstrated mutual correction of

prolonged clotting times when plasmas from two hemophiliacs were mixed *in vitro*. Thus, conclusively demonstrating different coagulation factor deficiencies. The subsequent study of the various phenotypes of factor IX deficiency was instrumental in emphasizing the marked laboratory heterogeneity in factor IX deficient patients despite apparent clinical homogeneity. Utilizing antibodies to factor IX, early investigators found occasional hemophilia B patients whose plasma neutralized these antibodies. This established the existence of cross-reacting material (CRM) in patient plasmas with no apparent functional activity. Based on reactivity of patient plasma with heterologous antisera to factor IX, three phenotypic groups have been identified (Table 48.5). The CRM^+ and CRM^R groups have been further characterized by their reactions with XIa, VIIa, ability to activate factor X, electrophoretic mobility, etc. Full discussion of these variants is beyond the scope of this text.

TABLE 48.5. PHENOTYPIC CLASSIFICATION OF HEMOPHILIA B

	Factor IX Assays		
Type	Activity	Antigen	PT with Bovine Thromboplastin
I CRM^+	Low	Normal	Normal
CRM^+ (Bm)	Low	Normal	Abnormal
CRM^+	Low	Normal	Variable
II CRM^R	Low	Intermediate	Normal
III CRM^-	Low	Low	Normal

Factor IX deficiency demonstrates a wide variety of phenotypes. Patients may have concordant decrease in both IX activity as measured by a coagulation assay and IX antigen, which may be quantitated utilizing various immunologic assays (e.g., ELISA, RIA, Laurell). The variants of factor IX deficiency have variable levels of IX antigen (ranging from normal to reduced), which exceed the activity levels. Some of the variant IX deficiencies also have an abnormal prothrombin time when a bovine thromboplast in is employed. (Modified from Giddings, J.C. *Molecular Genetics and Immunoanalysis in Blood Coagulation*. Ellis Horwood, Chichester, England, 1988, p: 55)
CRM, cross-reacting material

The spectrum of clinical symptoms in hemophilia B is similar to those of hemophilia A. With severe factor IX deficiency, patients have recurrent hemarthroses as well as intramuscular hemorrhages. Mild and moderate factor IX deficiency may not be detected until the patient is an adult. Complications are similar to hemophilia A. Recurrent intraarticular hemorrhages may lead to damage of the cartilaginous surfaces of the affected joints and, ultimately, destruction of the joint. Muscle atrophy, nerve injury, contractures, and pseudotumors also may occur.

Alloantibodies to factor IX has been reported in approximately 10% of patients with hemophilia B. In most instances, these inhibitors arise in patients with severe hemophilia B. Also the infectious complications associated with chronic administration of blood products are similar to those of hemophilia A. Treatment of the severe hemophilia B patient in the recent past required the frequent use of PCC. These concentrates are made from pools of plasma and initially were prepared by adsorption of plasma by tricalcium phosphate. Subsequently, alcohol fractionation of plasma and DEAE-cellulose adsorption were utilized to prepare more potent concentrates. Heat treatment of PCC has significantly improved the safety of these products with respect to post-transfusion hepatitis and HIV complications. Recombinant human factor IX is now available and is the preferred treatment of choice. Recipients of recombinant factor IX are not exposed to the potential viral infections previously associated with PCC. Also, the risk of thrombosis that was reported with PCCs is not encountered with recombinant factor IX. On occasion, patients with severe factor IX deficiency may develop anaphylaxis following factor IX replacement. Although this is a rare phenomenon, physicians responsible for the care of such patients need to be vigilant. In most of the cases described, underlying genetic abnormalities involve significant deletions or other mutations of the factor IX gene. These patients develop antibodies to factor IX and, thus, may have an anaphylactic response when given replacement therapy.

Once transfused, factor IX has an *in vivo* half-life of approximately 18 to 40 hours. However, the recovery of factor IX following transfusion is only 20% to 40%. This is because of the ready distribution of factor IX to the extravascular compartment. Consequently, it is extremely difficult to achieve factor IX levels of greater than 50% following transfusion. In most instances of severe hemorrhage, treatment should be aimed at achieving a factor IX level of 20% to 50%. This is particularly important during the acute episode and the first few days thereafter. Minor hemorrhages usually respond to factor IX levels of approximately 20%.

HEMOPHILIA C (FACTOR XI DEFICIENCY)

Part of "48 - Coagulation Abnormalities"

Factor XI deficiency is an incompletely autosomal-recessive hereditary disorder. The majority of factor XI deficiency occurs in individuals of Jewish descent. In an extensive study by Seligsohn of Ashkenazi Jews, the frequency of homozygotes for factor XI deficiency was 0.1% to 0.3% whereas the heterozygotes were found in 5.5% to 11.0% (7). Factor XI is a glycoprotein with a molecular weight of 160,000 daltons. Its concentration in plasma is approximately 5 ug/mL. Native factor XI exists as a dimer of two identical subunits linked by disulfide bonds. Factor XI is activated by surface bound factor XIIa (Hageman factor). High-molecular-weight kininogen (Fitzgerald factor) serves as a cofactor in the activation step of factor XI. The gene for human factor XI has been isolated from a human liver cDNA library. The gene is 25 kb in length and consists of 15 exons and 14 introns. The gene has been located on the distal end of the long arm of chromosome 4. Factor XI is 607 amino acids in length and has significant homology with prekallikrein (Fletcher factor). The major physiologic substrate for factor XIa is factor IX, which is cleaved at two sites to yield factor IXa. In contrast to the marked heterogeneity of factor IX deficiency, factor XI deficient patients typically have levels of factor XI antigen, which parallel the factor XI coagulant activity.

Two major types of factor XI deficiency have been described. The homozygous patients have factor XI activity below 20% (as related to normal plasma). These patients have a variable history of clinical bleeding and are at risk for significant surgical bleeding. Heterozygous patients have levels of factor XI activity of 30% to 65% and typically have a negative bleeding history. Perhaps the most perplexing aspect of diagnosing factor XI deficiency is the lack of correlation between factor XI assay results and clinical bleeding.

The spectrum of clinical symptoms includes mild mucocutaneous bleeding (epistaxis, menorrhagia) and bleeding following minor surgical procedures such as dental extraction and tonsillectomy. A particularly difficult aspect of management of factor XI deficiency is the variability within an individual patient in response to different surgical procedures. Consequently, it is not possible to accurately predict how an individual patient may respond to a subsequent surgery. Bleeding from organs with excess plasminogen activator activity (t·PA) has been observed frequently (e.g., post-tonsillectomy, dental extractions, and transurethral prostate resection). In these instances, the use of Amicar often is helpful.

The management of hemorrhage following surgery or significant trauma involves the use of fresh frozen plasma. The half-life of infused factor XI is approximately 40 to 80 hours. It is recommended the factor XI level be maintained above 50%. Arbitrarily, 1 mL of fresh frozen plasma will produce a 2% rise in factor XI activity. A factor XI concentrate is available in Europe (8).

FACTOR VII DEFICIENCY

Part of "48 - Coagulation Abnormalities"

Deficiency of factor VII is inherited in an autosomal-recessive manner. Severe factor VII deficient patients (homozygotes) may present with a spectrum of clinical bleeding ranging from central nervous system hemorrhage in the neonatal state, hemarthroses, to mild mucocutaneous bleeding. The heterozygous patients typically are asymptomatic.

Factor VII is a single-chain glycoprotein with an estimated molecular weight of 50,000 d. The mature protein contains 406 amino acids and there are 10 gamma carboxyglutamic acid residues (GLA) located on the amino-terminal end. Beta hydroxyaspartic acid also is found in the factor VII molecule. The activation of factor VII requires cleavage of an arginine isoleucine peptide bond. Factor VII can be activated by several enzymes including: thrombin, factor Xa, factor lXa, and factor XIIa.

The gene for factor VII is located on chromosome 13 (Q 34-qter). The complete sequence for the gene spans approximately 12.8 kb of DNA. There are eight exons and seven introns. The gene for factor X also is located on chromosome 13, very close (2.8 Kb) to the factor VII gene.

As noted, the spectrum of clinical bleeding in factor VII deficiency is probably the most diverse of any of the hereditary coagulopathies. Paradoxically, some patients with factor VII deficiency have been reported to have thromboembolic episodes. Factor VII deficiency also has been described in a variety of hereditary disorders including Dubin-Johnson's, Rotor's, and Gilbert's syndromes. Combined factor VII and factor X deficiency has been described with a hereditary form of carotid body tumors.

The diagnosis of congenital factor VII deficiency is established by specific factor VII assays. Typically, the screening coagulation test results include a normal APTT and thrombin time together with a prolonged PT. However, PT results may vary depending on the choice of thromboplastin. Thus, when indicated, it may be appropriate to utilize a panel of thromboplastins to evaluate patients in whom there is a possible factor VII deficiency (human, bovine, and rabbit tissue). Many variant molecules have been identified based on their reactivity with thromboplastins of various species. The best predictor of clinical bleeding is the level of factor VII activity obtained with a thromboplastin of human origin.

The half-life of factor VII is approximately 6 hours. As a result, it is very difficult to obtain levels of factor VII activity of greater than 50%. Transfusion therapy includes the use of fresh-frozen plasma or PCC. If PCCs are used, heat-treated preparations are indicated. Although not available in the United States, a factor VII concentrate is available in Europe. Interestingly, recombinant factor VIIa has been utilized to treated hemophilia A patients with inhibitors. Factor VIIa leads to direct activation of factor X, thus bypassing the requirement for factor VIII in the coagulation sequence.

HEREDITARY FACTOR X DEFICIENCY (STUART-PROWER FACTOR)

Part of "48 - Coagulation Abnormalities"

Hereditary factor X deficiency is an autosomal-recessive disorder with variable degrees of penetrance. It was originally independently described by two groups who noted there was apparent heterogeneity in patients who were thought to be factor VII deficient on the basis of a prolonged PT. Factor X deficient patients were first clearly separated from factor VII deficiency on the basis of an abnormal thromboplastin generation time. Subsequently, it was appreciated that the Russell Viper Venom Time (RVVT) and APTT also were abnormal in factor X deficiency (Table 48.6).

TABLE 48.6. LABORATORY RESULTS IN FACTOR X DEFICIENCY

Case	PT	APTT	RVVT	Factor X Antigen	X Assay
Stuart	Abnormal	Abnormal	Abnormal	Low	Low
Prower	Abnormal	Abnormal	Abnormal	Normal	Low
Friuli	Abnormal	Abnormal	Normal	Normal	Low

The table summarizes the more common forms of factor X deficiency. There is a relatively high incidence of CRM+ variant deficiencies among all of the vitamin K dependent proteins. Consequently, careful and thorough evaluation is suggested for every case.

APTT, activated partial thromboplastin time

CRM,

PT, platelet transfusions

Factor X is a glycoprotein with a molecular weight of approximately 59,000 d. It is composed of two chains (light-chain molecular weight 16,900 and heavy-chain molecular weight 42,100). Factor X is activated by either the complex of factor VIIIa, factor IXa, phospholipid, and calcium (intrinsic pathway) or tissue factor/VIIa (extrinsic pathway). Activation requires cleavage of a peptide bond in the amino-terminal end of the heavy chain.

The gene for human factor X is located on chromosome 13 in the region Q 34-qter.321. It contains an estimated 25 kb of DNA. There are seven introns and eight exons. Location of the introns is analogous to the introns in factor VII, factor IX, and protein C genes.

The spectrum of hereditary factor X deficiency is analogous to that of other hereditary deficiencies of vitamin K dependent proteins. Patients have been reported in whom there are discrepancies between the RVVT and PT results (Friuli defect). In addition, discrepancies between the level of factor X antigen as measured with either radioimmunoassays or antibody neutralization techniques and factor X activity based on clotting assays have been observed. Thus, there are CRM^{+}, CRM^{R}, and CRM^{-} variants of hereditary X deficiency (Table 48.6). Hereditary deficiency of factor X may be caused by mutations throughout the gene resulting in either reduced or absent synthesis and secretion of factor X or the synthesis of an abnormal molecule.

Clinically, patients may present with severe bleeding; however, the most common complaint is easy bruising and hematoma formation. Hemarthroses, exsanguinating post-operative hemorrhage and central nervous system hemorrhage have been reported in the most severely affected patients. Systemic amyloidosis is an important differential diagnostic consideration when isolated factor X deficiency is encountered. It appears amyloid deposits in these particular cases have an increased affinity for factor X resulting in adsorption of factor X from circulating plasma.

The half-life of transfused factor X is approximately 24 to 40 hours with a bimodal survival curve. Both fresh-frozen plasma and PCC are effective. If concentrates are used, heat treated products are indicated.

FACTOR V DEFICIENCY (LABILE FACTOR)

Part of "48 - Coagulation Abnormalities"

Hereditary factor V deficiency is inherited as an autosomal-recessive trait. Both CRM+ and CRM^{-} variants have been described. In addition, a disorder referred to as factor V Quebec has been identified. In this disorder, there is autosomal-dominant inheritance with severe clinical bleeding. However, plasma factor V activity levels are borderline normal with corresponding factor V antigen levels. Paradoxically, platelet factor V activity levels are very low. Thus, somewhat analogous to von Willebrand disease and afibrinogenemia, it may be necessary to evaluate both plasma and platelet factor V in order to accurately diagnose and characterize factor V deficiency. Several investigators have emphasized the correlation of platelet factor V with clinical bleeding as opposed to a lack of correlation with plasma levels.

The clinical picture in patients with hereditary deficiency of factor V is characterized by a pattern of mucocutaneous bleeding. Hemarthroses are relatively uncommon. The differential diagnosis includes combined deficiency of factor V and VIII and acquired factor V deficiency. Acquired deficiency of factor V usually is a result of specific antibodies. Inhibitors to factor V are most commonly seen in the post-operative setting or in association with administration of certain antibiotics. Acquired factor V antibodies in the postoperative setting are most frequently associated with exposure to topical bovine thrombin used in conjunction with a source of fibrinogen to produce “fibrin-glue.” In most cases, the thrombin preparations are of animal origin (bovine); consequently, particularly in situations where a patient is having a second surgery, reexposure to topical thrombin may result in clinical bleeding due to decreased levels of factor V. Patients at highest risk are those who have cardiovascular surgery, neurosurgery, orthopedic surgery, or plastic surgery. On occasion, patients may have significant postoperative bleeding.

Laboratory diagnosis of factor V deficiency is characterized by an abnormal PT and APTT. The diagnosis is confirmed with a factor V assay. Approximately one third of patients will have a prolonged bleeding time. As noted previously, factor V is carried within the platelet alpha granules and also may be associated with the platelet membrane. Activated factor V on the surface of the platelet serves as a receptor for factor Xa, thus facilitating the assembly of the prothrombinase complex.

Factor V deficiency may be treated with fresh-frozen plasma or fresh plasma. The half-life of transfused factor V is approximately 12 hours. Platelet concentrates have been used successfully to treat patients with inhibitors to factor V.

COMBINED FACTOR V AND FACTOR VIII DEFICIENCY

Part of "48 - Coagulation Abnormalities"

A combined deficiency of factor V and factor VIII has been reported. In most cases this appears to be an autosomal-recessive disorder. Thus, there is a history of consanguinity in many of these cases. The plasma levels of factors V and VIII usually are in the range of 15% to 20%. The genetic basis for this disorder is currently unknown.

PROTHROMBIN DEFICIENCY

Part of "48 - Coagulation Abnormalities"

Hereditary hypoprothrombinemia is an extremely rare autosomal-recessive disorder. Homozygous patients have levels of prothrombin activity varying from 2% to 25%. Prothrombin is a single-chain glycoprotein with a molecular weight of approximately 71,600. In addition to the gamma carboxyglutamic acid residues, which characterize all vitamin-K–dependent proteins, there are two kringle structures present. These kringles are analogous to similar structures seen in plasminogen, t·PA, urokinase, and factor XII.

The gene for human prothrombin is located on chromosome 11. It contains approximately 21 kb of DNA and has 14 exons with 13 introns.

A number of variants of abnormal prothrombin have been described. Defects in factor Xa cleavage site have been identified as well as abnormal calcium binding sites and abnormalities of the thrombin region.

The clinical findings are variable depending on the level of prothrombin activity. Spontaneous hemorrhage and hemarthroses are uncommon although they have been described in patients with severe deficiency states.

Laboratory findings are characterized by the presence of an abnormal PT and APTT. The PT results may be highly variable depending on the nature of the underlying defect. In order to establish the diagnosis, a two-stage functional assay of prothrombin is recommended as well as an immunologic assay to detect the presence of prothrombin antigen. In cases of true hypoprothrombinemia, the functional and antigenic assays will be decreased in parallel. In the dysprothrombinemic states, the antigen level will exceed the functional activity.

Treatment consists of the use of PCC.

AFIBRINOGENEMIA AND HYPOFIBRINOGENEMIA

Part of "48 - Coagulation Abnormalities"

Afibrinogenemia is a rare disorder inherited in an autosomal-recessive pattern. There often is a variable history of clinical bleeding. In many cases, there is bleeding at the time of separation of the umbilical cord or following circumcision. Also, patients may present with intracerebral hemorrhage, spontaneous hematoma formation, or mucocutaneous bleeding. Paradoxically, menorrhagia is uncommon with afibrinogenemia.

Laboratory abnormalities of all of the standard screening tests are present. No end point is detected with the PT, APTT, or thrombin time. The bleeding time may be slightly prolonged and platelet aggregation studies typically show a lack of response to the usual agonists (ADP, epinephrine, and collagen). Although fibrinogen may not be demonstrable in the patient plasma, most patients will have variable amounts of fibrinogen within the platelet alpha granules. Discrepancies between platelet and plasma concentrations of coagulation proteins also have been reported with factor V deficiency and von Willebrand's disease.

Replacement therapy is required to achieve a hemostatic level of fibrinogen between 50 and 100 mg/dL. Cryoprecipitate or fresh-frozen plasma is effective. A few cases of antibody formation to fibrinogen have occurred following replacement therapy.

Hypofibrinogenemic patients are characterized by a fibrinogen level, which is less than 100 mg/dL. Often these patients have a mild bleeding tendency with an autosomal dominant or, in some cases, an autosomal-recessive pattern of inheritance. In many cases, hypofibrinogenemic patients will have normal PT and APTT results. However, typically the thrombin time will be abnormal. Clottable and immunologic fibrinogen assay results are decreased thus establishing the diagnosis.

DYSFIBRINOGENEMIA

Part of "48 - Coagulation Abnormalities"

Hereditary dysfibrinogenemia is inherited in an autosomal-dominant pattern. These abnormal fibrinogen molecules are caused by mutations, which result in single amino-acid alteration in one of the three fibrinogen chains (a-alpha, b-beta, or gamma chains). Many cases of dysfibrinogenemia have been fully characterized. The mutations may affect any one of the functional properties of fibrinogen including delayed or absent release of fibrinopeptides A and B, abnormal polymerization, abnormal cross-linking, decreased thrombin binding, abnormal plasmin digestion, and defective secretion by hepatocytes. Clinically, patients may present with hemorrhage, spontaneous abortion, or thromboembolic complications. However, the vast majority of patients are asymptomatic. Laboratory findings include normal or only minimally prolonged values for PT and APTT. Typically, the thrombin time is prolonged as is the reptilase time. The abnormal thrombin time usually cannot be corrected by the addition of protamine or calcium. Laboratory diagnosis relies on the demonstration of a discrepancy between the level of clottable fibrinogen and antigenic fibrinogen. Specialized studies can be performed including immunoelectrophoresis and SDS polyacrylamide gel electrophoresis to evaluate molecular weights, polypeptide chains, formation of cross-linked gamma-chain dimers and alpha-chain polymers. In addition, polymerization of fibrin monomers may be evaluated by measuring turbidity changes at 305 nm.

Management of patients with dysfibrinogenemia is dependent upon the associated clinical findings. In the case of bleeding, the use of cryoprecipitate is the treatment of choice.

FACTOR XIII DEFICIENCY (FIBRIN STABILIZING FACTOR)

Part of "48 - Coagulation Abnormalities"

Hereditary deficiency of factor XIII is inherited in an autosomal-recessive pattern. Factor XIII is a plasma glycoprotein that is involved in stabilizing the fibrin clot by introducing covalent bonds between fibrin multimers. In addition, factor XIII also cross-links alpha-2 antiplasmin to the fibrin clot and fibronectin to fibrin or collagen.

Factor XIII circulates in plasma as a tetramer composed of two a-subunits and two b-subunits. The a-subunits are also found in other tissues such as platelets and megakaryocytes, placenta, uterus, and macrophages. The a-subunit is responsible for the functional activity of factor XIII.

The gene for the a-subunit is located on the distal end of the short arm of chromosome 6. While the gene for subunit-b is located on the long arm of chromosome I (1 q3l). In affected individuals, the first evidence of clinical bleeding is often manifested at the time of umbilical cord separation (9). Patients also may have intracranial hemorrhage as well as intramuscular hematoma formation and easy bruising. Many patients have abnormal wound healing and a history of habitual abortion.

The usual screening tests are normal. When factor XIII deficiency is suspected, clot solubility in five molar urea or monochloroacetic acid will be abnormal. In addition, a thromboelastogram also will have a markedly abnormal tracing. Subunit-a can be measured using the Laurell technique. In a few selected laboratories, factor XIII activity is quantitated using amine incorporation assays.

Cryoprecipitate and fresh-frozen plasma have been used to treat hereditary factor XIII deficiency. In addition, there is a concentrate of factor XIII available in Europe. Because factor XIII has a rather long half life and the majority of patients do not become

symptomatic until levels of activity are less than 1%, replacement therapy on an intermittent basis is remarkably effective.

HEREDITARY COAGULATION FACTOR DEFICIENCIES NOT ASSOCIATED WITH CLINICAL BLEEDING

Part of "48 - Coagulation Abnormalities"

Hageman factor (factor XII), Fitzgerald factor (high-molecular-weight kininogen), and Fletcher factor (prekallikrein) are proteins that are involved in the contact phase of coagulation (Table 48.7). Deficiencies of these proteins are not associated with clinical bleeding. Typically these patients are detected when a screening APTT is found to be markedly prolonged in the presence of a negative clinical history of bleeding. The diagnosis is established by specific factor assays. In the case of Fletcher factor deficiency, prolonged incubation (10 minutes) of the patient plasma with an activator (e.g., Kaolin, micronized silica) may appreciably shorten the prolonged APTT obtained with routine activation (3 to 5 minutes). Similar shortening is not seen with Hageman factor or Fitzgerald deficiencies.

TABLE 48.7. HEREDITARY DEFICIENCIES OF CONTACT FACTORS

	Factor XI	Factor XII	Prekallikrein	HMW-Kininogen
Year described	1953	1955	1965	1975
Mode of transmission	Autosomal Recessive	Autosomal Recessive	Autosomal Recessive	Autosomal Recessive
Ethnic background	Predominantly in Jews	Variable	Variable	Variable
Bleeding symptoms	Mild	None	None	None
Prothrombin time	Normal	Normal	Normal	Normal
APTT	Prolonged	Prolonged	Prolonged	Prolonged
Intrinsic fibrinolysis	Normal	Impaired	Impaired	Impaired
Kinin formation	Normal	Impaired	Impaired	Impaired
CRM^+ cases	Present	Present	Present	Unknown

APTT, activated partial thromboplastin time
CRM, cross reacting material

Paradoxically, a number of patients with Hageman factor deficiency and prekallikrein deficiency have been reported with thromboembolic events.

ACQUIRED DISORDERS

Part of "48 - Coagulation Abnormalities"

Anticoagulant Therapy (Heparin, Coumadin)

The role of the clinical laboratory in monitoring anticoagulant therapy is a very important contribution to patient care. In fact, monitoring anticoagulant therapy with the PT was the first form of therapeutic drug monitoring.

Heparin is a natural mammalian glycosaminoglycan. The manufacture of heparin involves extraction from bovine lung tissue and porcine or bovine intestinal mucosa. Two different preparations of heparin are available in the United States. The first of these is unfractionated heparin, which is a biological product obtained from either bovine lung or porcine mucosa. Unfractionated heparin has a distribution of molecular weights varying from 5,000 to 30,000+ d. Unfractionated heparin interacts with antithrombin resulting in inhibition of the two most important serine proteases (factor Xa and thrombin). Heparin is used in many areas of the hospital including cardiopulmonary bypass surgery, hemodialysis, keep open venous access, and to anticoagulate patients with a thromboembolic event. Recently, low-molecular-weight heparin (LMWH) has gained considerable momentum in replacing unfractionated heparin. LMWH preparations are manufactured by enzymatic or chemical degradation of unfractionated heparin. In general, LMWHs have significant differences in pharmacologic properties as well as their effect on various coagulation assays (Table 48.8).

Heparin requires a naturally occurring plasma constituent in order to express its anticoagulant activities. This plasma protein is antithrombin (formerly called antithrombin III), an alpha-2 globulin produced in the liver. Antithrombin (AT) is a member of the serpin family of proteins. Thus, the name antithrombin is something of a misnomer. AT inhibits all of the serine proteases involved in hemostasis. The inhibitory properties of AT are time dependent in the absence of heparin. With the addition of heparin, the ability of AT heparin complex to inhibit serine proteases is markedly accelerated.

The half-life of injected heparin is in the range of 1 to 2 hours. However, the disappearance and clearance times of heparin are dose related. Higher doses are associated with decreased clearance and longer disappearance times. Heparin may be cleared from the circulation both by the kidney as well as the liver. Endothelial cells also play a role in heparin clearance. Heparin may be neutralized in the circulation by platelet factor IV, which is a platelet specific protein found in the alpha granule. Heparin also interacts with other plasma proteins including vWF, fibronectin, and vitronectin.

Although historically heparin was given subcutaneously as well as intravenously (either intermittent or continuous infusion), most patients today receive heparin by continuous infusion. Continuous infusion appears to be the preferred mode of administration, not only because of the ease of obtaining samples for monitoring the heparin effect, but there also appears to be less clinical bleeding. The decrease in clinical bleeding is primarily related to a decrease in the cumulative dose a patient receives over the course of treatment. In the treatment of acute deep-vein thrombosis (DVT), usually a loading dose of 5,000 to 10,000

units of heparin is administered immediately followed by therapeutic doses of heparin based on body weight. Dosage may be affected by a variety of factors including the acute nature of the thrombotic process, body weight, and other complicating disease states (e.g., renal and liver disease).

TABLE 48.8. COMPARISON OF UNFRACTIONATED AND LMW HEPARINS

Property	Low-Molecular Weight Heparin	Unfractionated Heparin
Molecular weight	3,000-5,000	10,000-30,000
Activated partial thromboplastin time	++	++++
Thrombin time	++	++++
Anti-Xa assay	++++	++
Platelet aggregation	+	++++
Binding to endothelium	+	++
Protamine neutralization	+	++++
Lipoprotein lipase	+	++++
Adsorption (sub Q)	+++	++
Clinical bleeding (?)	++	+++

The laboratory monitoring of heparin has undergone an evolution beginning with the use of whole blood clotting times (Lee and White) to the recent introduction of synthetic substrate assays which allow quantitation of heparin in units per milliliter. Based on the College of American Pathology (CAP) Survey Program, the vast majority of laboratories (greater than 95%) utilize the APTT as a means of monitoring heparin. However, the activated clotting time (ACT) is utilized frequently in settings where immediate answers are required. This is primarily in the surgical suite for bypass procedures. Also, in dialysis units the ACT is a popular means of evaluating the presence of heparin and subsequent neutralization with protamine sulfate.

The APTT is readily available in virtually any laboratory. In addition, because it is part of an ongoing quality control program, it is the preferred test for monitoring heparin therapy (10). Commercially available, partial thromboplastins vary significantly in their sensitivity to heparin. When defining an APTT system, it is important for the laboratory to consider both the choice of reagent as well as instrumentation. In general, instruments and reagents from the same manufacturer perform better than situations in which there is manufacturer disparity. In addition to sensitivity to the presence of heparin, responsiveness is an important property of the APTT system. Responsiveness reflects the degree of prolongation present at a given level of heparin or factor deficiency. Thus, more responsive reagents will yield longer APTT results. It is important to separate the concept of sensitivity and responsiveness in choosing laboratory reagents. An optimal reagent will be both sensitive and responsive.

Historically, the therapeutic target for prolongation of the APTT was 1.5 to 2.5 times the upper limit of the normal reference interval. However, recent work has significantly changed the way laboratories and their anticoagulation committees set therapeutic ranges for heparin therapy. It is critical for the laboratory to define their test system based on an APTT reagent, coagulation instrumentation, collection tubes, centrifugation, etc. In order to develop a reference interval for therapeutic heparin, the best approach is to collect aliquots of plasma from patients receiving heparin and freeze these aliquots until approximately 30 to 40 samples are available. These samples then are thawed and evaluated with an APTT as well as a heparin assay. The heparin assay may be a chromogenic Xa inhibition assay or, alternatively, a protamine neutralization assay. The vast majority of laboratories utilize the factor Xa inhibition chromogenic assay. Once the APTT values and the factor Xa chromogenic inhibition results are available, one plots each point for an individual sample [APTT on vertical axis in seconds and Xa inhibition on the horizontal axis expressed in units of heparin (0.0 to 1.5 units)]. A line of best-fit regression analysis defines the slope. The therapeutic range for the Xa inhibition assay is 0.3 units to 0.7 units. It is a CAP requirement for laboratories to provide physicians with therapeutic ranges for heparin monitoring as well as INR values for monitoring oral anticoagulants.

Heparin-associated thrombocytopenia (HAT) is one of the most important complications of heparin therapy. HAT has been reported as varying from <1% of patients to as high as 30%. It has become evident that there are at least two types of HAT. Type I is seen frequently after the initiation of heparin therapy and consists of a drop in the platelet count into the range of 100,000 to 150,000/mL. This decrease in platelets may persist for several days; however, even though the patient continues to receive heparin, the platelet count subsequently returns to the original baseline value prior to the initiation of heparin therapy. The exact mechanism for this type of HAT is still speculative although many suggest it is the result of *in vivo* heparin-induced platelet aggregation with clearance of the aggregates in the liver and spleen.

Type II HAT is associated with antibodies directed against a complex of heparin and platelet factor 4 (H-PF4). The antibodies involved are usually IgG (predominantly IgG_4). The immune complex of IgG-H-PF4 then binds to FcγIIa receptors on the platelet membrane. This results in activation of the platelets with release of platelet microparticles as well as granular contents (α granules — dense bodies). The platelet microparticles provide a “prothrombotic environment” leading to generation of thrombin and further activation of platelets as well as endothelial cells. As a result of this process, there is consumption of platelets and, in some cases, profound thrombocytopenia (less than 100,000 per mL) and associated thromboembolic complications. Thrombi may occur in any of the vascular beds but principally involves arterial and venous sites.

Type II HAT usually occurs in patients who have received administration of heparin for greater than 6 days or, alternatively, patients who have recently been exposed to heparin and are re-exposed after a period of days or weeks of being off heparin. Type II HAT can be seen in situations where the patient is only minimally exposed to heparin (use of heparin to keep open an IV line).

When type II HAT is suspected, heparin should be discontinued immediately. Typically, in the patient receiving heparin for DVT, oral anticoagulants already have been initiated and the transition to this form of anticoagulant therapy is relatively easy. In the setting where HAT develops in the patient who requires bypass surgery or renal dialysis, management is considerably more difficult. Alternative forms of anticoagulation that appear to be safe include danaparoid and recombinant hirudin. In the

past, it was hoped LMWH preparations would not interact with antibodies to the complex of PF4-unfrationated heparin. Unfortunately, this was not the case. Patients with antibodies to PF4 UFH often will cross react with LMWH.

The laboratory confirmation of the presence of type II HAT is based on screening assays that are rather crude. Platelet aggregation studies should be performed in the presence of the heparin being utilized for the patient management as well as at least two sources of platelet rich plasma obtained from normal donors whose platelets are known to aggregate in the presence of antibodies to PF4-H. The aggregation studies consist of heparin (which the patient is receiving), normal platelet rich plasma and the patient platelet poor plasma mixed in the aggregation cuvette. The aggregation response typically is monitored over a 15-minute interval. The presence of aggregation suggests the possibility of HAT. It is important to appreciate the absence of a positive result does not rule out HAT. Other test systems that are more specific include the use of the serotonin platelet release assay. This assay is thought to be more sensitive and specific than the standard platelet aggregation assay described above. However, it is considerably more expensive and time-consuming because it requires the use of radiolabeled serotonin.

In addition to the functional assays for HAT, there are ELISA assays that utilize microtiter plates coated by the complex of heparin-PF4. The patient's serum or plasma is then added to the microtiter plate, appropriately incubated, washed and treated with a labeled antibody to IgG. This assay is very sensitive to the presence of antibodies to H-PF4. However, the specificity with respect to clinical complications is somewhat problematic.

ORAL ANTICOAGULANT THERAPY

Part of "48 - Coagulation Abnormalities"

Oral anticoagulant therapy is based on administration of coumarin or its derivatives. This class of drugs blocks the reductase enzyme in the vitamin K pathway (Fig. 48.2) resulting in increased levels of nonfunctional vitamin K epoxide. Vitamin K acts as a cofactor in a post-translational step converting various vitamin K-dependent protein precursors into functional procoagulant proteins. This vitamin K driven reaction involves the carboxylation of glutamic acid to give rise to gamma carboxy-glutamic acid (GLA). These GLA residues function to localize the vitamin K-dependent proteins to phospholipid membrane surfaces. Typically, activated platelets provide this surface; however, other cells such as endothelial cells, monocytes, and tumor cells may function in a similar fashion.

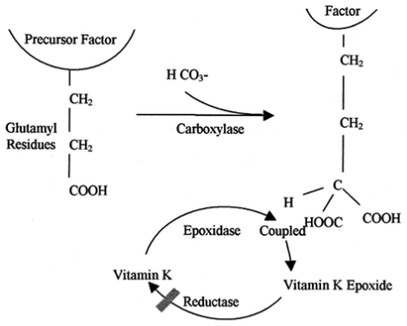

FIGURE 48.2. Vitamin K pathway.

In the presence of oral anticoagulants, formation of GLA residues is impeded. As a result, there is diminished surface localization of the vitamin K-dependent complexes resulting in an anticoagulant effect. Early reports also suggested the presence of PIVKAs (protein induced by vitamin K antagonist) serve an anticoagulant role as well. The PIVKA proteins represent the precursors of the functional procoagulants. Their role in the therapeutic effect of oral anticoagulants remains unresolved.

TABLE 48.9. CLINICAL CONDITIONS ASSOCIATED WITH LUPUS ANTICOAGULANTS

I. Autoimmune Diseases
- A. Systemic lupus erythematosus
- B. Rheumatoid arthritis
- C. Others, including “overlap” syndromes

II. Drug Exposure
- A. Chlorpromazine
- B. Procainamide
- C. Hydralazine
- D. Quinidine
- E. Antibiotics
- F. Phenytoin

III. Infections
- A. Bacterial
- B. Protozoan (Pneumocystis carinii)
- C. Viral

IV. Lymphoproliferative Disorders
- A. Hairy cell leukemia
- B. Malignant lymphoma
- C. Waldenstrom's macroglobulinemia

V. Miscellaneous Disorders
- A. Epithelial malignancies
- B. No underlying disease

The monitoring of oral anticoagulant therapy has relied upon the PT and variants of the PT. For many years there has been an international controversy regarding the optimal test system to monitor oral anticoagulants. For many years, virtually all of the thromboplastins marketed in the United States were of rabbit tissue origin (rabbit brain or rabbit brain/lung). However, in Europe a number of different types of thromboplastins have been utilized including bovine brain, monkey brain, and human brain. Dr. Leon Poller championed the human-brain thromboplastin as a sensitive reagent which more accurately reflected the anticoagulant status of a patient. His efforts resulted in the concept of an International Normalized Ratio (INR) to express PT results. With the introduction of recombinant thromboplastins, many laboratories have converted their PT reagents. The use of recombinant thromboplastin together with synthetic phospholipids results in a reagent with greater consistently between lots.

Furthermore, the ISI value for these reagents approaches 1.0. The vast majority of laboratories in the United States today utilize reagents with ISI values of 1.7 or lower.

In order to report an INR value, it is necessary to know the International Sensitivity Index (ISI) for the thromboplastin being used as well as the geometric mean of the PT range. The INR expresses the ratio of the patient PT to the mean of the normal range raised to the power of the ISI (Fig. 48.3). The INR, therefore, represents the PT, which would have been obtained on the patient plasma if the International Reference Preparation of thromboplastin (human brain) had been utilized. Thus, it provides a means of comparing PT results from laboratory to laboratory correcting for the differences in thromboplastin reagents. The concept of the INR has been well received in Europe and now is widely accepted in the United States. It is important to emphasize the INR is appropriate for patients who are *stably* anticoagulated. Patients who are in the early phases of oral anticoagulant therapy or patients in whom the PT is being obtained for other diagnostic purposes may have misleading INR results.

$$INR = \left[\frac{\text{Pat. PT}}{\text{Mean Normal PT}} \right]^{ISI}$$

FIGURE 48.3. Derivation of the international normalized ratio.

The introduction of the INR has emphasized the need for lower doses of oral anticoagulants. In the past when PT results were reported as ratios, the therapeutic range was typically quoted as PT ratios of 1.5 to 2.5. With the use of the INR, it is now evident the majority of patients are satisfactorily anticoagulated with INRs of 2.0 to 3.0. As a consequence, it is anticipated the incidence of bleeding in patients receiving oral anticoagulant therapy will significantly decrease.

FIBRINOLYTIC THERAPY

Part of "48 - Coagulation Abnormalities"

The use of fibrinolytic agents in the treatment of acute myocardial infarction (AMI) is now well accepted. Fibrinolytic agents such as streptokinase (SK) and urokinase (UK) have been available for many years. However, they were only approved for treatment of pulmonary embolism and massive DVT. Many clinicians were reluctant to use these agents because of their unfamiliarity with dose and the perceived high incidence of hemorrhagic complications. The introduction of tissue plasminogen activator (t·PA) renewed interest in fibrinolytic therapy and with the ready availability of acute coronary angiography led to the introduction of lytic agents in the treatment of AMI.

One of the primary complications associated with the use of fibrinolytic agents in the treatment of AMI is bleeding. Most commonly the bleeding is from arterial or venous access sites. The most catastrophic complication is cerebral bleeding.

The nature of the hemorrhagic defect in patients receiving lytic therapy has only recently been studied in detail. Among the alterations induced by lytic agents are a drop in the fibrinogen level together with a concomitant rise in fibrin/fibrinogen degradation products. It is well known that fibrin/fibrinogen degradation products will inhibit certain aspects of platelet function and, in addition, impede the assembly of fibrin multimers to form a fibrin clot. Also, plasmin will attack other plasma procoagulant proteins including factors V and VIII. Because plasmin is an indiscriminate serine protease, it will digest certain glycoprotein receptors on both platelets and endothelial cells (glycoprotein IIb/IIIa; glycoprotein Ib). As a result, the administration of lytic agents affects both primary and secondary hemostasis. Furthermore, many patients who are receiving lytic agents are also concomitantly receiving heparin and antiplatelet medications such as aspirin.

Therefore, the bleeding seen in association with fibrinolytic therapy is multifactorial. Appropriate management of these patients depends upon the individual case. The use of fresh-frozen plasma and/or platelets may be indicated in severe circumstances.

ACQUIRED CIRCULATING ANTICOAGULANTS

Part of "48 - Coagulation Abnormalities"

Circulating anticoagulants may be defined as endogenous substances that interfere with one or more of the *in vitro* tests of hemostasis. In most cases, they are immunoglobulins, however, there are situations in which other substances produce an anticoagulant effect including the presence of heparin or heparinlike compounds and fibrin/fibrinogen degradation products.

The most commonly encountered circulating anticoagulant is the so-called lupus anticoagulant (LA). A working definition of the LA is a circulating immunoglobulin (IgG or IgM or both) that interferes with one or more of the *in vitro* phospholipid dependent tests of coagulation (e.g., PT, APTT, dRVVT, etc.). The name LA is a misnomer because the vast majority of these patients *do not* have systemic lupus erythematosus. In fact, in most hospital settings, this anticoagulant is seen in a variety of other clinical circumstances including the convalescent phase of acute infections, as a result of drugs (chlorpromazine, hydralazine, hydantoin, procainamide, quinidine and various antibiotics), and in patients in whom there is no apparent underlying disease (Table 48.9). Although most inhibitors of blood coagulation are associated with clinical bleeding, paradoxically, LA is often associated with an increased risk of thrombosis. Clinical bleeding is distinctly uncommon unless there is an additional hemostatic abnormality. Most commonly, the hemostatic abnormalities which may be associated with clinical bleeding in LA patients include: thrombocytopenia, qualitative platelet functional defects, and an isolated deficiency of prothrombin. The latter appears to be directly related to the LA immunoglobulin, which binds to prothrombin creating an antigen antibody complex that is cleared rapidly from the circulation. The laboratory diagnosis of LA requires four distinct steps (11): (i) identification of an abnormal screening test (e.g., APTT, dRVVT); (ii) proof the abnormal test is because of an inhibitor (mixing studies); (iii) demonstrate the inhibitor is phospholipid dependent (Fig. 48.4); (iv) rule out other coagulopathies (e.g., factor VIII inhibitors, etc.).

In the vast majority of cases, the abnormal screening test is an unexplained prolonged APTT. In the past this was usually a serendipitous finding which then lead to further laboratory tests

to explain the abnormality. Recently clinicians are asking the laboratory: “Does my patient have an LA?” The latter scenario is distinctly different and requires a more extensive evaluation. The increased clinical awareness of LA is related to its association with a variety of complications including both arterial and venous thromboembolic events, neurologic complications, recurrent spontaneous abortions and intrauterine fetal death.

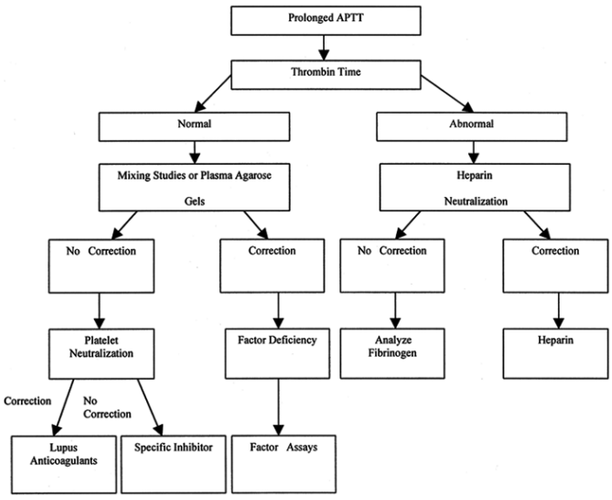

FIGURE 48.4. Workup of LA.

Following the demonstration of an abnormal APTT, mixing studies are indicated to identify the presence of an inhibitor. Although many texts recommend a one-part patient, one-part normal mixture, my experience suggests the use of four parts patient, one part normal plasma is a more sensitive means of identifying the presence of an inhibitor. This is particularly true in the cases where the patient's baseline APTT is only minimally prolonged. LA was initially thought to be an immediate inhibitor in contrast to the time dependency seen with factor VIII:C inhibitors.

TABLE 48.10. CLASSIFICATION OF CIRCULATING ANTICOAGULANTS

Neutralizing	Nonneutralizing
Specific	
Factor V	Prothrombin
Factor VIII:C	Factor VIII:C
Factor IX	Factor X
Factor XI	vWF
vWF	
Factor XIII	
Nonspecific	
Lupus anticoagulants	
Paraproteins	
FSP	
Global	
Heparinlike activity	

FSP, fibrin split product
vWF, von Willebrand factor

However, recently a number of studies have suggested as many as 30% of LAs are time dependent. Conversely, factor VIII:C inhibitors may be immediate. Thus, the presence or absence of time dependency is not a useful differential diagnostic point to separate factor VIII:C inhibitors from LA. An alternate method to identify the presence of a circulating inhibitor is the use of plasma agarose gels.

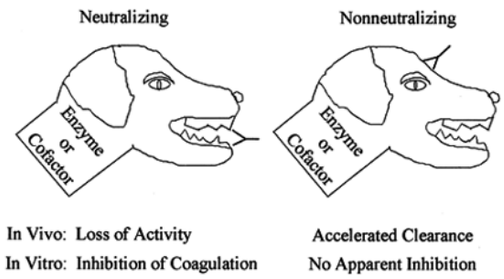

FIGURE 48.5. Neutralizing and nonneutralizing anticoagulants.

A variety of test systems have been utilized to identify phospholipid dependence of circulating anticoagulants. Two basic principles have been employed: (i) decreasing the phospholipid concentration in the test system to enhance the inhibitor effect, and (ii) increasing the amount or changing the configuration of phospholipid in the test system to either “neutralize” or “bypass” the LA.

Among the former tests, the tissue thromboplastin inhibition procedure (TTI) is most commonly employed. Unfortunately, this test system is not particularly sensitive or specific. Perhaps the most sensitive test system employing the concept of dilute phospholipid is the dilute Russell Viper Venom Time (dRVVT). The Platelet Neutralization Procedure (PNP) is the most commonly utilized test employing increased amounts of phospholipid. In this test, freeze-thawed platelets are added to the patient's platelet-poor plasma and the APTT repeated. In the presence of an LA, there will be significant shortening of the baseline APTT value (12). As a control, an appropriate buffer is added to the patient plasma.

Occasionally, the confirmatory tests may be misleading or uninterpretable. In this situation it is appropriate to perform factor assays. Typically in the presence of a LA there is nonparallelism of the factor assay curves with an apparent increase in factor activity as the patient plasma is progressively diluted.

In addition to the fibrin-based assays to demonstrate LA, many laboratories also utilize an ELISA system to demonstrate the presence of anticardiolipin antibodies (ACA). LA and ACA are often present in the same patient; however, in approximately 30% of cases, there will be a lack of concordance between these two test systems. Consequently, when the clinician requests an evaluation of the patient plasma for phospholipid antibodies, it is necessary to perform both fibrin based coagulation assays and the ELISA test system. Recent studies have indicated the antigenic targets for immunoglobulins responsible for LA activity include various plasma proteins, which bind to phospholipids. Among these, β_2 Glycoprotein I (apolipoprotein H) and prothrombin are the two most commonly recognized proteins (12). Consequently, specific ELISA tests for antibodies to β_2 glycoprotein I and prothrombin now are commercially available. It appears antibodies to β_2 Glycoprotein I have a higher frequency of thrombotic complications. Approximately 20% of patients with negative standard ACA results will have positive results utilizing a high sensitive microtiter plate coated with β_2 GPI.

Other inhibitors are rarely encountered (Table 48.10). The recent recognition of “nonneutralizing” inhibitors has further compounded the laboratories' difficulties in demonstrating the presence of an inhibitor (Fig. 48.5). With a nonneutralizing inhibitor the laboratory assays may suggest a factor deficiency since addition of normal plasma to the patient plasma results in correction of abnormal coagulation studies. In these patients it is necessary to demonstrate the presence of an antigen antibody complex utilizing a variety of techniques such as crossed immunoelectrophoresis. The most commonly encountered nonneutralizing inhibitor is the antiprothrombin antibodies encountered in patients with LA.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Part of "48 - Coagulation Abnormalities"

DIC may be encountered in a variety of different clinical situations (Table 48.11). In most cases it is associated with the exposure of tissue factor or thromboplastinlike material with resulting activation of coagulation pathways at the level of factor X. Clinical examples would include amnionic fluid embolus, head injuries, neurosurgery, and certain malignancies. Some tumor cells appear to have a specific enzyme (cysteine protease), which will directly activate factor X. Alternatively with endothelial injury, there may be activation of the extrinsic pathway leading to DIC.

TABLE 48.11. CLASSIFICATION OF CLINICAL STATES ASSOCIATED WITH DISSEMINATED INTRAVASCULAR COAGULATION

Obstetric Complications	
Abruptio placentae	
Placenta previa	
Dead fetus	
Amniotic fluid infusion	
Placenta accreta	
Toxemia of pregnancy	
Cesarean section	
Abortion	
Hydatid mole	
Extrauterine pregnancy	
Forceps delivery	
Normal delivery	
Tissue Trauma	
Major surgery (especially extracorporeal circulation)	
Severe trauma and burns	
Fat embolism	
Rejection of transplant	
Heatstroke	
Hemolytic Processes	
Transfusion of mismatched blood	
Drowning	
Acute hemolysis secondary to infection	
Immune mechanisms	
Ingestion of acid and other causes	
Neoplastic Diseases	
Solid tumor	
Leukemia (Promyelocytic M-3, and Monocytic M-5)	
Snakebites	
Infections (Especially Acute Forms)	gram-negative, meningococcal, and pneumococcal septicemia
Bacterial:	
Rickettsial:	Rocky Mountain spotted fever
Viral:	hemorrhagic smallpox and hemorrhagic fever (Thai, Korean, and others)
Mycotic:	acute histoplasmosis
Parasitic:	malaria (blackwater fever)
Miscellaneous	
Cirrhosis of the liver	
Glomerulonephritis	
Acute pancreatitis	
Purpura fulminans	
Thrombotic thrombocytopenic purpura	
Hemolytic uremic syndrome	
Shock	
Severe progressive stroke	
Severe heart failure	
Giant hemangioma (Kasabach-Merritt)	
Large aortic aneurysm	

It is important to appreciate that DIC is a rapidly evolving pathophysiologic response to an underlying disease. Consequently, laboratory testing to establish the diagnosis often is difficult because of the constantly changing balance of underlying mechanisms. In acute DIC with a predominance of thrombin generation with consumption of coagulation factors and activation of fibrinolytic activity, bleeding is the most common clinical manifestation. Typically, acute DIC presents as systemic bleeding with oozing from the sites of venipunctures or recent surgery. However, in the subacute and chronic states such as retained dead fetus or an underlying disseminated malignancy, the patient may actually present with thrombosis. In this setting,

there may be actual compensatory increase of coagulation factors such as fibrinogen and factor VIII, which may exceed the range found in normal subjects.

In acute DIC, the constellation of laboratory findings reflect both the consumption of coagulation proteins as well as the presence of plasmin. Typically, the APTT, PT, and TT will be prolonged. In addition, there is consumption of platelets as well as the regulatory proteins AT and protein C. Fibrinogen/fibrin degradation products will be increased and the level of fibrinogen will be decreased. The availability of immunologic assays based on monoclonal antibodies to neoantigens has resulted in test systems that are more specific for fibrin degradation products. The D-dimer represents the use of an antibody to such a neoantigen.

In chronic DIC, the platelet count will typically be slightly decreased whereas the coagulation assays (APTT, PT) may be within normal limits. Fibrin/fibrinogen degradation products and D-dimer will be elevated and there may also be consumption of AT.

The treatment of choice for DIC is management of the underlying clinical condition. For instance, in a patient with chronic DIC and retained dead fetus, evacuation of the uterus is the treatment of choice. In a patient with acute DIC secondary to endotoxic shock, appropriate support and antibiotic therapy are treatments of choice.

THROMBOTIC THROMBOCYTOPENIC PURPURA/HEMOLYTIC UREMIC SYNDROME

Part of "48 - Coagulation Abnormalities"

TTP and hemolytic uremic syndrome (HUS) are examples of complex disease states that are closely related. In TTP there is systemic deposition of intraluminal platelets in the smaller arterioles. In contrast, HUS is characterized by involvement of the glomeruli with platelet aggregates. Both diseases present as a microangiopathic hemolytic anemia. Typically, there are schistocytes on the peripheral smear together with thrombocytopenia. Recent work would suggest the etiology of these conditions is variable from case to case. Moreover, the mode of presentation, particularly with TTP, may be characterized by either a single clinical episode, a chronic relapsing form, or an intermittent form. Approximately two thirds of patients with acute TTP appear to have abnormal processing of vWF, which results in the presence of large vWF multimers during periods of remission. It may be difficult to demonstrate these abnormal multimers during the acute episodes. The persistence of large vWF multimers after recovery is sensitive for predicting a relapse. The treatment of choice in TTP is plasma exchange or plasmapheresis plus fresh-frozen plasma. Recent work has suggested abnormalities of a plasma metalloprotease explain both chronic relapsing and acquired TTP (13, 14). In some instances, the deficiencies of metalloprotease are hereditary whereas in others it appears patients form antibodies to the metalloprotease inhibiting its enzymatic activity. As a consequence of reduced metalloprotease activity, there is an accumulation of high molecular weight vWF in the patient plasma predisposing to TTP.

LIVER DISEASE

Part of "48 - Coagulation Abnormalities"

Hemostatic problems encountered in patients with liver disease usually are complex. Because the liver plays a key role in the synthesis of coagulation proteins, regulatory proteins and factors involved in the fibrinolytic system, the balance between these various components may be altered to varying degrees in any patient with significant compromise of liver function. Also the liver plays a role in removing activated clotting factors from the circulation

as well as fibrinolytic breakdown products. In end-stage liver disease often the plasma level of fibrinogen may be decreased. However, in uncomplicated, cirrhosis, obstructive jaundice, chronic hepatitis, and biliary cirrhosis, a high level of fibrinogen may be found. Often in these latter cases, the thrombin time will be prolonged because of an acquired dysfibrinogenemia. This is thought to be because of an increased sialic acid content of fibrinogen.

Levels of the vitamin K dependent proteins are also decreased in liver disease associated with obstructive jaundice or malabsorption of vitamin K. Since factor VII has the shortest half-life of the vitamin K-dependent proteins, the first laboratory abnormality encountered may be an isolated prolongation of the PT.

Patients with liver disease often show a hypofibrinogenemia together with elevation of fibrin/fibrinogen degradation products and thrombocytopenia. This constellation of laboratory findings may be difficult to differentiate from DIC. In the past, many clinicians have relied on the factor VIII:C assay as a means of separating DIC from primary liver disease. Conventional wisdom suggested DIC will have low levels of factor VIII:C in contrast to the elevated levels seen in liver disease. However, this is not a reliable criterion. Often in advanced liver disease there is low-grade intravascular coagulation making the differential diagnosis of DIC and liver disease an exercise in futility.

Management of hemostatic abnormalities in the setting of liver disease is often frustrating. In acute liver failure, replacement of coagulation factors by infusion of fresh-frozen plasma may be helpful. In more chronic states, management of the underlying liver disease is the primary objective. The use of fresh-frozen plasma and platelets may be helpful to treat acute bleeding episodes. The treatment of bleeding esophageal varices may require balloon tamponade or surgery.

BLEEDING ASSOCIATED WITH CARDIOPULMONARY BYPASS

Part of "48 - Coagulation Abnormalities"

Approximately one quarter of a million patients undergo cardiopulmonary bypass (CPB) procedures each year in the United States. This group of patients utilized approximately 25% of blood products in many institutions. However, there is marked institutional variability in the incidence of bleeding associated with CPB. A variety of risk factors have been identified including time on the extracorporeal system, history of previous cardiac surgery, the nature of the surgery, preoperative medications, and the use and reversal of heparin. As a result of exposure of the circulating blood to a foreign surface, there is platelet activation with the release reaction occurring. In addition, there is also activation of the fibrinolytic system, which may lead to consumption of fibrinogen, factor V, factor VIII, and other plasma proteins. Also with activation of the coagulation cascade, there may be consumption of the regulatory proteins AT, protein C, and protein S.

Consequently, bleeding associated with CPB is multifactorial and requires a systematic approach to the bleeding patient. The first step is to rule out an anatomic defect as a potential explanation of post-operative bleeding. Also, coagulation tests should include an APTT, thrombin time, heparin assay, and fibrinogen. The thrombin time and heparin assay, will provide information as to the possibility of excess heparin or heparin rebound.

Management may require the use of platelets. Occasionally fresh-frozen plasma is indicated for serious coagulopathies. Recently, the use of desmopressin (DDAVP) and aprotinin [Trasylol (Bayer Corp., West Haven, Connecticut)] has been advocated as a means of controlling bleeding without the use of blood products and their potential complications.

LABORATORY ANALYSIS OF COAGULATION

Part of "48 - Coagulation Abnormalities"

The most important step in the evaluation of a bleeding patient is a good medical history. Unfortunately, in the clinical laboratory the history is not available unless the laboratory physician takes the initiative to review the patient's chart and talk with the patient. In the majority of cases, the information provided will direct the subsequent laboratory evaluation. The clinical history of patients with abnormalities of primary and secondary hemostasis differ significantly. Thus, mucocutaneous bleeding should lead to an evaluation of primary hemostasis while musculoskeletal bleeding would initiate an evaluation of secondary hemostasis.

In most laboratories, six simple procedures can be performed to evaluate a patient with a potential hemostatic abnormality. These six procedures include: a review of the peripheral smear, bleeding time, platelet count, APTT, PT, and thrombin time. In virtually all cases, the peripheral smear and platelet count are a byproduct of a CBC and are readily available. The bleeding time is useful for evaluating primary hemostasis. In conjunction with the platelet count, it allows a differentiation of qualitative and quantitative platelet disorders. Recently, a new *in vitro* method for evaluating primary hemostasis has become available. The PFA-100 (Dade Behring, Deerfield, Illinois) allows one to evaluate platelet function utilizing a flow system *in vitro*. The patient's blood sample is obtained and is perfused through two tiny apertures that have collagen/epinephrine or collagen/ADP. The end point of the test is when there is no longer perfusion of blood through the aperture (clot formation). This test system is extremely sensitive to aspirin. A patient exposed to aspirin will have a prolonged time to closure with the epinephrine/collagen and a normal ADP/collagen results. Also, the PFA-100 is very sensitive in the detection of mild type I von Willebrand disease.

The PT and APTT provide an arbitrary dissection of coagulation into the intrinsic (APTT) system and the extrinsic (PT) system. Although in reality this division is artificial, it is very useful from the standpoint of patient evaluation. Isolated prolongation of the prothrombin time is associated with factor VII deficiency, which may be either hereditary or acquired. An abnormal APTT together with a normal PT is indicative of an abnormality in the more proximal part of the intrinsic system (factors XII, XI, VIII, IX, and Fletcher and Fitzgerald). Abnormalities of both test systems are suggestive of a final common pathway defect (factors X, V, II, and I).

The thrombin time is a very useful test and it is often overlooked. The thrombin time may be abnormal in a variety of clinical situations (Table 48.12). Thrombin time is extremely useful in ruling out the presence of heparin in a patient sample. The

finding of a prolonged thrombin time that corrects with the addition of protamine is virtually diagnostic of heparin. Also, the reptilase time may be used to identify heparin as an explanation of prolonged thrombin time. The reptilase time will be normal in the presence of heparin.

TABLE 48.12. ABNORMAL THROMBIN TIME

- Heparin
- Fibrin/fibrinogen degradation products
- Paraproteins
- Dysfibrinogenemia
- Hypofibrinogenemia
- Antibodies to thrombin
- Uremia
- Some patients with lupus anticoagulants

Factor assays are indicated in many instances to establish the exact cause for the abnormal screening studies. These assays, depending on the factor, may utilize either the APTT or PT systems. Appropriate attention is necessary to quality control factor assays. At least two dilutions of the patient's plasma should be used and the patient's values should be checked to ensure parallelism of the patient's values when compared to the reference curve. Nonparallelism of factor assay results is suggestive of an inhibitor.

Synthetic substrate assays have achieved a greater level of importance in the coagulation laboratory. These assays rely on the use of synthetic oligopeptides (three or four amino acids) that mimic amino acid sequences near the site of enzymatic cleavage in the native substrate (1, 10). For instance, the synthetic substrate utilized to evaluate factor Xa activity consists of the four amino acids, isoleucine-glutamine-glycine-arginine. These four amino acids are located adjacent to the peptide bonds in prothrombin where factor Xa activates prothrombin to thrombin. An indicator group is attached at the carboxy-terminal end of the oligopeptide. The indicator group may either be a chromogen or a fluorochrome. In most instances, laboratories utilize chromogenic assays.

Among the advantages of synthetic substrate assays are their ready adaptation to automated instrumentation and their basic enzymatic principles. Thus, utilizing synthetic substrates, it is possible to characterize the reactions with greater precision than the classical coagulation assays relying on a fibrin endpoint. Currently, synthetic substrate assays are most often utilized for evaluation of the fibrinolytic system. Also, there are commercially available kits for many components of the coagulation system (e.g., factor VIII). In addition, synthetic substrates are extremely useful in analysis of the regulatory proteins (AT and protein C).

Thrombophilia

Douglas A. Triplett

This chapter focuses on abnormalities of the regulatory proteins and other clinical states associated with thrombotic disorders. Thromboembolic disease and its complications are the most common cause of death in the western world. Although several hereditary abnormalities of regulatory proteins have now been linked to a familial thrombotic tendency, most patients with thrombosis have a complex multifactorial pathophysiology. The laboratory contribution to the diagnosis of thrombotic disorders, therefore, is most clearly defined in the case of patients who have hereditary thrombophilia. Thrombophilia is an acquired or hereditary condition(s) that predisposes to an increased incidence of thrombosis (1). The hereditary disorders are reviewed and various acquired states in which there is a thrombotic predisposition are discussed.

HEREDITARY DISORDERS OF REGULATORY PROTEINS

Part of "49 - Thrombophilia"

Antithrombin (AT) is a plasma glycoprotein that is a member of the SERPIN family (serine protease inhibitors) (2). AT inhibits all the serine proteases involved in hemostasis. This inhibition is achieved by forming a 1:1 enzyme-inhibitor complex. The reaction between AT and serine protease enzymes is greatly accelerated in the presence of heparin or other related glycosaminoglycans. Physiologically, the presence of heparan sulfate on the surface of endothelial cells is involved in the downregulation of hemostasis in conjunction with AT. Several investigators have utilized activation peptides (fibrinopeptide A, prothrombin fragment 1·2, and factor X activation peptide) to demonstrate there is an ongoing tonic activation of hemostasis. This low level of activation is successfully regulated in the normal individual by a variety of regulatory systems of which the heparan sulfate–AT component is extremely important. Hereditary deficiency of AT was the first plasma-protein deficiency successfully linked to a thrombotic predisposition (3). In contrast to hereditary disorders of coagulation proteins, AT-deficient patients were found to have levels of 40% to 50% of normal. The association of clinical symptoms with a borderline or slight deficiency of this regulatory protein would suggest the physiologic balance of procoagulant/anticoagulant activities is precarious. In contrast, patients with mild hemophilia and levels of factor VIII activity of 5% may be entirely free of bleeding complications unless significantly challenged by trauma or surgery.

AT deficiency is inherited as an autosomal dominant abnormality. The AT gene is located on human chromosome 1q23-25. The gene consists of six exons and five introns distributed over approximately 19 kb of DNA. There is some homology of the AT gene with the α_1-antitrypsin gene. The incidence of AT III deficiency in the general population has been estimated at 1:2,000 to 1:5,000.

Individuals with AT deficiency are usually symptomatic by the age of 40. Typically, the onset of thromboembolic events occurs in the late teens or 20s. On occasion, patients many be encountered who are in their 50s or 60s with no history of thrombosis. Most thromboembolic events are venous. In approximately 50% of cases, the initial event is related to some precipitating factor such as surgery, trauma, use of oral contraceptives, or pregnancy (4,5).

The laboratory evaluation requires specific assays of AT activity and antigen. The usual screening tests for hemostasis are entirely normal. Antigenic measurement of AT may use different techniques: radioimmunoassay, radial immunodiffusion, and Laurell rocket immunoelectrophoresis. Of these, techniques, the Laurell method is most commonly employed. Functional assays may utilize either fibrin end-point or synthetic substrate systems. The most practical functional assay assesses the ability of AT to inhibit an enzyme in the presence of heparin. The most frequently utilized system employs chromogenic substrates (Fig. 49.1). A second functional assay relies on progressive AT activity. In this assay, the patient's plasma containing AT is incubated with a known amount of enzyme (Xa or IIa) in the absence of heparin. Discrepancies between these two functional assays have been observed in a number of patient studies. Patients with normal progressive AT activity and decreased activity in the presence of heparin have gene mutations resulting in abnormalities of heparin binding sites.

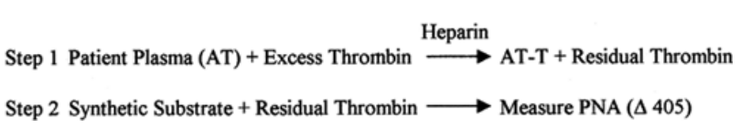

FIGURE 49.1. Antithrombin amidolytic assay. The reaction may be measured using a recording spectrophotometer or by an end-point method when the reaction is stopped by adding acetic acid. PNA, para-nitroaniline.

By utilizing both antigenic and functional assays, it is possible to divide inherited AT deficiency into two distinct types. Type I results in reduced synthesis of a biologically normal protein and type II results in normal antigenic amounts of AT but decreased functional activity in one of the two above functional assay systems (Table 49.1). Patients with type II AT deficiency secondary to an abnormality in the heparin-binding sites often have a milder clinical history and, in fact, may be asymptomatic in the heterozygous state. However, children who are doubly heterozygous for type II AT deficiency may have significant clinical thrombosis.

Acquired AT deficiency may be seen in a variety of clinical conditions. These include liver disease, nephrotic syndrome, disseminated intravascular coagulation, and acute thrombosis. Modest reductions may also be seen in patients using oral contraceptives. L-Asparaginase is associated with a striking decrease of AT.

TABLE 49.1. CLASSIFICATION OF ANTITHROMBIN DEFICIENCY

Type I	(↓ Ag & ↓ Act)
Type II	-RS
Type II	-HBS
Type II	-PE

Type II antithrombin deficiency is characterized by normal levels of antithrombin antigen and decreased inhibitory activity of thrombin and other serine proteases. Several variants of Type II have been described. Type II-RS involves mutations in the reactive site (RS) of the antithrombin molecule. Type II-HBS is characterized by variations in the heparin binding sites due to mutations of the antithrombin gene. In type II-HBS, the ability of heparin to interact with the binding sites is diminished. Type III-PE refers to a variant of antithrombin that has a pleiotropic affect. In this situation, more than one aspect of antithrombin function may be affected.

The clinical management of patients with AT deficiency consists of initial treatment with heparin followed by oral anticoagulants. When the diagnosis has been established, many clinicians maintain the patient on lifelong oral anticoagulant therapy. With the trend toward lower doses of oral anticoagulants and the use of thromboplastins with International Sensitivity Index (ISI) values of 1.0 to 1.7, the complication rate associated with the use of these drugs has decreased. An AT concentrate is also available. The concentrate is valuable in settings of surgery or trauma.

The diagnosis of any of the hereditary disorders of regulatory proteins is often complicated by the initial patient presentation during an acute thrombosis. Frequently, the patient is already receiving heparin before the laboratory is requested to evaluate the patient for possible regulatory protein deficiencies. In this setting, testing other family members may prove to be the best means of establishing a hereditary abnormality.

Protein C Deficiency

Protein C is a vitamin K–dependent protein that is readily converted to active protein C (APC) by a complex of thrombin and thrombomodulin on the surface of endothelial cells (2) (Fig. 49.2). APC in the presence of another vitamin K–dependent protein, protein S, inactivates factors Va and VIIIa. Thus, the protein C system is responsible for the regulation of the two essential cofactors in the intrinsic pathway of coagulation. The remaining cofactor (tissue factor) of the extrinsic pathway is regulated by a relatively newly discovered coagulation protein: extrinsic pathway inhibitor [also known as tissue factor pathway inhibitor (TFPI)].

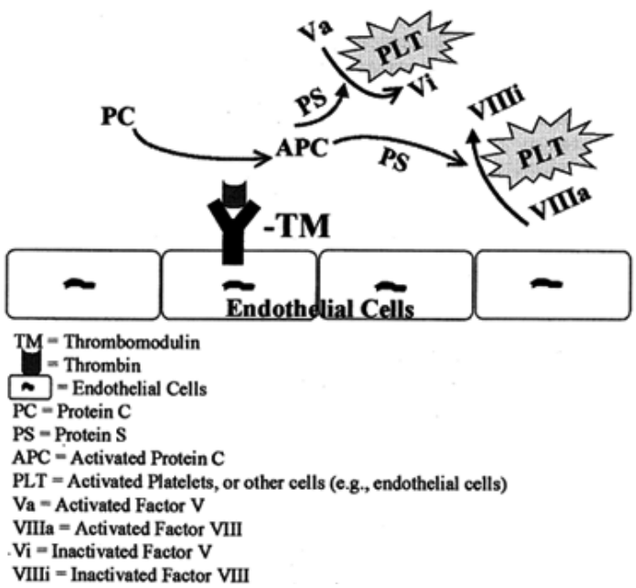

FIGURE 49.2. Protein C/S system. Proteins C and S are vitamin K–dependent proteins that participate in the downregulation of hemostasis. When thrombin is generated *in vivo*, it converts fibrinogen to fibrin. In addition, thrombin may also bind to an endothelial receptor, thrombomodulin. As the name implies, when thrombin binds to thrombomodulin, it loses it procoagulant activity and actively participates in the protein C/S anticoagulant pathway. Thrombin-thrombomodulin converts protein C to activated protein C (APC). APC in the presence of protein S (a cofactor) will inactivate the activated forms of factors V and VIII, thus inhibiting the generation of thrombin. Patients who have hereditary deficiencies of proteins C and S are predisposed to venous thromboembolic events.

Protein S functions in the above reaction as a cofactor for APC. Protein S binds both to endothelial cells and activated platelets and thus serves as a means of localizing APC to an appropriate cell surface. The complex of APC/protein S will then preferentially inactivate cofactors Va and VIIIa. APC is inhibited by at least two plasma proteins: protein C inhibitor and α_1-antitrypsin.

The gene for protein C is found on chromosome 2. The gene contains approximately 11 kb of DNA and has nine exons with eight introns. Protein C deficiency is inherited in an autosomal dominant fashion. Heterozygous patients present clinically with either deep or superficial vein thrombosis. The time of onset and other related clinical findings are very similar to those of AT deficiency. In addition, heterozygous protein C deficiency may be first suspected when a patient who presents with deep vein thrombosis is started on a loading dose of oral anticoagulants.

The appearance of coumadin-induced skin necrosis may alert the clinician to the possibility of protein C or S deficiency states (6). Not all patients who develop this complication prove to have hereditary deficiency of protein C. However, any patient with such a history should be evaluated for this possibility.

Doubly heterozygous or homozygous protein C deficiency is associated with purpura fulminans in the newborn. This is a particularly devastating presentation characterized by extensive areas of skin necrosis together with cerebral and retinal vein thrombosis. Unless appropriate treatment is initiated immediately, this disorder is fatal.

Laboratory evaluation of protein C includes both antigenic and functional assays. The antigenic assays available include Laurell rocket immunoelectrophoresis and enzyme-linked immunosorbent assay (ELISA). Patients with heterozygous protein C deficiency typically have a protein C level of 40% to 50% (reference interval, 65% to 130%). These results are similar to values for heterozygous AT deficiency.

Functional assays for protein C are based on either a fibrin end-point system or synthetic substrate technology. The fibrin end-point assays rely on an activated partial thromboplastin time (aPTT) system (Fig. 49.3). The synthetic substrate assays are more direct, requiring less technical time. Several situations have been described in which the functional coagulation assay is discrepant when compared with the synthetic substrate assay (Table 49.2). Both type I and II deficiency states have been identified. In type I deficiency, the patient has a decreased plasma level of both functional and antigenic protein C. In type II patients, the antigenic level of protein C is within normal limits, although there is decreased functional coagulation and/or substrate activities.

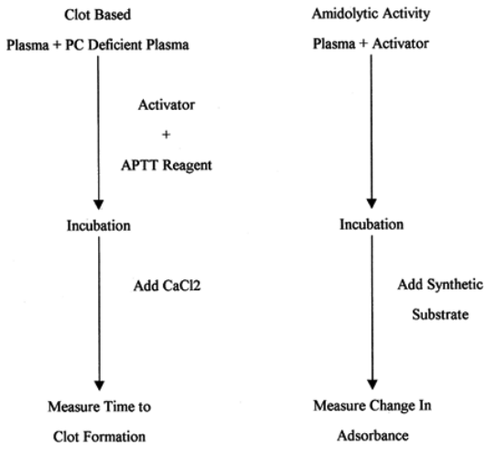

FIGURE 49.3. Protein C functional assays (venom activation).

TABLE 49.2. PROTEIN C/S SYSTEM

	PC Activation	APC Activity
Enzyme	Thrombin	APC
Cofactor	Thrombomodulin	Protein S/factor V
Surface	Endothelium	Plts/endothelium
Substrate	Protein C	Va, VIIIa

PC, protein C; APC, active protein C; Plts, platelets.

When the diagnosis has been established, treatment of protein C deficiency in the heterozygous patient is lifelong oral anticoagulation. In the homozygous patient, replacement of protein C using fresh-frozen plasma is critical in the initial stages of treatment. Oral anticoagulants are indicated for long-term management. The availability of protein C concentrates may prove to be valuable in treating these patients.

Protein S Deficiency

The clinical presentation of protein S deficient patients is similar to AT III and protein C deficiency states (6). In addition to venous thromboembolic events, several recent reports emphasized cerebral vein thrombosis (1,2). Also, warfarin-induced skin necrosis has been reported with protein S deficiency.

There are two forms of protein S present in the circulation: free and bound. The free protein S comprises approximately 40% of the plasma compartment and is the functionally active cofactor. In contrast, the bound protein S circulates complexed to a complement component: C4b-binding protein. C4b-binding protein is an acute phase reactant; consequently, a variety of clinical conditions in which acute phase proteins increase will result in some shift in the equilibrium between free and bound protein S.

The laboratory evaluation of protein S includes antigenic assays and functional assays. For practical purposes, most laboratories are restricted to the use of antigenic determinations. Total protein S may be assayed with a radioimmunoassay or ELISA. Free protein S is based on removing the protein S—C4b-binding complex by precipitation with polyethylene glycol. The supernatant is then assayed for residual protein S by either ELISA or radioimmunoassay.

Protein S deficiency has been categorized into two types. Type I includes patients in whom there are markedly reduced levels of free protein S but a normal amount of protein S complexed to C4b-binding protein. The type II patients have decreased amounts of both free and bound protein S. Most of the patients described have been type I. Acquired deficiencies of protein S have been described in patients with lupus anticoagulants. In addition, protein S has been found to decrease during pregnancy and in the postpartum period. Oral contraceptives have also been found to lower both total and free protein S. Because protein S is a vitamin K–dependent protein, plasma levels are decreased in liver disease and vitamin K deficiency.

Treatment of protein S deficiency requires long-term oral anticoagulant therapy.

Heparin Cofactor II Deficiency

Heparin cofactor II is a member of the SERPIN family. It is a single-chain polypeptide with a molecular weight of approximately 66,000. The gene for heparin cofactor II is located on

chromosome 22. In contrast to AT, heparin cofactor II inhibits thrombin but has no inhibitory activity toward other coagulation serine proteases. The ability to inhibit thrombin is greatly accelerated in the presence of high concentrations of heparin. It appears that the physiologic activator for heparin cofactor II is dermatan sulfate, which accelerates heparin cofactor II activity approximately 1,000-fold. Several patients have been described in whom hereditary deficiency of heparin cofactor II was associated with thrombosis. In these cases, the level of heparin cofactor II was approximately 40% to 60% of normal. Acquired heparin cofactor II deficiency has been seen in patients with disseminated intravascular coagulation, liver disease, and obstetric complications. Laboratory assays for heparin cofactor II rely on the use of dermatan sulfate as a means of preferentially accelerating the thrombin inhibitory activity of heparin cofactor II.

Hereditary Disorders of Fibrinolysis

Several hereditary abnormalities of the fibrinolytic system have been linked to a thrombotic predisposition. Perhaps the most frequently discussed have been dysplasminogenemia and hypoplasminogenemia (7). Unfortunately, the family histories in many of these cases have not proved to be as convincing as those seen in the hereditary disorders of AT, protein C, and protein S. Often, the propositus is the only symptomatic member of the family despite the fact that other family members have similar levels of plasminogen or the same dysfunctional molecule.

Less convincing cases have been reported in which it has been postulated that there is a decreased ability to release tissue plasminogen activator (t-PA) from the endothelial cells or alternatively elevated levels of plasminogen activator inhibitor (PAI). This disequilibrium between t-PA and PAI leads to a hypofibrinolytic state. Again, a hereditary abnormality of this ratio has been convincingly documented in few families. In many acquired situations such as hypertriglyceridemia associated, for example, with diabetes mellitus, systemic lupus erythematosus, abnormalities of the PAI:t-PA ratios have been documented. It appears that, in most instances, the altered PAI:t-PA ratio is acquired. European investigators have emphasized the frequency with which this is encountered when patients with thromboembolic diseases are screened for these two assays in a basal and stimulated state.

The laboratory evaluation of the fibrinolytic system includes measurement of plasminogen (antigenic and functional) and t-PA (antigenic and functional). In addition, it is important to measure PAI levels (antigenic). The stimulation tests are based on the concept of drawing baseline t-PA and PAI levels followed by venous occlusion at 100 mm Hg for 10 to 20 minutes. After stimulation, samples are obtained for repeat PAI and t-PA levels. Intravenous infusion of 1-desamino-8-D-arginine vasopressin (DDAVP) has also been used as a stimulatory test.

Dysfibrinogenemia

Several congenital dysfibrinogenemias have been reported in association with familial thrombosis. Both arterial and venous thromboembolic events have been described. In some cases, the molecular defect has been identified. It may involve abnormalities in either the thrombin-fibrinogen interaction or plasmin-fibrinogen interaction. In the latter case, the binding of plasminogen to the fibrin clot is impaired with resulting increased resistance of fibrin to fibrinolysis.

ACQUIRED DISORDERS

Part of "49 - Thrombophilia"

Various acquired conditions are associated with a predisposition to thrombosis. The presence of a lupus anticoagulant (LA) has been linked to thrombotic events (8). Whether the LA is causative, coincidence, or a consequence is still unresolved. Consequently, patients who present with unexplained thrombosis should be evaluated for the presence of LA. This evaluation includes a screening aPTT. In addition, because LA is merely one member of the family of antiphospholipid antibodies, solid phase assays for anticardiolipin antibodies (ACA) and antibodies to $ß_2$ glycoprotein I and prothrombin should be obtained. In most instances, patients who are LA positive will also be ACA positive. In approximately one third of cases, there will be lack of concordance between these two assay systems. LA-associated thromboembolic events are both venous and arterial. Consequently, the clinical presentation of these patients may be significantly different than the situation encountered with hereditary thrombotic disorders. For instance, young adults with cerebrovascular accidents are frequently found to have LA/ACA (30% of strokes under age 50).

Numerous other clinical conditions are associated with thrombotic predispositions. Among these are Trousseau's syndrome, diabetes mellitus, hyperlipidemia, various vasculitides, paroxysmal nocturnal hemoglobinuria, and Kawasaki's syndrome.

Trousseau's syndrome is the presence of recurrent deep or superficial venous thrombosis in association with malignancies. Often the malignancy may be gastrointestinal or pancreatic in origin. In many cases, the malignancy may be occult and the patient presents initially with thrombosis. Patients who present with deep vein thrombosis or superficial thrombophlebitis that fails to respond to oral anticoagulant therapy or antiinflammatory medications should be suspected of possible Trousseau's syndrome. Typically, heparin is the only satisfactory therapy for management of these patients. The mechanism of increased procoagulant activity in association with malignancy has recently been extensively explored. Initially, it was believed that mucus-secreting tumors produced a substance that directly activated factor X to Xa. In addition, a tumor cell cysteine protease has been identified.

The presence of antiendothelial antibodies has been linked to several thrombotic conditions including Kawasaki's syndrome, hemolytic uremic syndrome, and acute allograft rejection.

LABORATORY EVALUATION OF A THROMBOPHILIA

Part of "49 - Thrombophilia"

Candidates for a thrombotic evaluation include young adults with a positive family history of thromboembolic events who present with a thrombosis. There may or may not be a precipitating

event. The evaluation of these patients requires assays for AT, protein C, protein S as well as molecular assays for factor V Leiden, prothrombin G20210A, among others (Table 49.3 and Table 49.4) (9). Establishing the diagnosis of a hereditary disorder associated with thrombosis is important. Not only from the standpoint of patient management but also family counseling and appropriate precautions for family members who are found to be heterozygous for a deficiency with no history of thrombosis. For instance, young women with a family history of factor V Leiden should be cautioned regarding the use of oral contraceptives. Management of pregnancy in these patients may require the use of low molecular weight heparin.

TABLE 49.3. VENOUS THROMBOSIS RISK FACTORS

Genetic[a]	Acquired/Environmental	Mixed
MTHFR (polymorphism)	History of prior thrombosis	↑ Factor VIII
Factor V Leiden (FVR506Q)	Age	↑ Homocysteinemia
Prothrombin 20210A	Surgery/trauma	↑ Fibrinogen
Protein S deficiency	Extended bed rest	
Protein C deficiency	Malignancy	
Antithrombin deficiency	Oral contraception	
Dysfibrinogenemias	Hormonal replacement	
	Antiphospholipid antibodies	
	Pregnancy/puerperium	
	Myeloproliferative disorders	
	Obesity/inactivity	

[a] Listed in order of frequency. Boldface denotes entries that are most common high risk factors. Note there is a relatively low incidence of venous thrombosis in Asian and African populations.
MTHFR, methylenetetrahydrofolate reductase.
Modified from Rosendaal FR. Risk factors for venous thrombosis: Prevalence, risk and interaction. *Semin Hematol* 1997; 34:171-187.

TABLE 49.4. ARTERIAL THROMBOSIS: RISK FACTORS

Genetic[a]	Acquired/Environmental	Mixed
Hypercholesterolemia	Anticardiolipin antibodies	↑ Factor VIII
↓ HDL	Antioxidized LDL	↑ Fibrinogen
Hypertriglycerides	Diet (↑ fat, ↑ carbohydrates)	↑ Factor VII
Diabetes mellitus	Smoking	↑ Homocysteine
↑ Lipoprotein(a)	Hypertension	↑ C reactive protein
Hemochromatosis (2 genes)	Infections (e.g., chlamydia, CMV)	↑ von Willebrand factor
PLA_2 (glycoprotein IIa/IIIb)	Social class	
Factor VII polymorphisms	Body mass index	
Hyperhomocysteinemia (Variant MTHFRs)		
PAI-1 polymorphisms		
Gender		
Family history of accelerated ASHD		

[a] Boldface denotes genetic based disorders identified by molecular testing in the laboratory.
HDL, high density lipoproteins; CMV, cytomegaloinclusion virus; MTHFRs, methylenetetrahydrofolate reductases; ASHD, arteriosclerotic heart disease.

Because approximately 50% of thrombotic events in patients are unexplained, the future exploration of these patients offers the possibility of a number of new assays. No doubt, a significant number of patients will be found to have abnormalities of endothelial regulatory functions including deficiencies or functional abnormalities of thrombomodulin as well as other regulatory components such as tissue factor expression and upregulation of adhesive proteins.

ACTIVATED PROTEIN C RESISTANCE AND FACTOR V LEIDEN

Part of "49 - Thrombophilia"

The preceding portion of this chapter focused on a chronologic sequence of discovery of abnormalities of plasma proteins that predispose to thrombosis (Table 49.5). The description of Dahlback et al. (10) of a family with a strong autosomal dominant pattern of thrombosis was first reported in 1993. Dahlback et al. evaluated the family with all the available assays that were known to be of value in identifying thrombophilia. All these studies were negative. They subsequently performed an experiment that involved adding APC to the patient's plasma and evaluating the degree of prolongation of the aPTT. In the normal control, the aPTT was significantly prolonged; however, in the patient samples, there was a blunted response to APC. Consequently, Dahlback et al. used the term APC resistance (APC-R), to describe the underlying patient problem that appeared to be linked with thrombosis. Very shortly after their description, Bertina and colleagues (11) at the University of Leiden identified a single amino acid substitution in factor V that led to APC-R.

This mutation affected a cleavage site in factor Va. This site was at 506 and involved the substitution of glutamine for arginine. Consequently, there was decreased ability to downregulate factor Va, thus predisposing to thrombosis. Subsequent studies identified factor V Leiden/APC-R only in the white population. In some parts of southern Sweden, the frequency of factor V Leiden is 15% (12). In southern Europe, the frequency of factor V Leiden was 3% to 4%. There are clear geographic differences in the incidence of factor V Leiden. Based on additional studies, it is thought that the mutation occurred in Europe approximately 30,000 to 40,000 years ago.

TABLE 49.5. HISTORY OF THROMBOPHILIA

1856	Virchow	Thrombosis hypothesis
1965	Egeberg	Antithrombin deficiency
1981	Griffin et al.	Protein C deficiency
1994	Comp et al.	Protein S deficiency
1993	Dahlback et al.	APC-R
1994	Bertina et al.	Factor V Leiden
1996	Poort et al.	Prothrombin G20210A

APC-R, activated protein C-resistance.

Factor V Leiden is found in approximately 20% of patients who present with an initial deep vein thrombosis. In patients who present with a history of two or more venous thromboembolic events, 30% to 50% of these individuals will have factor V Leiden (13). Consequently, it is very important to consider testing for factor V Leiden in patients with venous thromboembolic events. In many cases, there are other contributing factors (e.g., history of recent trauma, use of oral contraception, hormonal replacement therapy, pregnancy, prolonged bed rest).

Heterozygous factor V Leiden patients have approximately a two- to fourfold increased relative risk of thrombosis. It has been estimated that carriers without a history of thrombosis have an absolute risk of thrombosis of approximately 0.45% per year; however, this increases to approximately 1% per year by age 60.

Individuals with homozygosity for factor V Leiden have a significantly increased relative risk of thrombosis. In women who use oral contraception, the presence of homozygosity for factor V Leiden results in a relative increased risk of approximately 80- to 100-fold. In addition, it is important to consider the possibility of underlying factor V Leiden in patients who present with cerebral vein thrombosis.

There are two functional assays available to test for APC-R (14). The original assay utilized patient plasma. APC is added to the patient plasma and the prolongation of the aPTT is determined. A source of normal plasma is used as a reference value. The results are expressed as a ratio:

$$\frac{\text{Patient plasma} + \text{APC}}{\text{Normal plasma}}$$

In most assays, values greater than 2.2 are considered to be within the normal reference interval. Values less than 2.2 are consistent with APC-R. Recently, a second assay has been introduced. In this assay system, the patient plasma is diluted one part to four parts factor V–deficient plasma. This assay is highly specific for identifying factor V Leiden. It eliminates the positive results that one may see in the original assay that are not attributable to factor V Leiden. Conditions that affect the original assay include lupus anticoagulants, pregnancy, and underlying chronic inflammation.

Use of molecular testing to identify factor V Leiden is readily available in most reference laboratories (15). Various techniques have been used including polymerase chain reaction (PCR) and, more recently, the Invader OS(Third Wave Technologies, Madison, WI). The latter assay is quicker and costs less than PCR. It is possible to see discrepancies between gene-based assays and APC-R. There are familial cases in which the baseline level of factor VIII is significantly elevated (greater than 150%). In these cases, an acquired APC-R is readily demonstrated in the original assay for APC-R. The presence of persistent elevated factor VIII levels confirms a risk of thrombosis analogous to or slightly greater than heterozygous factor V Leiden.

PROTHROMBIN GENE MUTATION

Part of "49 - Thrombophilia"

In 1994, Poort and colleagues (16) at the University of Leiden described a mutation in the prothrombin gene. This mutation is found in the white population and is most frequent in southern Europe as opposed to northern Europe. The defect involves the 3′ untranslated region of the prothrombin gene (G20210A). The frequency in the population is approximately 1.5% to 3%. Approximately 4% to 8% of the patients presenting with the first deep vein thrombosis are found to have this mutation. In individuals with recurrent venous thromboembolic events, it occurs at a frequency of 15% to 18%. The risk of thrombosis is these patients appears to correlate with levels of prothrombin activity in plasma.

In contrast to factor V Leiden, most patients with prothrombin G20210A present with superficial venous thrombophlebitis. There is also a relatively high frequency of cerebral vein thrombosis in patients with this mutation (17,18). Often, the cerebral vein thrombotic events are seen in young women who have started using oral contraception.

Unlike factor V Leiden, the prothrombin mutation has been linked to arterial disease. In young women who are smokers, there is approximately a 10-fold increased risk of myocardial infarction (19). Other risk factors such as obesity, hypertension, and diabetes may act synergistically with G20210A.

OTHER HEREDITARY RISK FACTORS PREDISPOSING TO VENOUS/ARTERIAL THROMBOSIS

Part of "49 - Thrombophilia"

With the ready availability of molecular testing, many polymorphisms have been identified as potential causes of both venous and arterial thrombosis. Among these are factor VII polymorphisms, familial elevated levels of factor VIII, abnormalities of PAI-1, and polymorphisms of fibrinogen. Currently, laboratory testing for these is not readily available. There is a need for more data and better clinical studies to evaluate these polymorphisms.

ARTERIAL THROMBOSIS

Part of "49 - Thrombophilia"

Arterial thrombosis and atherosclerosis present an even greater challenge with respect to identifying tests and their relevance to clinical management. More than 50% of patients who present with myocardial infarction are found to have normal lipids (20). Consequently, investigators have been searching for other risk factors. One of the most prominent has been homocysteine (21). Elevated levels of plasma homocysteine may be seen in individuals with underlying molecular defects. Abnormalities of the gene coding for methylenetetrahydrofolate reductase (MTHFR) have been described (22). The C677T polymorphism that leads to a labile variant of MTHFR is the most commonly studied. Approximately 35% to 40% of the white population are heterozygous for labile MTHFR and an additional 10% are homozygous (23). In cases of folate deficiency, patients heterozygous for labile MTHFR may develop increased plasma levels of homocysteine (24).

Homocysteine normal reference intervals are often quoted as 6 to 15 µmol/L. However, it is important to appreciate that the relative risk of thrombosis is based on a gradient approach to reporting homocysteine levels. Optimally, individuals should have a homocysteine level less than 9 µmol/L.

Other arterial risk factors include lipoprotein(a), antiphospholipid antibodies, fibrinolytic capacity, fibrinogen, and apolipoprotein A-I. The clinical utility of these markers remains limited.

Section 9 Microbiology

Microbiology - Introduction

Gail Woods

Section Chief

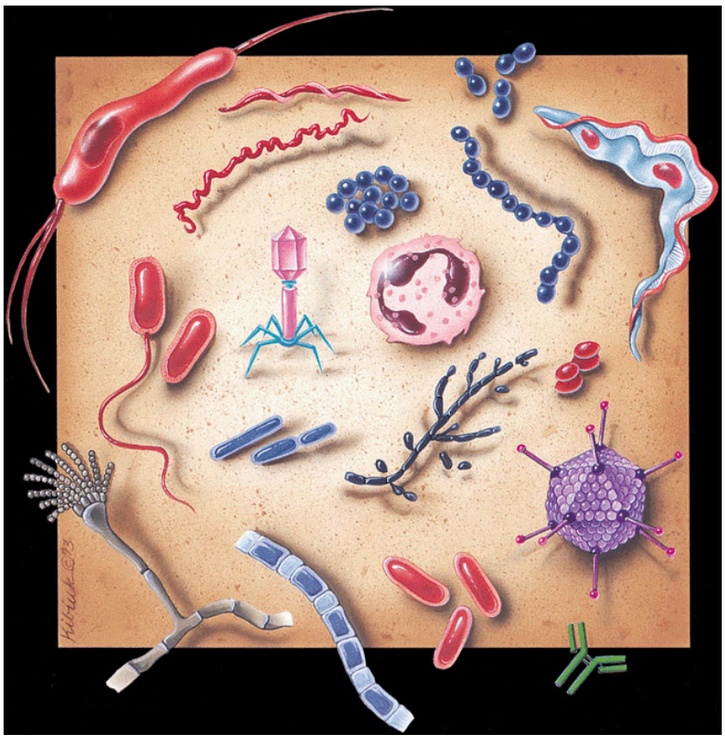

Figure.

During the past two decades, several major changes in the area of clinical microbiology and infectious diseases have occurred. Advances in medical technology and life-support systems have resulted in dramatic increase in the number of patients with profoundly compromised immune status and/or serious underlying diseases. These patients, as well as those who are victims of the AIDS epidemic, are at high risk for infections from both classic “true” pathogens and many opportunistic pathogens. At the same time, we have witnessed the development and application of new technology for the detection and identification of these agents of infection. Developments in immunology, molecular biology, and laboratory automation have both enhanced and complicated the job of the clinical microbiologist. These many changes and advances have placed new demands on the clinical microbiology laboratory. The laboratory must remain flexible enough to develop and offer expanded testing for new and unusual microorganisms as they become recognized as important pathogens in highly immunocompromised patients. The demand for rapid methods and decreased turnaround time has become particularly acute, underscoring the need for prompt therapeutic intervention in the infected immunocompromised patient. Finally, all these tasks must be accomplished in a high-quality, cost-effective manner as the laboratory comes under scrutiny by administrators and third-party payer and external accreditation agencies.

The increased cost of many diagnostic tests, combined with severe financial constraints, has caused many laboratories to send out their high-cost, low-volume tests to a reference laboratory. In other instances, simplification of some tests, such as viral cultures, has allowed laboratories to bring these tests back into the laboratory. Recent developments in immunology and molecular biology have resulted in an increased number of rapid direct-testing methods in which the quality of the specimen submitted is of utmost importance. In each case, these changes make sample collection, handling, and transportation important considerations.

50
Specimen Collection and Processing for Microbiology

Barbara S. Reisner

Gail L. Woods

Successful laboratory diagnosis of a microbial infection depends on many factors, beginning with a well-collected sample. Proper specimen selection, collection, and transport are all essential to ensure that a specimen is representative of the disease process and minimally contaminated with microorganisms present in adjacent tissues. The first part of this chapter focuses on general specimen collection and processing issues; the remainder contains specific recommendations for each specimen type.

One of the most important rules for specimen procurement is to collect the sample from the correct anatomic site; for example, a superficial sample of a lesion is not useful in identifying the cause of a deep wound infection. The timing of sample collection is also important; for example, when submitting a specimen for bacterial culture, samples should be collected before the administration of antibiotics.

Recommended specimen collection techniques may vary by institution; however, all laboratories should have written guidelines for proper specimen collection and these should be followed. In general, specimens other than stool are collected using sterile technique and equipment. Whenever possible, pieces of tissue or aspirated material rather than swab specimens should be obtained. Use of swabs result in the collection of very small volumes of specimen, specimens are more likely to dry out during transport to the laboratory, and specimens are difficult to remove for examination. Sufficient volume of specimen must be collected for the number of tests requested. If the volume is inadequate, the health care provider must prioritize the test requests.

After collection, the specimen must be placed in an appropriately labeled leak-proof container. Use of a specific type of container, containing special media or preservative, may be required by the laboratory. Containers are then placed in a biohazard bag for transport to the laboratory. Each specimen must be accompanied by a requisition slip containing all the information required to evaluate the specimen appropriately and relay the test results back to the health care provider without delay. This includes patient name, age, gender, identification number, location, name of health care provider, time and date of collection, specimen type, diagnosis, and test(s) requested. A mechanism must be in place to match a specimen with a requisition slip. Usually this is accomplished by using a number that is on both the requisition slip and a detachable label that is then placed on the specimen itself.

Transport of specimens to the laboratory should be rapid, optimally in less than 2 hours. For delays in transport, most specimens should be refrigerated; exceptions are blood, cerebrospinal fluid (CSF), and specimens to be examined for anaerobes, fastidious organisms such as *Neisseria gonorrhoeae* and *Bordetella pertussis*, and *Trichomonas vaginalis*, all of which should be maintained at room temperature.

On arrival at the laboratory, the specimen and requisition are examined to ensure that all criteria for acceptance are fulfilled. Minimum criteria for an acceptable specimen are listed in Table 50.1. In addition, some specimens may not be acceptable for particular microbiological procedures. For example, some specimens are not acceptable for anaerobic culture (Table 50.2) because the normal anaerobic flora contained in these specimens make it difficult to distinguish pathogens from nonpathogens. When specimens are rejected, the health care provider is notified so that another specimen may be properly submitted. If information on the requisition is incomplete, laboratory personnel should ask a responsible person to provide the information before processing the specimen further. If a specimen is mislabeled, the sample should be recollected. Relabeling of a specimen is acceptable only for difficult to collect specimens, such as tissue obtained during a surgical procedure or CSF.

TABLE 50.1. SPECIMEN REJECTION CRITERIA

Improper transport temperature
Improper transport container or medium
Prolonged transport time
Unlabeled or mislabeled specimen
Broken or cracked container
Leaking specimen
Dried-out specimen
Inappropriate specimen for test requested
Inadequate volume
Specimen in fixative (for culture)
Duplicate sample in 24-hr period (for urine, sputum, feces culture)

All specimens should be presumed to contain transmissible agents and therefore should be collected and handled using standard precautions. Standard precautions are equivalent to what had previously been termed universal precautions and are designed to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection. This includes the use of gloves, gown, mask, and protective eyewear when there is a risk of coming in contact with the specimen. In most clinical laboratories, a special area is designated for processing clinical samples for culture. Ideally all specimen processing, but at a minimum processing of respiratory secretions and specimens submitted for the detection of mycobacteria or fungi, should be performed in a class II biological safety cabinet.

Many specimen types submitted for detection of bacteria are examined directly using Gram stain; if mycobacteria are suspected, a stain for acid-fast bacilli (AFB) is also performed. Some specimens submitted for detection of fungi will be examined directly with a potassium hydroxide (KOH) and/or calcofluor

white preparation; however, for some specimen types, this is only performed on request. Stool specimens may be examined directly for parasites with a wet mount but more often are placed in a fixative and examined after a concentration procedure. Other techniques for directly examining specimens, such as direct fluorescent antibody stains (DFA), enzyme immunoassays (EIAs), and DNA hybridization or amplification assays are used only in selected situations.

TABLE 50.2. SPECIMENS NOT ROUTINELY ACCEPTED FOR ANAEROBIC CULTURE

Throat, nasopharyngeal, or gingival swabs
Sputa
Bronchial wash, lavage, or brush (except when collected with a protected double lumen catheter)
Gastric and bowel contents
Ileostomy and colostomy effluent
Voided or catheterized urine
Female genital tract specimens collected through the vagina
Surface swabs of ulcers, wounds, and abscesses

A combination of media types is used to isolate bacteria and fungi. These may include enriched, nonselective, selective, or differential media. Viruses are obligate intracellular parasites and can only be cultured within mammalian cells, of which there are three main categories: primary, low-passage finite, and continuous cell lines. With few exceptions, culture of parasites is generally not performed.

Most routine bacterial cultures are incubated for 2 to 3 days. Mycobacterial and fungal cultures are incubated for as long as 6 weeks. Viral cell cultures are incubated for varying lengths of time depending on the specimen source and the growth rate of the viruses that are typically recovered from that site (Table 50.3). The more rapid shell vial technique used for culture of some viruses requires from 24 to 72 hours of incubation. The temperature of incubation is usually 35°C for bacteria and viruses and 30°C for fungi. Various atmospheric conditions may be utilized including ambient, CO_2 enriched, microaerophilic, and anaerobic.

BLOOD

Part of "50 - Specimen Collection and Processing for Microbiology"

Detection of organisms in blood is one of the most important functions of the clinical microbiology laboratory. Fortunately, there have been many improvements in the media and technology for culturing blood during the past decade, resulting in highly reliable manual and automated systems. To optimize these blood culture systems, important guidelines for collection must be followed. In general, blood for culture should not be obtained using an intravascular device. If a reason exists to culture blood using such a device, for example, to evaluate a possible line-related infection, blood obtained by peripheral venipuncture should be submitted at the same time.

When performing a venipuncture, the skin must be adequately disinfected to minimize contamination with normal skin flora. For maximum antisepsis, the skin is first cleansed with 70% isopropyl alcohol followed by application of an iodophor or iodine tincture that must remain in contact with the skin for 1.5 to 2 minutes. Blood should be collected and inoculated into the blood culture bottles using the same needle. Most routine blood cultures are collected as sets of one anaerobic and one aerobic bottle. In some institutions where the incidence of anaerobic bloodstream infection is extremely low, two aerobic blood culture bottles may be used. Special bottles are available for low-volume blood draws and for mycobacterial or fungal culture.

Blood specimens should be collected before administering antimicrobial agents, although media that contain substances designed to minimize the effect of such agents on bacterial growth are available. Optimally, the specimen should be collected just before a fever spike; however, practically, the specimen should be collected immediately after the spike.

The total volume of blood cultured is one of the most important factors in the recovery of the bacterial pathogen. In one study, increasing the volume of blood cultured over a 24-hour period from 40 to 60 mL increased recovery by 10% (2). For adults, 20 to 30 mL of blood should be collected per venipuncture. Less blood is required for children because there are more microorganisms per milliliter of blood. Most blood culture systems specify the volume of blood that should be placed in the blood culture bottle for optimal recovery. It is particularly important to adhere to these guidelines when using the Isolator system (Wampole Laboratories, Cranbury, NJ), which contains factors that inhibit growth of microorganisms if the minimum blood volume is not present.

For adult patients, two sets of cultures should be collected per

febrile episode to help distinguish probable pathogens from possible contaminants, especially when considering the significance of coagulase-negative staphylococci, corynebacteria, viridans streptococci, and *Bacillus* spp. In general, contaminants are more likely to be recovered from a single set of cultures, whereas pathogens typically are recovered from more than one set. No more than four sets should be submitted in a 24-hour period. This limit allows the evaluation of two febrile episodes per day with two blood cultures sets submitted per episode. Greater numbers of cultures are not necessary based on data that show that more than 95% of bacteremias are detected with the first two to three cultures (3). When culturing blood specifically for mycobacteria, two cultures per week are generally adequate.

TABLE 50.3. USUAL VIRAL GROWTH RATES

Virus	Growth Rate (days)
Adenovirus	2–10
Cytomegalovirus	5–28
Enterovirus	2–8
Herpes simplex	1–7
Influenzavirus	2–10
Mumps	5–10
Parainfluenza	4–10
Respiratory syncytial virus	3–10
Rhinovirus	4–10
Varicella-zoster	5–28

Adapted from Forbes BA, Sahn DF, Weissfeld AS, eds. *Bailey and Scott's* diagnostic microbiology, 10th ed. St. Louis; Mosby, 1998.

Inoculated blood culture vials should be held at room temperature until they reach the laboratory. Direct microscopic examination of blood specimens is not useful because this procedure is not sensitive enough to detect the small numbers of organisms generally present in the blood stream [less than 10 colony-forming units (CFU) per milliliter]. Blood cultures for rapidly growing bacteria and yeast are usually incubated for 5 to 7 days. Cultures for mycobacteria and slowly growing fungi are held for as long as 42 days. As soon as growth is detected from the blood specimen, a stain is performed [Gram, acid-fast, or Giemsa stain] to determine the type of microorganism present. Positive stain results are considered a critical value and called directly to the patient's health care provider.

Many types of blood culture systems are available, including both manual and automated. With conventional manual blood culture systems, blood is inoculated into a culture bottle containing a nutritionally enriched liquid medium. The bottles are examined daily for visual evidence of growth (gas production, lysis of red cells, turbidity) and are also subcultured to solid media. The manual biphasic Septi-Chek system (Becton Dickinson Microbiology Systems, Cockeysville, MD) consists of a bottle containing broth to which an agar paddle is attached. The agar is inoculated by inverting the bottle until the broth comes in contact with the agar medium. The agar and the broth are then visually inspected for evidence of growth. The Isolator lysis centrifugation system is another manual blood culture method that consists of a tube containing the anticoagulant ethylenediaminetetraacetic acid (EDTA) and saponin (a lysing agent). After the tube is inoculated with blood, it is centrifuged and the resulting pellet is plated onto agar media. This system works exceptionally well for the recovery of mycobacteria and fungi, especially *Histoplasma capsulatum*.

The fully automated, continuously monitoring blood culture systems are the newest type of systems developed for the detection of bacteria and fungi in blood. The systems available in the United States are the BacT/Alert (Organon Teknika Corporation, Durham, NC), Bactec 9000 (Becton Dickinson Microbiology Systems), and ESP (Trek Diagnostic Systems Inc., Westlake, OH). The systems are alike in that the culture bottles are incubated in an instrument, where they are continuously monitored (typically at 10-minute intervals) for the production and/or consumption of gas. The data collected are transmitted to a computer and analyzed to allow rapid detection of microbial growth. Each system utilizes a noninvasive method (i.e., colorimetric, fluorescent, or manometric methods for detecting CO_2 or other gases) to monitor growth.

Various bacteria capable of causing bloodstream infections may not be recovered using routine blood culture procedures. Brucellae grow in routine blood culture media in as few as 3 days; however, as much as 21 days of incubation may be required and, in some cases, a terminal subculture is necessary. The HACEK group of bacteria (i.e., *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*), associated with bacterial endocarditis, also are recovered from routine media; however, as much as 14 days of incubation and terminal subculture of the broth may be useful. *Leptospira interrogans* requires special media such as Fletcher's, Ellinghausen-McCullough/Johnson-Harris, or Polysorbate 80, and cultures should be incubated for as long as 6 weeks.

Recovery of *Bartonella henselae* from blood is difficult. With the Isolator system, processed blood is plated to freshly prepared enriched blood or chocolate blood agar and incubated at 35°C under conditions of elevated CO_2 and humidity for as long as 4 weeks. Using the Septi-Chek system, growth may be achieved after incubation for 40 days. In broth-only systems, the organisms may be observed by staining a smear of the broth with acridine orange; however, the organism does not produce turbidity or enough CO_2 to be detected using instrumentation.

Culture of catheter tips may be performed to determine the source of a bacteremia. One commonly used technique utilizes the semiquantitative catheter tip culture method (4), in which the segment is rolled across a blood agar plate four times. Cultures yielding organisms present in more than 15 CFU are considered to be significant, potentially indicating a catheter-related infection.

A limited number of viruses are recovered from blood specimens. In most diagnostic virology laboratories, cytomegalovirus (CMV) and the enteroviruses are the most common isolates. Specialized reference laboratories are required to isolate human immunodeficiency virus (HIV), parvovirus B19, and the arthropod-borne viruses. For routine viral culture, 5 to 10 mL of blood should be collected in a sterile tube with an anticoagulant such as citrate; however, enteroviruses and arboviruses may also be recovered from serum.

Processing blood to obtain serum is accomplished by allowing the blood to completely clot at 4°C followed by centrifugation. Processing blood to obtain the leukocyte fraction can be accomplished by harvesting the buffy coat fraction obtained after a low-speed centrifugation; however, more purified preparations are obtained using density-gradient centrifugation with one of several commercially available products.

Direct microscopic examination of peripheral blood neutrophils for CMV can be accomplished using an antigenemia assay, a quantitative DFA that utilizes a monoclonal antibody against the pp65 antigen. This assay is most useful in the management of CMV infection in solid-organ allograft recipients. An alternative direct assay for CMV is the DNA hybrid capture assay (Digene, Silver Spring, MD).

For traditional viral culture, specimens are added to a monolayer of mammalian cells, culture medium is added, and the cells are incubated for as long as 28 days. The cell lines are examined throughout the culture period for viral cytopathic effects. When cytopathic effects are observed, the virus present is determined

with additional tests, e.g., staining the monolayer with a virus-specific antibody. For some viruses, especially CMV, the shell vial technique in which the specimen is centrifuged onto a monolayer of cells growing on a coverslip enhances recovery and allows more rapid reporting of results. With this technique, the coverslips are removed and stained with a monoclonal antibody early in the incubation period (24 to 48 hours).

Several parasites may be found in the bloodstream at some time during their life cycle. These include *Plasmodia* spp, *Trypanosoma* spp, *Babesia* spp, *Leishmania donovani*, and the microfilaria. For some of these organisms (trypanosomes and filaria), examination of fresh whole blood is useful to observe motility; however, in most cases, thick- and thin-stained blood films are required to determine the species of organism present. Blood films of whole, anticoagulated, or various concentrated fractions of blood may be prepared. Buffy coat fractions are useful when looking for *Leishmania* or *Trypanasoma* spp. The time of blood collection is important when evaluating a patient for parasitemia (Table 50.4). Giemsa, Wright's or Wright-Giemsa stain may be used to stain the blood film. Giemsa is the best stain for determining the species of plasmodia. Blood films are first examined under low power to visualize microfilaria and then under progressively higher power to detect other parasites. A thick smear should always be examined along with the thin smear to detect light parasitemia. When malaria is suspected, several smears should be submitted each day for 3 days.

TABLE 50.4. OPTIMAL TIME TO COLLECT BLOOD SAMPLE FOR PARASITE EXAMINATION

Parasite	Collection Time
Babesia microti	Any time
Brugia malayi	Midnight
Leishmania donovani	Any time
Loa loa	Noon
Mansonella ozzardi	Any time
Mansonella perstans	Night
Plasmodium spp	Between chills
Trypanosoma spp	Acute stage
Wuchereria bancrofti	Midnight

CEREBROSPINAL FLUID

Part of "50 - Specimen Collection and Processing for Microbiology"

CSF is submitted for microbiological analysis when meningitis or encephalitis is suspected. For meningitis, the likely infectious agent differs depending on the duration of symptoms (Table 50.5). The most likely bacterial agent of acute meningitis will also vary with the age of the individual and whether the disease is community or nosocomially acquired. Most infectious cases of encephalitis are a result of viral infection, both arthropod and nonarthropod borne. Parasitic infections of the central nervous system also occur, with varying clinical presentations.

CSF for microbiological examination is usually obtained by lumbar spinal puncture. The specimen should be collected before antibiotic treatment. Each type of procedure (smear, culture, antigen test) generally requires at least 0.5 mL of CSF with the notable exception of the mycobacterial culture, which requires at least 3 mL (greater volumes increase recovery). Because of this, the largest aliquot of specimen should always be sent to the microbiology laboratories, with lesser volumes sent to the chemistry and hematology laboratory. The specimen should be transported to the laboratory promptly and processed as soon as possible. If a delay in processing is unavoidable, the specimen should be held at room temperature.

If greater than 1.0 mL of CSF is received for a given test, the fluid is centrifuged to allow the test to be performed on the concentrated sediment. A cytocentrifuge may be used to prepare a concentrated specimen for direct microscopic evaluation.

A Gram stain should be performed on all CSF specimens immediately on receipt in the laboratory. Rapid tests for bacterial antigens of group B streptococci, *Streptococcus pneumoniae*, some serotypes of *Neisseria meningitidis*, *Escherichia coli* (K1 capsular antigen cross-reacts with that of *N. meningitidis* type B), and *Haemophilus influenzae* type b are available; however, data from several studies indicate that the sensitivity of these tests is less than or equal to that of Gram stain and the results of these tests have little impact on the care of the patient (6,7 and 8). The exception is partially treated meningitis, in which the antigen tests may be more sensitive. For these reasons, many laboratories no longer offer these expensive and labor-intensive tests or strictly limit their use.

For bacterial culture, an aliquot of the specimen is plated onto solid media and incubated for 3 days. Broth cultures of CSF and other sterile body fluids are no longer performed in many laboratories because studies that have shown that most organisms recovered in the broth only are not clinically significant, potentially leading to use of unnecessary antimicrobial agents (9,10). In these studies, broth cultures were found to be useful only for culture of CSF collected for the evaluation of a shunt infection and chronic ambulatory peritoneal dialysis fluid, both examples of clinical conditions in which low numbers of organism may be present. Anaerobic culture is not routinely performed on CSF specimens because anaerobes very rarely cause meningitis.

Leptospires can be seen in CSF during the first 10 days of illness using dark-field microscopy of a concentrated specimen. Leptospires can be recovered in culture by inoculating a special

medium that is incubated in the dark at room temperature for as long as 6 weeks.

TABLE 50.5. PROBABLE INFECTIOUS CAUSE OF MENINGITIS

Duration of Symptoms	Probable Pathogen
<24 hr	Pyogenic bacteria
1–7 days	Enteroviruses
	Pyogenic bacteria
≥4 wk	*Mycobacterium tuberculosis*
	Treponema pallidum
	Brucella spp
	Leptospira interrogans
	Borrelia burgdorferi
	Cryptococcus neoformans
	Coccidioides immitis
	Histoplasma capsulatum
	Candida spp

T. pallidum cannot be grown in routine culture; therefore, the diagnosis must be made based on the clinical presentation and abnormal CSF parameters: pleocytosis, elevated protein, and/or a positive VDRL (Venereal Disease Research Laboratory) test. The VDRL is the only useful test for detecting syphilis antibodies in CSF. Because a positive CSF VDRL is usually associated with a positive serum rapid plasma reagin or VDRL, the serum status should be determined before performing the CSF test.

B. burgdorferi also cannot be grown in routine culture; therefore, the clinical presentation, history, and serologic testing for organism-specific immunoglobulin (Ig) G and IgM are used for diagnosis.

With the exception of specimens from patients with acquired immunodeficiency syndrome, processing CSF for mycobacteria is indicated only for samples with pleocytosis or abnormal glucose or protein values. Because the number of mycobacteria present in CSF is low, a large volume of specimen (3 to 5 mL optimal) is necessary to maximize recovery of the organism in culture. Organisms can be seen directly in the specimen using a special stain for AFB (Kinyoun, Ziehl-Neelson, or auramine-rhodamine). Specimens are plated to both solid and liquid medium for culture.

Most yeast and fungi, with the possible exception of *H. capsulatum*, will be detected in the Gram stain. A special stain such as Wright's or Giemsa may be performed to detect *H. capsulatum*. A direct antigen test for the capsular antigen of *Cryptococcus neoformans* is available and is the most sensitive test for diagnosing cryptococcal meningitis. The India ink test is no longer recommended for this purpose because it lacks sensitivity and specificity (white cells present in CSF may be misidentified as encapsulated yeast). For culture, the specimen is inoculated to solid medium only.

Viral culture of the CSF is generally useful only for recovery of enteroviruses. Culture for other viruses, such as HIV and arboviruses, are only performed by specialized laboratories. For the arboviruses, diagnosis requires serologic testing for viral antibodies in most cases. Use of a nucleic acid amplification test is the most reliable way to diagnose herpes simplex virus (HSV) encephalitis. Amplification tests are also available for the enteroviruses and in the future may become part of the routine testing in cases of possible enteroviral meningitis.

A wet mount examination and the Giemsa stain are used to examine CSF for free-living amebae (*Naeglaria* spp, *Acanthamoeba* spp, *Balamuthia mandrillaris*). Culture of *Naeglaria* and *Acanthamoeba*, using nonnutrient agar with a bacterial overlay, may also be available in some laboratories. For neurocysticercosis, detection of antibodies against *Taenia solium* in the CSF, along with clinical history and characteristic findings on head computed tomography scan, is diagnostic.

Body Fluids Other Than CSF

Specimens in this category include pericardial, pleural, peritoneal, and synovial fluids. For optimal microbiological analysis, it is essential that fluid, rather than a fluid-saturated swab, be submitted. A volume of 1 to 5 mL is adequate for bacterial culture; however, larger volumes (10 to 15 mL) should be submitted for fungal or mycobacterial culture. For diagnosing peritonitis associated with chronic ambulatory peritoneal dialysis, collection of at least 50 mL of fluid may improve recovery of the responsible pathogen.

Body fluids should be submitted in a sterile container. If the syringe used to collect the specimen is submitted to the laboratory, the needle must first be removed. Transferring the specimen to a tube containing an anticoagulating agent is not recommended for bacterial culture because heparin, sodium citrate, and EDTA have all been shown to inhibit particular bacterial species (11,12). For culture of bacteria other than mycobacteria, a sample may be directly inoculated into a blood culture bottle at the bedside. For viral culture, the specimen should be placed in viral transport medium and placed on ice. Body fluids should be transported promptly to the laboratory.

Direct examination of the specimen by Gram stain should always be performed. If more than 1 mL of specimen is received, it should be concentrated by centrifugation first. An acid-fast stain or calcofluor white/KOH preparation of the sediment from a concentrated specimen should be performed if mycobacteria or fungi are suspected. Solid media used for culture of body fluid specimens should be selected to allow recovery of fastidious organisms. As previously mentioned with regard to CSF, inoculating a liquid medium for routine bacterial culture of body fluid specimens may be necessary only when culturing dialysate from patients undergoing chronic ambulatory peritoneal dialysis (9,10). Both liquid and solid culture media should be inoculated for mycobacterial culture.

Pericarditis owing to Coxsackie A and B virus may be diagnosed by viral culture of the pericardial fluid; however, virus may also be recovered from throat and rectal specimens. Parasites may rarely be found in body fluids and may be seen in either a wet mount or Giemsa-stained smear. These include microfilariae, *Strongyloides stercoralis* in cases of hyperinfection, *Entamoeba histolytica* as a result of a ruptured liver abscess, or scoleces and hooklets (hydadid sand) of *Echinococcus granulosis* after rupture of a hydatid cyst.

EAR

Part of "50 - Specimen Collection and Processing for Microbiology"

Types of ear specimens include swab specimens for the diagnosis of otitis externa and middle ear fluid obtained by tympanocentesis for the diagnosis of otitis media. The potential pathogens at these two sites differ.

The causes of an infection of the external ear are similar to those of other infections of skin and soft tissue. Localized infections may be a result of *Staphylococcus aureus* and group A streptococci. Diffuse infections are often owing to gram-negative bacilli, especially *Pseudomonas aeruginosa*. Chronic infections may occasionally be a result of tuberculosis, syphilis, or leprosy. Fungal infections may be a result of *Aspergillus* spp and *Candida albicans*.

Otitis media is most often caused by organisms derived from the respiratory flora, including *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis*, as well as *S. aureus* and gram-negative bacilli. Anaerobic bacteria can be involved in middle ear infections;

therefore, anaerobic culture may be useful. Respiratory syncytial virus (RSV), influenza viruses, enteroviruses, and rhinoviruses have also been associated with otitis media.

Direct examination of a smear of the middle ear fluid using Gram stain may be performed if an adequate volume is submitted. Direct examination of other types of ear specimens is not usually done. Specimens from the inner ear should be plated to media capable of supporting the growth of fastidious bacteria. *Candida* spp will grow on routine media used for bacterial culture, but special fungal media should be used to recover molds. Viral culture generally is not performed because antiviral therapy typically is not administered.

EYE

Part of "50 - Specimen Collection and Processing for Microbiology"

Several types of specimens may be submitted for the microbiological analysis of eye infections, including conjunctival specimens collected with a swab or a sterile spatula for the diagnosis of conjunctivitis, corneal scrapings collected with a sterile spatula for the diagnosis of keratitis, vitreous fluid for the diagnosis of endophthalmitis, and purulent material for the diagnosis of cellulitis. If a swab is used, it should be dipped in sterile broth media before collecting the specimen. Multiple samples should always be obtained, one for each stain and media type. Because it is difficult to transport the small volumes of specimen collected, samples are applied directly to glass slides and growth media at the collection site. Smears should be fixed immediately after preparation.

Special procedures are required when collecting specimens for *Chlamydia trachomatis* and viral culture. Using swabs with a wooden shaft should be avoided because the wood may be toxic to the organisms, and specimens should be placed directly in transport medium containing antimicrobial agents (usually gentamicin, vancomycin, and nystatin or amphotericin B; penicillin should not be used for *C. trachomatis*) to inhibit overgrowth of bacteria and fungi. Specimens should be placed on ice for transport to the laboratory.

Direct examination of smears is important for rapid diagnosis of eye infections and should always include a Gram stain for detection of bacteria. To detect *C. trachomatis* directly in a conjunctival specimen, a Giemsa stain of conjunctival scrapings may be examined for the presence of epithelial cells containing basophilic intracytoplasmic inclusions. However, monoclonal antibodies for use in direct immunofluorescent assay are preferred because they are more sensitive and specific than Giemsa stain. For optimal results with the direct fluorescent antibody tests, the collection kit provided by the manufacturer should be used, and the specimen should contain at least 10 columnar or metaplastic squamous cells. A commercial EIA (Clamydiazyme, Abbott Laboratories, Abbott Park, IL) and a nucleic acid probe assay (Pace, Gen-Probe Inc., San Diego, CA) are also available for detection of *C. trachomatis* in conjunctival specimens.

An AFB stain should be performed if mycobacteria are suspected. Calcofluor white and/or a KOH preparation should be examined if fungi are suspected. In fungal keratitis, fungi may not be seen unless tissue from deep in the corneal parenchyma is examined. Rapid detection of adenovirus, HSV, and varicella zoster virus (VZV) can be accomplished using fluorescent immunostains. Stains used to detect parasites include Giemsa and hematoxylin and eosin (H&E), which are useful for detecting *Acanthamoeba* spp and microfilaria, and modified trichrome stain to detect microsporidia.

Whether inoculated at the bedside or in the laboratory, the media for routine bacterial culture of eye specimens should include an enriched medium for the recovery of fastidious organisms (e.g., *S. pneumoniae*, *N. gonorrhoeae*, and *H. influenzae*). Cell culture is required to recover *C. trachomatis*. The rapidly growing mycobacteria may be recovered on media used for routine bacterial culture; however, the laboratory should be notified so that cultures can be incubated for additional time to ensure recovery. If mycobacterial culture is specifically requested, special solid and liquid media will be inoculated. *Candida* spp will be recovered using procedures for routine bacterial culture; however, recovery of molds requires fungal media and incubation conditions. Cell culture is required to recover viruses. The more rapid technique of shell vial culture is often used to detect CMV. *Acanthamoeba* are one of the only parasites for which culture is attempted (using nonnutrient agar with a bacterial overlay), but the procedure is not available in all laboratories.

GASTROINTESTINAL TRACT

Part of "50 - Specimen Collection and Processing for Microbiology"

Feces, and in some cases rectal swabs, are submitted to the laboratory primarily to determine the etiologic agent of infectious diarrhea or food poisoning. With the availability of a new EIA for *Helicobacter pylori* antigen (Meridian Diagnostics Inc., Cincinnati, OH), submission of stool to determine the etiologic agent of gastritis and peptic ulcers may become common practice in the future. Feces should be collected in a clean container with a tight lid and should not be contaminated with urine, barium, or toilet paper. Feces should optimally be examined within 2 hours of collection. If this is not possible, a portion should be placed in Stuart's or Amies transport medium for bacterial culture or in preservative for parasitology examination. Rectal swabs should be placed in a tube transport system containing modified Stuart's medium. Unpreserved stool specimens should be maintained at refrigerator temperature during storage and transport to the laboratory.

It is becoming standard practice to reject stool specimens for bacterial culture and parasite examination from patients who have been hospitalized longer than 3 days because diarrhea that develops in the hospital is not likely to be caused by food- or water-borne pathogens. For such patients, examination for the toxins produced by *Clostridium difficile* is recommended.

For bacterial culture, the media inoculated should allow the detection of *Salmonella*, *Shigella*, and *Campylobacter* spp at a minimum. This usually consists of a selective and differential medium such as MacConkey agar, a more selective medium such as Hektoen enteric or xylose-lysine-desoxycholate agar, and a medium for growth of *Campylobacter* spp, such as *Campylobacter* agar with 10% sheep blood. Media for the recovery of *Campylobacter* spp are incubated in a microaerophilic environment at 42°C for as long as 3 days.

The prevalence of gastroenteritis caused by *Aeromonas* spp,

Plesiomonas spp, *Vibrio* spp, and *Yersinia enterocolitica* is sufficiently low in most countries that cultures for these organisms generally are performed on request only. Media routinely used to culture for enteric pathogens are sufficient to recover *Aeromonas* spp and *Plesiomonas* spp. *Vibrio* spp and *Y. enterocolitica* will also grow on routine stool culture media, but the selective medium thiosulfate citrate bile salts sucrose agar should be inoculated for optimal recovery of *Vibrio* spp, and cefsulodin-irgasan-novobiocin agar should be inoculated and incubated at room temperature for the optimal recovery of *Y. enterocolitica*.

The prevalence of enterohemorrhagic *E. coli*-associated enterocolitis varies in different parts of the United States, and in many areas of the country, it is so low that laboratories look for it on request only. However, in 1993, the Council of State and Territorial Epidemiologists recommended that bloody stools be routinely cultured for this organism. To detect enterohemorrhagic *E. coli*, the stool specimen is inoculated onto sorbitol-MacConkey agar, a medium that differentiates isolates of enterohemorrhagic *E. coli*, which do not ferment sorbitol, from almost all other *E. coli*, which are sorbitol fermentation positive. In addition, stool filtrates can be tested for toxin production in Vero cells or by a commercial EIA.

Diseases associated with *C. difficile*, such as pseudomomembranous colitis and antibiotic-associated diarrhea, are caused by the toxins produced by the organism and are diagnosed by detecting toxin in feces. The reference method for detection of the cytotoxin is cell culture assay. To extract toxin, the stool specimen is clarified by centrifugation and filtered through a 0.45-µm membrane filter. Serial dilutions of the filtrate are prepared and inoculated to monolayers of human diploid lung fibroblasts. Alternatively, toxin may be detected in stool by one of many commercial EIAs, which are less sensitive than cell culture but provide results within a few hours. A latex agglutination test, which detects glutamate dehydrogenase produced by the organism, is available; however, this enzyme is not found exclusively in toxin-producing isolates of *C. difficile*, and cross-reactivity with other bacterial species occurs.

For epidemiologic purposes, stool or rectal swabs placed in an anaerobic transport system may be cultured anaerobically to isolate *C. difficile*. The sample is inoculated to a selective medium such as cycloserine-cefoxitin-fructose agar and incubated anaerobically for 48 hours. Isolates identified as *C. difficile* must be tested for toxin production to determine the association of the organism with disease

Stool specimens or gastric contents collected from persons with short-incubation food poisoning should be evaluated for *S. aureus* and *Bacillus cereus*. Specimens should be examined by Gram stain, and, because both of these organisms may be present normally in food, quantitative cultures are performed. A series of dilutions of the specimen is prepared, and 0.1 mL of the undiluted specimen and each of the dilutions is planted onto colistin nalidixic–acid or phenylethyl alcohol blood agar. The presence of 10^5 CFU or more of *S. aureus* or *B. cereus* per gram of specimen is of potential significance.

The clinical diagnoses of food-borne botulism and infant botulism may be confirmed by detecting botulinal toxin, *Clostridium botulinum*, or both in feces. Optimally, 25 to 50 mL of stool, 15 to 20 mL of serum, and a sample of the suspect food should be collected. Most clinical laboratories are not properly equipped to process specimens from persons with suspected botulism. In the United States, when a case of botulism is suspected, investigators at the Centers for Disease Control and Prevention (CDC) should be notified to assure appropriate diagnosis, treatment, and investigation of the potential outbreak.

With regard to mycobacterial culture, stool specimens usually are submitted for isolation of *Mycobacterium avium* complex (primarily in patients with acquired immunodeficiency syndrome). Processing the specimen involves decontamination, concentration, preparation of smears, and inoculation of appropriate media. Gastric aspirates, representing swallowed sputum, are occasionally submitted for mycobacterial culture from infants, young children, and persons who are obtunded. These should be obtained in the early morning before the patient eats and collected in a container containing sodium carbonate to neutralize the pH.

Fungal culture of stool is not recommended. As many as 40% of healthy individuals, and 75% of immunocompromised individuals may be colonized with yeast. Biopsy of tissue should be performed to diagnose definitively fungal infections of the gastrointestinal tract.

Viral culture of stool or rectal swabs may be used to determine the cause of many types of viral illness (e.g., fever, rash, gastroenteritis) in which the infectious agent is shed for weeks after an illness. Direct immunoassays are available to detect rotavirus in stool or in material collected on a rectal swab. Electron microscopy is also used to detect rotavirus, adenovirus, calicivirus, astrovirus, or Norwalk-like viruses in stool.

To detect parasites, stool is examined microscopically for the presence of protozoa, helminth eggs, and larvae. Stool from patients who have received medications such as barium sulfate, mineral oil, bismuth, some antidiarrheal preparations, antimalarials, and tetracycline should be rejected because they may obscure the parasites. A single stool specimen should be submitted initially, and, if negative, collection of at least two additional stool specimens is recommended. Fresh stool must be examined immediately after collection to visualize protozoa. If this is not possible, stool should be placed in a preservative for transport. Generally, a portion of the specimen is placed into each of two vials, one containing formalin and one containing polyvinyl alcohol; however, one-vial systems and systems utilizing other types preservatives may also be used.

On receipt in the laboratory, the specimen is treated to remove fecal debris and concentrated by centrifugation. If more than one specimen is received from a patient, the specimens may be pooled into one centrifuge tube. A wet mount with saline or iodine is used to examine the sediment, and a permanent stain (i.e., trichrome or iron hematoxylin) of either concentrated or unconcentrated specimen is prepared. Although many organisms are observed first in the wet mount preparation, a definitive identification often requires examination of the stained material. Many parasites observed in feces are not pathogenic; however, their presence may indicate that the patient has been exposed to contaminated food or water or that a pathogenic parasite is present at an undetectable concentration.

Special stains must be performed to detect some parasites. Microsporidia are detected with the modified trichrome stain or

calcofluor white. *Cryptosporidium parvum* and *Cyclospora cayatenensis* are best observed with the modified acid-fast stain. A DFA for *Giardia lamblia* and *C. parvum* is available, as are EIAs for *G. lamblia*, *C. parvum*, and *Entamoeba histolytica*.

The Scotch tape preparation, in which a piece of Scotch tape is applied to the skin across the anal opening and applied to a glass slide for microscopic evaluation is the optimal method for detecting *Enterobius vermicularis* (pinworm).

GENITAL TRACT

Part of "50 - Specimen Collection and Processing for Microbiology"

Genital tract specimens are sent to the laboratory for determining the cause of various clinical syndromes, including vulvovaginitis, bacterial vaginosis, genital ulcers, urethritis, cervicitis, endometritis, salpingitis, and ovarian abscess in females, and urethritis, epididymitis, prostatitis, and genital ulcers in males. Many specimens will be contaminated with the normal microbiota of the genital tract or skin; therefore, the microbiologist must differentiate the normal flora from potential pathogens. Organisms such as *N. gonorrhoeae*, *C. trachomatis*, and *Haemophilus ducreyi* are always pathogenic, whereas organisms such as the Enterobacteriaceae, *S. aureus*, and group B streptococci are pathogenic only in some clinical situations.

A direct Gram stain should be performed on any aspirated material. Gram stains of other specimens are useful in only a few situations. For example, in urethral discharge from males, the presence of gram-negative diplococci within polymorphonuclear leukocytes is sufficient for the presumptive diagnosis of gonorrhea. A decreased ratio of lactobacilli to *Gardnerella* spp, *Bacteroides* spp, and curved, gram-variable bacilli in a Gram-stained smear of a vaginal specimen can be useful for the diagnosis of vaginosis.

A wet mount preparation of vaginal secretions is a rapid and simple method for determining the etiologic agent of bacterial vaginosis as well as vulvovaginitis. For optimal results, the wet mount should be performed and examined within 1 to 2 hours of specimen collection. To prepare the wet mount, a sample of the discharge is mixed with saline, a portion of the mixture is placed on a glass slide, covered with a coverslip, and examined under low and high power for the presence of clue cells (epithelial cells covered with small coccobacillary bacteria), consistent with the diagnosis of vaginosis, pseudohyphae, suggestive of vaginal candidiasis, and motile trichomonads. Two other diagnostic tests performed in conjunction with the wet mount are vaginal pH and the “whiff test.” The vaginal pH is usually 4.5 or less in the absence of infection and in women with vulvovaginal candidiasis but more than 4.5 in those with bacterial vaginosis or trichomoniasis. A positive whiff test (i.e., generation of a pungent, fishy odor on addition of 10% KOH to the specimen) is associated predominantly with bacterial vaginosis but occasionally occurs with trichomoniasis.

Direct examination by dark-field or DFA (reagents are available from the CDC) is required for the detection of *Treponema pallidum* in tissues and tissue exudates. For dark-field microscopy, the specimen should be examined within 20 minutes of collection to ensure retention of motility. The test requires a microscope with a dark-field condenser and well-trained and experienced personnel who are able to recognize *T. pallidum* spirochetes based on the tightness and regularity of the spirals and its characteristic corkscrew movement. DFA, conversely, is performed on air-dried smears of tissues, body fluids, secretions, and lesion exudates, and is specific for *T. pallidum*, making it easier to interpret.

Both EIA and DFA tests are commercially available for the direct detection of *C. trachomatis* in genital specimens. If these kits are used, the specimen must be collected using the procedures and collection kits recommended by the manufacturer.

Nucleic acid probe and amplification methods for direct detection of *N. gonorrhoeae* and *C. trachomatis* in endocervical and urethral specimens, and a combination probe assay (Affirm VPIII microbial identification test, Becton Dickinson Microbiology Systems), for the detection of *Candida* spp, *Gardnerella vaginalis*, and *T. vaginalis* in vaginal secretions, are commercially available. As with the immunoassays, the specimen must be collected using the procedures and collection kits recommended by the manufacturer.

HSV may be detected directly in a smear of a specimen collected from the base of a herpetic lesion. For the traditional Tzanck smear, the material is stained with Wright or Giemsa stain and examined for the presence of characteristic multinucleated giant cells with molded nuclei and homogeneously staining “ground glass” nuclear chromatin (Fig. 50.1). The sensitivity of this approach ranges from 23% to 70%. Alternatively, a DFA may be used. The sensitivity of the DFA varies with the stage of the lesion, ranging from 10% to 87%. Several EIAs are commercially available. The sensitivity of these assays varies, but they generally perform very well in symptomatic populations. *Molluscum contagiosum* is detected by direct examination of specimens using histopathologic techniques. Human papillomavirus is detected by histology or with the DNA hybrid capture assay (Digene).

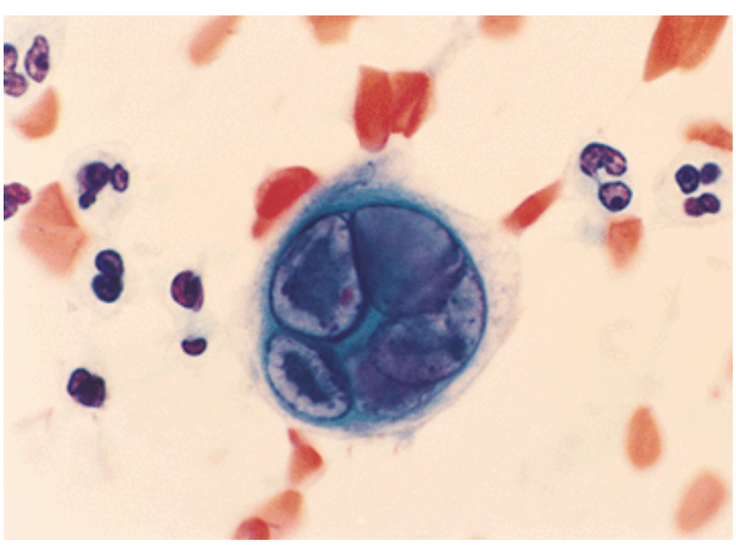

FIGURE 50.1. A multinucleate squamous cell demonstrates typical herpes simplex virus cytopathic effect (Papanicolaou stain, original magnification ×250). (Courtesy of Vicki J. Schnadig, M.D., Department of Pathology, University of Texas Medical Branch, Galveston, TX.)

The optimal media and incubation conditions for bacterial culture of genital specimens depend on the source and the organisms likely to cause disease at that site. Tissue and aspirates

should be plated to media capable of recovering fastidious organisms. Specimens from the cervix, vagina, and urethra should at a minimum be evaluated for *N. gonorrhoeae* and *C. trachomatis* by culture or a direct detection method. Culture is currently the only acceptable diagnostic procedure in a medicolegal case. The optimal approach for isolating *N. gonorrhoeae* is direct inoculation of a selective agar medium, such as modified Thayer-Martin, at the patient's bedside, with transport to the laboratory in a CO_2-containing environment. Alternatively, the swab specimen (cotton swabs should be avoided because they may be toxic) can be placed in a transport system containing Stuart's or Amies medium and delivered to the laboratory within 24 hours. If a delay in transport cannot be avoided, the swab should be left at room temperature, never refrigerated. For recovery of *C. trachomatis*, the specimen should be placed in liquid transport medium and transported to the laboratory without delay, where it is inoculated to cells using the shell vial technique.

It is important to detect group B streptococci in vaginal and perineal specimens from obstetric patients because this organism may cause sepsis and/or meningitis in neonates. For optimal recovery of group B streptococci, the procedure outlined by the CDC (13) should be followed: a swab specimen of the vaginal introitus and anorectum is inoculated into Lim broth, an enrichment broth for streptococci, which is incubated at 35°C and subcultured to a blood agar plate after overnight incubation.

If infection with *H. ducreyi* is suspected, material from the base of the ulcer is collected and held at room temperature until processed. One swab is used to prepare a smear for Gram staining. The presence of many small pleomorphic gram-negative bacilli and coccobacilli arranged in chains and groups suggests *H. ducreyi*. Recovery of the organism on an enriched medium such as chocolate agar supplemented with IsoVitaleX (Becton Dickinson Microbiology Systems) is necessary to confirm the diagnosis.

Actinomyces spp may cause pelvic inflammatory disease in women who use an intrauterine contraceptive device (IUD). An IUD submitted for culture should be placed in a sterile liquid medium, vortexed, and the liquid used to inoculate the culture medium. Cultures for *Actinomyces* spp should be incubated anaerobically for 14 days.

Fungal culture of female genital tract specimens is not productive. *Candida* spp are part of the normal flora in the genital tract of as many as 20% of healthy women; however, culture may be a useful tool after treatment of candidiasis.

Viral culture remains the gold standard for detection of HSV. The shell vial culture technique, in which the monolayer is stained after 16 to 48 hours with a monoclonal antibody, yields a more rapid result; however, traditional cell culture remains the most sensitive technique. Adenovirus may also be isolated by cell culture.

T. vaginalis is most often detected by examination of a wet mount examination of vaginal or urethral discharge, prostatic secretions, or urine sediment. However, culture may also be performed by inoculating the specimen at the bedside into commercially available pouches containing a medium designed to support the growth of trichomonads. The inoculated pouch must remain at room temperature during transport to the laboratory because cold temperatures will cause the organisms to lose viability. On receipt in the laboratory, the medium is examined immediately for motile trichomonads and held for an additional 7 days at 35°C, before issuing a final report.

LOWER RESPIRATORY TRACT

Part of "50 - Specimen Collection and Processing for Microbiology"

Specimens from the lower respiratory tract are submitted primarily to determine the etiologic agent of pneumonia. The most common respiratory specimen received in the laboratory is sputum, expectorated or induced. Other types of specimens are tracheal aspirates, transtracheal aspirates, bronchial washes, bronchial brushings, and bronchoalveolar lavage fluids

Lower respiratory tract specimens should be delivered promptly to the laboratory, but if delays in transport or processing are unavoidable, the specimen should be refrigerated. In general, expectorated sputa and tracheal aspirates should be screened microscopically before processing for bacterial culture to determine whether they are representative of lower respiratory secretions or saliva. This is accomplished by examining a Gram-stained smear prepared from the purulent portion of the specimen under low-power magnification to determine the number of squamous epithelial cells and/or neutrophils present. There are many ways that this information may be used to assess the quality of the specimen. A simple screening method involves assessment of the squamous epithelial cells only: more than 10 squamous epithelial cells per low-power field indicate that the specimen is contaminated with saliva and hence is not acceptable for culture. This criterion is particularly useful when evaluating specimens from neutropenic patients because the presence of neutrophils is not required for a specimen to be acceptable. Expectorated sputa for detection of *Mycoplasma pneumoniae*, *Legionella* spp, and mycobacteria do not need to be screened for adequacy.

For all acceptable lower respiratory tract specimens, the Gram-stained smear is examined under oil immersion to determine the relative amounts of organisms present. Intracellular organisms should be specifically noted. With regard to culture, use of both selective and nonselective media is recommended. In addition, a medium capable of recovering fastidious organisms, such as *Haemophilus* spp, may be inoculated if gram-negative coccobacilli are observed in the Gram-stained smear.

It is recommended that bronchoalveolar lavage and bronchial brush specimens from patients with suspected ventilator-associated pneumonia be cultured quantitatively to optimally evaluate the significance of the organisms recovered (14,15 and 16). Bronchial brush specimens, which contain approximately 0.01 to 0.001 mL of secretions, are placed in 1 mL of sterile saline or broth immediately after collection, and the sample is promptly transported to the laboratory, where a smear for Gram staining is prepared by cytocentrifugation, and 0.01 mL of the specimen is plated to appropriate media using a pipette or calibrated loop. Colony counts greater than 1,000 organisms per milliliter of broth (corresponding to 10^6 CFU/mL of original specimen) appear to correlate with infection. During bronchoalveolar lavage, 10 to 100 mL of fluid is collected. A portion of this sample is transported to the laboratory, where a smear is prepared by cytocentrifugation and Gram stained. The Gram-stain report should

include a statement regarding the presence or absence of intracellular organisms. A 0.001-mL aliquot of the specimen is inoculated onto agar media, and the recovery of 10,000 colonies or more of a specific organism per milliliter of fluid correlates with pneumonia.

Legionella spp are not an uncommon cause of community-acquired or nosocomial pneumonia. Legionellosis can be diagnosed by culture, detection of antigens in the urine, or serologic testing. Culture is preferred because, unlike the other methods, it is not limited to detection of particular species or serotypes. Because legionellae grow slowly, their optimal isolation from highly contaminated specimens, such as sputa or tracheal aspirates, is achieved by decontaminating the specimens with acid before plating. Specimens then are inoculated to buffered charcoal yeast extract agar with and without antimicrobial agents and are incubated for a minimum of 5 days.

M. pneumoniae is a major cause of primary atypical pneumonia. Because mycoplasmas are fastidious and grow very slowly, a definitive diagnosis often is based on results of serologic tests. When culture is required, the specimen of choice is a throat swab; however, sputa or other respiratory specimens are also acceptable. The specimen should be placed immediately into a transport medium containing protein, such as albumin, and penicillin to reduce growth of contaminating organisms. Specimens may be stored in the transport medium for as long as 48 hours at 4°C or frozen for longer periods at -70°C. Mycoplasma are cultured using a biphasic culture system that is incubated for 3 weeks.

Burkholderia (formerly *Pseudomonas*) *cepacia* is an important respiratory pathogen in persons with cystic fibrosis. This organism grows well on routine media; however, selective media such as PC (for *Pseudomonas cepacia*) and oxidative-fermentative-polymyxin B-bacitracin-lactose agars are useful for its optimal recovery from respiratory secretions.

C. trachomatis can cause serious respiratory disease in infants, and *Chlamydia pneumoniae* causes illness in all age groups, but the most severe disease generally occurs in young children and the elderly. *Chlamydia psittaci* is primarily an animal pathogen but occasionally causes disease in humans. *C. pneumoniae* is difficult to culture and identify and *C. psittaci* presents a significant laboratory hazard; therefore, diagnosis of infections with these two agents usually relies on serology. Specimens for *C. trachomatis* culture are collected in a medium that contains antimicrobial agents. To maintain viability of chlamydiae, the specimen should be transported to the laboratory immediately, where it is inoculated to McCoy or buffalo green monkey cells using the shell vial technique. For delays in processing of as long as 48 hours, the specimen may be stored in the refrigerator; for longer delays, the specimen should be stored at -70°C or colder.

Nocardia spp may cause respiratory disease. Specimens for culture should be transported promptly to the laboratory; however, for short delays, storage at 4°C is acceptable. Direct examination of a Gram-stained smear of the specimen may reveal thin, beaded, gram-positive organisms that are branching, filamentous, or coccobacillary in appearance (Fig. 50.2). These organisms also are partially acid fast. There are no specific media for recovery of *Nocardia*. These organisms grow on Sabouraud dextrose agar with heart infusion supplementation, brain heart infusion agar, sheep blood agar, or tryptic soy agar and usually survive mycobacterial decontamination procedures and are recovered on media designed for mycobacterial culture. For heavily contaminated specimens, such as sputa, selective buffered charcoal yeast extract agar is recommended. Cultures are incubated for as long as 3 weeks at temperatures ranging from 25° to 37°C, but 37°C is optimal.

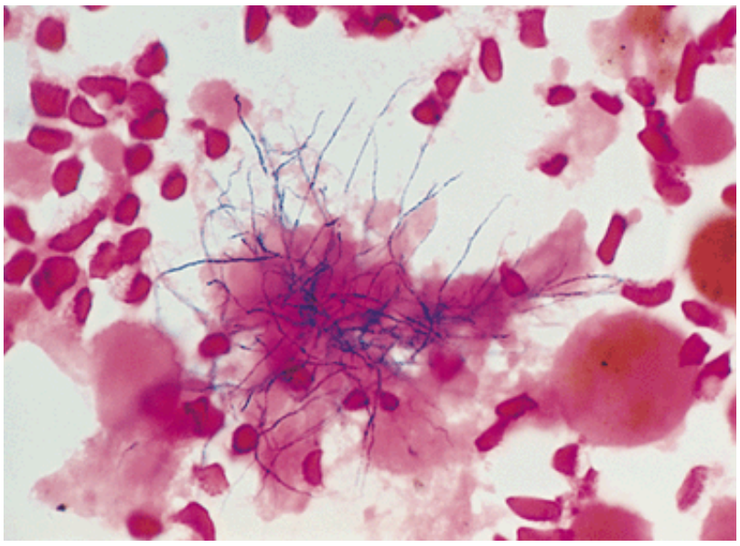

FIGURE 50.2. *Nocardia* spp in bronchoalveolar lavage fluid (Gram-Weigert stain, original magnification ×250). (Courtesy of Vicki J. Schnadig, M.D., Department of Pathology, University of Texas Medical Branch, Galveston, TX.)

To recover mycobacteria from contaminated respiratory tract specimens, the specimen must first be decontaminated and concentrated. A smear prepared from the concentrated specimen is stained for AFB. Fluorescent stains containing rhodamine and/or auramine are recommended for optimal sensitivity. Commercial nucleic acid amplification methods for direct detection of *Mycobacterium tuberculosis* complex in respiratory specimens are available. For culture, specimens are inoculated to at least one liquid and one solid medium and incubated for at least 6 weeks.

Viruses that cause respiratory tract disease in the nonimmunocompromised patients include RSV, influenza and para viruses, and adenoviruses. Diagnosis of infection with these viruses is generally accomplished utilizing a nasopharyngeal specimen; however, the virus may also be present in specimens obtained from the lower respiratory tract. Immunoassay reagents that can be used directly on specimens are available for all the viruses listed above. In most cases, culture is more sensitive than a direct assay. Traditional or shell vial culture may be performed. CMV is an important pathogen in immunocompromised individuals. For these patients, a more invasive specimen, such as the bronchoalveolar lavage, should be obtained for culture. Serology is the method of choice for diagnosing hantavirus infection.

Important fungal pathogens of the lower respiratory tract include *Coccidioides imitis*, *H. capsulatum*, *C. neoformans*, *Blastomyces dermatididis*, and *Aspergillus* spp. Fungi may be observed in a direct microscopic examination of a calcofluor/KOH preparation; however, fungal culture should also be performed. Specimens are plated to media containing antibacterial agents to prevent bacterial overgrowth and to media with and without

cycloheximide to inhibit saprophytic fungi. *Pneumocystis carinii* is an important fungal pathogen in the immunocompromised host. No culture methods are available for this organism; therefore, diagnosis relies on microscopic examination of a smear stained with Gomori methenamine silver stain (for detection of cysts) and Giemsa stain (for trophozoites), or DFA (detects both cysts and trophozoites).

Various parasites may be identified by microscopic examination of stained preparations of lower respiratory tract specimens. The modified AFB stain or an immunostain is recommended for detection of *C. parvum*, and the modified trichrome stain is recommended for microsporidia. Several stains including H&E and periodic acid–Schiff stain may be useful for detecting strongyloides, other helminths or helminth eggs, and amebae.

UPPER RESPIRATORY TRACT

Part of "50 - Specimen Collection and Processing for Microbiology"

Nasopharynx

Nasopharyngeal aspirates, washings, and swab specimens are primarily used for the diagnosis of viral respiratory infections but may also be submitted to diagnose pertussis, diphtheria, chlamydia infections, and candidiasis, as well as to identify carriers of *N. meningitidis* or *S. aureus*. Nasopharyngeal cultures have little utility in the diagnosis of otitis media; however, they may have epidemiologic value for monitoring the antibiotic susceptibility of *S. pneumoniae* in children.

The preferred specimen for the recovery of *B. pertussis* is nasopharyngeal cells collected with a small-tipped calcium alginate or Dacron swab. Rayon or cotton swabs should not be used because they may contain fatty acids that are toxic to the organism. Optimally, media should be inoculated at the bedside; however, if this is not feasible, the swab specimen may be transported to the laboratory in special transport media. For delays in transport of less than 2 hours, a 1% casamino acid solution is suitable. For delays as long as 24 hours, Amies medium with charcoal can be used. If the transport time is more than 24 hours, Regan-Lowe transport medium should be used.

Direct examination of the nasopharyngeal specimen for *B. pertussis* is performed using a DFA procedure. Depending on the antibodies used, these assays may or may not distinguish between *B. pertussis* and *Bordetella parapertussis*. In general, DFA has relatively low sensitivity and specificity for the diagnosis of pertussis and should only be performed as a supplement to and not a replacement for culture.

The preferred medium for culture of *B. pertussis* is Regan-Lowe charcoal agar containing 10% horse blood with and without cephalexin. At the bedside, the specimen is inoculated onto one third of the agar surface, and in the laboratory, the inoculum is streaked further for isolation. Cultures are incubated at 35°C for 5 to7 days in a humid atmosphere without CO_2.

For the optimal recovery of *Corynebacterium diphtheriae*, both nasopharyngeal and throat specimens should be submitted for culture. When specimens are processed for culture with no delay, no special transport medium or conditions are required. For transport to a reference laboratory, it is recommended that the specimen be sent dry in a container with dessicant. Alternatively, the specimen may be placed in Stuart's or Amies transport medium or plated on a Loeffler's serum or tellurite medium and preincubated overnight at 35°C in 5% CO_2.

A smear of specimens for diagnosis of diphtheria may be stained with the Gram stain and examined for pleomorphic gram-positive rods or with Loeffler's methylene blue and examined for pleomorphic beaded rods with swollen ends and reddish-purple metachromatic granules. The presence of organisms having the described morphology by either staining method is consistent with but not specific for *C. diphtheriae*. The specimen should be planted onto Loeffler's serum medium or a medium containing potassium tellurite for the recovery of *C. diphtheriae*.

Infections with *C. pneumoniae* most often are diagnosed serologically; however, when culture is required, a nasopharyngeal swab specimen is optimal.

To identify carriers of *S. aureus*, nasal secretions are collected from the anterior nares with a polyester tipped swab, which is placed in a tube transport system and promptly delivered to the laboratory. The specimen is planted onto 5% sheep blood agar, an agar medium selective for gram-positive organisms (i.e., colistin-nalidixic acid agar or phenylethyl alcohol agar), or mannitol salt agar, a medium selective for staphylococci and helpful in differentiating coagulase-positive from coagulase-negative species.

To identify carriers of *N. meningitidis*, a nasopharyngeal swab specimen is collected and transported to the laboratory in Amies or Stuart's medium or plated directly onto medium and transported in a CO_2-containing system. A Gram-stained smear is not useful because *N. meningitidis* cannot be distinguished morphologically from other commensal neisseriae in the upper respiratory tract. Specimens should be inoculated onto an enriched medium such as blood or chocolate agar; modified Thayer-Martin, Martin-Lewis, or New York City medium may be used as well. The cultures are incubated in a humidified atmosphere at 35°C in the presence of 5% CO_2.

Nasopharyngeal aspirates and washes are superior to nasal swab specimens for the diagnosis of viral respiratory tract infection. Specimens collected for viral culture should be placed directly into a viral transport medium and maintained on ice during storage and transport to the laboratory. Specimens are centrifuged and the sediment is used to prepare a smear for immunostaining or for other immunoassays as well as to inoculate shell vial or traditional cell cultures.

Throat

Throat swab specimens are generally collected to diagnose group A streptococcal pharyngitis or to detect shedding of viruses such as enteroviruses, HSV, or CMV. The specimen is collected by depressing the tongue, inserting the swab between the tonsillar pillars and behind the uvula, and obtaining material from the pharynx without contamination with saliva. For bacterial culture, swabs should be placed in a tube transport system containing modified Stuart's medium, and for viral culture into viral transport medium and stored on ice during transport to the laboratory.

Throat swabs for bacterial culture are routinely only evaluated for group A streptococci. Many rapid direct tests for group A streptococci are commercially available, including EIA, optical

immunoassay, and nucleic acid–based assays. The reported sensitivities of the EIA tests vary between 31% and 95% (17,18). The sensitivity of the optical immunoassay also varies, but some reports suggest that it is higher than that of EIA (19,20). In general, the nucleic acid–based test has a sensitivity greater than 90% (21,22). The specificity of all the direct tests generally is 95% to 100%. When a rapid, direct test is requested, two throat swabs should be collected. If the direct test is positive, the second swab may be discarded, but if the direct test is negative, the second swab must be cultured because the sensitivity of the direct tests is less than 100%.

To culture group A streptococci, either blood agar or selective blood agar may be used. Cultures should be incubated in an environment with reduced oxygen tension, achieved by incubating anaerobically, in 5% to 10% CO_2, or in air with a coverslip placed over the primary inoculum. These culture conditions may also allow the recovery of groups C and G streptococci, both of which may cause pharyngitis but do not cause the serious sequelae associated with group A streptococci.

Throat swabs may be helpful in determining the etiologic agent of epiglottitis, a rapidly progressing cellulitis with the potential to cause obstruction of the airway (almost always due to *H. influenzae* type b but occasionally *S. aureus* or *S. pneumoniae*). The specimen should be collected only by a physician in a setting where intubation of the patient may be performed immediately, if necessary. Specimens should be plated to an enriched medium. Alternatively, the etiologic agent of epiglottitis may be determined using blood cultures.

Culture of throat specimens is important in the diagnosis of diphtheria. Direct evaluation of the specimen and culture should be performed as previously described for nasopharyngeal specimens.

Arcanobacterium haemolyticum may cause pharyngitis and peritonsillar abscess. The organism will be recovered on the selective media used to recover group A streptococci.

To detect *N. gonorrhoeae* in the throat, the swab specimen should be inoculated at the bedside or transported promptly and inoculated as soon as possible onto a selective medium, such as modified Thayer-Martin agar.

Vincent's angina is an acute necrotizing ulcerative tonsillitis, caused by *Fusobacterium* spp, *Borrelia vincentii*, and other anaerobes, that usually occurs in adults who have poor mouth hygiene or serious systemic disease. The laboratory diagnosis is made by direct examination of a smear of a swab specimen collected from the ulcerated lesion and stained with dilute carbol fuchsin (Ziehl-Neelson stain diluted 1:10 with water) or Gram stain. The presence of many spirochetes, fusiform bacilli, and polymorphonuclear leukocytes is presumptive evidence of this disease. Cultures of the involved area usually are not helpful because many species of anaerobes are present in the oral cavity; however, blood cultures should be collected because the illness commonly is accompanied by sepsis.

The enteroviruses and CMV do not cause pharyngitis but are shed from the throat for prolonged periods after illness. Both viruses as well as HSV, which may cause symptomatic disease or may be shed asymptomatically during periods of reactivation, may be recovered in cell culture.

TISSUES

Part of "50 - Specimen Collection and Processing for Microbiology"

Tissue specimens obtained surgically are procured at great expense and considerable risk to the patient; therefore, for optimal evaluation enough material should be collected to allow both histopathologic and microbiologic examination of the specimen. The histopathology of the lesion serves to differentiate between infection and malignancy and to distinguish between acute and chronic infectious processes. For chronic infections, potential pathogens include actinomycetes, *Brucella*, mycobacteria, fungi, and parasites, any one of which may be present in small numbers, emphasizing the need for adequate samples for examination and culture. Swabs are rarely adequate, and their use should be discouraged.

After collection, tissues should be placed in a sterile container and transported rapidly to the microbiology laboratory to prevent drying. For most procedures, the specimen is placed in a small amount of sterile medium or sterile saline and homogenized by mincing with a sterile scalpel, grinding with a mortar and pestle or tissue grinder, or using a stomacher. The resulting homogenate is used to prepare smears for Gram stain or other stains as indicated by the clinical picture and to inoculate culture media. The Gram stain should be examined for the presence of microorganisms, leukocytes, and squamous epithelial cells (suggestive of surface contamination). For routine culture, tissue should be inoculated to a liquid medium (9,10) and an enriched agar medium to recover fastidious organisms.

Optimally, bone marrow aspirates are submitted to the microbiology laboratory in collection tubes for the lysis centrifugation blood culture system. Pediatric tubes should be used when less than 7 mL is collected. Bone marrow may also be submitted in a sterile container or containers containing anticoagulants. However, because anticoagulants inhibit growth of some organisms (11,12), their use is not recommended. If the laboratory chooses to process a specimen containing an anticoagulant, the ordering physician must be informed about the limitations of the results.

Gastric biopsies or brushings may be submitted for detection of *H. pylori*, an important cause of gastritis and peptic ulcer disease. The organism can be observed in tissue sections using Giemsa, H&E, or Warthin-Starry silver stain. In addition, organisms can be visualized in stained touch preparations of minced tissue. The urease test is an indirect method for diagnosing *H. pylori* gastritis or peptic ulcer disease. The organism produces large amounts of this enzyme, which can be detected by inoculating urea broth or media with a portion of the homogenized tissue. Alternatively, a piece of tissue can be placed directly into a commercially available test kit. The urease test may be positive in as little as 15 minutes but should be held for 24 hours before issuing a negative report. To recover *H. pylori* in culture, the biopsy is homogenized in 0.9% saline and inoculated onto chocolate, brain heart infusion, or brucella agar supplemented with horse or rabbit blood. The optimal agar medium for recovery of *H. pylori* has not yet been determined. The cultures are incubated at 35°C in a microaerophilic, humid environment for 7 days.

B. henselae is one agent of cat scratch disease and bacillary angiomatosis. Because culture of this organism is very difficult, diagnosis

is most often made by clinical manifestations and exclusion of other diseases or by serologic analysis. The organism may be observed in sections of fixed tissue specimens stained with Warthin-Starry silver stain or a tissue Gram stain. This organism may rarely be recovered by inoculating the specimen onto freshly prepared heart infusion agar containing 5% to 10% defibrinated rabbit or horse blood, chocolate agar, or sheep blood agar. The plates are incubated in high humidity at 35°C for as long as 1 month.

Legionella spp, *Nocardia* spp, *C. diphtheriae*, and mycobacteria are recovered using methods previously described. If an infection with a zygomycete is suspected, the tissue should be carefully minced rather than ground before microscopic examination and culture to preserve the hyphal elements. To recover pathogenic fungi, media with antibacterial agents and cycloheximide should be inoculated if there is a possibility of bacterial and fungal contamination of the specimen.

Tissue biopsies are recommended for the diagnosis of tissue parasites. In the liver and spleen, *Echinococcus*, *E. histolytica*, *L. donovani*, and microsporidia may be observed. In muscle, *Taenia solium*, *Trichinella spiralis*, *Onchocerca volvulus*, and *T. cruzi* and microsporidia are possible pathogens. Impression smear and tease or squash preparations may be examined in addition to the standard histologic preparation.

URINE

Part of "50 - Specimen Collection and Processing for Microbiology"

Acceptable methods of urine collection include midstream clean catch (preferably a first voided morning specimen), catheterization, and suprapubic aspiration. Foley catheter tips should not be accepted for culture because they usually are contaminated with urethral organisms. Most commonly, the midstream flow of a clean-catch urine is collected. All urine specimens should be transported promptly to the laboratory and processed within 2 hours of collection. If a delay in transport or processing cannot be avoided, specimens may be refrigerated for as long as 24 hours. Collection kits containing preservatives to maintain the bacterial population stable for 24 hours at room temperature are commercially available, but they offer no advantage over refrigeration.

The urinary tract above the urethra is sterile in healthy humans, but the urethra normally is colonized with many different bacteria, so urine specimens collected by a noninvasive method become contaminated during passage. Commensal bacteria are differentiated from potential pathogens in urine by quantitative culture. Originally, growth of 10^5 CFU/mL or greater was considered highly indicative of infection, but this criterion has been modified for different situations. For example, in young, sexually active women with acute urethral syndrome, as few as 10^2 CFU/mL is significant in the presence of concomitant pyuria. True urinary infections associated with fewer than 10^5 CFU/mL may occur in infants and children; in males; and in persons who are catheterized, recently treated with antimicrobial agents, drink large amounts of fluids, have symptoms and concomitant pyuria, have urinary obstruction, or have pyelonephritis acquired from hematogenous spread.

Several methods for examination of urine to identify quickly those samples that most probably will not yield clinically significant organisms are available. These screening methods correlate well with culture when growth of 10^5 CFU/mL or greater is the reference, but they compare less favorably in the presence of lower colony counts (23). Screening urine specimens by staining with Gram stain is rapid and economical with regard to reagents but is very time-consuming. Finding one or more organisms per oil immersion field in a smear prepared from an uncentrifuged specimen correlates with growth of 10^5 CFU/mL or greater. Commercially available dipstick tests that combine nitrate reductase (an enzyme produced by most gram-negative bacilli that cause urinary tract infections) and leukocyte esterase (an enzyme produced by neutrophils) are rapid, inexpensive, and simple to perform, but their sensitivity is low. Several automated urine screening systems are also commercially available including the FiltraCheck-UTI colorimetric filtration system (Meridian Diagnostics Inc., Cincinnati, OH), the UTI screen Bacterial ATP Assay (Coral Biotechnology, San Diego, CA), and the Urine ID card (bioMerieux Vitek, Inc., Hazelwood, MO).

Quantitative bacterial culture of a urine specimen is accomplished by inoculating appropriate media (e.g., blood and MacConkey agars) with a measured amount of urine, most commonly with a plastic or wire calibrated loop designed to deliver a known volume. A 0.001-mL loop is used to inoculate all urine specimens, except those collected from women with suspected acute urethral syndrome and suprapubic aspirates. Both of these latter specimens are inoculated with a 0.01-mL loop. The loop is inserted vertically into the well-mixed specimen, and the loopful of urine removed is spread over the surface of the agar plate by streaking from top to bottom in a vertical line and again from top to bottom perpendicular to the line in a back-and-forth fashion to facilitate the determination of an accurate colony count.

L. interrogans may be recovered from urine after the first week of illness and for several months thereafter. Urine should be processed as soon as possible after collection because acidity may harm the organisms. If a delay in processing is expected, the urine should be diluted 1:10 in 1% bovine serum albumin and stored at 5° to 20°C. Both undiluted urine and urine diluted 1:10, 1:100, and 1:1,000 in sterile buffered saline should be inoculated to Fletcher's, Ellinghausen-McCullough/Johnson-Harris, or polysorbate 80 medium with and without neomycin. Cultures are incubated at room temperature for at least 6 weeks.

Mycobacteria can be recovered from urine using procedures previously discussed.

Many commercial bacterial antigen test kits developed to diagnose bacterial meningitis include procedures for use on urine specimens. In general, these kits should not be used on urine specimens for the diagnosis of bacterial meningitis, and their use on CSF should be limited, as discussed previously. Of note, in 1996, the U.S. Food and Drug Administration issued a product alert specifically cautioning against the use the group B streptococci antigen kits on urine specimens because of the risk of both false-positive and -negative results.

A radioimmunoassay and an EIA are commercially available for the detection of the *Legionella pneumophila* serogroup 1 antigen in urine. Antigen may be detectable for months in the urine after an infection. These assays have sensitivities of 80% or greater when performed on concentrated urine and specificities

of greater than 98%. The drawback of both assays is that only one *L. pneumophila* serogroup is detected.

Recently, nucleic acid amplification assays have become commercially available for the detection of *N. gonorrhoeae* and *C. trachomatis* in both male and female urine samples. The assays have different specimen collection and handling instructions (refrigeration of specimen or addition of a special reagent immediately after collection) that must be followed to obtain accurate results.

Candida spp may be isolated from routine bacterial urine cultures. Recovery of other fungi from a urine specimen is best achieved by centrifuging the specimen and plating the sediment to fungal media. The *H. capsulatum* urine antigen test, which is performed in one reference laboratory, may be useful for diagnosis of disseminated histoplasmosis.

The most commonly isolated viruses from urine are CMV, HSV, and adenovirus. The shell vial technique is often used for CMV, and traditional cell culture is used to recover HSV and adenovirus.

T. vaginalis is probably the most frequently observed parasite in urine. The organism is identified in a wet mount of the specimen, examined under low power magnification for organisms with the characteristic shape and motility. *T. vaginalis* may also be recovered in culture using one of several commercially available media that is inoculated with the specimen at the time of sample collection. For both the wet mount and culture, the specimen should never be refrigerated because this causes the organisms to rapidly lose motility and die. Other parasites that may be seen in a wet mount or stained preparation of urine specimens are *Schistosoma haematobium*, microsporidia, or the microfilariae.

SKIN AND SUBCUTANEOUS LESIONS

Part of "50 - Specimen Collection and Processing for Microbiology"

Ideally, the infected material is aspirated with a needle and syringe. For transport, the material is expelled into a sterile container that is tightly capped and promptly delivered to the laboratory. If an aspirate cannot be obtained, swab specimens of exudate collected from the deep portion of the lesion are acceptable. A minimum of two swab specimens should be collected, one for culture, the other for preparation of smears for staining. For bacterial and fungal cultures, swabs may be placed in tube transport systems containing modified Stuart's medium. To recover anaerobes, an additional swab specimen must be collected and placed in an anaerobic transport system. For viral culture, the specimen (aspirate or swab) should be placed in viral transport media and kept on ice. Specimens should be transported promptly to the laboratory. If a delay in processing is unavoidable, specimens may be stored in the refrigerator, except those for recovery of anaerobes, which should be maintained at room temperature. Processing specimens involves preparation of a smear for Gram-stain examination and inoculation of appropriate media for culture. When swab specimens are processed, it is not necessary to inoculate a broth medium because organisms recovered from broth cultures of swab specimens are rarely significant (10,24).

If detection of mycobacteria is requested, specimens should be decontaminated and concentrated. The sediment is used to prepare a smear for staining for AFB and to inoculate mycobacterial media. If the specimen is from a skin lesion, a separate set of media should be inoculated and incubated at 30°C to enhance recovery of mycobacteria that preferentially grow at lower temperatures such as *Mycobacterium marinum*, *M. ulcerans*, *M. chelonae*, and *M. haemophilum*. To recover *M. haemophilum*, inoculation to a medium containing blood is also required. *M. leprae* may be observed in the acid-fast smear but will not grow *in vitro*. A nucleic acid amplification test for detection of *M. leprae* in tissue biopsies is available by special request through the Gillis W. Long Hansen's Disease Center in Carville, LA.

Exudates submitted for fungal culture should be examined carefully for granules, and, if present, they must be crushed and examined for fungal elements. Nail specimens submitted for dermatophyte examination should be cut into small pieces before microscopic examination and culture. Skin (and hair) may be examined without processing. Other specimens are minced and then examined microscopically for fungal elements in a calcofluor/KOH preparation. Specimens should be inoculated to media containing antimicrobial agents and cycloheximide to prevent overgrowth with bacteria and saprophytic fungi.

Viruses that cause a maculopapular exanthem will not be present in the lesion, which is caused by the host's hypersensitivity response to the infection. In contrast, virus is present in vesicular lesions. For vesicles of VZV, a Tzanck preparation should be prepared by carefully removing the top of the vesicle with a needle, soaking up the excess fluid with gauze, and pressing a slide against the base of the lesion. The smear is optimally examined using a direct immunofluorescent stain. The Tzanck smear may also be used to detect HSV, but the most sensitive method of detection is cell culture of the vesicular fluid and material collected from the base of the lesion. In most cases, culture is positive within 48 hours. Enteroviruses may also be isolated from samples of vesicular lesions.

Parasites present in ulcers and other skin lesions include *Leishmania* spp, *Acanthamoeba* spp, microfilaria, and *O. vulvulus*. As for other specimens, detection of parasites relies on microscopic evaluation of stained material.

Bacteriology

David L. Sewell

The purpose of a clinical microbiology laboratory is to provide accurate, timely, clinically relevant information about the identity, antimicrobial susceptibility, and significance of microorganisms isolated from a given specimen and to help prevent the spread of infection. The issue is complex because of the ubiquitous presence of microorganisms that colonize skin and mucous membranes; the transient presence of organisms in normally sterile sites; the enormous diversity of specimen type and source; the importance of the appropriate selection, collection, and transport of the specimen to the laboratory; and the need to interpret the significance of the recovery of a microorganism on the basis of the patient's history and symptoms. The routine workup of a specimen must be flexible enough to accommodate the special situations related to the patient's history and underlying condition. Compounding the problem is the rapidly increasing diversity of methods to perform these tasks, ranging from basic culture techniques to miniaturization and automation of conventional identification schemes to immunoassays and molecular methods. These techniques must be evaluated in the target population while remaining cost-effective. The operation of an efficient laboratory requires close communication between the laboratory and the clinician to expedite the early diagnosis and treatment of the patient.

This chapter attempts to address some of these points. The emphasis is on the type of disease produced, the diagnostic procedures used to identify the causative agent, interpretation of clinical significance, and some consideration of antimicrobial therapy. Detailed descriptions of methods are not presented, but the reader is directed to the excellent texts listed as suggested readings.

STAPHYLOCOCCI AND RELATED GENERA

Part of "51 - Bacteriology"

Microbiology

Until recently, the family Micrococcaceae consisted of the four genera *Staphylococcus, Micrococcus, Planococccus*, and *Stomatococcus* (1). However, the staphylococci and micrococci are not closely related based on DNA base composition, nucleic acid hybridization, or 16S ribosomal RNA analysis. The genus *Staphylococcus* is closely related to the new genus *Macrococcus* (2) and the broadly defined *Bacillus-Lactobacillus-Streptococcus* cluster (1,3). Members of the genus *Micrococcus* have been divided into the six genera *Micrococcus, Kocuria, Kytococcus, Nesterenkonia, Arthrobacter*, and *Dermacoccus* and are referred to as micrococci in this chapter. Members of the genera *Planococcus* and *Macrococcus* are infrequently, if ever, isolated from clinical specimens and are not discussed further. Micrococci and *Stomatococcus mucilaginosus* are common inhabitants of the skin and mucous membranes of humans and are infrequently implicated in significant infections.

Staphylococci are catalase-positive, gram-positive cocci, 0.5 to 1.5 μm in diameter that occur singly, in pairs, and in tetrads, and usually divide in more than one plane to form irregular grapelike clusters. The cell wall contains peptidoglycan and teichoic acid. Most species are facultative anaerobes, capable of growing in the presence of 10% NaCl and between 18° and 40°C. *Staphylococcus aureus* subsp *anaerobius* and *S. saccharolyticus* are catalase negative and grow best under anaerobic conditions. Most staphylococci grow well on noninhibitory media, but infrequently some strains may require hemin, menadione, or CO_2 for growth. Staphylococci are susceptible to lysis by lysostaphin but resistant to lysozyme.

Currently, there are 32 species and 15 subspecies of staphylococci, seven of which are coagulase positive (3). *S. aureus, S. epidermidis*, and *S. saprophyticus* are the most frequently isolated species of staphylococci, but more than half the other coagulase-negative species have been implicated as opportunistic pathogens (Table 51.1).

Spectrum of Disease

Because of the prevalence of staphylococci on skin and mucous membranes, they are implicated in various infections ranging from skin infections to bacteremia and meningitis. *S. aureus* often produces an acute, pyogenic infection that may lead to bacteremia and metastatic foci in other organs or sites in the body. Most common localized infections involve the skin and soft tissue, including pustules, furuncles, impetigo, cellulitis, and postsurgical wounds. Dissemination may result in a more serious infection such as bacteremia, endocarditis, meningitis, osteomyelitis, septic arthritis, pneumonia, pericarditis, or renal abscess. Factors predisposing to *S. aureus* infections include impaired integrity of the skin barrier (e.g., burns, surgery, ulcers, minor trauma, poor personal hygiene) and underlying conditions (e.g., eczema, acne, impaired humoral and cellular immunity, presence of foreign bodies) and diseases (e.g., malignancy, viral infections).

In addition to pyogenic infections, *S. aureus* is associated with toxin-induced diseases. The most common form is gastroenteritis. This self-limited disease occurs 2 to 6 hours after the consumption of food containing thermostable enterotoxins produced by *S. aureus* after contamination and improper storage of food. Symptoms consist of acute onset of nausea and vomiting, followed by diarrhea.

TABLE 51.1. PATHOGENIC SIGNIFICANCE OF *STAPHYLOCOCCUS* SPECIES

Species	Pathogenic Significance
S. aureus	Common
S. epidermidis	Common
S. saprophyticus	Common
S. cohnii	Uncommon
S. haemolyticus	Uncommon
S. hominis	Uncommon
S. saccharolyticus	Uncommon
S. simulans	Uncommon
S. warneri	Uncommon
S. intermedius[a]	Rare/undetermined
S. capitis	Uncommon
S. caprae[a]	Uncommon
S. auricularis	Rare/undetermined
S. xylosus	Uncommon
S. arlettae[a]	Rare/undetermined
S. equorum[a]	Rare/undetermined
S. gallinarum[a]	Rare/undetermined
S. kloosit[a]	Rare/undetermined
S. carnosus[a]	Rare/undetermined
S. sciuri[a]	Rare/undetermined
S. lentus[a]	Rare/undetermined
S. hyicus[a]	Rare/undetermined
S. lugdunensis	Uncommon
S. schleiferi	Uncommon
S. chromogenes[a]	Rare/undetermined
S. delphini[a]	Rare/undetermined
S. pasteuri[a]	Rare/undetermined
S. muscae[a]	Rare/undetermined
S. vitulus[a]	Rare/undetermined
S. piscifermentans[a]	Rare/undetermined
S. felis[a]	Rare/undetermined
S. lutrae[a]	Rare/undetermined

[a] Isolated from animals or animal products. Modified from Pfaller MA, Koontz F. Coagulase-negative staphylococci: rationale for species identification. *Am Soc Clin Pathol Check Sample* 1989; 32:1-7.

The other toxin-mediated diseases, toxic shock syndrome (TSS) and scalded skin syndrome, are often associated with infection or colonization with *S. aureus*. Scalded skin syndrome occurs primarily in children and is caused by an exfoliative toxin. TSS results from the *in situ* production of TSS toxin-1 (TSST-1) and is manifested by high fever, rash, profound hypotension, diarrhea, and shock. TSST-1 is a superantigen that stimulates T cells and induces the production of tissue necrosis factor and interleukin-1 (4). Initially, most patients were young menstruating women who used highly absorbent tampons, but now TSS is seen in men and women.

Coagulase-negative staphylococcal infections are usually indolent, associated with implanted prosthetic devices, usually caused by *S. epidermidis*, and hospital acquired. The exception is *S. saprophyticus*, which causes urinary tract infections in young sexually active women (5). Infections caused by other coagulase-negative staphylococci are increasing as the numbers of catheters and indwelling foreign bodies placed in patients increase. Usually these infections are associated with intravenous catheters, peritoneal dialysis catheters, vascular grafts, cerebrospinal fluid shunts, prosthetic joints, and heart valves. Other infections include endocarditis, bacteremia, surgical wound infections, osteomyelitis, peritonitis, infections after ocular surgery, or genitourinary infections associated with catheterization. *S. intermedius* (coagulase positive) is associated with dog-bite infections and may be misidentified as *S. aureus* (6).

Epidemiology

Staphylococci are ubiquitous in the human ecosystem, inhabiting the skin, mucous membranes, and gastrointestinal (GI) tract, and are a leading cause of both community- and hospital-acquired infections.

S. aureus colonizes the skin, perineal area, umbilical stumps, and sometimes the GI tract of neonates shortly after birth. The anterior nasal vestibule is the primary colonization site in adults. Approximately 20% to 40% of adults in the community are carriers, with much higher rates observed in hospital personnel, patients receiving periodic hemodialysis, and injection drug abusers. Although *S. aureus* can survive on inanimate objects in the environment, person-to-person transmission is the most important route of spread, especially on the hands of the hospital staff.

Staphylococcal food poisoning follows the contamination of foodstuffs by food handlers who are either infected or colonized, and the subsequent inadequate refrigeration of the contaminated food. Foods most commonly associated with this disease include meats, dairy products, and salads.

Infections by coagulase-negative staphylococci are usually hospital acquired, caused by *S. epidermidis*, and occur in patients with an indwelling foreign body. The patient's endogenous flora is the usual reservoir for coagulase-negative staphylococci infections, but transmission from hospital personnel to the patient has been documented. Hospital strains are usually multiple antibiotic resistant and colonize the skin and GI tract of hospitalized patients and hospital staff. Frequent hand washing and the use of gloves by hospital personnel are the most effective methods for minimizing the spread of staphylococci within the hospital environment. Most likely, coagulase-negative staphylococci gain access to deeper tissues during the insertion of the foreign body. Strains of coagulase-negative staphylococci often exhibit a propensity to adhere to plastics and other biomaterials by producing a capsular polysaccharide-adhesion followed by formation of a biofilm (7). This may allow the organisms to escape host defenses.

Of the coagulase-negative staphylococci, *S. epidermidis* is most frequently isolated from the skin (nares, head, axillae, leg, arms, toe webs) and represents 65% to 90% of all staphylococci recovered (8). *S. hominis* is the next most frequently isolated species. Other coagulase-negative staphylococcal species are only occasionally isolated from the skin (*S. simulans, S. xylosus, S. cohnii, S. warneri, S. saccharolyticus,S. haemolyticus*) or occupy special niches on the skin [*S. capitis* (head), *S. auricularis* (ear), *S. saprophyticus* (genitourinary skin)].

It is often difficult to differentiate infection from colonization and to document transmission and spread of specific strains within the hospital environment. Historically, phage typing, phenotypic markers, or antibiograms were used to identify an outbreak strain with a unique pattern. These techniques lack sensitivity and specificity for following transmission of coagulase-negative staphylococci. More recently, molecular and genetic techniques have provided excellent discrimination between species and strains. These methods include endonuclease restriction analysis of plasmid and chromosomal DNA, ribotyping, and nucleic acid probe hybridization.

Diagnostic Procedures

Microscopy

Gram-stained smears of clinical specimens provide rapid and presumptive evidence of staphylococcal infection. Staphylococci appear as gram-positive cocci (0.5 to 1.5 µm in diameter) and occur singly or in pairs, short chains, or small clusters (Fig. 51.1). These features are not always observed in clinical specimens in which staphylococci have been ingested by phagocytes or exposed to cell wall–active antimicrobial agents or are in the stationary phase of growth. In these situations, the bacteria may appear gram variable or negative. The Gram-stain morphology cannot definitively differentiate staphylococci from other gram-positive cocci seen in clinical specimens.

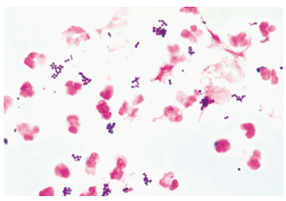

FIGURE 51.1. Gram stain of material containing polymorphonuclear neutrophils and *Staphylococcus aureus*.

Culture Techniques

Most staphylococci grow well on nonselective agar and broth media containing peptone (e.g., sheep blood agar, brain-heart infusion, thioglycollate). On sheep blood agar, growth occurs within 24 hours at 35° to 37°C. Colonies are 1 to 3 mm in diameter, usually opaque, smooth, and circular, and have a butyrous consistency. Colonies of *S. aureus* may be pigmented (yellow or yellow-orange) and exhibit β hemolysis on sheep blood agar, but these observations may also occur with some other staphylococcal species. Colonies of *S. epidermidis* are usually gray-white and nonhemolytic. Nutritionally variant staphylococci require supplementation of the medium with hemin, menadione, thiamine, or pantothenate for growth.

Specimens likely to be contaminated with other bacteria are inoculated onto a selective medium such as colistin-nalidixic acid (CNA) agar, phenylethyl alcohol (PEA) agar, mannitol-salt agar (MSA), Schleifer-Kramer agar, or lipase-salt-mannitol agar or tellurite-glycine agar. These media inhibit the growth of gram-negative bacteria. On MSA, *S. aureus*, *S. simulans*, *S. capitis*, and *S. saprophyticus* are differentiated from other clinical species of coagulase-negative staphylococci by their ability to produce acid from mannitol. Selective media should be incubated at least 48 hours for optimal growth.

Identification Methods

The initial identification of a suspected colony begins with colonial morphology, Gram-stain morphology, and a spot-catalase test to eliminate organisms such as streptococci and corynebacteria. When it is clinically relevant to differentiate between staphylococci and micrococci, three relatively simple tests can be used in the clinical laboratory (9). They include susceptibility to bacitracin (micrococci), lysostaphin (staphylococci), and furazolidone (staphylococci). Some clinically significant *Staphylococcus* species are identified by the colony morphology, growth characteristics, enzyme activities, and other biochemical characteristics listed in Table 51.2. In addition to these conventional methods, several commercial identification systems and automated instruments provide clinical laboratories with the capability of identifying the staphylococci with an accuracy of 70% to 90% (3, 10).

TABLE 51.2. IDENTIFICATION OF CLINICALLY SIGNIFICANT *STAPHYLOCOCCUS SPECIES*

Modified from Kloos WE, Bannerman TL. *Staphylococcus* and *Macrococcus*. In: Murray PR, Baron EJ, Pfaller MA, et al., eds. *Manual of clinical microbiology*, 7th ed. Washington, DC: American Society for Microbiology, 1999:272.

S. aureus, *S. epidermidis*, and *S. saprophyticus* can also be identified with a high degree of accuracy on the basis of colony morphology; coagulase and phosphatase activities; acid production from D-mannitol, D-trehalose, maltose, sucrose, and D-xylose; and novobiocin resistance. *S. aureus* is identified in most cases by the coagulase test. Although *S. intermedius*, *S. schleiferi* subsp *coagulans*, *S. lutrae*, *S. delphini*, and *S. hyicus* are also coagulase positive, they are rarely isolated from humans. The standard tube test detects free staphylocoagulase and is the more definitive test, whereas the slide coagulase test detects clumping factor. These two tests have been replaced in large part by the commercially available particle agglutination tests that measure clumping factor and protein A. These systems are quite accurate but may miss some methicillin-resistant *S. aureus* (11). Other alternative methods to the coagulase test are available (10).

Direct Antigen or Nucleic Acid Detection

Rapid identification of *S. aureus* in culture can be accomplished by the Accuprobe method (GenProbe, Inc., San Diego, CA). This test has also been used for the direct identification of *S. aureus* in blood cultures (12). Currently, there is no commercially available nucleic amplification test for the direct detection of *S. aureus* in clinical specimens.

Serologic Procedures

The serologic response to various extracellular products and cell-wall components of *S. aureus* has been measured in an attempt

to diagnose some forms of staphylococcal disease. With the exception of antibodies to TSST-1, most of these tests have little clinical utility.

Antibodies to TSST-1, measured by immunodiffusion (ID), radioimmunoassay (RIA), and enzyme immunoassay (EIA), may aid in the diagnosis of TSS, but TSS is usually diagnosed by clinical signs and symptoms. The patient also has TSS if no antibodies are detected, but the strain produces TSST-1 because convalescent antibodies are detected in only approximately 40% of TSS patients.

Interpretation of Results

Staphylococci are frequently isolated in the clinical microbiology laboratory because of their ubiquitous presence on the skin and mucous membranes of humans. The isolation of *S. aureus* from an infected site should be considered clinically relevant until proven otherwise.

The complete identification of coagulase-negative staphylococci should be considered on clinically significant isolates recovered from normally sterile body sites, peritoneal dialysates, tissue, or multiple sets of blood cultures. The clinical relevance of a specific isolate is based on clinical, microbiological, and epidemiologic criteria such as the immune status and presence of a foreign body in the patient, the species of *Staphylococcus* isolated, and the number of specimens from which the identical strain is isolated.

Therapeutic Considerations

Accurate antimicrobial susceptibility testing must be performed on all clinically significant isolates of staphylococci because of their variable resistance to commonly used antimicrobial agents. Resistance to methicillin and other semisynthetic penicillins is widespread throughout the world. In addition, methicillin-resistant *S. aureus* and other staphylococci usually exhibit cross-resistance to other β-lactam antibiotics as well as increased resistance to macrolides, clindamycin, aminoglycosides, trimethoprim-sulfamethoxazole, tetracyclines, and quinolones. Most strains are susceptible to rifampin, but this drug cannot be used alone because of the high mutation rate to resistance. Currently, the drug of choice for the empiric treatment of infections caused by methicillin-resistant staphylococci is vancomycin until susceptibility to other β-lactam antibiotics can be determined.

The recent appearance of *S. aureus* and coagulase-negative staphylococci with reduced susceptibility to vancomycin [minimum inhibitory concentration (MIC), 4 to 16 mg/mL] is a serious concern (13,14 and 15). Infection control guidelines for the prevention and control of staphylococci with increased resistance to vancomycin have been developed (16,17).

Summary and Conclusions

S. aureus, S. epidermidis, and *S. saprophyticus* are associated with the majority of staphylococcal infections. *S. aureus* causes infections of skin, soft tissue, bloodstream, and internal organs; staphylococcal food poisoning; and toxic shock syndrome. *S. epidermidis* causes nosocomial infections, especially in patients with indwelling foreign bodies. *S. saprophyticus* causes urinary tract infections in young women.

Staphylococci are usually transmitted from person to person with the primary reservoir being the skin and mucous membranes of humans and animals. Most staphylococci are easily isolated on routine media and are identified by morphology, conventional biochemical and metabolic characteristics, and commercial identification kits. Because of the variability of resistance to antimicrobial agents (especially the penicillinase-resistant penicillins), susceptibility testing must be performed.

STREPTOCOCCI, ENTEROCOCCI, AND RELATED GENERA

Part of "51 - Bacteriology"

Microbiology

Molecular taxonomic studies have clarified, to some extent, and expanded the taxonomy of the streptococci and related genera.

The taxonomic picture is improving but will continue to change in the coming years. Although the new taxonomic information is critical for a better understanding of streptococci and related genera, the older identification schemes based on phenotypic characteristics are still useful in the clinical laboratory. The preliminary classification of streptococci is based on their hemolytic action on blood agar and differentiates β-hemolytic, α-hemolytic, and nonhemolytic (γ-hemolytic) groups. Further differentiation (especially of the β-hemolytic streptococci) is achieved by serologic classification based on the presence of group-specific antigens and currently performed by commercial particle agglutination kits. With the exception of the group D streptococci, the majority of the α-hemolytic (viridans streptococci) and nonhemolytic species are classified by physiologic tests. The interrelationship of these three schemes is depicted in Table 51.3.

TABLE 51.3. CLASSIFICATION OF *STREPTOCOCCUS* SPECIES MOST FREQUENTLY CAUSING HUMAN INFECTIONS

Species	Group Antigen	Hemolysis	Sherman Classification	Clinical Features
S. pyogenes (large colony)	A	β, γ	Pyogenic	Pharyngitis, tonsillitis, otitis media, mastoiditis, sinusitis, scarlet fever, erysipilus, cellulitus, impetigo, pneumonia, toxic shock-like syndrome, endometritus, bacteremia. Nonsuppurative sequelae: acute rheumatic fever, acute glomerulonephritis
S. agalactiae	B	β, γ	Pyogenic	Neonatal sepsis and meningitis, chorioamnionitis, puerperal sepsis, bacteremia, skin and soft tissue infection, urinary tract infection
S. dysgalactiae subsp. *equisimilis* (large colony)	C, G	β	Pyogenic	Upper respiratory, skin and soft tissue infections, bacteremia, deep tissue infection
E. faecalis (other enterococci)	D	α, β, γ	Enterococci	Endocarditis, urinary tract infection, bacteremia, intraabdominal abscess, soft-tissue infection
S. bovis	D	γ	Nonenterococci	Endocarditis, bacteremia
S. pneumoniae	—	α	—	Pneumonia, bacteremia, meningitis, otitis media, sinusitis
S. anginosus/milleri (*S. intermedius, S. constellatus*)	F,A,C,G, None	α, β, γ	Pyogenic viridans	Endocarditis, bacteremia, deep-tissue infection
S. mitis, S. mutans *S. salivarius* *S. morbillorum*	None or A-O	α, γ	Viridans	Endocarditis (*S. mutans* major cause of caries)
Abiotrophia	None	α	Viridans	Endocarditis
Other viridans streptococci	None	α	Viridans	Rare

The β-hemolytic streptococci with Lancefield group A, C, or G antigen are further divided into large (more than 0.5 mm in diameter) and small (less than 0.5 mm in diameter) colonies (18). The large colony groups are pyogenic, and the small colony streptococci belong to the *S. milleri* or *S. anginosus* group (*S. anginosus, S. intermedius, S. constellatus*), which also includes non-β-hemolytic, viridans streptococci. Other β-hemolytic streptococci are principally animal pathogens and include *S. dysgalactiae* subsp *dysgalactiae* (groups C and L), *S. equi* subsp *equi* (group C), *S. equi* subsp *zooepidemicus* (group C), and *S. canis* (group G).

Historically, the group D streptococci were divided into enterococcal and nonenterococcal strains based on tolerance to salt. Currently, the enterococci are placed in the genus *Enterococcus*, which is composed of 17 species (19). *E. casseliflavus* and *E. flavescens* are closely related at the species level (20). *E. faecalis*, and *E. faecium* are isolated most often from human sources. The nonenterococcal group D isolates *S. bovis, S. alactolyticus*, and *S. equinus* remain as streptococci.

The non-β-hemolytic strains (viridans) include *S. pneumoniae* and five groups: the Bovis group (*S. bovis, S. alactolyticus, S. equinus*), the Mutans group (*S. mutans, S. sobinas, S. cricetus, S. rattus, S. downei, S. macacae*), the Salivarius group (*S. salivarius, S. vestibularis, S. thermophilus*), the Mitis group (*S. mitis, S. sanguis, S. parasanguis, S. gordonii, S. crista, S. oralis*), and the Anginosus group (*S. anginosus, S. intermedius, S. constellatus*) (18). The nutritionally variant streptococci were considered forms of *S. mitis* or *S. sanguis* but are not genetically related to the streptococci and are placed in a new genus, *Abiotrophia*.

The medically important streptococci are catalase-negative, gram-positive cocci and spherical to ovoid (less than 2 μm in diameter) and tend to form pairs or chains. Some species may appear as short rods on initial isolation. Most species are facultative anaerobes, exhibit a fermentative metabolism, and have complex but variable nutritional requirements. Growth on solid agar is enhanced by blood, serum, or glucose.

The examination of gram-positive cocci by molecular-based taxonomic methods has characterized several genera that are opportunistic pathogens in compromised patients but are infrequently isolated from clinical specimens (21). These organisms can be preliminary differentiated based on morphology of cells grown in broth. The genera *Leuconostoc, Lactococus*, and *Globicatella* appear as coccobacilli in pairs and chains, whereas *Aerococcus, Alloiococcus, Gemella, Helcococcus*, and *Pediococcus* are spherical cocci in pairs, tetrads, or clusters. These bacteria are catalase negative or weakly positive. *Leuconostoc* and *Pediococcus* (and *Lactobacillus*) are resistant to vancomycin and may be confused with viridans streptococci (22). Additional characteristics useful for differentiation of these genera include gas produced from glucose (positive only for *Leuconostoc*),

pyrrolidonyl arylamidase activity (negative for *Leuconostoc, Pediococcus*, and *A. urinae*), and leucine aminopeptidase activity (negative for *Leuconostoc, A. viridans, Helcococcus*, and *Globicatella*).

Spectrum of Disease

Streptococci are part of the normal flora that cause a wide variety of infections, including upper respiratory infections, skin and soft-tissue infections, bacteremia, meningitis, urinary tract infections, deep-tissue infections, endocarditis, arthritis, and osteomyelitis, as well as nonsuppurative sequelae observed after infection by *S. pyogenes* (Table 51.3).

Group A streptococci (*S. pyogenes*) are important human pathogens and a major cause of upper respiratory and skin infections. Suppurative complications of streptococcal pharyngitis include parapharyngeal space abscesses, otitis media, sinusitis, mastoiditis, and meningitis. Bacteremia may lead to infections in the joints, bones, or other foci. In addition, group A streptococci can cause a severe invasive infection associated with a TSS-like syndrome. It is believed that the pyrogenic exotoxins function as superantigens, capable of inducing the release of lymphokines and cytokines, causing the TSS-like syndrome (23). Nonsuppurative sequelae after pharyngitis include acute rheumatic fever (ARF) and acute glomerulonephritis (AGN). Skin infections precede the development of AGN but not ARF.

Group B streptococci (*S. agalactiae*) are a major cause of infections in neonates and postpartum women, including neonatal sepsis and meningitis, puerperal sepsis, and chorioamnionitis. The most common adult infections occur in postpartum women and are associated with the genital tract, but various other infections also occur. Age, diabetes mellitus, malignancy, and liver disease are important risk factors.

Group C and G streptococci are not frequent human pathogens but are associated with infections of the respiratory tract and skin, otitis media, bacteremia, pneumonia, meningitis, neonatal sepsis, puerperal sepsis, endocarditis, and arthritis.

Of the enterococci, *E. faecalis* causes disease more frequently than the other species and is implicated in the following infections: endocarditis, intraabdominal infections, soft-tissue infections, urinary tract infections, and bacteremia. It is rarely associated with meningitis or pneumonia.

The group D streptococci (nonenterococcal) *S. bovis* causes primarily endocarditis and bacteremia, which is often associated with malignancies or instrumentation of the GI tract.

S. pneumoniae is a major pathogen in infants and adults, especially the elderly or persons with asplenia, sickle cell disease, or immune disorders. It is the most frequent cause of community-acquired pneumonia and may cause mastoiditis, sinusitis, otitis media, meningitis, arthritis, and peritonitis.

S. anginosus/milleri group is associated with abscesses in various areas of the body (e.g., skin, brain, liver, abdomen, cervicofacial area, and lung).

The viridans streptococci are usually associated with cases of endocarditis but are increasingly recovered from neutropenic patients (24,25).

Epidemiology

The epidemiology of the streptococci is as diverse as the number of species in this group, which reside on the mucous membranes of the respiratory, genital, and GI tracts. Group A streptococcal pharyngitis is a common infection of young school-aged children, with a peak incidence occurring during the winter and spring. Transmission is ordinarily by person-to-person contact and via nasal or salivary droplets. Outbreaks owing to food or water contamination are also documented. Crowding, such as occurs in schools and military barracks, favors transmission. Asymptomatic carriage of group A streptococci occurs in the throats of as many as 20% of school-aged children. The epidemiology of ARF parallels that of streptococcal pharyngitis.

Streptococcal pyoderma occurs primarily as an endemic disease in children but can occur in epidemics. Crowding, a tropical or subtropical climate, and poor living conditions favor the spread of skin streptococci. AGN may occur after streptococcal pharyngitis or pyoderma.

Group B streptococci colonize the genital and/or lower GI tract of pregnant women at a rate ranging from 5% to 40%. Colonization of the newborn occurs either *in utero* or more commonly during delivery. Nosocomial transmission also occurs, especially in the setting of heavy maternal colonization and crowded nursery conditions.

Enterococci and group D streptococci are found as normal flora in the GI and genital tract of humans. Nearly all adults harbor *E. faecalis* as well as *E. faecium* (26). *S. bovis* occurs in 5% to 10% of normal adults but is found more frequently in patients with colon cancer.

S. pneumoniae is part of the normal oropharyngeal flora in 5% to 70% of adults. Transmission is person to person and is increased by crowding such as occurs in military barracks. Of the 84 capsular serotypes, the majority of infections are caused by the lower number serotypes.

The viridans streptococci constitute 30% to 60% of the oral flora, with various species residing in different ecological niches of the oropharynx. They also colonize the mucous membranes of the urogenital and GI tracts.

Diagnostic Procedures

Microscopy

Streptococci and enterococci are typically ovoid or lancet shaped but may elongate to resemble short rods. Most often they occur in pairs or chains when grown in broth (Fig. 51.2). *S. pneumoniae* appears with the adjacent cell wall flattened, lancet shaped, and encapsulated and occurs predominantly in pairs but may form short chains (Fig. 51.3). It may occasionally appear to be gram-negative if observed in phagocytes, if the patient is receiving antimicrobial agents, or if the culture is old. The other related genera usually appear coccoid except that *Gemella haemolysans* is easily decolorized and may appear gram negative.

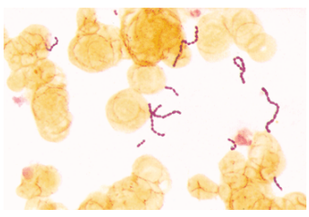

FIGURE 51.2. Gram stain of blood culture broth positive for streptococci.

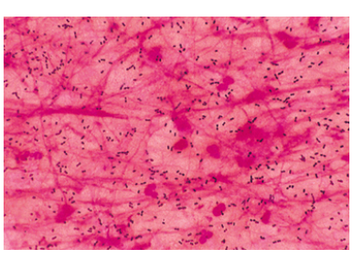

FIGURE 51.3. Gram stain of *Streptococcus pneumoniae* in sputum.

Culture Techniques

Streptococci and enterococci grow well on rich, nonselective broths and agars such as trypticase soy, heart infusion, or Todd-Hewitt,

which may be supplemented with blood. Selective agars such as PEA or CNA can be used with specimens containing gram-negative organisms. Trimethoprim-sulfamethoxazole is added to sheep blood agar to improve the recovery of group A streptococci from throat cultures. *Abiotrophia* species are recovered by satelliting around a *Staphylococcus* streak, by adding pyridoxal to the growth medium, or by placing a disk containing pyridoxal on the agar plate.

Streptococci and enterococci are facultative anaerobes, often requiring 5% to 10% CO_2 (especially *S. pneumoniae*) for optimal growth. Approximately 90% to 95% of *S. pyogenes* isolates from patients with pharyngitis can be recovered from sheep blood agar incubated in air or sheep blood agar (with or without trimethoprim-sulfamethoxazole) incubated anaerobically for 48 hours (27).

The Centers for Disease Control and Prevention (CDC) recommend that all pregnant women should be screened for the perineal vaginal carriage of group B streptococci at 35 to 37 weeks of gestation with a selective broth medium (28). To achieve a more rapid detection of group B streptococcal colonization, growth in the selective broth is detected by a molecular nucleic acid probe assay (29,30).

Identification Methods

The initial characterization of streptococci and enterococci is based on catalase reaction, hemolysis, colony morphology, and source of the specimen. Streptococci are catalase negative, but weak reactions may occur, especially with enterococci and some related genera. The type of hemolytic reaction is usually observed with surface colonies, but the most accurate method uses subsurface colonies. Group A streptococci produce large zones of ß hemolysis; group B streptococci produce large colonies with a small zone of ß hemolysis; enterococci usually have large gray colonies with no hemolysis (may be α- or rarely ß-hemolytic), and the viridans streptococci are small, raised colonies with α or no hemolysis. *S. pneumoniae* is α-hemolytic with dome-shaped colonies that may have a depressed center or appear mucoid.

Cultures of the *S. anginosus*/*S. milleri* group may produce a buttery or caramel odor (31). Clinically significant streptococci and enterococci are presumptively identified by the tests listed in Table 51.4. Group A streptococci are inhibited by bacitracin and hydrolyze L-pyrrolidonyl-ß-naphthylamide (PYR). Group B streptococci are hippurate and CAMP positive and PYR negative. Other ß-hemolytic streptococci are negative for these tests but are susceptible to trimethoprim-sulfamethoxazole. The ß-hemolytic streptococci are definitively identified by detection of the group-specific cell-wall carbohydrate antigen by any of a number of commercially available particle agglutination kits.

TABLE 51.4. PRESUMPTIVE IDENTIFICATION OF STREPTOCOCCI AND ENTEROCOCCI

		Susceptibility		Hydrolysis of						
Category	Hemolysis	Bacitracin	SXT[a]	Hippurate	PYR[a]	CAMP	Bile Esculin	Growth in 6.5% NaCl	Optochin and Bile[b]	VP[a]
Group A	ß	+	-	-	+	-	-	-	-	-
Group B	ß	-[c]	-	+	-	+	-	+[c]	-	-
ß-Hemotytic streptococci (not group A, B, or D)	ß	-[c]	+	-	-	-	-	-	-	-

Group D, non-*Enterococcus*	α, none	-	+[c]	-	-	-	+	-	-	+
Viridans group	α, none	-[c]	+	-[c]	-	-	-[c]	-	-	-[c]
S. pneumoniae	α	±	?	-	-	-	-	-	+	?
S. milleri group	α,ß	?	?	-	-	-	-	-	-	+

[a] SXT, trimethoprim-sulfamethoxazole; PYR, L-pyrroidonyl-ß-naphthylamide; VP, voges-proskauer, +, positive reaction or susceptible: -, negative reaction or resistant.

[b] Optochin susceptibility and bile solubility.

[c] Exceptions occasionally occur.

α-Hemolytic colonies are tested for bile solubility or susceptibility to optochin. *S. pneumoniae* is positive for both tests; other streptococci are negative. The slide bile solubility test is useful for the rapid presumptive identification of *S. pneumoniae* from blood cultures (32). Enterococci and group D streptococci are presumptively identified by hydrolysis of esculin in the presence of bile, growth in 6.5% NaCl, and hydrolysis of PYR. Further identification of enterococci, group D streptococci, and the viridans streptococci require additional identification schemes (18,19,21), or identification by commercial kits. Strains belonging to the *S. anginosus*/*S. milleri* group can be presumptively identified by positive reactions for Voges-Proskauer and arginine hydrolysis, esculin hydrolysis, and lack of growth in 6.5% NaCl (33).

Direct Antigen or Nucleic Acid Detection

Several commercial particle agglutination kits are available for the direct detection of streptococcal cellular or capsular antigens in body fluids [e.g., cerebrospinal fluid (CSF), urine, serum] or throat swabs. Many factors affect the sensitivity and specificity of the test, including the type of specimen and the particular kit.

The identification of group A streptococcal antigen from throat swabs is a rapid method to aid in the diagnosis of streptococcal pharyngitis. A positive test is an excellent predictor of infection, but the sensitivity is often lower than 90%, especially when few organisms are present. A negative test should be followed with a culture.

The direct detection of other streptococcal antigens in clinical specimens is possible but generally not clinically useful. The Neufeld capsular swelling reaction (or Quellung reaction) is another method to detect directly pneumococci in sputum or CSF.

Antiserum is not widely available but can be obtained from the Statens Seruminstitut, Copenhagen, Denmark.

Molecular probe assays are commercially available for the direct detection of group A streptococci in throat swabs, group B streptococci in vaginal specimens, and culture identification of enterococci and *S. pneumoniae*.

Serologic Procedures

The detection of antibodies to streptococcal cell-wall antigen or extracellular products aids in the diagnosis of recent group A streptococcal infection. These tests are used most frequently for the diagnosis of ARF or AGN in the absence of a recently documented infection. The most helpful tests are antistreptolysin O, antihyaluronidase, and antideoxyribonuclease B. The lack of significant titers to these three antigens makes the diagnosis of ARF very doubtful. In cases of AGN, antistreptolysin O titers are usually very low.

Interpretation of Results

The clinical relevance of the isolation of any of the streptococcal species depends on the type of specimen from which the organism was recovered and knowledge of the spectrum of infections caused by the organism. In addition, one must consider the clinical signs and symptoms of the patient because all the streptococci are either normal human flora or can be carried asymptomatically. In general, the isolation of ß-hemolytic streptococci and *S. pneumoniae* should be interpreted as clinically relevant unless shown otherwise.

The clinical relevance of the recovery of enterococci and viridans streptococci from specimens is related to the severity of the infection. However, it is important to identify the *S. anginosus*/*S. milleri* group and *S. bovis* from body fluids and blood cultures because of their association with deep-seated abscesses and GI cancer, respectively.

Therapeutic Considerations

The ß-hemolytic streptococci remain uniformly susceptible to penicillin and vancomycin and thus do not require routine susceptibility testing. If erythromycin is considered, the isolate should be tested for susceptibility to the drug. Nearly all strains of *S. bovis* are susceptible to penicillin or ampicillin. The enterococcal isolates exhibit intrinsic resistance to the cephalosporins, clindamycin, aminoglycosides, and trimethoprim-sulfamethoxazole at standard concentrations. In addition, the most active agents such as the penicillins and vancomycin are not bactericidal, requiring the use of combination therapy (penicillin plus aminoglycoside) for life-threatening infections. High-level resistance to aminoglycosides is increasing. More disturbing is that several enterococcal species now exhibit resistance to vancomycin, the penicillins, and high levels of aminoglycosides.

A significant change has occurred in the antimicrobial susceptibility patterns of the viridans streptococci and *S. pneumoniae*. Penicillin resistance, resistance to the extended spectrum cephalosporins, and other antimicrobial agents are increasing worldwide. Pneumococcal strains demonstrating multiple resistance to erythromycin, tetracycline, trimethoprim-sulfamethoxazole, and chloramphenicol have been isolated. The extent of resistance to antimicrobics varies with the geographic area.

Although most strains of viridans streptococci, including the *S. anginosus*/*S. milleri* group, remain susceptible to penicillin, the frequency of penicillin resistance is increasing. Because of this unpredictable resistance to antimicrobics, susceptibility testing should be performed on clinically relevant isolates.

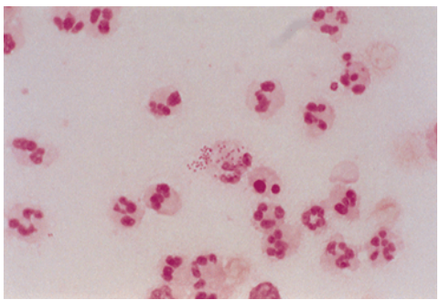

FIGURE 51.4. Gram stain of *Neisseria gonorrhoeae* in urethral exudate.

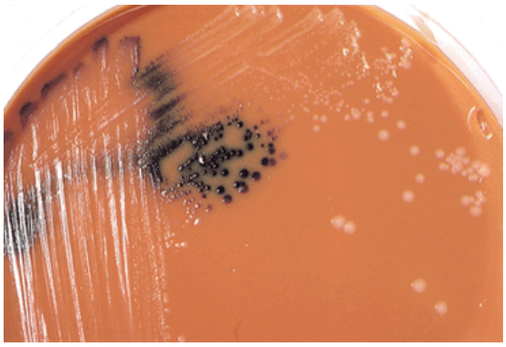

FIGURE 51.5. Colonies of *Neisseria gonorrhoeae* on Martin-Lewis medium after addition of oxidase reagent. Oxidase-positive colonies turn purple.

Summary and Conclusions

The streptococci and related genera represent a heterogeneous collection of medically important bacteria that cause a broad spectrum of infections (e.g., pharyngitis, skin and soft-tissue infections, deep-tissue infections, meningitis, and urinary tract infections). The application of nucleic acid techniques has improved the classification of the streptococci and related genera. Most strains can be isolated readily from clinical specimens with the use of enriched laboratory media and can be identified with a combination of serologic, physiologic, and biochemical tests. Commercial identification systems are also available as are kits for the direct detection of streptococcal antigen in clinical specimens. Although many of the streptococci remain susceptible to penicillin, increasing resistance to penicillins, cephalosporins,

aminoglycosides, and, in the case of enterococci, to vancomycin is being observed.

NEISSERIA AND BRANHAMELLA (*MORAXELLA*)

Part of "51 - Bacteriology"

Microbiology

The family Neisseriaceae contains four genera, *Neisseria, Moraxella, Acinetobacter*, and *Kingella*. The latter three genera are discussed later. In addition to the two commonly recognized pathogens *Neisseria gonorrhoeae* and *N. meningitidis*, the genus *Neisseria* contains several usually nonpathogenic species of human origin. These include *N. lactamica, N. sicca, N. subflava, N. mucosa, N. polysaccharea, N. flavescens, N. cinerea*, and *N. elongata*. *N. canis* and *N. caviae* are found in the upper respiratory tract of cats and *N. denitrificans* in guinea pigs. *N. kochii* is most likely a subspecies of *N. gonorrhoeae* (34).

The genus *Branhamella* contains four species, of which only *B. catarrhalis* is medically important. Because *Branhamella* has been designated as a subgenus within *Moraxella*, this species is referred to as *Moraxella (Branhamella) catarrhalis* (35). Because the taxonomic position remains uncertain and similar morphology to *Neisseria* and the common identification systems, the terminology *B. catarrhalis* is used here.

Neisseria and *Branhamella* species are gram-negative, oxidase- and catalase-positive cocci that appear most often in pairs with the adjacent sides flattened (kidney-bean shape). *N. elongata* exists as a small coccobacillus and is catalase negative. These bacteria are aerobic and grow best on enriched media containing blood or serum incubated in a humid atmosphere (5% to 7% CO_2) at 35°to 37°C.

Spectrum of Disease

The clinical spectrum of gonococcal infections involves primarily the mucous membranes of the lower genitourinary tract and less frequently those of the rectum, oropharynx, and conjunctiva. A small proportion of men may be asymptomatic, whereas as many as 80% of women may be asymptomatic or minimally symptomatic, contributing to the transmission of gonorrhea.

Gonorrhea in men usually presents as acute urethritis. If untreated, it may progress to prostatitis, epididymitis, or periurethral abscess, but these complications are rare. Anorectal gonorrhea occurs in approximately 40% of homosexual men and pharyngeal infection in approximately 25%.

Mucopurulent cervicitis is the primary manifestation in women, although involvement of the urethra, rectum, periurethral glands, and the Bartholin gland ducts may occur. The genital infection in 10% to 20% of women progresses to pelvic inflammatory disease (e.g., endometritis, salpingitis, tuboovarian abscess, peritonitis). Infected mothers may transmit the disease to their babies *in utero*, during delivery, or postpartum. The conjunctiva is the major site of infection in newborns. Gonococcal vulvovaginitis may occur in prepubertal girls.

Spread of gonococci from the genitourinary tract, the rectum, or the pharynx to the bloodstream occurs in 0.3% to 5% of infected persons. Disseminated gonococcal infection results in arthritis and dermatitis, with rare complications including meningitis, osteomyelitis, and endocarditis.

N. meningitidis causes bacteremia (meningococcemia), meningitis, chronic meningococcemia (with arthritis and dermatitis), arthritis, and pneumonia. Rarely, it has been implicated as the cause of sinusitis, endocarditis, pharyngitis, and urethritis. The presentation may be subacute to fulminant.

The other *Neisseria* species rarely cause diseases such as meningitis, bacteremia, endocarditis, pericarditis, and ocular infections. *B. catarrhalis* is an important cause of otitis media and sinusitis in children and bronchopulmonary infections in the elderly or persons with underlying pulmonary deficiency, malignancy, or immune deficit. Infrequently, *B. catarrhalis* is the cause of meningitis, septic arthritis, endocarditis, bacteremia, and ocular infections.

Epidemiology

Gonorrhea is a common, worldwide sexually transmitted disease, second only to *Chlamydia trachomatis* infections in the United States (36). Because *N. gonorrhoeae* colonizes only human mucous membranes, close contact between individuals is required for transmission. Risk factors include young age (younger than 24 years old), urban residence, low educational and socioeconomic background, nonwhite race, prostitution, and multiple sexual partners.

Humans are the only natural host for *N. meningitidis*. The organism resides on the nasopharyngeal mucosal membranes and is transmitted via respiratory droplets. The disease predominates in infants and children during endemic periods and shifts to older populations during epidemic periods. Although 13 serogroups are recognized, strains belonging to the serogroups A, B, C, Y, and W-135 are most frequently associated with disease.

The other *Neisseria* species are found as part of the oropharyngeal flora in humans. *B. catarrhalis* is not frequently isolated from the oropharynx of adults, but carriage is much higher in children, elderly adults, and patients with chronic pulmonary or respiratory tract disease (34,37).

Diagnostic Procedures

Microscopy

A Gram-stained smear of the appropriate clinical specimen revealing numerous polymorphonuclear leukocytes and many intracellular and extracellular Gram-negative diplococci is nearly diagnostic for *B. catarrhalis* pulmonary infection, gonococcal urethritis and cervicitis, and meningococcal meningitis (Fig. 51.4). The sensitivities of the Gram stain relative to the culture for the detection of gonococci in urethral exudates from symptomatic men, endocervical exudates, and rectal specimens are 95% to 100%, 40% to 60%, and 40% to 60%, respectively (38). The specificity of the smear is 95% to 100% for specimens other than rectal.

Culture Techniques

Neisseria species and *B. catarrhalis* can be isolated on 5% sheep blood and enriched chocolate agars. *N. gonorrhoeae* requires chocolate agar (grows poorly on blood agar). *N. meningitidis*

grows on blood agar, and the other *Neisseria* species and *B. catarrhalis* grow on media devoid of blood. Optimal growth occurs in 5% to 7% CO_2-enriched humid atmosphere at 35° to 37°C. Plates should be incubated for 72 hours. A selective medium (e.g., modified Thayer-Martin, Martin-Lewis, New York City medium) is used for the isolation of *N. gonorrhoeae* and *N. meningitidis* from sites that are heavily colonized with other bacterial flora. Some strains of *N. lactamica, N. cinerea, N. polysaccharea, N. subflava*, and *B. catarrhalis* grow on these selective media, and some strains of *N. gonorrhoeae* are inhibited.

N. gonorrhoeae appears as gray to white opaque glistening colonies of 0.5 to 1.0 mm in diameter (Fig. 51.5). *N. meningitidis* produces a round, translucent blue-gray colony that is approximately 1 to 2 mm in diameter. *B. catarrhalis* colonies are grayish-white, opaque, and smooth. The other *Neisseria* species may or may not produce pigmented colonies.

Identification Methods

The definitive identification of *Neisseria* species and *B. catarrhalis* is based on carbohydrate utilization tests and other physiologic characteristics (Table 51.5). *Kingella denitrificans* is included in the table because it grows on the *Neisseria* selective agar and produces acid from glucose. Consequently, it may be mistaken for pathogenic *Neisseria*. *N. gonorrhoeae* grows on selective media and produces acid from glucose, whereas *N. meningitidis* produces acid from both glucose and maltose. *B. catarrhalis, N. flavescens, N. elongata*, and *N. cinerea* are all asaccharolytic. *B. catarrhalis* is differentiated by the DNase reaction. *N. flavescens* produces polysaccharide in 1% sucrose, whereas *N. cinerea* does not. *N. elongata* is catalase negative.

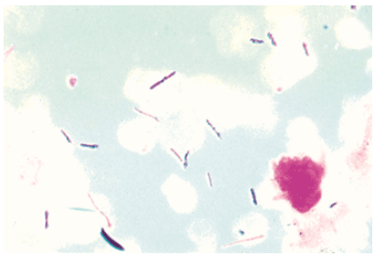

FIGURE 51.6. Gram stain of blood culture broth containing *Bacillus* species.

[a] Pigment observed in colonies on nutrient agar. Strains of *N. cinerea* and *N. lactamica* are yellow-brown and yellow pigmented when growth is harvested on a cotton applicator or smeared on filter paper.

[b] All *Neisseria* species and *B. catarrhalis* give a positive catalase best with 3% H_2O_2; *N. gonorrhoeae* strains give strong reactions with 30% H_2O_2 [superoxol] whereas other species are negative.

[c] Some strains may be inhibited by 5% sucrose; reactions may be obtained on a starch-free medium containing 1% sucrose. Strains of *N. gonorrhoeae, N. meningitidis*, and *N. kochii* do not grow on this medium.

[d] Results for tests in 0.1% (wt/vol) nitrite; *N. gonorrhoeae* strains and strains of some other species that are negative in 0.1% nitrite can reduce 0.01% (wt/vol) nitrite.

[e] Extra CO_2: VI, very important; I, important for growth; No, not needed for growth.

[f] ≥90% of vancomycin-susceptible strains of *N. gonorrhoeae* may not grow on TM or MTM medium.

[g] Some strains of *N. cinerea* may give a weak reaction in glucose in some rapid tests for the detection of acid from carbohydrates.

[h] Some strains of *N. cinerea* have been isolated on gonococcal selective medium, but are colistin susceptible and will not grow when subcultured on selective media. Colistin-resistant mutants of *N. cinerea* have not been described.

[i] Strains of *N. subflava* biovars give consistent patterns of acid production when tested in appropriate media.

[j] Some strains of *N. subflava* biovar *perflava* grow on gonococcal selective media in primary culture, are colistin resistant, and grow on selective media on subculture.

From Knapp JS. Historical perspectives and identification of *Neisseria* and related species. *Clin Microbiol Rev* 1988;1:417.

ONPG, *o*-Nitrophenyl-β-D-galactopyranoside; DNase, deoxyribonuclease; MTM, modified Thayer-Martin medium; ML, Martin-Lewis medium; NYC, New York City medium; +, most strains (≥90%) positive; -, most strains (≥90%) negative: d, some strains positive, some strains negative.

Commercial kits are available for the rapid identification of *Neisseria* and *B. catarrhalis* based on reactions with carbohydrate or chromogenic substrates. The accuracy and the number of species identified vary with the system. Confirmation of an isolate as *N. gonorrhoeae* can be done by fluorescent antibody techniques, particle agglutination tests, enzyme immunoassay (EIA), or by use of nucleic acid probe.

Direct Antigen or Nucleic Acid Detection

The direct detection of gonococci in clinical specimens can be performed by EIA, molecular probe, or nucleic acid amplification methods. The EIA (Abbott Laboratories, North Chicago, IL) is as sensitive and specific as the Gram stain for detecting gonococci in urethral and urine specimens (collected from symptomatic men) but less sensitive and specific than culture in women (39,40). The nucleic acid probe (GenProbe) is sensitive (more than 95%) and specific (more than 99%) for the detection of gonococci in endocervical and urethral specimens (41,42) but less sensitive for pharyngeal specimens (43). Highly sensitive and specific nucleic amplification tests are available for the detection of gonococci in urine (single and pooled), endocervical, and urethral specimens (44,45 and 46). Because of the use of urine specimens, the ease of transport, and the ability to detect concurrently *Chlamydia trachomatis*, the molecular methods are replacing the traditional culture.

Commercial particle agglutination kits are used for the direct detection of *N. meningitidis* in body fluids. The sensitivity of the procedure (70% to 90%) varies with the concentration of antigen and the kit. Most kits exhibit a high degree of specificity.

Serologic Procedures

There are no reliable commercially available tests to diagnose gonococcal infections serologically. The serologic determination of an individual's exposure to *N. meningitidis* is primarily of epidemiologic interest.

Interpretation of Results

The isolation of *N. gonorrhoeae* is always clinically relevant. Because *N. meningitidis* and *B. catarrhalis* are normal flora in the upper respiratory tract, their significance depends on the type and quality of the specimen from which they were recovered and the nature of the infectious process. Assessing the clinical significance of the other *Neisseria* species is more difficult because they rarely cause disease.

TABLE 51.6. MICROSCOPIC MORPHOLOGY OF GRAM-POSITIVE BACILLI

Genus	Microscopic Appearance	Comments
Kurthia	Rods in chains, cocci in old cultures	Strict aerobe
Arthrobacter	Marked rod-coccus cycle	Strict aerobe
Brevibacterium	Short rod, cocci in old cultures	Strict aerobe
Bacillus	Medium to large rods	Spores, decolorizes easily
Listeria	Small rods, coccobacilli, short chains	
Oerskovia	Coccoid, extensive branching filaments	
Rothia	Diphtheroid, coccoid, branching filaments	
Mycobacterium	Small to medium rods	Acid-fast, aerobe
Rhodococcus	Rod, coccoid, branching	Pink-coral; sometimes acid fast
Corynebacterium	Diphtheroid, coccobacilli	
C. matruchotii	Rod attached to filament (whip), branching	
Arcanobacterium	Diphtheroid, curved, pleomorphic	
Erysipelothrix	Rods, chains, coccobacilli, pleomorphic	
Nocardia	Branching filaments, short rods	Weakly acid-fast
Lactobacillus	Medium-thick rods, chains	Anaerobe but some grow in CO_2
Propionibacterium	Diphtheroid, some branching	Anaerobe but some grow in CO_2
Actinomyces	Rods, filaments with branching	Anaerobe but some grow in CO_2
Clostridium	Medium to large rods, some filaments	Anaerobe but some grow in CO_2

FIGURE 51.7. Gram stain of blood culture broth containing *Listeria*.

The isolation of a gram-negative, oxidase-positive diplococcus

on *Neisseria*-selective agar from a genital specimen is presumptively *N. gonorrhoeae*. The identity must be confirmed by additional testing, especially in low-risk patients because of the medicolegal implications of a diagnosis of gonorrhea (47).

Therapeutic Considerations

All clinically relevant isolates of *Neisseria* species and *B. catarrhalis* should be tested for ß-lactamase production because of the increasing incidence of plasmid or chromosomally mediated resistance to the penicillins. Ceftriaxone is recommended for the treatment of uncomplicated gonorrhea in adults. Additional consideration should be given for other coexisting sexually transmitted diseases. A follow-up culture should also be obtained after treatment. Penicillin, the extended spectrum cephalosporins, or chloramphenicol is recommended for the treatment of severe meningococcal infections. Rifampin is recommended for the chemoprophylaxis of the household contacts. Generally, the other *Neisseria* species are susceptible to penicillin.

The emergence of resistance to penicillins, tetracyclines, and spectinomycin in *N. gonorrhoeae* has prompted the CDC to recommend treatment with the extended spectrum cephalosporins and the newer fluoroquinolones (48,49). Resistance to ciprofloxacin and ofloxacin has been reported, especially in the Far East. If patients fail to respond to treatment, the isolate should be recovered from culture and susceptibilities determined. As always, the patient should be evaluated for other sexually transmitted diseases.

Approximately 85% of strains of *B. catarrhalis* produce ß-lactamase and should be considered resistant to penicillin, ampicillin, and amoxicillin (50). The majority of isolates are susceptible to cephamycins, ß-lactamase-resistant penicillins, trimethoprim-sulfamethoxazole, fluoroquinolones, and the newer macrolides.

Summary and Conclusions

The two clinically important species of *Neisseria* are *N. gonorrhoeae* (causing gonorrhea with all the clinical manifestations) and *N. meningitidis* (causing meningococcemia and meningitis). *B. catarrhalis* is an important cause of otitis media and sinusitis in children and bronchopulmonary infections in adults.

The definitive laboratory diagnosis is made by isolation and identification of the etiologic agent. Numerous commercial systems are available for identification of *Neisseria* and *B. catarrhalis*. Direct detection of gonococci by EIA and molecular methods are available.

The emergence of *N. gonorrhoeae* strains resistant to the penicillin, tetracyclines, and fluoroquinolones has resulted in the use of more third-generation cephalosporins for the treatment of infections.

GRAM-POSITIVE AEROBIC TO FACULTATIVELY ANAEROBIC BACILLI

Part of "51 - Bacteriology"

Microbiology

The gram-positive aerobic to facultatively anaerobic bacilli are a taxonomically diverse group of bacteria that have been grouped together based primarily on cellular and colony morphology, endospore formation, and aerobic growth. When a gram-positive rod is isolated from a clinical specimen, the genera that should be initially considered include *Bacillus, Erysipelothrix, Corynebacterium, Mycobacterium, Nocardia, Lactobacillus*, and occasional strains of *Clostridium, Actinomyces*, and *Propionibacterium* because these genera are more commonly isolated or associated with infections. *Lactobacillus, Clostridium, Actinomyces*, and *Propionibacterium* are discussed in the anaerobe section. *Mycobacterium* and *Nocardia* are addressed in another chapter. Other genera that need to be considered but are rarely isolated or infrequently associated with human infections include *Arcanobacterium, Brevibacterium, Kurthia, Rothia, Arthrobacter, Oerskovia, Rhodococcus, Turicella, Dermabacter, Curtobacterium, Microbacterium, Aureobacterium, Cellulomonas, Exiguobacterium, Gordona, Tsukamurella, Dermatophilus, Dietza, Micromonspora*, and the actinomycetes. Most of these organisms are either part of the normal skin or mucous membranes of humans or are found in soil, water, or foodstuffs. For a discussion of these genera, see references 51 and 52.

It has been proposed that the genus *Bacillus* be divided to include five new genera: *Alicyclobacillus, Paenibacillus, Brevibacillus, Aneurinibacillus*, and *Virgibacillus* (53). It is likely that further taxonomic changes will occur.

The genus *Bacillus* contains more than 50 recognized species, arranged into rRNA sequence groups. *B. anthracis* and *B. cereus* are the two most important pathogens. They are gram-positive straight rods of variable size (2 to 10 µm in length and 0.5 to 2.5 µm in width) that occur singly or in chains (Fig. 51.6). The major characteristic for inclusion in this genus is the formation of endospores (which does not always occur on routine laboratory media). The organisms grow on simple media and are strict aerobes or facultative anaerobes, catalase positive, oxidase variable, and motile (except *B. anthracis* and *B. mycoides*).

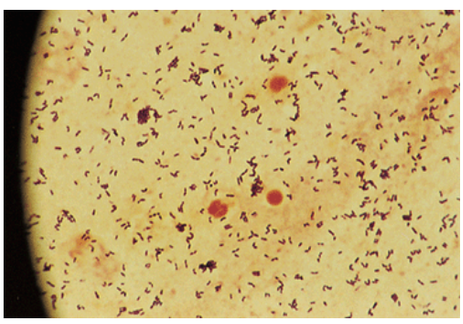

FIGURE 51.8. Gram stain of *Corynebacterium* in sputum.

Based on DNA homology and 16 S rRNA sequencing, the genus *Listeria* contains six species and two subspecies (54). Only *Listeria monocytogenes* and rarely *L. ivanovii* are pathogenic for humans. Because species other than *L. monocytogenes* are seldom isolated from clinical specimens, they are not discussed. *Listeria* is a short gram-positive rod that occurs singly, in short chains, or

in parallel or V forms (Fig. 51.7). It grows on most laboratory media and is facultatively anaerobic, catalase positive in most strains, and motile at room temperature.
The genus *Erysipelothrix* contains two species, *E. rhusiopathiae* and *E. tonsillarum*. They are catalase-negative, nonmotile, gram-positive, straight or slightly curved rods that occur singly, in pairs, in short chains, or in filaments. Only *E. rhusiopathiae* causes infections in humans.
The genus *Corynebacterium* is most closely related to *Mycobacterium* and the partially acid-fast genera *Nocardia* and *Rhodococcus*, based on cell-wall and fatty-acid composition (1). There are currently 46 species of which 31 cause infections (55). Corynebacteria are gram-positive, straight or slightly curved rods with tapered or club-shaped ends that occur singly or in angular (V or L) forms and palisade arrangements (Fig. 51.8). They are nonmotile, catalase positive, and facultatively anaerobic and form metachromatic granules. *Arcanobacterium haemolyticum* may morphologically resemble *Corynebacterium* and is catalase negative and nonmotile.
Rothia dentocariosa is a gram-positive rod that may appear coccoid, diphtheroid, or filamentous. It is catalase variable, facultatively anaerobic, and nonmotile and is part of the normal oropharyngeal flora.

Spectrum of Disease

B. anthracis is the etiologic agent of anthrax that, depending on the portal of entry, presents in three forms: (a) cutaneous anthrax (most common), (b) pulmonary anthrax (rare), or (c) GI anthrax (no reported cases in the United States). If untreated, anthrax is often fatal. Anthrax is rarely seen in the United States. *B. cereus*, the most frequently isolated *Bacillus* species, causes food poisoning and along with the numerous other *Bacillus* species, causes a variety of opportunistic infections such as localized infections related to trauma (especially fulminant eye infections) and systemic infections (e.g., meningitis, endocarditis, bacteremia, and pneumonia).
L. monocytogenes causes a mild febrile illness, especially in pregnant women; it also causes severe disease, including meningitis, bacteremia, *in utero* infections, or localized infections (including skin, ocular, arthritis, abscess, osteomyelitis, and endocarditis), which occur most often in immunocompromised patients.
E. rhusiopathiae infections usually involve localized cutaneous lesions (erysipeloid) or less frequently a disseminated form that is often associated with endocarditis.
C. diphtheriae causes infections of the human upper respiratory tract (diptheria) and skin. The other corynebacteria cause a wide array of infections in patients who are immunocompromised or have a prosthesis (56). *C. jeikeium* is associated with endocarditis, bacteremia, foreign body infections, and wound infections; *C. pseudodiphtheriticum* with respiratory tract infections and endocarditis, and *C. urealyticum* with urinary tract infections.
A. haemolyticum is associated with pharyngitis in young adults. *Rothia* strains are associated with endocarditis, bacteremia, abscesses, dental caries, and periodontal disease but are infrequently encountered.

Epidemiology

Anthrax occurs worldwide and is primarily a disease of herbivores. Transmission to humans occurs by contact with infected animals or their products (e.g., wool, hides, goat hair). The reservoir is contaminated soil where spores can survive for long periods. The other *Bacillus* species are inhabitants of soil and therefore common contaminants of nearly all articles. Contamination of foodstuffs and subsequent improper storage may result in food poisoning.
L. monocytogenes is widespread in nature and has been isolated from the environment (e.g., soil, water, sewage), animals (e.g., mammals, birds, fish, and humans), and foodstuffs (e.g., vegetables, dairy products, meats). The source of the infection in many cases is unknown, but food-borne transmission is recognized as an important factor. Although large numbers of people are exposed, most infections occur in immunocompromised individuals. It is also an occupational disease of veterinarians and abattoir workers.
E. rhusiopathiae is found in animals, fish, and birds. Transmission occurs by contact with contaminated meat or other objects. Infection is seen most often in fish handlers, meat processing workers, veterinarians, farmers, and housewives.

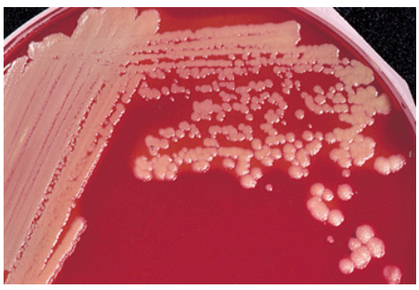

FIGURE 51.9. Colony of *Bacillus cereus* on sheep blood agar.

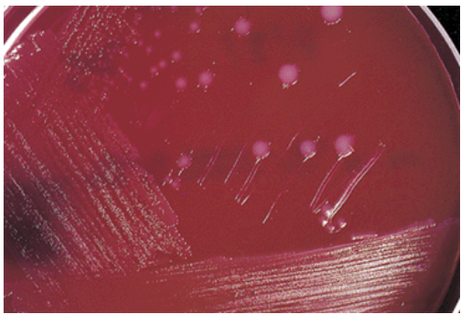

FIGURE 51.10. Colony of *Listeria* on sheep blood agar after 72 hours of incubation. Note the diffuse zone of ß hemolysis surrounding the colonies.

The upper respiratory tract and skin of humans serve as the

reservoir for *C. diphtheriae*. Transmission occurs via respiratory secretions or direct contact with exudate or contaminated fomites. The incidence of diphtheria is nearly absent in developed countries owing to immunization programs but is endemic in other underdeveloped countries. The other *Corynebacterium* species are common inhabitants of the skin and mucous membranes and are often isolated in the laboratory and dismissed as contaminants. Most infections are nosocomial or occur as the result of contact with animals or their products. *A. haemolyticum* is found in the pharynx and skin of humans.

Diagnostic Procedures

Microscopy

The identification of this heterogeneous group of organisms begins with a Gram stain of the clinical specimen. A predominant single morphology is sought, as well as correlation with the source of the specimen and the signs and symptoms of the patient (Table 51.6).

In suspected cases of diphtheria, growth from the Loeffler's slant is stained with alkaline methylene blue. The typical coryneform morphology and the presence of metachromatic granules suggest *C. diphtheriae*.

Some strains of *Bacillus* stain gram negative as they age. In addition, because they may be oxidase positive, they are sometimes confused with gram-negative rods. Spores produced by *Bacillus* appear clear with a Gram stain but must be confirmed by phase-contrast microscopy or a spore stain.

Culture Techniques

Bacillus species grow well on all noninhibitory blood-containing media and most nutrient media. They produce a variety of colony morphologies and pigments (Fig. 51.9). Heat-shock or ethanol spore selection methods followed by plating on PEA agar may be used for contaminated sites. Cultures are incubated at 35°C in air or CO_2. Strict safety precautions (e.g., biological safety cabinet, gloves) must be used for specimens and cultures suspected of containing *B. anthracis*.

Listeria grows on most laboratory media. After 24 hours of incubation on sheep blood agar, it produces a small (less than 1 mm), translucent, whitish-gray colony with a narrow zone of ß hemolysis, which is best seen after removal of the colony from the medium (Fig. 51.10). Columbia CNA agar is recommended for isolation from contaminated specimens. New, shortened enrichment procedures have been developed for the isolation of *Listeria* from food and are now recommended for tissues, feces, or environmental cultures (57). Listeria grows at 35°C in air or CO_2 but will also grow at 4°C.

E. rhusiopathiae grows on blood-containing media (e.g., blood, chocolate, CNA), but growth in infusion broth containing 1% glucose or trypticase soy broth subcultured at 2 and 7 days may be superior to direct plating. Media should be incubated at 35°C in CO_2 for 3 to 7 days.

TABLE 51.7. CHARACTERISTICS OF SELECTED GRAM-POSITIVE BACILLI

Genus	Catalase	Growth	Motility	Esculin	H_2S (TSI)	TSI s/b[a]	Nitrate Reduction	Urease	Hemolysis	Comments
Kurthia	+	A	+	-	-	-/-	-	+	N	Grows best 20–30°C
Brevibacterium	+	A	-	+	-	+/+	v	-	v	
Bacillus	+	FA	v	+	-	v/v	v	v	v	Easily decolorized spore formation
Listeria monocytogenes	+	FA	+	+	-	+/+	-	-	B	Motile at room temperature
Oerskovia	+	FA	+	+	-	+/+	v	v	N,A	Yellow pigment
Rothia	+	FA	-	+	-	+/+	+	-	N	Coccoid in broth
Mycobacterium	+	A	-	-	-	-/-	+	v	N	Acid-fast
Rhodococcus	+	FA	-	v	-	-/-	v	v	N	Pink coral pigment
Corynebacterium	+	FA	-[b]	-	-	v/v	v	v	v	
Arcanobacterium	-	FA	-	v	-	+/+	-	-	B	
Nocardia	+	FA	-	+	-	NA	v	v	N	Weakly acid-fast
Erysipelothrix	-	FA	-	-	+	+/+	-	-	N,A	
Lactobacillus	-	AN[c]	-	v	-	+/+	-	-	N,A

Arachnia	-	AN[c]	-	-	-	+/+	-	-	N	
Clostridium	-	AN[c]	v	v	+	v/v	+	v	v	Easily decolorized spore formation

[a] s/b, slant/butt; +, acid; -, no change.

[b] Some species positive.

[c] Some species grow in CO_2.

TSI, triple-sugar iron; +, >90% of strains positive; -, <10% of strains positive; v, variable; A, strict aerobe; FA, facultative anaerobe; AN, anaerobe; B, beta: A, alpha; N, nenhemolytic.

Corynebacterium grows well on most routine enriched media (e.g., blood, CNA) and produces colonies that are translucent, opaque, white, or gray. For lipophilic corynebacterium, Tween

80 should be added to the plate (55). In cases of suspected diphtheria, selective agar (e.g., cystine-tellurite agar, modified Tinsdale agar) should be used. Loeffler's or Pai agar should be inoculated for demonstration of metachromatic granules. Cultures are incubated at 35°C in air or CO_2 for at least 72 hours.

Identification Techniques

Differential characteristics to presumptively group the different genera of gram-positive rods are depicted in Table 51.7. Additional testing is usually required for definitive identification.

Overdecolorized *Bacillus* species may be differentiated from gram-negative rods by spore formation (stimulated on esculin or triple sugar iron (TSI) agar), susceptibility to vancomycin, and resistance to KOH (potassium hydroxide) (57). Other tests useful for the identification of clinically relevant isolates are shown in Table 51.8. *Bacillus* species that produce medusa head colonies and are nonmotile, penicillin susceptible, and nitrate positive are presumptively *B. anthracis* and need to be confirmed by the CDC. The laboratory diagnosis of *B. cereus* food poisoning requires quantitative examination of the food, vomitus, or feces.

TABLE 51.8. IDENTIFICATION OF SELECTED *BACILLUS*, *BREVIBACILLUS*, AND *PAENIBACILLUS* SPECIES

Species	Width ≥ µm	Penicillin	Motility	Lecithinase	V-P	Nitrate Reduction	Starch Hydrolysis	Anaerobic Growth	Growth in 7% NaCl	Growth at 50°C
B. anthracis	+	s	-	+	+	+	+	+	+	-

[a] Brevibacillus.

+, >90% of strains positive; -, <10% of strains positive; v, variable reactions; V-P, Voges-Proskauer reaction; NA, no data available.

The misidentification of *Listeria* as *Enterococcus*, group B streptococci, or *Corynebacterium* should not occur. All gram-positive rods or coccobacilli, especially from sterile body fluids, are screened to rule out *Listeria* by positive tests for catalase, tumbling motility at room temperature, esculin hydrolysis, and ß hemolysis on sheep blood (Table 51.7). *L. monocytogenes* should be identified to species level when isolated from food sources.

E. rhusiopathiae is nonmotile and catalase negative. It is the only gram-positive rod that produces H_2S in triple sugar iron or Klingler's iron agar slant. Additional characteristics are presented in Table 51.7.

C. diphtheriae (including other stains of *Corynebacterium, S. aureus*, and *Listeria*) produces grayish-black colonies on tellurite-containing media and a brown halo of Tinsdale medium. *C. ulcerans* and*C. pseudotuberculosis*, closely related if not actually strains of *C. diphtheriae*, also form a brown halo. All suspected isolates of *C. diphtheriae* must be identified (Table 51.9) and shown to produce diphtheria toxin by *in vivo* or *in vitro* tests. *C. diphtheriae, C. ulcerans*, and *C. pseudotuberculosis* lack pyrazinamidase activity.

TABLE 51.9. IDENTIFICATION OF MEDICALLY RELEVANT *CORYNEBACTERIUM* SPECIES

Species	Fermentation Oxidation	Lipophilism		Nitrate Reduction	Urease	Esculin Hydrolysis	Pyrazinamidase	Alkaline Phosphatase	Acid Production from Glucose	Maltose	Sucrose	Mannitol	Xylose	CAMP Reaction	Other Traits

C. xerosis	F	-	V	-	-	+	+	+	+	+	-	-	-	O/129 susceptible

V, variable; parenthese, delayed or weak reaction; ND, no data; REV, reverse cAMP reaction; F, fermentation; O, oxidation; +, positive reacton; -, negative reaction.From Funke G, Bunard KA, Coryneform Gram-positive rods. In: Murray PR, Baron EJ, Pfaller MA, et al. eds. *Manual of clinical microbiology*, eds. Washington, DC: American Society for Microbiology, 1999: 328–329, with permission.

The identification of clinically significant *Corynebacterium* species (Table 51.9) can be difficult because of the heterogeneity and biochemical diversity of the group (55,56,58). *C. jeikeium* exhibits poor growth in routine biochemical tests and multiple resistance to most antimicrobial agents except vancomycin. Various

commercial identification kits have been used to identify some of the *Corynebacterium* species (55).

Direct Antigen or Nucleic Acid Detection

B. anthracis can be identified directly in specimens by fluorescent antibody stain at the CDC. Various commercial immunoassays and a DNA probe are available for the rapid detection of *Listeria* in food but these tests cannot be used on clinical specimens. A DNA probe (GenProbe) can be used for culture confirmation. Fluorescent antibody techniques have also been described for *C. diphtheriae*. Nucleic acid detection is not commercially available for these organisms.

Serologic Procedures

B. anthracis can be diagnosed by an indirect hemagglutination procedure performed at the CDC. Serology for listeriolysin (performed only in some reference or research laboratories) may be useful for diagnosis of systemic listeriosis and gastroenteritis (59,60).

Interpretation of Results

The isolation of *Listeria, Erysipelothrix, C. diphtheriae*, or *B. anthracis* is clinically relevant. The significance of any of the other numerous species of gram-positive rods depends on the type and quality of the specimen, the frequency of isolation, and the nature of the infectious disease process.

Therapeutic Considerations

The drug of choice for the treatment of anthrax is penicillin. The other *Bacillus* species demonstrate variable susceptibility to the penicillins and cephalosporins, but most appear susceptible to aminoglycosides, tetracycline, clindamycin, erythromycin, chloramphenicol, vancomycin, imipenem, and ciprofloxacin.

Most of the recommended therapy for listeriosis is based on isolated case reports. Penicillin or ampicillin plus an aminoglycoside administered over a 3- to 6-week period is probably the optimal combination. Trimethoprim-sulfamethoxazole is a second choice.

Erysipelothrix is susceptible to penicillin, clindamycin, erythromycin, fluoroquinolones, imipenem, tetracycline, and cephalosporins. Isolates are usually resistant to the aminoglycosides, vancomycin, and sulfonamides.

Patients with diphtheria should be given antitoxin and started on erythromycin. Clindamycin or rifampin may also be used. Susceptibility of the other *Corynebacterium* species must be determined by testing. *C. jeikeium* is susceptible to vancomycin and resistant to most other antimicrobial agents. *A. haemolyticum* is susceptible to the ß-lactams.

Summary and Conclusions

Gram-positive, aerobic to facultatively anaerobic rods describe a heterogeneous group of organisms containing more than 20 genera. Most of these organisms are seldom if ever isolated from clinical specimens and are found in the environment (e.g., soil, food) or on the skin and mucous membranes of humans and animals. Because of taxonomic and identification difficulties, many of these species are just now being recognized as important agents of opportunistic infections. *B. anthracis, L. monocytogenes, E. rhusiopathiae*, and *C. diphtheriae* should always be considered clinically significant when isolated.

In general, most of these bacteria are readily isolated on laboratory media containing blood but are difficult to identify definitively. Susceptibility to antimicrobial agents is variable and must be determined for many of these species.

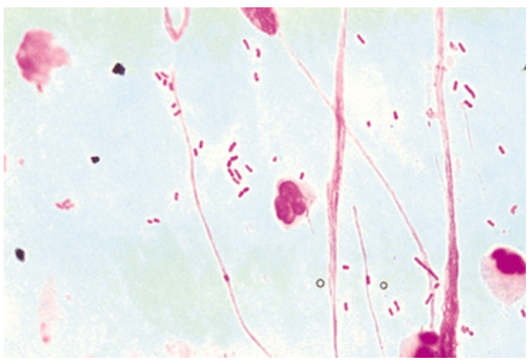

FIGURE 51.11. Gram stain of *Klebsiella pneumoniae* in sputum.

ENTEROBACTERIACEAE

Part of "51 - Bacteriology"

Microbiology

The family Enterobacteriaceae encompasses 30 genera and more than 100 species, CDC groups, and biogroups (Table 51.10).

Many of the new species are rarely or never found in human specimens. Others are isolated from specimens but seldom cause disease. Currently, two *Salmonella* species are recognized, *S. enterica* (six subspecies) and *S. bongori* that include all of the subspecies and serotypes (61). Regardless of these changes most clinical microbiology laboratories will continue to report the genus and serotype (e.g., *Salmonella* serogroup B).

TABLE 51.10. NOMENCLATURE AND CLASSIFICATION OF THE FAMILY ENTEROBACTERIACEAE

Genus	No. of Species
Budvicia	1
Buttiauxella	7

The members of this family are generally straight, gram-negative rods that are catalase positive and oxidase negative, reduce nitrate to nitrite, and are facultatively anaerobic. They are motile by peritrichous flagella or nonmotile, do not form spores, and usually grow on MacConkey agar. They demonstrate a vast heterogeneity in their habitats and pathogenic potential for plants, animals, and humans.

Spectrum of Disease

The members of the Enterobacteriaceae are among the most important bacteria medically and have been associated with infections in every major organ system. Their ubiquitous presence in the environment, in foodstuffs, and on animals and humans; their ability to develop antimicrobial resistance; and the increasing numbers of susceptible patients who are compromised or have prosthetic implants have ensured the involvement of these bacteria in both community- and hospital-acquired infections. Some genera and species such as *Salmonella, Shigella, Yersinia*, and some strains of *Escherichia coli* are primary enteric pathogens causing dysentery, gastroenteritis, enteric fever, hemolytic anemic syndrome, and hemorrhagic colitis. The diarrheic *E. coli* is comprised of at least four groups; the Shiga toxin producing *E. coli* or enterohemorrhagic *E. coli*, enterotoxigenic *E. coli*, enteropathogenic *E. coli*, and enteroinvasive *E. coli* based on clinical features and pathogenic mechanisms (61).

Epidemiology

The members of the family Enterobacteriaceae are widely distributed in soil and water, on plants, and in food and colonize the GI tract of animals and humans. They also contaminate many types of medical supplies and devices. Community-acquired GI disease occurs via consumption of contaminated water or foodstuffs. Bacteria causing nosocomial infections (usually found in the GI or upper respiratory tract of the patient) are transmitted on the hands of hospital personnel or introduced into the patient via contaminated solutions or devices. Numerous techniques are available to track specific strains in food-related outbreaks or in the hospital environment, including serologic typing, biotyping, bacteriocins, antibiograms, and nucleic acid analysis.

Diagnostic Procedures

Microscopy

On Gram stain, the “enterics” exhibit a characteristic morphology consisting of straight, thick, barrel-shaped rods that may exhibit bipolar staining and are often pleomorphic (Fig. 51.11). *Yersinia pestis* may have a “safety pin” appearance.

Culture Techniques

All members of this group grow luxuriantly within 24 hours in air at 35°C on routine laboratory media such as blood, MacConkey (or eosin methylene blue), or chocolate agar. On blood agar, colonies are usually 1 to 3 mm in diameter, dull, gray, opaque, sometimes mucoid (e.g., *Klebsiella*), sometimes hemolytic (e.g., *E. coli*), and sometimes swarming (e.g., *Proteus*). More selective agars, as well as enrichment broths, are used to isolate enteric pathogens from feces. The characteristic appearances of colonies on these media are listed in Table 51.11. Newer plating media for the isolation of *Salmonella* are available (62).

Sorbitol-MacConkey and cefsulodin-irgasan-novobiocin agars are used to isolate *E. coli* O157 and *Y. enterocolica*, respectively. Other selective media for the isolation of *E. coli* 0157 strains are available (61,63,64). It is recommended that media for the isolation of *Yersinia* be incubated at 22 to 25°C for 48 hours.

TABLE 51.11. APPEARANCE OF COMMONLY ISOLATED ENTEROBACTERIACEAE ON VARIOUS ENTERIC MEDIA

	MacConkey Agar	Eosin-Methylene Blue Agar	Hektoen Enteric Agar	Xylose-Lyslne Deoxycholate Agar	Salmonella-Shigella Agar	Deoxycholate Citrate Agar	Bismuth Sulfite Agar	Brilliant Green Agar
Escherichia coli								
Lac +	Flat; red or dark pink; surrounded by zone of precipitated bile	Red black with metallic sheen[a]	Yellow-orange	Yellow	Pink	Deep red-pink	Usually do not grow	Usually do not gorw
Lac -	Colorless	Colorless	Yellow-orange or green	Yellow	Colorless	Colorless	Usually do not grow	Usually do not grow
Klebsiella	Pink; mucoid	Purple	Yellow-orange	Yellow	Pink	Pink	Usually do not grow	Usually do not grow
Enterobacter	Pink; not usually as mucoid as *Klebsiella*	Purple	Yellow-Orange	Yellow	Pink	Pink	Usually do not grow	Usually do not grow
Citrobacter, Serratia, Hafnia, Providencia,	May appear colorless after 24 hr or slightly pink in 24–48 hr	Lavender or colorless	Colorless	Red, yellow, or colorless with or without black centers	Colorless	Colorless	Usually do not grow	Usually do not grow
Proteus, Morganella, Edwardsiella	Colorless[b]	Colorless	Colorless	Red, yellow, or colorless with or without black centers	Colorless	Colorless	Usually do not grow	Usually do not grow
Salmonella	Colorless	Colorless	Green or blue-green	Pink to red with black center	Colorless with black center	Colorless	Green-black	Pink white opaque: surrounded by brilliant red medium
Shigella	Colorless	Colorless	Green or blue-green	Colorless	Colorless	Colorless	Usually do not grow	Usually do not grow
Yersinia	Colorless to peach	Colorless or purple[c]	Salmon	Yellow	Colorless	Colorless	Usually do not grow	Usually do not grow

[a] Not all strains produce a metallic sheen; conversely, other species of entetic bacilli (e.g., *Yersinia enterocolitica*) may produce a sheen.

[b] *Proteus mirabilis, Proteus vulgaris*, and *Proteus penneri* may swarm.

[c] *Yersinia enterocolitica*, a nonlactose fermenter that ferments sucrose, produces colorless colonies on Levine EMB agar and purple colonies on the modified Holt-Harris Teague formula, which contains sucrose.

From Howard BJ, Klass J II, Rubin SI, et al. eds. *Clinical and pathogenic microbiology*. St. Louis: Mosby, 1987:295, with permission.

Identification Techniques

With respect to identification, the clinical laboratory has three levels of need: (a) a screen for enteric pathogens, (b) a presumptive identification of isolates from significant but not life-threatening infections, and (c) definitive identification.

Two tests (urea and triple sugar iron or lysine iron agar) have been used to screen stool cultures for potential pathogens (Table 51.12). The urease test aids in the detection of *Proteus* and urease-positive *Providencia*. Commercial latex agglutination kits are available to identify colonies of *E. coli* 0157, *Salmonella*, and *Shigella* or to detect their growth in enrichment broth.

TABLE 51.12. TYPICAL REACTION PATTERNS OF ENTERIC PATHOGENS ON TRIPLE-SUGAR IRON AND UREA AGAR

Genus	Urea	TSI (Slant/Butt)	H_2S	Oxidase
Salmonella	–	K/A	+ or -	–
Salmonella (rare)	–	A/A	+	–
Shigella	–	K/A	–	–
Edwardsiella	–	K/A	+	–
Yersinia	+	A(K)/A	–	–
Aeromonas	–	A(K)/A	–	+
Plesiomonas	–	A(K)/A	–	+

TSI, triple-sugar iron; A, acid; K, alkaline; +, positive; -, negative; (), occasional reactions.

Clinically relevant isolates from nonlife-threatening infections can be presumptively identified by colony morphology and a few rapid tests. The identification of the most frequently isolated bacteria is based on lactose fermentation and colony morphology on MacConkey agar, swarming on blood agar, spot indole, motility, and ornithine decarboxylase (Table 51.13). Members of the Enterobacteriaceae family are definitely identified by inoculation of numerous conventional biochemical tests, use of commercial manual kits, or by automated systems. All *Salmonella, Shigella*, and *E. coli* 0157 isolates should be identified both biochemically and serologically. Biochemicals for the identification of *Yersinia* should be incubated at 22 to 25°C.

TABLE 51.13. PRESUMPTIVE IDENTIFICATION OF COMMON ISOLATES OF ENTEROBACTERIACEAE

Characteristic	*Escherichia coli*	*Klebsiella*	*Enterobacter*	*Proteus mirabilis*	*Proteus vulgaris*

Motility	NA	–	+	NA	NA

+, positive; -, negative; NA, not applicable.

Direct Antigen or Nucleic Acid Techniques

Currently, there are no commercially available systems for the direct detection of Enterobacteriaceae in clinical specimens. However, several tests are available for the identification of colonies or the detection of virulence factors. As mentioned previously, *Salmonella, Shigella*, and *E. coli* 0157 can be identified by latex agglutination or serotyped by antisera. Also, colonies of *E. coli* can be screened for production of toxins by EIA. Nucleic acid probes are used to identify enterotoxigenic, enteroinvasive and enteropathogenic *E. coli*. At present, EIA and probes are used primarily for epidemiologic studies by reference centers. Both DNA hybridization and monoclonal antibody systems are being evaluated for the detection of *Salmonella* in food. Immunoassays for the direct detection of *E. coli* 0157 (65,66) or Shiga toxin (61) in stool are commercially available.

Serologic Procedures

The Widal test is used to help diagnose *S. typhi* infections by measuring an antibody response to the O and H antigens. However, numerous factors can produce both false-positive and false-negative reactions, and the test should not be used alone to diagnose typhoid fever.

Serodiagnosis of *Y. enterocolitica* is useful only when one or two serogroups cause the majority of the infections. Serodiagnosis is difficult in the United States because numerous O serogroups cause enteric infections. The criteria for positive and negative tests are also poorly defined.

Interpretation of Results

The isolation of *Salmonella, Shigella*, or *Yersinia* from any site is clinically relevant. The isolation of any member of the Enterobacteriaceae from a normally sterile body fluid or site is significant until proven otherwise. The significance of recovery of these organisms from other specimens (e.g., sputum, urine) must be interpreted considering the patient's underlying condition, prosthesis (including catheters), intubation, type of specimen, and frequency of isolation.

Therapeutic Considerations

Antimicrobial resistance has always been and continues to be a problem with the members of the Enterobacteriaceae. The emerging resistance to the newer cephalosporins and fluoroquinolones may pose problems for adequate therapy. Because antimicrobial resistance is unpredictable and varies within geographic areas, all clinically relevant isolates should be tested. However, *Salmonella* isolates from uncomplicated gastroenteritis are an exception because antimicrobial therapy is not recommended.

Summary and Conclusions

The members of the family Enterobacteriaceae are ubiquitous in nature, causing a significant number of GI, urinary tract, and nosocomial infections. They are readily isolated on routine media and are identified by numerous manual and commercial methods. Antimicrobial therapy must be based on susceptibility testing of the isolated bacterium.

AEROMONAS AND PLESIOMONAS

Part of "51 - Bacteriology"

Microbiology

Aeromonas and Plesiomonas are included in the family Vibrionaceae based primarily on polar flagella and the oxidase reaction. It has been proposed that aeromonads be placed in the family Aeromonadaceae, whereas *Plesiomonas* probably is related to the genus *Proteus* (67). Both are gram-negative, motile, catalase- and oxidase-positive rods that are facultatively anaerobes. The genus *Aeromonas* now contains 16 species: *A. hydrophila, A. caviae, A. sobria, A. media, A. veronii, A. schubertii, A. eucrenophila, A. salmonicida, A. bestiarum, A. jandaei, A. encheleia, A. trota, A. allosaccharophila, A. popoffii*, and two unnamed species.

Spectrum of Disease

Aeromonas causes four types of infections in humans, including diarrhea, cellulitis or wound infections (usually after exposure to water or soil), bacteremia (primarily in the immunocompromised host), and a variety of soft-tissue and deep-seated infections (68,69). Only three species, *A. hydrophila, A. caviae*, and *A. sobria* are commonly associated with clinical disease. *Plesiomonas shigelloides* primarily causes GI disease but has been associated with cases of meningitis, bacteremia, wound infections, septic arthritis, and cholecystitis (70).

Epidemiology

Both *Aeromonas* and *Plesiomonas* are found in soil and water, where they cause infections in frogs, reptiles, snakes, birds, and fish. Transmission to humans probably occurs via contaminated water or foodstuffs or contamination of an injury. Transmission via water or food is rarely documented.

Diagnostic Techniques

Microscopy

There are no available microscopic techniques to detect these bacteria directly in clinical specimens. The morphology on Gram smear is not specific for either genus.

Culture Techniques

Both genera grow well on blood and MacConkey agar and most enteric screening agars. Strains of *A. hydrophila* and *A. sobria* may be ß-hemolytic on blood agar. Selective agar is available for recovery from stool specimens.

Identification Methods

A motile, oxidase- and indole-positive organism can be tentatively identified as *Aeromonas*/*Plesiomonas*/*Vibrio*. Vibrios grow in 6% NaCl, whereas *Aeromonas* and *Plesiomonas* do not. Commercial systems will generally identify *Aeromonas* and *Plesiomonas* to the genus level. Key characteristics are listed in Table 51.14. There is no commercial test for the direct detection of antigen or nucleic acid in clinical specimens. Tests are not available for serologic diagnosis.

TABLE 51.14. DIFFERENTIAL CHARACTERISTICS OF AEROMONAS AND PLESIOMONAS SPECIES

Organism	DNase	Esculin Hydrolysis	Acid from Mannitol	Voges-Proskauer	Arginine Dehydrolase	Lysine Decarboxylase	Ornithine Decarboxylase
A. hydrophilia	+	+	+	+	+	+	-
A. caviae	+	+	+	-	+	-	-
A. sobria	+	-	+	+	+	+	-
A. schubertii	+	-	-	+	+	+	-
A. veronii	+	+	+	+	-	+	+
A. jandaei	ND	-	+	+	+	+	-
A. trota	ND	-	+	-	+	+	-
P. shigelloides	-	-	-	-	+	+	+

+, positive; -, negative; ND, not determined.

Interpretation of Results

The isolation of either *Aeromonas* or *Plesiomonas* from specimens other than stool should be considered significant. Isolation from stool is significant in children. In adults, only *A. hydrophila* and *A. veronii* seem to be significant.

Therapeutic Considerations

Aeromonas is resistant to ampicillin and other penicillins, including some of the ureidopenicillins. Isolates are generally susceptible to the third-generation cephalosporins, quinolones, trimethoprim-sulfamethoxazole, and the aminoglycosides. The susceptibility of *Plesiomonas* has not been evaluated extensively, but isolates appear susceptible to most classes of antimicrobics except aminoglycosides and tetracycline. Because both genera can easily acquire resistance to antimicrobial agents, therapy should be based on the results of *in vitro* susceptibility tests.

Summary and Conclusions

The genera *Aeromonas* and *Plesiomonas* are common inhabitants of the aquatic environment. Infections are seen in both normal and immunocompromised hosts, usually after exposure to or consumption of contaminated water or foodstuffs. Therapy is based on the result of *in vitro* susceptibility testing.

VIBRIO

Part of "51 - Bacteriology"

Microbiology

The general *Vibrio, Photobacterium, Aeromonas*, and *Plesiomonas* are in the family Vibrionaceae. Two genera (*Listonella* and *Shewanella*) have been proposed for inclusion in this family. Although more than 35 *Vibrio* species are recognized, only 12 have been associated with infections in humans. In general, *Vibrio* species share the following characteristics: gram-negative, curved or straight rod, oxidase positive, reduce nitrate to nitrite, sodium required for or stimulates growth, susceptible to vibriostatic compound 0/129, motile by polar flagella, and facultatively anaerobic. *Photobacterium* is not associated with human infections.

Spectrum of Disease

V. cholerae serogroup 01 is the etiologic agent of epidemic cholera. The other pathogenic species are usually associated with food-borne gastroenteritis, soft-tissue infections or systemic infections such as meningitis, septicemia, cholecystitis, cellulitis, and a variety of other wound infections. *V. parahaemolyticus* gastroenteritis is the most frequently encountered noncholera *Vibrio* infection. *V. vulnificus* is an especially virulent species associated with primary sepsis (often in patients with preexisting liver disease) or with serious soft-tissue infections in normal hosts.

Epidemiology

Vibrio species inhabit aquatic environments worldwide. Although found primarily in marine ecosystems, some species can live in fresh water. Disease is transmitted via contaminated food (especially shellfish) or water and exposure of wounds to contaminated water. In epidemic cholera, food and water are usually contaminated by feces of patients and carriers. Gastroenteritis from the noncholera vibrio occurs in sporadic or common source outbreaks after consumption of raw, improperly prepared, or recontaminated seafood. Wounds are infected from exposure to contaminated water. Most infections occur in coastal locations, but more inland cases are being reported because of travel and shipment of contaminated food.

Diagnostic Procedures

Microscopy

Direct examination of stools by wet mount for rapid, darting motility or by Gram smear for gram-negative curved rods may be helpful in an outbreak situation but is not useful for identification of a sporadic case.

Culture Techniques

Routine primary isolation media such as blood and MacConkey agar are adequate for recovery of vibrios from extraintestinal specimens. Stool specimens are inoculated to thiosulfate-citrate-bile salts-sucrose (TCBS) agar. Some pathogenic species may grow poorly or not at all on this medium (71). All cultures should be incubated at 35°C in air or CO_2 where most species form 1 to 2 mm colonies after 24 hours. Alkaline peptone broth can be used for the enrichment of fecal specimens.

Vibrio species may exhibit ß hemolysis on blood agar, are nonlactose fermenters (except *V. vulnificus*) on MacConkey agar, and are differentiated by sucrose fermentation on TCBS. Nonsucrose-fermenting strains produce green colonies, whereas sucrose-fermenting strains form yellow colonies. Oxidase testing should be done from nonselective media.

TABLE 51.15. CHARACTERISTICS USEFUL FOR DIFFERENTIATING *VIBRIO* FROM OTHER OXIDASE-POSITIVE GENERA

Characteristic	*Vibrio*	*Pseudomonas*	*Aeromonas*	*Plesiomonas*
Growth on TCBS	+	-	-	-
Oxidase	+[a]	+	+	+
Fermentative	+	-	+	+
Growth stimulated by NaCl	+	-	-	-
Susceptibility to 0/129 (150 µg)	+	-	-	v
Susceptibility to ampicillin (10 µg)	+	-	-	-

TCBS, thiosulfate-citrate-bile salts; +, positive; -, negative; v, variable.

[a] *V. metschnikovii* is oxidase negative.

Identification Techniques

Initially, *Vibrio* species are separated from other genera by the oxidase reaction, fermentative metabolism, requirement of NaCl for growth, and susceptibility to 2,4-diamino-6, 7-diisopropylpteridine (0/129) (Table 51.15). Identification can be made

using routine biochemical tests if the NaCl concentration is increased to 1% (wt/vol) (Table 51.16). Commercial kits identify the more common *Vibrio* species (if the inoculum is prepared in saline) but cannot be used to identify the less common isolates. However, misidentification of *Aeromonas* as *Vibrio* has occurred (72).

From Janda JM, Powers C, Bryant RG, et al. Current perspectives on the epidemiology and pathogenesis of clinically significant *Vibrio* spp. *Clin Microbiol Rev* 1988;1;259, with permission.

Direct Antigen or Nucleic Acid Detection

Nucleic acid probes have been used in epidemiologic studies but are not commercially available and have not been evaluated as a direct diagnostic test. However, immunoassays for the direct detection of *V. cholerae* 01 in stool specimens are commercially available (71).

Serologic Procedures

V. cholerae is identified as serogroup 01 or non-01 based on somatic antigens tested by a slide agglutination procedure. A retrospective diagnosis of cholera can be made by a serologic test if the patient has not been vaccinated for cholera.

Interpretation of Results

The isolation of *V. cholerae* is a reportable event because of the potential public health consequences. The isolation of other *Vibrio* species is clinically relevant, especially in the case of *V. vulnificus*, which has devastating consequences for the patient.

Therapeutic Considerations

Fluid replacement is the primary treatment for epidemic cholera and is sometimes necessary in gastroenteritis caused by other *Vibrio* species. Antimicrobial agents are generally not necessary.
Soft-tissue or systemic infections are usually treated with doxycycline ± ceftazidime. Most strains are also susceptible to chloramphenicol, aminoglycosides, and fluoroquinolones. Antimicrobial susceptibility testing can be performed without added NaCl.

Summary and Conclusions

V. cholerae, V. parahaemolyticus, and *V. vulnificus* are the most clinically important species of the pathogenic vibrios. All vibrios inhabit an aquatic environment, primarily a marine ecosystem. Cholera is of worldwide importance, whereas other noncholera vibrios cause significant gastroenteritis and soft-tissue and systemic infections. *Vibrio* species are transmitted to humans through fecally contaminated food and water (*V. cholerae*), contaminated shellfish, or exposure to contaminated water. These bacteria are easily isolated on routine media, but TCBS agar is recommended for stool specimens. Identification is performed by routine biochemical tests containing 1% NaCl or in some cases by commercial kits. The key to the isolation of *Vibrio* is recognition of the colony on the primary isolation plate.

CAMPYLOBACTER, *ARCOBACTER*, AND *HELICOBACTER*

Part of "51 - Bacteriology"

Microbiology

The taxonomy and nomenclature of the genus *Campylobacter* is changing rapidly as old species are renamed and new species identified. Currently, two genera, *Campylobacter* and *Arcobacter*, are included in the family Campylobacteraceae, which includes 18 species and subspecies in the genus *Campylobacter* and four species in the genus *Arcobacter* (73). Two *Campylobacter* species were reclassified as *Arcobacter*, two *Wolinella* species were reclassified in the genus *Campylobacter*, and two *Campylobacter* species were placed in the genus *Helicobacter*. The genus *Helicobacter* contains 19 species, seven of which are associated with humans.
Campylobacter species are slender, curved, gram-negative rods (0.5 to 5 µm in length) that may have a comma, S, gull-wing, or spiral shape and exhibit a characteristic darting motility (polar flagella) on wet mount. They are oxidase positive, microaerophilic, and capnophilic (5% O_2, 10% CO_2, and 85% N_2) and are inactive toward carbohydrates. *Arcobacter* species are similar except that they show variable growth at 37° and 42° C. *Helicobacter* species are spiral or curved, motile, gram-negative rods (1.5 to 10 µm in length). They are oxidase positive, inactive toward carbohydrates, microaerophilic, and require a humid atmosphere with reduced oxygen (5% to 10%) and increased carbon dioxide (5% to 12%).

Spectrum of Disease

Campylobacter species are associated with two categories of disease: GI and extraintestinal. *C. fetus* subsp *fetus* typically causes extraintestinal infections such as bacteremia, cholecystitis, meningitis, septic abortion, and septic arthritis. Infection is often associated with underlying disorders such as hepatic disease, immunodeficiency, alcoholism, and diabetes. *Arcobacter* and other *Campylobacter* species less commonly cause infection. *Helicobactor pylori* is associated with ulcers of the gastric or duodenal mucosa and cancer of the GI tract. *C. jejuni* and *C. coli* are the two species most commonly associated with gastroenteritis in the United States. Extraintestinal infection is most commonly bacteremia but can include arthritis, meningitis, peritonitis, among other diseases (74). *C. jejuni* is an antecedent cause of Guillain-Barré syndrome.

Epidemiology

Campylobacter species are found in the GI tract of wild and domesticated animal species, including cattle, sheep, swine, goats, dogs, cats, rodents, and all fowl. This results in the contamination of food (especially meat), milk, and water that is consumed by humans. Transmission also occurs from direct contact with infected pets (dogs and cats), person-to-person contact, or the sexual practices of homosexual men. Cases occur year-round but with a peak incidence in the summer and fall. *Helicobacter* inhabit the stomach or the lower GI tract of humans. Person-to-person transmission occurs via oral-oral or fecal-oral routes, although transmission from dogs or cats may occur also. To date, *H. pylori* has not been recovered from the environment.

Diagnostic Techniques

Microscopy

A presumptive diagnosis of *Campylobacter* enteritis is made by the examination of a stool specimen by Gram stain or wet mount using dark-field or phase-contrast microscopy. *Campylobacter* species will have a very rapid, darting motility on wet mount or have a slender, curved morphology on Gram stain (Fig. 51.12). Safranin should remain on the smear for 2 to 3 minutes to enhance staining or carbolfuchsin should be used as the counterstain. *Helicobacter* species can be visualized in tissue collected at endoscopy and stained by hematoxylin and eosin or Giemsa stain.

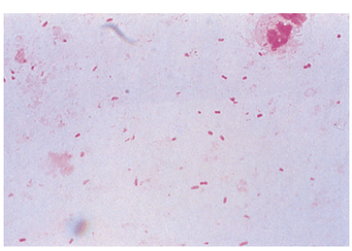

FIGURE 51.12. Gram stain of *Campylobacter jejuni* in stool. Note the curved and S-shaped forms.

Culture Techniques

Campylobacter and *Arcobacter* species grow on most blood-containing media (e.g., blood or chocolate agar). Isolation from stool usually requires direct inoculation to a selective agar or filtration (0.45 to 0.65 µm) and then inoculation to nonselective medium. The latter method is optimal for the recovery of *C. jejuni* and atypical enteric campylobacters. However, selective media containing cephalothin should not be used. Enrichment broths are not necessary for isolation from stool specimens. Most *Campylobacter* species grow at 35° to 37°C, but *C. jejuni, C. coli*, and *C. lari* will also grow at 42°C. Colonies are 1 to 2 mm in diameter, smooth, convex, and translucent after 24 to 48 hours. Enteric *Campylobacter* species produce two colony types: round and raised or flat and watery with an irregular edge. Cultures for *C. jejuni* are routinely incubated for 72 hours but may be held as long as 5 days for the uncommon *Campylobacter*. Microaerophilic conditions (5% O_2, 10% CO_2, 85% N_2) are required

for growth. Some *Campylobacter* species require hydrogen for initial isolation. *H. pylori* and other *Helicobacter* species grow best on blood (especially horse blood)-containing media in a moist atmosphere containing 5% O_2, 10% CO_2, and 85% N_2 (75). Some species require increased hydrogen. Both selective and nonselective media should be used for optimal recovery. Enteric *Helicobacter* species can be cultivated from feces on the media used for *Campylobacter*. Plates need to be incubated for as long as 7 days.

Identification Techniques

Campylobacter species from stool are presumptively identified by their typical cellular morphology, oxidase-positive reaction, and a rapid, darting motility in broth. Alternatively, suspect colonies can be tested by using a commercial immunoassay or a DNA probe. *H. pylori* is presumptively identified by demonstrating urease, catalase, and oxidase reactions.

Conventional biochemical and physiologic tests and, in some cases, molecular methods are necessary for the definitive identification of *Campylobacter* species (Table 51.17). Guidelines for setting up these tests can be found in reference 76. Phenotypic tests do not reliably differentiate between *Campylobacter*, *Arcobacter*, and enteric *Helicobacter* species.

Adapted from Nachamkin I. *Campylobacter* and *Arcobacter*. In: Murray PR, Baron EJ, Pfaller MA, et al. eds. *Manual of clinical microbiology*, 7th ed. Washigton, DC: American Society for Microbiology, 1999: 717.

Direct Antigen or Nucleic Acid Detection

A nucleic acid probe for *Campylobacter* is available to identify suspected colonies or growth in enrichment cultures. Probes are not commercially available for the direct detection of *Campylobacter* or *Helicobacter* in stool specimens. However, an immunoassay for the detection of *H. pylori* antigens in fecal specimens is commercially available.

Serologic Procedures

Currently, there are no commercial systems available for the detection of antibodies to *Campylobacter* infection. Commercial EIAs are used to screen patients for exposure to *H. pylori* and have sensitivities and specificities of 86% to 100% and 76% to 98%, respectively (77,78).

Interpretation of Results

The isolation of *C. jejuni, C. coli*, C. fetus subsp *fetus*, or *H. pylori* is considered clinically significant. The isolation of the other *Campylobacter, Arcobacter*, and *Helicobacter* species should be evaluated with respect to the source and symptoms of the patient.

Therapeutic Considerations

Treatment of gastroenteritis is effective in reducing the duration of symptoms and elimination of the organism, but most cases of gastroenteritis are self-limited and do not require antimicrobial therapy. Septic or bacteremic patients require therapy. *C. jejuni* is variably susceptible to a number of antimicrobial agents (e.g., macrolides, tetracyclines, aminoglycosides, quinolones, and clindamycin); erythromycin is the drug of choice for gastroenteritis. Treatment of serious extraintestinal infections should be based on susceptibility testing. *H. pylori* is generally susceptible to amoxicillin, macrolides, nitrofurans, metronidazole, and bismuth salts. Multidrug regimens for as long as 14 days are often used.

Summary and Conclusions

Campylobacter species are isolated from a variety of animals are most often transmitted to humans via contaminated food (e.g., meat and milk) and cause significant human disease such as gastroenteritis and disseminated infections. A microaerophilic environment is necessary for their isolation on laboratory media. Selective media or filtration is required for isolation from stool specimens. A limited number of tests are available for the differentiation of the various *Campylobacter* species. Erythromycin is the drug of choice in GI infections. *Campylobacter* species are among the most frequently isolated bacterial agents of diarrheal disease. *H. pylori* is associated with ulcers of the gastric or duodenal mucosa.

LEGIONELLA

Part of "51 - Bacteriology"

Microbiology

Legionella, the only genus in the family Legionellaceae, contains more than 41 species and subspecies. Most of the species are environmental isolates not associated with human infections.

Legionella species are aerobic, gram-negative rods that are 0.5 µm in width and 1.5 to 5 µm in length. The organisms appear coccobacillary in clinical specimens but may be filamentous when grown on some culture media. They stain poorly with safranin, are nutritionally fastidious, and do not grow on routine laboratory media. L-Cysteine is essential for initial growth on culture media, whereas iron stimulates growth. The cellular fatty acids of *Legionella* are primarily branched chain, and the bacteria contain large amounts of ubiquinones. *Legionella* are catalase positive, urease negative, and weakly oxidase positive. They liquefy gelatin, do not reduce nitrates, and do not metabolize carbohydrates. Some strains produce a pigment that fluoresces yellow-green, blue-white, or red-pink under long-wave ultraviolet light.

Spectrum of Disease

There are four categories of *Legionella* infections: (a) subclinical disease, (b) nonpneumonic infection, (c) pneumonia, and (d) extrapulmonary disease (79). The high prevalence of antibodies (5% to 10%) in the general population supports the concept that many individuals are exposed to *Legionella* species. Nonpneumonic infection is generally self-limited. Extrapulmonary infections are not common but have included bacteremia, sinusitis, pyelonephritis, pericarditis, hepatic and perirectal abscess, endocarditis, peritonitis, and wound infections. Risk factors for the development of pneumonia include cigarette smoking, advanced age, chronic lung disease, and immunosuppression. Most infections are caused by *L. pneumophila* or *L. micadei*.

Epidemiology

The natural habitat of *Legionella* is aquatic environments, including surface and potable water. Almost all water distribution systems can be contaminated with *Legionella* and serve as reservoirs for human exposure. The mode of transmission from potable water to humans is via aerosolization or aspiration of contaminated water. Dissemination from the GI tract after ingestion has been proposed but not documented. Epidemic outbreaks are usually associated with institutions such as hospitals, hotels, and resorts.

Diagnostic Techniques

Microscopy

Legionella stains faintly with a routine Gram stain. Visualization is enhanced by staining with carbol-fuchsin as the counterstain or staining only with crystal violet and Gram's iodine without decolorization. The organisms are more difficult to stain in tissue, where the recommended procedure is the Warthin-Starry or Dieterle stain. *L. micadei* may appear acid fast in tissue.

Culture Techniques

The preferred culture method is to inoculate the specimen to two agar plates, one of which is buffered charcoal yeast extract (BCYE) agar without inhibitory agents. A second medium, BCYE with antimicrobial agents, is recommended for specimens that are likely to be contaminated with other microbial flora. Acid treatment of potentially contaminated specimens may increase the yield (80). *Legionella* has been recovered from blood culture (e.g., biphasic, Bactec, and lysis centrifugation) but may require blind subculture from broth media. BCYE agar is incubated at 35° to 37°C in air or CO_2 (not more than 5%) for as long as 5 days. Pinpoint growth may be detected in 2 to 3 days. After 5 to 7 days of incubation, colonies are 3 to 4 mm in diameter, gray, convex, and iridescent.

Identification Methods

Suspected colonies on BCYE agar are subcultured to another BCYE plate and to blood agar or preferably to a BCYE plate without added cysteine. Growth on BCYE but not on the other medium is presumptive evidence of a *Legionella* species. *Francisella tularensis* and *Bordetella pertussis* grow on BCYE and may not grow on cysteine-deficient medium.

The isolate is identified at the genus level by commercial immunologic reagents or nucleic acid probes. *Legionella* species can be separated into groups based on a limited number of phenotypic characteristics but require genetic analysis for definitive identification. Because therapy is similar for all species, identification to the genus level is adequate for most clinical laboratories.

Direct Antigen or Nucleic Acid Detection

Kits for the direct detection of antigen by direct fluorescent antibody (DFA) or immunoassay are commercially available. The sensitivities of the DFA and immunoassay for urinary antigen are 25% to 80% and more than 70%, respectively (79). Specificity for the two methods is 96% to 100%.

Serologic Procedures

Several serologic tests are available for epidemiologic studies and diagnosis of *Legionella* infection. However, 2 to 8 weeks are sometimes needed to demonstrate an antibody rise. Cross-reactions with other gram-negative organisms are infrequently observed. The sensitivity and specificity of serologic diagnosis are 80% and 96% to 99%, respectively (79).

Interpretation of Results

Because *Legionella* species are not part of the normal human flora, the isolation of any species is clinically significant. Culture is the mainstay of diagnosis, with a sensitivity of 51% to 80% from respiratory secretions (81). Direct detection methods are helpful when positive but cannot be used to rule out infection by *Legionella*. A fourfold rise to a 1:128 antibody titer is presumptive evidence of a recent infection. A single high titer is suggestive of recent infection but is not diagnostic.

Therapeutic Considerations

A macrolide or fluoroquinolone remains the drug of choice for the treatment of *Legionella* infections. Rifampin may be added in some cases because the organism is primarily intracellular. Anecdotal reports suggest that imipenem, trimethoprim-sulfamethoxazole, or tetracycline may be efficacious. Standardized methods for *in vitro* susceptibility testing of *Legionella* are not available.

Summary and Conclusions

Legionella species are ubiquitous inhabitants of natural and man-made aquatic systems. Transmission is thought to occur from inhalation of aerosolized bacteria. Infections are usually asymptomatic or present as a flulike illness or pneumonia. Laboratory diagnosis is made by isolation on BCYE agar, direct detection of antigen in clinical specimens, or retrospectively by serology. Identification of the isolate to the genus level is sufficient in most instances. A macrolide or fluoroquinolone is the drug of choice for treatment.

HAEMOPHILUS

Part of "51 - Bacteriology"

Microbiology

The genus *Haemophilus* is one of three genera in the family Pasteurellaceae. Currently, the genus includes eight species associated with humans and five species with animals. *Haemophilus* species are facultatively anaerobic, nonmotile, pleomorphic, coccoid to coccobacillary, gram-negative rods that require hemin (X factor) or nicotinamide adenine dinucleotide (NAD, V factor) or both for growth. They are usually oxidase and catalase positive, and CO_2 enhances the growth of some species.

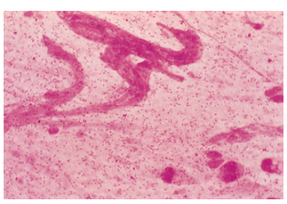

FIGURE 51.13. Gram stain of *Haemophilus influenzae* in sputum.

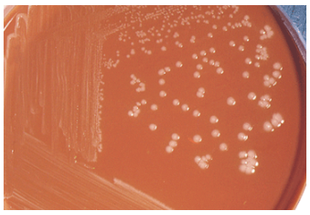

FIGURE 51.14. Colony of Haemophilus influenzae on chocolate agar.

Spectrum of Disease

H. influenzae consists of six capsular serotypes (a to f) and unencapsulated strains. Most *Haemophilus* infections in humans are caused by *H. influenzae*, and approximately 95% of cases of invasive disease were due to serotype b in the prevaccine era. *H. influenzae* infections occur primarily in children and include meningitis, bacteremia, epiglottitis, pneumonia and empyema, septic arthritis, cellulitis, pericarditis, osteomyelitis, and a variety of less frequently encountered infections. Unencapsulated strains are associated with infections such as chronic bronchitis, otitis media, sinusitis, and conjunctivitis. After introduction of the vaccine, invasive infection declined 95% in children (82).

The other *Haemophilus* species are uncommon causes of infection. *H. ducreyi* is the etiologic agent of the sexually transmitted disease chancroid (soft chancre).

Epidemiology

Haemophilus species are residents in the upper respiratory tract (nasopharynx, pharynx, and oral cavity) and the urogenital tract. Unencapsulated strains of *H. influenzae* are isolated from 50% of the population, whereas serotype b is carried by less than 5% of children and rarely by adults. Transmission of *H. influenzae* is thought to occur via respiratory droplets and is enhanced in crowded conditions (e.g., day care centers). *H. ducreyi* is transmitted by sexual contact. The highest incidence of chancroid is in Asia, Africa, and Central America.

Diagnostic Techniques

Microscopy

The presence of small, gram-negative coccobacilli in sterile body fluids (e.g., CSF, synovial fluids) or in respiratory secretions is suggestive of *Haemophilus* (Fig. 51.13).

Gram-stained smears of exudate from genital lesions revealing large numbers of gram-negative coccobacilli occurring in parallel chains (schools of fish) is suggestive of *H. ducreyi*, but smears are usually negative.

Culture Techniques

Specimens should be plated on enriched chocolate agar and incubated in 5% CO_2 at 35° to 37°C for 2 to 3 days. *Haemophilus* may be isolated on blood agar as satelliting colonies around staphylococci or other organisms.

Although *H. ducreyi* may be isolated on enriched chocolate agar containing vancomycin (3 µg/mL), other media (e.g., gonococcal base with 5% Fildes reagent, 5% horse blood with 3 µg/mL vancomycin) and multiple cultures are recommended for optimal recovery (82). Media should be incubated at 33°C in 5% CO_2 in a moist environment for 72 hours.

Haemophilus colonies on chocolate agar are usually small (0.5 to 1 mm), grayish, round, translucent, and smooth (Fig. 51.14). *H. haemolyticus* and *H. parahaemolyticus* may be ß-hemolytic on horse blood. Colonies of *H. ducreyi* are small, flat, smooth, and yellow-gray and can be pushed across the agar. *H. aphrophilus* and *H. paraphrophilus* produce larger colonies (1 to 1.5 mm) that are opaque, granular, and yellowish.

Identification Methods

Most laboratories presumptively identify *Haemophilus* species based on their growth around the disks containing hemin or NAD or by using the commercially available porphyrin test. Additional testing is necessary for a definitive identification (Table 51.18). *H. influenzae* and *H. parainfluenzae* can be further differentiated into biotypes (82). Commercial systems are available for the identification and biotyping of some *Haemophilus* species. A DNA probe is available for the culture identification of *H. influenzae*.

TABLE 51.18. DIFFERENTIAL CHARACTERISTICS OF THE GENUS *HAEMOPHILUS*

[d] Weak.

Modified from Albritton WL *Haemophilus influenzae* infections. In: Balows A, Hausler WJ Jr, Ohashi M, et al. eds. *Laboratory diagnosis of infectious disease principles and practice, vol 1*. New York: Springer-Verlag, 1983:302–311.

Direct Antigen and Nucleic Acid Detection

Particle agglutination kits are available for the direct detection of *H. influenzae* type b capsular antigen in clinical specimens but are seldom used by laboratories. The systems have the highest sensitivity and specificity when performed on CSF rather than on urine or serum. The sensitivity of the test on CSF specimens varies from 70% to 90%.

Serologic Procedures

Serologic procedures are not generally useful for assisting in the diagnosis of infection by *Haemophilus* species.

Interpretation of Results

The isolation of *H. ducreyi*, other *Haemophilus* species from normally sterile body fluids or deep tissues, or *H. influenzae* from the eye is clinically relevant. The significance of the isolation of *H. influenzae* (especially serotype b) or other species from respiratory secretions depends on the evaluation of the patient.

Therapeutic Considerations

Empiric treatment for life-threatening infections caused by *H. influenzae* type b consists of third-generation cephalosporins. ß-Lactamase activity and susceptibility testing should be performed on isolates from serious infections.

Summary and Conclusions

Haemophilus species are a component of the normal flora of the upper respiratory tract and, in part, the genital tract. *H. influenzae* (especially serotype b) causes the majority of human infections, which range from invasive life-threatening infections (e.g., meningitis) to less serious problems such as bronchitis. The other species are infrequently implicated but can cause similar types of infections, especially endocarditis. *H. ducreyi* is the etiologic agent of chancroid. The requirement of hemin and NAD for growth helps determine the identity of some species. The increasing antimicrobial resistance of *H. influenzae* has complicated therapy; therefore, routine susceptibility testing of clinically significant isolates is necessary.

NONFERMENTATIVE GRAM-NEGATIVE BACILLI

Part of "51 - Bacteriology"

Microbiology

The group of nonfermentative gram-negative bacilli (NFB) is one of convenience for the clinical microbiologist and describes bacteria that are gram-negative rods and relatively inert biochemically. On the oxidation-reduction medium of Hugh and Leifson, they may produce an oxidative or alkaline reaction or no reaction. Most species are strict aerobes, are catalase positive (*Eikenella* is catalase negative and facultatively anaerobic), and are oxidase positive (*Acinetobacter* and CDC group Ve-1,Ve-2 are negative and *Burkholderia cepacia* and *Stenotrophomonas maltophilia* are weakly positive). *Kingella* and CDC group EF-4a are weak fermenters and may be mistaken for NFB. Most species grow on MacConkey agar (except *Eikenella, Moraxella*, some *Flavobacterium* species) at 35°C in air. Some species grow better at 25° to 30°C. The arrangement of the flagella may be useful for the identification of some species.

TABLE 51.19. TAXONOMY OF NONFERMENTATIVE GRAM-NEGATIVE BACILLI

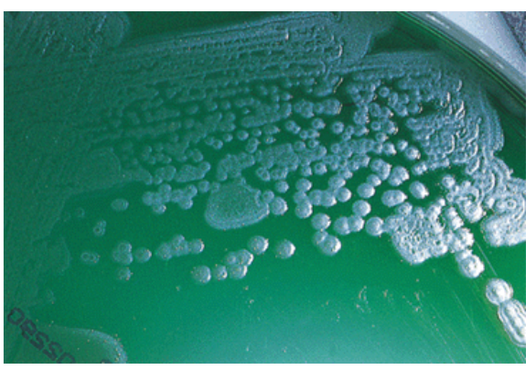

FIGURE 51.15. Colony of *Pseudomonas aeruginosa* on Mueller-Hinton agar. Note the blue-green diffusible pigment.

Members of the genus *Pseudomonas* are now classified into nine additional genera: *Burkholderia, Stenotrophomonas, Comamonas, Acidovorax, Brevundimonas, Shewanella, Methylobacterium, Sphingomonas*, and *Ralstonia* (83). The classification of the NFB is constantly being revised. Table 51.19 lists the current name and the former name for selected species. The reader is referred

to the reference section for a more thorough discussion of the classification of NFB (84).

Spectrum of Disease

The NFB comprise approximately 15% to 20% of all the gram-negative rods that are isolated in the clinical laboratory. *Pseudomonas aeruginosa* is the most frequently recovered NFB and a major cause of nosocomial infections, especially in the immunocompromised person. Infection with *P. aeruginosa* is often life-threatening and can present as bacteremia, pneumonia, skin and soft-tissue infection, urinary tract infection, or GI infection. Burn and cystic fibrosis patients are highly susceptible to infection. Community-acquired infections include folliculitis associated with whirlpools; otitis externa in divers, swimmers, and diabetics; osteomyelitis associated with deep puncture wounds; ocular infections associated with wearing contact lenses; and endocarditis and vertebral osteomyelitis in injection drug users. The next most frequently isolated species are *Acinetobacter, B. cepacia*, and *S. maltophilia*. Infections by the other species are rare, and most isolations are not clinically significant but represent colonization. Infections, when they occur, are usually hospital-acquired necrotizing pneumonia, urinary tract infection, wound infection, bacteremia, and endocarditis. These organisms are not associated with GI disease and are seldom isolated from feces.

Acinetobacter is recovered primarily as a colonizer but has caused suppurative infections in nearly every organ system. It is primarily a nosocomial pathogen, with most infections caused by *A. baumannii*. Nosocomial infections include respiratory infection, catheter site infection, and urinary tract infection.

B. pseudomallei causes melioidosis, a rare infection in North America. Most cases occur in people returning from travel to Southeast Asia or northern Australia. The disease often presents with acute pneumonia but may occur as a localized infection. A high mortality rate is associated with septicemia and dissemination.

B. mallei causes glanders, a disease of horses, mules, and donkeys that may be transmitted to humans. It is rarely seen today.

B. cepacia and *S. maltophilia* are important nosocomial pathogens. Although less virulent than *P. aeruginosa*, these organisms cause similar types of infections in the hospitalized patient. *B. cepacia* infection in patients with cystic fibrosis or chronic granulomatous disease produces significant morbidity and mortality. Cystic fibrosis patients experience a rapid decrease in lung function, frequent bacteremia, and death (85).

Alcaligenes xylosoxidans has been reported to cause individual cases of meningitis, pneumonia, peritonitis, urinary tract infection, bacteremia, and endocarditis (prosthetic valve). *Oligella* species have been recovered primarily from the urinary tract and may cause bacteremia. *Chryseomonas* species cause infrequent cases of neonatal meningitis, bacteremia, endocarditis, wound infections, and respiratory tract infections. *Weeksella zoohelcum* is isolated from bites and scratches of dogs and cats and *W. virosa* from urinary tract infections. *Ochrobactrum* causes catheter-related septicemia. *Methylobacterium* species has been associated with bacteremia, skin ulcers, and peritonitis in patients on continuous ambulatory peritoneal dialysis. *Moraxella* (especially *M. lacunata*) causes primarily eye infections. *Eikenella* has been recovered from a variety of infections, including human bites, head and neck infections, skin infections in injection drug users, and a variety of other deep-seated or systemic infections.

Epidemiology

Most NFB can be isolated from soil, water, vegetation (including fruits and vegetables), or nearly any moist location. Minimal nutritional requirements and their antimicrobial resistance, particularly *P. aeruginosa*, have led to their emergence as nosocomial pathogens. Hospital reservoirs include respiratory equipment, disinfectants, sinks, solutions, food, whereas disease-related reservoirs outside the hospital include whirlpools, swimming pools, cosmetics, illicit injectable drugs, hot tubs, and contact lens solution. *P. aeruginosa* colonizes the skin, oropharynx, and GI tract in 2% to 10% of healthy persons. The rate of colonization is usually higher in hospitalized patients. Transmission occurs via contaminated solutions, equipment, food, and probably on the hands of hospital personnel.

B. pseudomallei inhabits soil and water but is restricted primarily to Southeast Asia and other tropical or subtropical parts of the world. Transmission is primarily through abrasions or cuts but may occur by inhalation or ingestion.

Eikenella and *Moraxella* are common inhabitants of the mucous membranes of the upper respiratory tract. *Eikenella* is also part of the GI flora. Infections arise from breaks in the mucous membranes.

Diagnostic Procedures

Microscopy

All the NFB are gram-negative rods. In general, *Pseudomonas* species appear as thin rods, whereas *Acinetobacter* and *Moraxella* are coccobacillary. The morphology alone cannot be used for a definitive identification. *Acinetobacter* and *Moraxella* may resemble *Neisseria*.

TABLE 51.20. CHARACTERISTICS OF GENERA OF NONFERMENTATIVE BACTERIA

Genus	Catalase	Oxidase	Growth on MacConkey Agar	Motility	Utilization of Glucose
Pseudomonas	+	+	Good	Motile by means of polar flagella	Oxidative
Achromobacter	+	+	Good	Motile by means of peritrichous flagella	Oxidative
Alcaligenes	+	+	Good	Motile by menas of peritrichous flagella	Inactive
Acinetobacter	+	-	Good	Nonmotile	Oxidative or inactive
Chryseobacterium	+	+	Variable	Nonmotile	Oxidative
Moraxella	+/-	+	Variable	Nonmotile	Inactive
Eikenella	-	+	Negative	Nonmotile	Inactive
Kingella	-	+	Variable	Nonmotile	Delayed fermentative
EF-4	+	+	Variable	Nonmotile	Delayed fermentative

+, positive; -, negative; +/-, most strains positive.

Modified from Oberhofer TR, Howard RJ. Nonfermentative gram-negative bacteria. In: Howard BJ, Klass J M, Rubin SJ, et al. eds. *Clinical and pathogenic microbiology*. St. Louis: Mosby, 1987:329–358.

Culture Techniques

Most NFB are recovered on blood or MacConkey agars after 24 hours at 35°C in air or CO_2. *Eikenella, Methylobacterium, Weeksella*,

some *Moraxella*, *Chryseobacterium* species and CDC groups do not grow on MacConkey agar, and some NFB grow better at 25° to 30°C. The use of selective media is recommended for the recovery of *B. cepacia* from cystic fibrosis patients.

P. aeruginosa produces a flat colony with a feathered edge, may be ß-hemolytic, has a grapelike odor, and may produce a variety of pigments [pyocyanin (blue-green), pyoverdin (yellow-green), pyorubin (red), or pyomelanin (brown)] (Fig. 51.15). *B. pseudomallei*, *P. stutzeri*, *P. luteola*, and *P. oryzihabitans* form dry, wrinkled colonies. *Alcaligenes* may produce a fruity odor, whereas *B. pseudomallei* and some strains of *P. aeruginosa* may have a pungent, earthy odor. The *Chyrseobacterium*, *Myroides*, and *Flavobacterium* species generally produce a yellow pigment; *Acinetobacter* colonies resemble the Enterobacteriaceae; *Moraxella* colonies are tiny (less than 1 mm) after 24 hours; and *Eikenella* colonies may pit or corrode the agar.

Identification Methods

The initial characterization of NFB is based on the presence of pigment, oxidase reaction, catalase reaction, growth on MacConkey agar, motility, and whether the organism uses glucose fermentatively, oxidatively, or not at all (Table 51.20).

The differential characteristics of *P. aeruginosa* and the other NFB are presented in Table 51.21,Table 51.22,Table 51.23, and Table 51.24. If pyocyanin is present and the isolate is oxidase positive, it is identified as *P. aeruginosa* without any additional tests. *B. cepacia*, *S. maltophilia*, and *Pseudomonas* species are motile with polar flagella, grow on MacConkey agar, are oxidase positive (*B. cepacia*, *S. maltophilia*, *P. luteola*, and *P. orzihabitans* may be negative), glucose oxidizers, and catalase positive.

TABLE 51.21. CHARACTERISTICS OF *PSEUDOMONAS* SPECIES FOUND IN CLINICAL SPECIMENS

Data from Kiska DL, Gilligan PH. *Pseudomonas*. In: Murray R, Baron EJ, Pfaller MA, et al., eds. *Mannual of clinical microbiology*, 7th ed., Washington, DC: American Society for Microbiology, 1999: 518-519.

Alcaligenes are motile by peritrichous flagella, are oxidase and catalase positive, grow on MacConkey agar, do not oxidize glucose, and are relatively inert. Species of *Acinetobacter* are nonmotile, catalase positive, oxidase negative, and nitrate negative, grow on MacConkey agar, and are nonfermentative. *Chyrseobacterium*, *Myroides*, *Flavobacterium* species, some *Weeksella*, and some *Sphingobacterium* species are nonmotile, are catalase and oxidase positive, exhibit variable growth on MacConkey agar, produce a yellow pigment, and may be oxidative or inactive toward glucose. The *Moraxella* species are nonmotile, inactive toward glucose, oxidase and catalase positive, and exhibit variable growth on MacConkey agar. *Eikenella corrodens* is oxidase positive, catalase negative, and inactive toward glucose, does not grow on MacConkey agar, is nonmotile, may pit the agar, and has a bleachlike odor.

Several commercial systems with variable accuracy are available for the identification of NFB. Another commercially available system analyzes cell-wall fatty acids by gas-liquid chromatography.

Direct Antigen or Nucleic Acid Detection

No commercial system is available for the direct detection of NFB in clinical specimens, although research methods are available for *B. pseudomallei* and *B. cepacia*.

Serologic Procedures

A fourfold rise in titer with the hemagglutination, complement-fixation, or agglutination test aids in the diagnosis of melioidosis. Titers greater than 1:8 (complement fixation) or greater than 1:160 (agglutination) are highly suggestive of infection during the acute illness. These tests are performed only in reference laboratories because of the low incidence of the disease. Serologic tests for the diagnosis of infections caused by the other NFB are not routinely available.

Interpretation of Results

The isolation of *B. pseudomallei* or *B. mallei* is always clinically significant. Because *P. aeruginosa* is primarily a nosocomial pathogen and is so devastating in the compromised host, its presence in clinical specimens should be considered relevant until proven otherwise. The colonization of the skin and mucous membranes in the compromised patient often precedes systemic infection. *P. aeruginosa* and *B. cepacia* are significant isolates in cystic fibrosis patients. The other NFB are often colonizers, and the clinical significance of their isolation depends on the underlying condition of the patient, the source of the specimen, the number of other bacterial species isolated, and the need for epidemiologic data.

Therapeutic Considerations

The antimicrobial susceptibility of *P. aeruginosa* and many of the other genera is not predictable. Appropriate therapy depends on the results of susceptibility testing. However, interpretive breakpoints for many of the NFB have not been determined. Empiric therapy involves one, two, or three agents, depending on the severity of the disease and the susceptibility pattern of local isolates. In general, therapy will include an aminoglycoside and an antipseudomonal penicillin or parenteral cephalosporin active against *P. aeruginosa*. The currently recommended treatment for the septicemic form of melioidosis is trimethoprim-sulfamethoxazole, ceftazidime, amoxicillin-clavulanate, or imipenem. Trimethoprim-sulfamethoxazole can be used for *B. cepacia* or *S. maltophilia* infections.

Alcaligenes is usually susceptible to trimethoprim-sulfamethoxazole and variably susceptible to most other antimicrobial agents. *Moraxella* and *Eikenella* are usually susceptible to penicillin and ampicillin, although isolates containing β-lactamase have been reported. *Eikenella* is resistant to clindamycin, cephalexin, erythromycin, and metronidazole.

Summary and Conclusions

The NFB are ubiquitous in soil, water, and most environments. *Eikenella* and *Moraxella* are part of the normal flora of the mucous membranes in humans and cause endogenously acquired infections. The other NFB, particularly *P. aeruginosa*, are important nosocomial pathogens found in numerous hospital reservoirs (e.g., contaminated solutions, equipment, food, and sinks) and infect nearly every organ system. *B. pseudomallei* and *B. mallei* are the etiologic agents of melioidosis and glanders, respectively. In general, the NFB are easily isolated and grow on most routine media, but they are difficult to identify by either conventional tests

or commercial systems. Pyocyanin pigment is a definitive characteristic of *P. aeruginosa*. The susceptibility of the NFB to antimicrobial agents must be determined by testing. *Eikenella* and *Moraxella* are usually susceptible to penicillin or ampicillin.

MISCELLANEOUS FACULTATIVELY ANAEROBIC GRAM-NEGATIVE BACILLI

Part of "51 - Bacteriology"

Microbiology

The genera and species discussed in this section are usually slow growing; may not grow on MacConkey, blood, or chocolate agar; and often grow better in a CO_2-enriched atmosphere. They include *Gardnerella, Cardiobacterium, Chromobacterium, Pasteurella, Actinobacillus, Kingella, Capnocytophaga, Streptobacillus, Suttonella*, and CDC group EF-4.

G. vaginalis was previously classified as *Haemophilus vaginalis* or *Corynebacterium vaginale*. The cell wall is similar to but much thinner than gram-positive organisms. *G. vaginalis* is a small (0.5 × 1.5 µm), pleomorphic, fastidious, facultatively anaerobic, nonmotile, oxidase- and catalase-negative, gram-negative to gram-variable rod that does not grow on MacConkey agar.

Cardiobacterium hominis and *Suttonella indologenes* are a facultatively anaerobic, slow-growing, fastidious, nonmotile, oxidase-positive, catalase-negative, pale-staining gram-negative rods. They do not grow on MacConkey agar, and growth is enhanced by humidity and CO_2.

The genus *Chromobacterium* contains two species, but only *C. violaceum* is isolated from clinical specimens. It is a facultatively anaerobic, motile, oxidase- and catalase-positive, gram-negative rod that usually produces a violet pigment. Unlike the other organisms in this section, *C. violaceum* grows on most routine laboratory media in ambient air.

The genus *Pasteurella* contains 20 recognized species and is similar to *Actinobacillus* based on moles percent G + C of their chromosomal DNA and phenotypic characteristics. *P. multocida* is the most common human pathogen of the genus. The other species are only rarely isolated from clinical specimens. *P. multocida* is a facultatively anaerobic, nonmotile, catalase- and oxidase-positive, gram-negative rod that may exhibit bipolar staining and does not grow on MacConkey agar.

The genus *Actinobacillus* contains six species, *A. ureae, A. lignieresii, A. equuli, A. suis, A. hominis*, and *A. pleuropneumoniae*. The *Actinobacillus* species are primarily animal pathogens. *A. actinomycetemcomitans* is closely related to *H. aphrophilus* and *H. segris*. These latter three species do not belong in the genus *Haemophilus* or *Actinobacillus* and probably will be classified in a new genus in the future. *A. actinomycetemcomitans* is a facultatively

TABLE 51.24. CHARACTERISTICS OF *EIKENELLA CORRODENS*, *MORAXELLA*, *PSYCHROBACTER*, AND *OLIGELLA* SPECiEs

anaerobic, fastidious, slow-growing, small (0.5 × 1.5 μm), nonmotile, catalase-positive, gram-negative coccobacillary rod that does not grow on MacConkey agar and grows best in humidity and CO_2.
The genus *Kingella* consists of three species: *K. kingae, K. denitrificans*, and *K. oralis*. *Kingella* species are facultatively anaerobic, nonmotile, catalase-negative, oxidase-positive, gram-negative rods that do not grow on MacConkey agar.
Seven species of *Capnocytophaga* are recognized: *C. ochracea, C. gingivalis, C. sputigena, C. canimorsus, C. cynodegmi, C. haemolytica*, and *C. granulosa*. They are facultatively anaerobic, fastidious, capnophilic, oxidase-variable, catalase-negative, gram-negative fusiform rods that may exhibit gliding motility and do not grow on MacConkey agar. *C. canimorsus* is a weakly oxidase-positive, catalase-positive, nonmotile, fermentative, long, thin, gram-negative fusiform rod that does not grow on MacConkey agar and grows poorly on other laboratory media (86).
CDC group EF-4 is an oxidase- and catalase-positive, nonmotile, fermentative (for glucose), gram-negative rod that grows poorly on MacConkey agar.

Spectrum of Disease

G. vaginalis is associated with BV (nonspecific vaginitis), which is characterized by a malodorous vaginal discharge and overgrowth with various anaerobic bacteria. Extragenital infections include bacteremia, vaginal abscesses, neonatal bacteremia, and soft-tissue infections. *C. hominis* and *S. indologenes* have been implicated in cases of endocarditis and bacteremia (87,88). *C. violaceum* is associated with urinary tract infections, localized abscesses, and fulminant sepsis with abscesses in multiple organs.
P. multocida is associated with three broad categories of disease: (a) localized infection after an animal bite or scratch (usually from a cat), (b) chronic pulmonary disease, particularly in patients with underlying pulmonary disease, and (c) bacteremia with or without metastatic foci. The latter group includes meningitis; brain, liver, and renal abscesses; otitis; mastoiditis; sinusitis; endocarditis; septic arthritis; and peritonitis. Spontaneous peritonitis and septicemia occur most often in patients with cirrhosis.
Actinobacillus is associated with juvenile periodontitis; endocarditis (particularly damaged or prosthetic heart valves); and infrequent reports of meningitis, brain abscess, osteomyelitis, urinary tract infection, pericarditis, and pulmonary infections.
Kingella infections include endocarditis, meningitis, bacteremia, septic arthritis, osteomyelitis, intervertebral disk infections, and infections of the eye. *K. kingae* infections occur primarily in children and young adults. *K. denitrificans* causes endocarditis in adults.
Capnocytophaga is associated with juvenile periodontitis, bacteremia, endocarditis, osteomyelitis, septic arthritis, sinusitis, pulmonary infections, conjunctivitis, and keratitis. Most infections occur in immunocompromised patients with severe granulocytopenia and oral ulcerations. *C. canimorsus* and *C. cynodegma* are associated with animal bites.
C. canimorsus causes two patterns of disease: (a) shock and disseminated intravascular coagulation seen in splenectomized patients, and (b) a milder form of disease in patients with a spleen. Infections include septicemia, meningitis, endocarditis, pneumonia, necrotizing wound infections, brain abscess, cellulitis, septic arthritis, corneal ulceration, and glomerulonephritis. Predisposing factors include splenectomy and a history of alcoholism.
CDC group EF-4 is associated with dogs and cats and cause wound infections and rarely bacteremia after bites, scratches, or contamination of a preexisting wound.

Epidemiology

G. vaginalis is part of the endogenous flora of the human genital tract and is associated with bacterial vaginosis (BV), the most common cause of vaginal discharge in sexually active women. BV is associated with preterm birth, premature rupture of membranes, and chorioamnionitis (89). Sexual transmission of the disease is not proven, but a high proportion of the male sex partners of women with the syndrome carry *G. vaginalis* on their urethral mucosa.
C. hominis, S. indologenes, A. actinomycetemcomitans, Kingella species, and *Capnocytophaga* species are part of the oropharyngeal flora in humans. Most infections result from endogenous spread of the bacterium, often after dental manipulations or oral disease such as periodontitis.
C. violaceum inhabits soil and water, particularly in warmer climates such as the southeastern United States, Southeast Asia, or South America. Infections generally occur after contamination of wounds with soil or water, or rarely after ingestion of contaminated water.
P. multocida, C. canimorsus, C. cynodegma, and CDC group EF-4 are found in the upper respiratory tract of dogs and cats. *C. canimorsus, C. cynodegma*, and EF-4a infections in humans generally follow dog bites or exposure to dog secretions. *C. canimorsus, C. cynodegma*, and EF-4b are also associated with cat bites and scratches. The reservoir for *P. multocida* is the upper respiratory tract of cats, dogs, other mammals, birds, and probably humans. The frequency of carriage varies with the species but is most common in cats. Transmission to humans occurs after bites, scratches, or exposure to secretions.

Diagnostic Procedures

Microscopy

BV can be presumptively diagnosed by Gram stain of vaginal secretions that demonstrate numerous clue cells (vaginal epithelial cells covered by gram-variable coccobacilli) associated with a mixed flora of large numbers of gram-negative to gram-variable coccobacilli in the absence of lactobacilli (90). The syndrome is best diagnosed by clinical criteria, a Gram stain or wet mount preparation of discharge, vaginal pH, and 10% KOH preparation of discharge rather than by culture of *G. vaginalis*.
The organisms discussed in this section are gram-negative rods that cannot be definitely identified by direct examination of the clinical specimen. *C. hominis* is a pale-staining pleomorphic (sometimes teardrop-shaped) rod; *P. multocida* is a small coccobacillus that may exhibit bipolar staining; *A. actinomycetemcomitans*

is a small coccobacillus; *Kingella* are small coccobacilli arranged in pairs or chains; *Capnocytophaga* are thin fusiform rods; and *C. canimorsus* is a filamentous, sometimes curved fusiform rod. Both *C. hominis* and *Kingella* have a tendency to retain the primary stain.

Culture Techniques

G. vaginalis is most easily isolated on human blood bilayer Tween agar (HBT), vaginalis agar (V-agar), or Columbia CNA. Media are incubated at 35° to 37°C in a humid atmosphere containing 5% CO_2 for 2 days. After 48 hours, colonies are approximately 0.5 mm in diameter and gray and exhibit diffuse ß hemolysis on human but not on sheep blood. On routine sheep blood agar, colonies are pinpoint to barely visible.

C. hominis produces pinpoint colonies on chocolate or blood agar after 2 to 3 days incubation in a moist, 5% CO_2 atmosphere. A slight green to brown color may develop around the colony.

C. violaceum grows well on blood and MacConkey agar in 24 hours at 35° to 37°C in air. Most colonies exhibit a characteristic violet pigment (produced optimally at 22°C) and often produce an odor of cyanide (almond).

Actinobacillus and *Capnocytophaga* grow best on blood or chocolate agar incubated in high humidity and in a 5% to 10% CO_2-enriched atmosphere. After 2 to 3 days of incubation, colonies of *Actinobacillus* are small (0.5 mm), punctate, and adherent with a mixed morphology. On continued incubation, a starlike, opaque center may be observed under 100× magnification (Fig. 51.16). *Capnocytophaga* produces yellow nonhemolytic colonies with fingerlike projections and an almond odor after 2 to 3 days of incubation. Some strains will grow only anaerobically on initial isolation. Colonies may pit the agar.

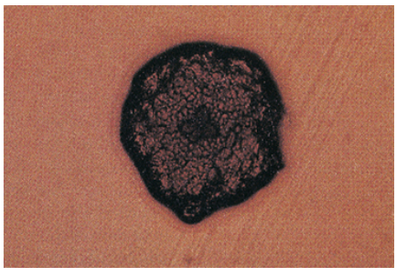

FIGURE 51.16. Colony of *A. actinomycetemcomitans* on heart infusion agar. Note the central star-shaped structure. (From Baron EJ, Finegold SM. *Bailey and Scott's diagnostic microbiology*, St. Louis: Mosby, 1990, with permission.)

Kingella grows in air or CO_2 (may enhance growth) but grows poorly under anaerobic conditions. Colonies are 0.5 to 1 mm in diameter after 48 hours of incubation at 35°C and may pit the agar or produce a "fried-egg" appearance. *K. denitrificans* grows on Martin-Lewis agar and may be confused with *N. gonorrhoeae*.

Pasteurella grows well on nonselective media such as blood or chocolate agar at 35°C in air or CO_2. Colonies are usually smooth, gray and 1 to 2 mm after 24 hours of incubation, have a musty odor, and may produce a green to brown discoloration on blood agar.

C. canimorsus grows slowly (2 to 4 days) on enriched chocolate agar incubated at 35°C in a humid, CO_2-enriched atmosphere. Growth is poor under anaerobic conditions.

EF-4 grow well on nonselective media (e.g., blood or chocolate agar) within 24 hours of incubation at 35°C. Colonies are small and yellow-orange and produce a popcornlike odor.

Identification Methods

G. vaginalis can be identified presumptively on the basis of negative catalase and oxidase tests, ß-hemolytic colonies on HBT agar, and a typical Gram-stain morphology. Confirmatory tests include starch and hippurate hydrolysis, α- and ß-glucosidase tests, or use of some commercial systems for identification of *Corynebacterium*.

C. hominis and *S. indologenes* are oxidase positive and catalase negative and are differentiated from similar organisms (e.g., *Eikenella, Kingella*, and *H. aphrophilus*) by the production of indole (Table 51.25). Serum may have to be added to carbohydrate tests to ensure growth.

TABLE 51.25. DIFFERENTIATION OF SELECTED GENERA AND SPECIES OF GRAM-NEGATIVE BACILII

Organism	Fusiform Shape	Catalase	Oxidase	Indole	Motility	Nitrate Reduction	Glucose Fermentation	Growth on MacConkey
Cardiobacterium	-	-	+	+	-	-	+	v

Actinobacillus actinomycetemcomitans	-	+	v	-	-	+	+	-
Pasteurella multocida	-	+	+	+	-	+	+	-
Eikenella corrodens	-	-	+	-	-	+	-	-
Kingella	-	-	+	v	-	v	+	v
Haemophilus aphrophilus	-	-	v	-	-	+	+	-
CDC Group EF4a	-	+	+	-	-	+	+	v

+, >90% positive; -, 90% negative; v, variable reaction; [a]Some nonpigmented stains are positive.

C. violaceum is oxidase and catalase positive and motile, reduces nitrate, and ferments glucose. It can be distinguished from other genera such as *Aeromonas, Plesiomonas*, and *Vibrio* by negative tests for indole, ornithine, and lysine decarboxylase reactions and lack of fermentation of mannitol and maltose.

Actinobacillus may be differentiated from similar genera with a minimum number of tests, but the definitive identification of a suspected isolate requires a more comprehensive battery.

Kingella species are catalase negative, oxidase positive, and nonmotile (Table 51.25). *K. kingae* is distinguished from the other two species by ß hemolysis on sheep blood agar and the absence of indole production, nitrate reduction, and growth on Martin-Lewis agar.

Pasteurella species are generally catalase negative, oxidase positive, and nonmotile (Table 51.25). Other characteristic reactions for *P. multocida* include a positive ornithine decarboxylase and indole reaction.

Characteristics useful for the identification of the genus *Capnocytophaga* are listed in Table 51.25. Commercial identification systems are also available. *C. canimorsus* often requires the addition of rabbit serum to obtain adequate growth in the biochemical tests. It is weakly oxidase (positive) and catalase positive; indole, urease, and nitrate-reduction negative; and arginine dihydrolase positive.

CDC group EF-4 strains are oxidase and catalase positive, reduce nitrate, and are negative for urease and indole production.

Direct Antigen to Nucleic Acid Detection

No commercial systems are available for the direct detection of any of these bacteria in clinical specimens.

Serologic Procedures

No routine serologic tests are available for the diagnosis of infections caused by this group of organisms.

Interpretation of Results

With the exception of *G. vaginalis,* these bacteria are seldom isolated from clinical specimens. Therefore, their isolation is clinically significant until proven otherwise. The isolation of any members of the HACEK group (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, Kingella*) from blood is highly suspicious of endocarditis, especially if the patient has oral trauma or poor dentition. The presence of large numbers of *G. vaginalis* organisms in vaginal secretions is suggestive of BV but does not prove that *G. vaginalis* causes the syndrome.

Therapeutic Considerations

Standardized susceptibility tests are often difficult to perform because of the growth requirements of some of these bacteria. Oral metronidazole or clindamycin treatment is the treatment of choice for BV.

Cardiobacterium and *Suttonella* are susceptible to ß-lactam agents, tetracycline, chloramphenicol, and aminoglycosides but variably resistant to clindamycin, erythromycin, oxacillin, and vancomycin.

C. violaceum should be tested for susceptibility to antimicrobial agents. Most isolates are susceptible to tetracycline, chloramphenicol, erythromycin, and trimethoprim-sulfamethoxazole with variable resistance to aminoglycosides. They are often resistant to the ß-lactam antibiotics and clindamycin.

P. multocida is susceptible to penicillin, cephalothin, trimethoprim-sulfamethoxazole, and tetracycline. Limited experience is available for the treatment of infections with the newer antimicrobial agents.

Actinobacillus is generally susceptible to chloramphenicol, tetracycline, carbenicillin, and streptomycin, and is variably susceptible to penicillin. *In vitro* tests indicate susceptibility to the newer cephalosporins, rifampin, trimethoprim-sulfamethoxazole, and fluoroquinolones. Combined penicillin-aminoglycoside therapy has been recommended for endocarditis.

Kingella are generally susceptible to the ß-lactams (*K. denitrificans* may be moderately resistant to penicillin), cephalothin, aminoglycosides, tetracycline, chloramphenicol, and sulfonamides.

Capnocytophaga are susceptible to penicillin, extended-spectrum cephalosporins, chloramphenicol, tetracycline, erythromycin, clindamycin, quinolones, and are resistant to vancomycin, aminoglycosides, metronidazole, and trimethoprim-sulfamethoxazole.

CDC group EF-4a organisms appear susceptible to the ß-lactams, chloramphenicol, and tetracycline based on limited studies.

Summary and Conclusions

The miscellaneous facultatively anaerobic gram-negative bacilli discussed in this section are usually inhabitants of the upper respiratory tract of humans (e.g., *Actinobacillus, Kingella, Cardiobacterium*, and *Capnocytophaga*), the genital tract (e.g., *Gardnerella*), the upper respiratory tract of animals (e.g., *Pasteurella, C. canimorsus*, and CDC group EF-4), or soil and water (e.g., *Chromobacterium*). Infections usually follow the spread of the bacterium from a colonized site or after exposure to animal bites, scratches, or secretions. These species cause a variety of diseases ranging from localized soft-tissue infections to systemic life-threatening infections. Most of the organisms are fastidious, do not grow on MacConkey agar, and require increased humidity and CO_2-enriched atmosphere for growth. *Chromobacterium* grows well on most routine media. *C. violaceum* is resistant to penicillin and *A. actinomycetemcomitans* is moderately resistant; the other species are susceptible to penicillin.

MISCELLANEOUS GRAM-NEGATIVE BACILLI WITH SPECIAL GROWTH REQUIREMENTS

Part of "51 - Bacteriology"

Microbiology

The microorganisms discussed in this section are not usually isolated on routine laboratory media (e.g., blood and MacConkey agars) after 24 hours of incubation. In general, these bacteria are associated with a specific clinical syndrome of which the laboratory needs to be aware. Many of these organisms pose a considerable challenge regarding their isolation and identification.

The genus *Francisella* contains two species, *F. tularensis* and

F. philomiragia. The latter organism rarely causes disease in humans. *F. tularensis* is composed of three biovars: type A (biovar *tularensis*), type B (biovar *palaearctica*), and biovar *novicida*. Type A is the most virulent. *F. tularensis* is an aerobic, small (0.2 × 0.2 to 0.7 μm), nonmotile, oxidase-negative, weakly catalase positive, gram-negative rod that generally requires enriched media with added cystine or cysteine for growth.

There are six recognized species of the genus *Brucella*, four of which are pathogenic for humans (*B. abortus, B. melitensis, B. suis*, and *B. canis*). *B. neotomae* (found in the desert wood rat) and *B. ovis* (a pathogen of sheep) have not been shown to cause disease in humans. A new species, *B. maris*, has been isolated from marine mammals but not humans. DNA hybridization studies suggest that all species are very closely related. *Brucella* species are nonmotile, catalase-positive, usually oxidase-positive, gram-negative coccobacilli or short rods (0.5 × 0.6 to 1.5 μm) that are usually arranged singly but may occur in short chains or groups. The organisms are strict aerobes, often requiring a CO_2-enriched atmosphere on primary isolation. The addition of glucose (1.5% to 2.5%), serum, thiamine, nicotinamide, and magnesium to the medium promotes growth.

The genus *Bordetella* consists of seven species: *B. pertussis, B. parapertussis, B. bronchiseptica, B. avium, B. hinzii, B. holmesii*, and *B. tematum*. *B. pertussis* is the etiologic agent of whooping cough. *B. parapertussis* may be a variant of *B. pertussis*, although some studies suggest it is more closely related to *B. bronchiseptica*. *B. bronchiseptica* is an animal pathogen and rarely causes symptomatic disease in humans. *B. avium* and *B. hinzii* are avian pathogens. The other two species rarely cause bacteremia and wound and ear infections. *Bordetella* species are strictly aerobic, small (0.3 × 0.5 to 2.0 μm), gram-negative coccobacilli that often exhibit bipolar staining and are arranged singly or in pairs. The two human strains and *B. holmisii* are nonmotile. All species require nicotinic acid or nicotinamide and grow best at 35° to 37°C.

Calymmatobacterium granulomatis is the only species in this unassigned genus. It is a nonmotile, encapsulated, gram-negative coccobacillus (0.5 × 1 to 2 μm) that appears to be antigenically related to *Klebsiella rhinoscleromatis*. It is isolated in chicken embryos, egg yolk slants (Dulaney slants), or special fluid medium.

Streptobacillus moniliformis is one agent of rat-bite fever. It is a highly pleomorphic, catalase- and oxidase-negative facultatively anaerobic, gram-negative rod (0.1 to 0.7 × 1 to 5 μm). Single cells, chains, or filaments (10 to 150 μm in length) may show beaded central swelling. The organism grows only on medium containing blood, serum, or ascitic fluid.

The genus *Bartonella* contains 11 species, five of which cause human infections: *B. bacilliformis, B. quintana, B. henselae, B. elizabethae*, and *B. clarridgeiae*. The other six species are found in small mammals, fish, birds, and other animals (91). The genus *Afipia* consists of three species (*A. felis, A. broomeae*, and *A. clevelandensis*) and five genospecies (92). *Bartonella* species are small (0.6 to 1.0 μm), slightly curved, gram-negative rods that are oxidase-negative and relatively inert biochemically. All species require hemin or blood for growth. *Afipia* species are oxidase and urease positive and motile and do not require blood for growth.

Spectrum of Disease

F. tularensis is the etiologic agent of tularemia, which can present in the following clinical forms: ulceroglandular (80% of all cases), oculoglandular, oropharyngeal, glandular (no lesion detected), typhoidal, pleuropulmonary, GI, or combinations of these.

Brucellosis is primarily a genitourinary tract infection in animals and affects the reticuloendothelial system in humans. The disease ranges from subclinical to acute infections with the potential to develop relapses or become a chronic infection. Complications may affect almost any organ system. *Brucella* infections are often difficult to diagnose because of their chronicity and varied clinical manifestations.

Whooping cough (pertussis) is caused by *B. pertussis* and is characterized by a series of short expiratory coughs followed by an inspiratory gasp that results in the whoop. Complications are primarily owing to secondary infections. *B. parapertussis* or rarely *B. bronchiseptica* may cause a pulmonary infection or opportunistic infections in compromised hosts.

Granuloma inguinale, donovanosis, and granuloma venereum are synonyms for the disease caused by *C. granulomatis*. The disease begins as single or multiple subcutaneous nodules that progress to open granulomatous lesions that are usually painless. The genitalia are involved in approximately 90% of cases, the rectum in 5% to 10 %, and other sites in 1% to 5%.

S. moniliformis is an agent of rat-bite fever that begins with an abrupt onset of fever, chills, rash, and headache. Complications include arthritis, pneumonia, endocarditis, myocarditis, meningitis, and nephritis.

The disease caused by *B. bacilliformis* can present in two forms: Oroya fever (systemic form) and verruga peruana (cutaneous form). The organism grows within and on the surface of erythrocytes as well as in the vascular endothelium. *B. henselae* and *B. quintana* (and infrequently *B. elizabethae*) are associated with bacteremia, endocarditis, bacillary angiomatosis, and peliosis (91). Infections occur in the immunocompetent individual but are more common in immunocompromised persons, especially human immunodeficiency virus–infected. Cat-scratch disease is the most common infection caused by *Bartonella* species (91). Most, if not all, cases are caused by *B. henselae*, but some may be caused by *B. clarridgeiae* or *A. felis*.

Epidemiology

Tularemia occurs exclusively in the northern hemisphere. *F. tularensis* is found in wild mammals (e.g., rabbits, muskrats, beavers, deer, bear), domestic animals (e.g., sheep, cats, cattle, dogs), birds, some amphibians and fish, insects (e.g., ticks, deerflies, mosquitoes), and water from streams and wells. The disease is transmitted most often by contact with infected animals or bites of infected insects and less frequently by aerosols, consumption of contaminated water or improperly cooked meat, and bites of animals. Tick-borne cases occur primarily in the spring and summer months, whereas rabbit and muskrat associated cases increase in the winter.

Brucellosis is largely a disease of domestic animals throughout the world, especially in the Mediterranean countries of Europe,

Africa, Asia, and Central and South America where there are no cattle vaccination programs. The organisms, normal flora of the genital and urinary tracts of animals, are transmitted to humans by direct contact with infected animal tissue, inhalation of aerosols, or consumption of contaminated meat or dairy products. Brucellosis is an occupational disease of persons who handle livestock (e.g., veterinarians, ranchers, slaughterhouse workers).

Pertussis continues to cause significant morbidity and mortality in populations that are not vaccinated. Humans are the only known reservoir of *B. pertussis*. In nonvaccinated populations, the disease occurs primarily in children 1 to 5 years of age. Currently in the United States, approximately 50% of the cases occur in children younger than 1 year of age and 30% occur in adults.

C. granulomatis is endemic in New Guinea, India, Australia, the Caribbean, and other tropical countries. It is transmitted sexually but may be contracted by other direct contact. The disease is only mildly contagious and has a higher prevalence among individuals of low socioeconomic status and poor personal hygiene.

Wild and laboratory rats and other rodents are the primary reservoir for *S. moniliformis*, although the bacterium has been found in turkeys and milk. Transmission occurs after the bite of a rodent, handling infected tissue, or occasionally after consumption of contaminated food (e.g., milk).

B. bacilliformis is restricted to the habitat of the sandfly vector (*Phlebotomus*) in the Andes Mountains of Peru, Ecuador, and Colombia. Asymptomatic human carriers serve as a reservoir. *B. quintana* and *B. henselae* are found worldwide and transmission is associated with exposure to *Pediculus humanus* and cats, respectively (92,93). *B. clarridgeiae* is also associated with cat exposure (91).

Diagnostic Procedures

Microscopy

Gram-stained smears of material containing *B. pertussis, F. tularensis*, or *Brucella* species may appear negative because the organisms stain poorly and are small. Material should be stained with fluorescent antibody reagents for the detection of *F. tularensis* and *B. pertussis*. These stains are best performed by reference laboratories.

C. granulomatis is usually observed in a Giemsa- or Wright-stained smear of a scraping of the lesion as clusters of safety pin–shaped rods in the cytoplasm of macrophages (Donovan bodies). The organism appears blue to deep purple with a pink capsule.

S. moniliformis may be directly seen in Giemsa-, Wayson-, Gram-, or acridine orange–stained smears of clinical specimens as extremely pleomorphic gram-negative rods with long filaments, chains, and swollen cells.

The diagnosis of bartonellosis can be made by demonstrating pleomorphic, rod or ring-shaped bacteria in Wright- or Giemsa-stained blood smears.

Culture Techniques

Cystine-glucose blood agar is recommended for the isolation of *F. tularensis*, but growth is also observed on enriched chocolate, Thayer-Martin, and charcoal yeast extract agars. Occasional strains will grow on sheep blood agar. Growth has also occurred in blood culture bottles inoculated with blood or pleural fluid (94). Colonies are pinpoint, gray, and smooth after incubation for 24 to 48 hours at 35°C. *F. tularensis* is highly infectious. Gloves should be worn and cultures worked up in a biological safety hood.

Brucella species are commonly isolated from blood and bone marrow specimens plated on sheep blood, chocolate, and charcoal yeast extract (95) agars as well as selective medium for the isolation of *N. gonorrhoeae*. Commercial blood culture broths will also support growth in 5 to 21 days. Solid media should be incubated in 5% to 10% CO_2 at 35° to 37°C for 3 weeks. After 3 to 4 days, colonies are pinpoint and gray on blood agar. All suspected cultures should be handled in a biological safety cabinet.

B. pertussis was originally isolated on Bordet-Gengou medium, but this medium has been generally replaced by charcoal blood agars or Regan-Lowe medium. Both selective and nonselective media should be used. The organism produces small colonies (less than 1 mm) that are shiny and anthracite in color. Cultures should be incubated 3 to 7 days at 35° to 37°C in a moist environment without added CO_2.

C. granulomatis can be cultured but requires specialized media or eggs. The laboratory diagnosis is usually based on smear results.

Isolation of *S. moniliformis* requires the use of medium containing blood, serum, or ascitic fluid. It has been recovered on sheep blood and chocolate agars. Cultures are incubated at 35° to 37°C in 5% to 10% CO_2 and high humidity for 1 to 2 weeks. Colonies are round, gray, and glistening and remain viable for 3 to 7 days.

Bartonella has been detected in commercial blood culture systems by acridine orange staining of a smear after 7 days incubation, but more often blood is processed by lysis centrifugation and plated on enriched media (chocolate or blood agar) and incubated at 35° to 37°C in 5% to 10% CO_2 and high humidity for as long as 30 days (91). Freshly prepared heart infusion agar containing 5% to 10% rabbit or horse blood is optimal. *B. bacilliformis* and *Afipia* cultures should be incubated at 25° to 30°C.

Identification Methods

The biochemical identification of *F. tularensis* is not recommended because of the highly infectious nature of the organism. Presumptive identification is based on growth characteristics (absence of growth on routine media), morphology (small coccobacillus), oxidase negativity, and catalase positivity (weak). Specific identification is performed by fluorescent antibody or agglutination procedures and most often performed in a reference laboratory.

Brucella species are usually urease, oxidase, and catalase positive and nonmotile and reduce nitrates. Presumptive species identification is based on urease activity (*B. canis* and *B. suis* are positive in less than 30 minutes, *B. abortus* in 1 to 2 hours, and *B. melitensis* is variable), H_2S production (*B. abortus* and *B. canis* are positive), and CO_2 requirement (*B. abortus* usually requires CO_2 for growth). Definitive identification is accomplished by additional tests and agglutination in specific antiserum.

A fluorescent antibody test or agglutination with specific antisera for *B. pertussis* and *B. parapertussis* can be used for the rapid presumptive identification of suspicious colonies. Some antisera may cross-react with *Haemophilus* species.
Differentiation among the *Bordetella* species is accomplished by determination of the growth rate (fresh isolates of *B. pertussis* take 3 to 5 days, other species 1 to 2 days); urease activity (*B. pertussis* is negative); growth on blood agar (fresh isolates of *B. pertussis* do not grow); and growth on MacConkey agar (*B. bronchiseptica* is positive). Isolates resembling *B. bronchiseptica* must be differentiated from *Alcaligenes* species.
S. moniliformis is presumptively identified by its growth characteristics and Gram-stain morphology. Biochemical tests must be supplemented with serum. *S. moniliformis* does not liquify gelatin, produce indole, or reduce nitrates; nor does it contain catalase, oxidase, or urease activity.
Presumptive identification of *Bartonella* species is based on their characteristic cellular morphology, growth requirements, “twitching” motility, and negative catalase and oxidase reactions.

Direct Antigen or Nucleic Acid Detection

Nasopharyngeal specimens can be examined for *B. pertussis* and *B. parapertussis* by the DFA test. In experienced laboratories, the sensitivity and specificity of the DFA test are 60% to 65% and 90% to 99%, respectively (96,97). The detection of *B. pertussis* in nasopharyngeal specimens by DNA amplification is more sensitive and specific but is not widely available.

Serologic Procedures

Tularemia is diagnosed by a standard agglutination test indicating a fourfold rise in titer or a single titer of 1:160 or greater (indicates current or past infection). The test cross-reacts with *Brucella* at low titers.
Several tests have been employed for the serologic diagnosis of brucellosis. Antibodies against all *Brucella* species, except *B. canis*, are detected in the standard agglutination test using *B. abortus* antigens. A fourfold rise in titer or a single titer of 1:160 or greater with a compatible illness is diagnostic of brucellosis. Other serologic methods such as EIA may be useful for differentiating acute from chronic infection. Populations exposed to *Brucella* (e.g., veterinarians, slaughterhouse workers) often have baseline titers of 1:80 or 1:160.
Serologic tests for *B. pertussis* exposure have been used primarily for epidemiologic purposes but may be helpful for the diagnosis of acute infection when the patient presents late in the course of the disease.
Patients with rat-bite fever usually have an agglutination titer of 1:80 or greater or demonstrate a fourfold rise in titer. The test is performed only at national reference laboratories. No serologic tests are commercially available for the diagnosis of granuloma inguinale or bartonellosis. Serologic tests are available for the diagnosis of infections caused by *B. bacilliformis, B. quintana*, and *B. henselae*. Cross-reactions have occurred with *Coxiella* and *Chlamydia* and between *B. quintana* and *B. henselae*.

Interpretation of Results

The isolation or direct identification of any of the aforementioned bacterial species (except *B. parapertussis* and *B. bronchiseptica*) from patients with a compatible illness is clinically significant.

Therapeutic Considerations

The organisms discussed in this section have special growth requirements that make *in vitro* susceptibility testing difficult. Therefore, most recommendations for therapy are based on clinical response. Streptomycin is the drug of choice for the treatment of tularemia, although some data suggest that gentamicin may be an alternative. The use of tetracycline or chloramphenicol is associated with a higher relapse rate. Limited data suggest that the fluoroquinolones, imipenem, or rifampin may be useful.
Because brucellosis is difficult to eradicate, some investigators recommend the use of tetracycline plus streptomycin or gentamicin. Aminoglycosides, rifampin, trimethoprim-sulfamethoxazole, chloramphenicol, and fluoroquinolones have also been used, but single-drug therapy is associated with a 10% to 40% relapse rate. Therapy should be continued for 3 to 6 weeks.
B. pertussis infections can be treated with erythromycin, trimethoprim-sulfamethoxazole, or chloramphenicol. Few clinical data are available on the efficacy of other antimicrobials.
C. granulomatis is susceptible to tetracycline, sulfonamide, trimethoprim-sulfamethoxazole, chloramphenicol, and gentamicin. The drug of choice for the treatment of rat-bite fever is penicillin. Other alternatives include chloramphenicol, tetracycline, and streptomycin. Most infections caused by *B. quintana* or *B. henselae* respond to treatment with erythromycin or doxycycline. Alternative drugs include other macrolides and fluoroquinolones. *B. bacilliformis* infections are usually treated with chloramphenicol.

Summary and Conclusions

The diseases discussed in this section are infrequently observed, and the laboratory diagnosis is difficult because of the special growth requirements of the etiologic agents. The clinician must alert the laboratory to the possibility of infection by one of these agents so that appropriate culture procedures will be used. The laboratory must also exclude these bacteria when unusual isolates are seen on Gram smear or isolated.

ANAEROBIC BACTERIA

Part of "51 - Bacteriology"

Microbiology

Anaerobic microorganisms are a genetically and phenotypically heterogeneous group that includes both aerotolerant and anaerobic strains. Many of the genera have or will undergo significant taxonomic revision. For example, Collins et al. (98) have proposed five new genera of spore-forming rods. Changes in the taxonomy are expected to continue, but fortunately for the clinical microbiology laboratory, relatively few species cause human disease. A list of the medically important genera of anaerobic bacteria based on Gram-stain morphology is provided in Table 51.26.

TABLE 51.26. GENERA OF MEDICALLY IMPORTANT ANAEROBIC BACTERIA

Gram-negative rods
Bacteroides
Fusobacterium
Prevotella
Porphyromonas
Bilophilia
Wolinella
Sutterella
Oribaculum
Johnsonella
Hallella
Campylobacter
Catonella
Dialister
Gram-negative cocci
Veillonella
Gram-positive rods
Clostridium
Actinomyces
Propionibacterium
Bifidobacterium
Eubacterium
Lactobacillus
Mobiluncus
Gram-positive cocci
Peptostreptococcus
Streptococcus
Staphylococcus
Gemella

The anaerobic gram-negative bacilli are straight, curved, or helical and motile or nonmotile. They are among the most common components of the normal flora of the human mucous membranes. Among these genera, *Bacteroides, Fusobacterium, Prevotella*, and *Porphyromonas* are isolated most frequently from infections.
Of the gram-negative cocci, only three of the seven *Veillonella* species are occasionally isolated from human infections. *Megasphaera* and *Acidaminococcus* are seldom associated with infections in humans.
The genera of anaerobic gram-positive bacilli consist of *Clostridium* (spore formers) and seven genera of non-spore formers (*Actinomyces, Propionibacterium, Bifidobacterium, Eubacterium, Atopobium, Mobiluncus*, and *Lactobacillus*). *Mobiluncus* species stain gram variable to gram negative. Some species are aerotolerant and vary in their morphology with the type of medium and growth conditions, which cause confusion with the aerobic bacilli and streptococci. In general, the aerotolerant anaerobes grow better anaerobically (produce larger colonies) than aerobically, and the aerotolerant clostridia (catalase negative) rarely produce spores aerobically. *Bacillus* species are catalase positive and rarely produce spores anaerobically.
The anaerobic gram-positive cocci are the second most common group of anaerobes encountered in clinical infections. Major taxonomic changes (Table 51.27) have occurred recently with these genera and several new species have been described. All pathogenic *Peptococcus* species (except *P. niger*) were transferred to the genus *Peptostreptococcus*. Other anaerobic cocci were transferred to the genus *Streptococcus*, and *P. saccharolyticus* was transferred to the genus *Staphylococcus*. Some of the many nomenclature changes that have occurred in recent years are listed in Table 51.27.

TABLE 51.27. RECENT TAXONOMIC CHANGES OF ANAEROBIC BACTERIA

Current Nomenclature	Previous Nomenclature
Bacteroides distasonis	*Porphyromonas*
Bacteroides furcosus	*Porphyromonas*
Bacteroides putredinis	*Rikenella*
Campylobacter gracilis	*Bacteroides gracilis*
Campylobacter showae	*New species*
Campylobacter cuvus	*Wollinella cuvus*
Campylobacter rectus	*Wollinella rectus*
Dialister pneumosintes	*Bacteroides penumosintes*
Johnsonella ignava	*Clostridium*
Porphyromonas catoniae	*Oribaculum catoniae*
Prevotella dentalis	*Mitsuokella dentalis*
Prevotella enoeca	New species
Prevotella pallens	New species
Prevotella tannerae	New species
Sutterella wadsworthensis	New genus and species

Spectrum of Disease

Anaerobic bacteria are recovered from all types of infections in any organ of the body (99). The most frequently encountered anaerobic infections or toxin-related diseases include pleuropulmonary infection (e.g., pneumonia, abscess, empyema), intraabdominal infection (e.g., abscess, appendicitis, cholecystitis, peritonitis), antibiotic-associated colitis, and female genital tract infection (e.g., abscess, pelvic inflammatory disease, endometritis, BV). Other types of infections include head and neck infections (e.g., brain abscess, meningitis, sinusitis, otitis media, dental and periodontal infection), soft-tissue infections (cellulitis, myonecrosis), bone and joint infections, bacteremia, endocarditis, bite wounds, botulism (including infant and wound), tetanus, and food poisoning.

Epidemiology

Anaerobic infections caused by non–spore-forming organisms generally arise from the host's indigenous flora after a break in the skin or mucosal barrier (e.g., trauma, surgery, implantation of a device). The resulting tissue damage and the presence of microaerophiles or facultative anaerobes act to produce the appropriate environment for the growth of anaerobes and explains why most deep-seated abscesses and necrotizing lesions contain multiple species of bacteria.
Infections or intoxications caused by spore-forming bacilli (*Clostridium*) are usually transmitted via improperly prepared or stored food (e.g., botulism, *C. perfringens* food poisoning), contamination of damaged tissue with soil or bowel contents (e.g., clostridial myonecrosis, tetanus), or contaminated objects or medical personnel in hospitals (e.g., antibiotic-associated colitis caused by *C. difficile*).

Diagnostic Procedures

This section provides a limited overview of the procedures that may aid in the isolation or preliminary identification of anaerobic bacteria. The extent to which anaerobes are identified depends on the available facilities, the technical competence of the personnel, and the clinical need for the information (e.g., the detection of the agent or toxin responsible for the disease may indicate a therapy change or the need for an antimicrobial susceptibility test). The selection, collection, and transport of specimens are crucial to clinically relevant laboratory results. The workup of inappropriate or poorly transported specimens is a waste of effort and money. The presence of anaerobes in a specimen is suggested when the material has a foul odor or black discoloration, contains sulfur granules, or fluoresces brick-red under long-wave ultraviolet light (366 nm). All laboratories should be able to isolate and presumptively identify anaerobic isolates based on cellular and colony morphology and a few essential characteristics. More definitive identification of common isolates can be accomplished with the use of commercial kits, and other significant isolates can be submitted to a reference laboratory for identification.

Microscopy

The Gram stain can provide useful clinical information on the presence of anaerobes and suggest additional media to set up based on the characteristic morphology of some species. The *Bacteroides fragilis* group may be uniform or pleomorphic with a safety-pin appearance (Fig. 51.17), whereas the pigmented species are often coccobacillary (*Haemophilus*-like) and can be mistaken for gram-negative cocci (Fig. 51.18). *Fusobacterium nucleatum* is usually very thin with tapered ends (spindle shaped), often appearing end to end in pairs (Fig. 51.19). *F. mortiferum* and *F. necrophorum* are filamentous and pleomorphic, with swollen areas and large round bodies. *Actinomyces* appear as thin, branching gram-positive rods with beaded staining. *Bifidobacterium* species often exhibit clubbing or terminal bifurcation. Peptostreptococci appear as clusters and chains of irregularly stained, somewhat pleomorphic, gram-positive cocci. *P. magnus* is usually large, and *P. tetradius* occurs in tetrads. *C. perfringens* is a gram-positive rod (may appear gram-negative) with square ends and usually does not contain a spore (Fig. 51.20). The presence of clostridia and absence of inflammatory cells in a Gram smear of a wound is highly suggestive of clostridial myonecrosis.

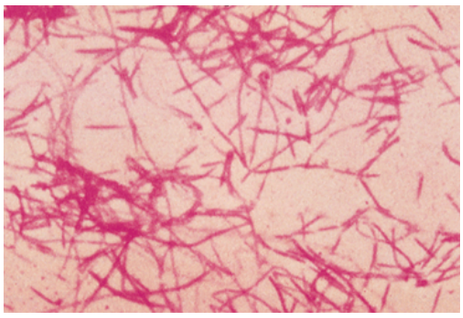

FIGURE 51.19. Gram stain of *Fusobacterium nucleatum*. Fusiform shape. (From Baron EJ, Finegold SM. *Bailey and Scott's diagnostic microbiology*. St. Louis: Mosby, 1990, with permission.)

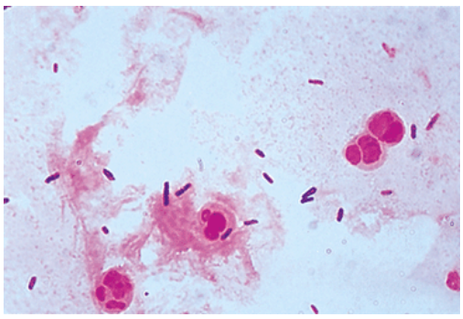

FIGURE 51.20. Gram stain of body fluid containing *Clostridium perfringens*.

Culture Techniques

A combination of enriched, prereduced, nonselective (e.g., *Brucella* sheep blood agar), selective (e.g., *Bacteroides* bile esculin, kanamycin-vancomycin–laked blood, phenylethyl alcohol agars), and enriched thioglycollate media should be used for the recovery and presumptive identification of anaerobes. Primary plates are incubated under anaerobic conditions at 35°C for 48

hours before examination and are reincubated for 5 to 7 days. In serious infections or suspected actinomycosis, the broth medium should be held for 2 to 4 weeks. During the examination of primary plates and subculture of anaerobic isolates, a holding jar should be used to minimize the exposure of the isolates to oxygen. Colony morphology is examined with a dissecting microscope or a hand-held lens, and each type Gram-stained and subcultured for incubation in CO_2 and anaerobically. Gram-positive cocci that are capnophiles may not grow in CO_2 on initial subculture and require a second subculture to demonstrate growth. The thioglycollate medium should be Gram stained and subcultured if morphologic types appear on smear that are not seen on the primary plates. The cellular and colony morphology on the primary plates can be suggestive of some groups of organisms (Table 51.28). Cycloserine-cefoxitin-fructose agar is one medium that is recommended for the isolation of *C. difficile* from stool specimens.

TABLE 51.28. MICROSCOPIC AND COLONIAL MORPHOLOGY OF SELECTED ANAEROBES

Organism	Medlium[a]	Microscopic Morphology	Colonial Morphology
Bacteriodes fragilis group	BBE	gnb, pleomorphic	>1 mm ± esculin hydrolysis
Bacteroides spp	KVLB	gnb	Nonpigmented
Porphyromonas or *Prevotella* spp	KVLB	cb, gnb	Brown to black or fluorescing brick-red
Bacteriodes ureolyticus	BA	gnb	Pitting
Bacteriodes fragilis group	BA	gnb, pleomorphic	Circular, grayish-white translucent to opaque
Pigmenting species	BA	cb, gnb	Circular, darker in center with brown edges
Fusobacterium nucleatum	BA	Fusiform gnb with pointed ends	Opalescent and speckled, fluoresces chartreuse
Fusobacterium necrophorum	BA	pleomorphic gnb, many contain round bodies	Convex to umbonate, fluoresces chartreuse
Actinomyces israelii	BA	branching gpb	Molar tooth
Clostridium perfringens	BA	gpb, square ends	Double zone of ß-hemolysis
Clostridium difficile	CCFA	gpb	Yellow colonies that may fluoresce
Clostridium septicum	BA	gpb ± spores	Swarming, ß-hemolysis medusa head
Clostridium tetani	BA	gpb, “drumstick”	May swarm, narrow zone ß-hemolysis
Peptostreptococcus	BA	gpc	Grow only on BA after 48 hr
Veillonella parvula	BA	gnc	Fluoresce red

BBE, *Bacteroides* bile esculin-agar; KVLB, kanamycin-vancomycin laked blood agar; BA, *Brucella* blood agar: CCFA, cycloserine-cefoxitin-fructose agar; gnb, gram-negative bacillus; cb, coccobacillus; gpb, Gram-positive bacillus; gpc, Gram-positive coccus.

Identification Methods

The preliminary or presumptive identification of anaerobes can be accomplished by using some special tests such as colonial fluorescence, susceptibility to special-potency antibiotic and polyanethol-sulfonate disks, and catalase, urease, and nitrate reduction (Table 51.29) (100,101 and 102). Dowell and Lombard (103) devised a modified conventional plate system (presumpto method) that can be used for the preliminary identification of anaerobes. The definitive identification of anaerobes by reference laboratories includes conventional biochemical tests and gas-liquid chromatographic analysis of fatty acid metabolites and is beyond the scope of this discussion. For the nonreference laboratory, several commercial systems are available that will correctly identify 70% to 90% of the more commonly encountered anaerobes and offer a rapid alternative to the conventional method.

Direct Antigen or Nucleic Acid Detection

Gas-liquid chromatographic analysis of specimens can presumptively detect the presence of *Bacteroides, Prevotella, Porphyromonas*, or *Fusobacterium* species but is not widely used. Currently, there are no commercial nucleic acid probes for the detection or identification of anaerobes.

The laboratory diagnosis of antibiotic-associated colitis (AAC) is made by demonstrating the organism, glutamate dehydrogenase, or toxins in the stool specimen of a symptomatic patient. The recovery of *C. difficile* by culture is reliable test for AAC if the isolate is tested for toxin production. Commercial EIA tests for the detection of toxin A or toxin A and B are also available but vary in their accuracy (104). The detection of *C. difficile* toxins by cytopathic effect in tissue culture remains the gold standard. An EIA test that detects glutamate dehydrogenase is rapid and comparable with toxin detection by EIA or cytotoxin neutralization assays (105). A latex test for glutamate dehydrogenase lacks sensitivity (104).

The detection of botulinal neurotoxin in the patient's vomitus, serum, feces, or consumed food should be performed by the State Health Department or CDC.

Serologic Procedures

Serologic procedures are not important tests for the diagnosis of anaerobic infections.

TABLE 51.29. PRELIMINARY IDENTIFICATION OF ANAEROBES

Group/Species	Antibiotic Disk Pattern			Characteristics
	K (1 mg)	Co (10 µg)	Va (5 µg)	
Bacteriodes fragilis group	R	R	R	Bile, R; catalase, V
Pigmenting species	R	V	V	Tan to black colonies[a]
				Brick-red fluorescence[b]
Prevotella spp	R	V	R	Brown to black colonies[a]
Porphyromonas spp	R	R	S	
Other *Bacteriodes* spp	R	V	R	
Bacteroides ureolyticus	S	S	R	Colonies pit agar or require formate/fumarate for growth; nitrate, +, urease +
Bilophila spp	S	S	R	Urease, +; motile -; catalase +; nitrate +
Fusobacterium spp	S	S	R	Colonies generally larger and more opaque than *B. ureolyticus* group
F. nucleatum	S	S	R	Slender cells with pointed end. Indole, +; greens agar; yellow-green fluorescence; three possible colony types
F. necrophorum	S	S	R	Indole, +; lipase, +[a] Umbonate colony[b]
Gram-negative cocci	S	S	R	Three genera; requires GLC, if not *Veillonella*
Veillonella spp	S	S	R	Nitrate, + Small coccus
Gram-positive cocci	V	R	S	
Peptostreptococcus anaerobius	R	R	S	Sodium polyanethol sulfonate, S
Peptostreptococcus asaccharolyticus	S	R	S	Indole, +
Clostridium spp	V	R	S	Spores present: may appear gram-negative
C. perfringens	S	R	S	Double-zone ß-hemolysis. Cells boxcar shape; spore test, V; reverse CAMP test, +; Nagler test, +
Non-spore-forming bacilli	V	R	S	
Propionibacterium acnes	S	R	S	Indole, +[a], catalase, +[a]; nitrate, +[b]; cells may show short branching
Eubacterium lentum	S	R	S	Cells and colonies small; arginine required for growth in broth: nitrate, +

[a] Not all strains positive; if negative, more tests required.

[b] Not all strains positive.

R, resistant; S, susceptible; V, variable; +, positive; -, negative; GLC, gas-liquid chromatography.

Interpretation of Results

The significance of the isolation of anaerobes that are a part of the indigenous flora depends on the quality of the specimen submitted and the subsequent Gram stain and must be interpreted in light of the clinical picture. The presence of botulinal neurotoxin is diagnostic of botulism.

Tests used for the laboratory diagnosis of AAC should be interpreted in conjunction with the clinical setting of the patient. The use of two tests can often improve the detection of affected patients.

Therapeutic Considerations

For most institutions, antimicrobial susceptibility testing of anaerobic isolates should be limited to circumstances related to the seriousness of the infection, lack of response to empiric therapy, or lack of established data with a specific agent or to monitor susceptibility patterns of local isolates. The susceptibility pattern of specific anaerobes cannot always be predicted because of the increasing resistance to ß-lactam drugs and the differing degrees of effectiveness of the newer agents.

Metronidazole (inactive against *Propionibacterium* and *Actinomyces*), chloramphenicol, imipenem, and the ß-lactam plus ß-lactamase inhibitor drugs are active against most anaerobes. Agents that are usually active include clindamycin (increasing resistance among *B. fragilis* group and clostridia), cefoxitin (increasing resistance among *B. fragilis* group and poor activity against clostridia), and antipseudomonal penicillins. Penicillin, cephalosporins (other than cefoxitin and cefotetan), tetracycline, macrolides, and vancomycin (active against gram-positive anaerobes) have variable activity. The aminoglycosides, monolactams, and most quinolones have poor activity against anaerobes.

Summary and Conclusions

Anaerobic bacteria are common, indigenous organisms found on the mucosal surfaces of humans that cause a variety of infections in any tissue or organ system. The most important aspect of anaerobic microbiology is to ensure the appropriate selection, collection, transport, and inoculation of the specimen. The extent of isolate identification depends on the seriousness of the infection, the clinical need for information, the technical expertise of the laboratory personnel, and the availability of resources.

SPIROCHETES

Part of "51 - Bacteriology"

Microbiology

The order Spirochaetales consists of two families. The family Spirochaetaceae contains the genera *Spirochaeta, Cristispira, Treponema, Brevinema*, and *Borrelia*, and the family Leptospiraceae contains two genera: *Leptospira* and *Leptonema*. Spirochetes of medical importance are in the genera *Treponema, Borrelia*, and

Leptospira. The pathogenic species are restricted to a living host and are heterogeneous in their physiology and habitat. Common features include spiral morphology and unique flexuous motility related to axial filaments located in the periplasmic space between the outer membrane and protoplasmic cylinder. In general, the spirochetes are slender, flexible, helix-shaped bacteria that exhibit a corkscrewlike motility and can be loosely grouped into genera by their morphology (Fig. 51.21).

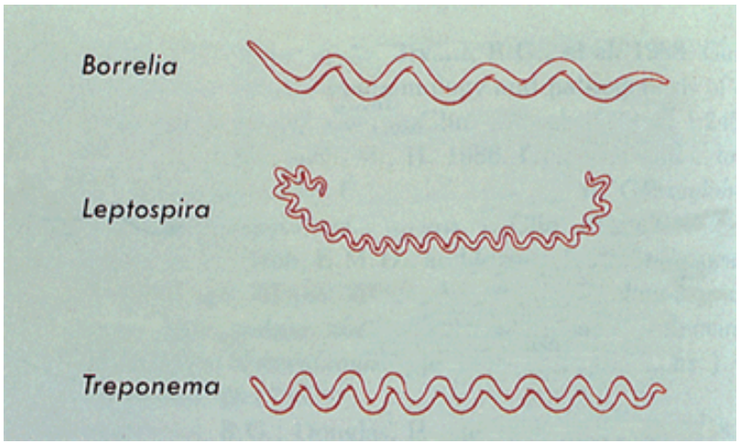

FIGURE 51.21. Schematic designation of spirochetes based on general morphology. (From Baron EJ, Finegold SM. *Bailey and Scott's diagnostic microbiology*. St. Louis: Mosby, 1990, with permission.)

The genus *Treponema* currently contains 12 species. The pathogenic species are 6 to 20 µm in length and 0.1 to 0.2 µm in width with regularly spaced coils (six to 14 per cell) and a rotational back-and-forth (corkscrew) motility with some bending and snapping.
The treponemes pathogenic for humans can be continuously cultured only by animal passage and consist of two species: *T. carateum* (causes pinta) and *T. pallidum*, which contains three subspecies: *pallidum* (causes syphilis), *pertenue* (causes yaws), and *endemicum* (causes nonvenereal endemic syphilis or bejel).
The genus *Borrelia* contains 36 species. This classification may not be correct and awaits further clarification by genetic relatedness techniques. *B. burgdorferi* (Lyme disease) has been divided into two additional species, *B. garinii* and *B. afzelii* (106). *Borrelia* are 0.2 to 0.5 × 5 to 25 µm, have three to 10 loose coils, and grow well from 30° to 35°C in specialized media.
The genus *Leptospira* contains two new species: *L. biflexa*, which is a nonpathogenic, free-living spirochete with more than 60 serovars, and *L. interrogans*, which causes leptospirosis in animals and humans with more than 218 serovars (107). Molecular techniques suggest grouping the *L. interrogans* serovars into seven named and five unnamed species (108). *Leptospira* are 6 to 20 × 0.1 to 0.2 µm with very tightly wound coils that may be hooked at one or both ends. They are aerobic and require particular nutrients (e.g., long-chain fatty acids) and a specific pH (7.0 to 7.8) for growth at 28 to 30°C.

Spectrum of Disease

T. pallidum subsp *pallidum* is the etiologic agent of syphilis, which presents in three stages: primary (a chancre at the site of entry), secondary (flulike illness with generalized rash), and tertiary (lesions in the central nervous, cardiovascular, or any other organ system). Infection of the fetus (congenital syphilis) can occur in untreated women.
Yaws, pinta, and endemic syphilis are distinguished from syphilis based on their clinical manifestations and geographic area of occurrence. Yaws occurs primarily in rural populations of tropical countries; pinta is found in remote areas of Central and South America; and endemic syphilis primarily affects children in the arid areas of Africa and the Middle East.
B. recurrentis is the etiologic agent of louse-borne (epidemic) relapsing fever, whereas other *Borrelia* species cause tick-borne (endemic) relapsing fever. *B. burgdorferi, B. garnii*, and *B. afzelii* are associated with Lyme disease.
Leptospirosis is primarily a disease of animals that is occasionally transmitted to humans. The clinical manifestations of the infections range from a mild febrile illness to a fulminating fatal disease.

Epidemiology

Syphilis occurs worldwide and is generally transmitted through sexual contact or transplacentally. Infections may also be acquired through nonsexual contact with lesions or blood. The highest prevalence of the disease is associated with economically deprived individuals engaged in prostitution or sexual activity with multiple partners.
Louse-borne (epidemic) relapsing fever (*B. recurrentis*) is transmitted by the human body louse (*Pediculus humanus*). The infective organisms penetrate intact skin or mucous membranes. Humans are the only hosts for *B. recurrentis* and *B. drottonii*. Disease usually occurs from overcrowding such as during famine or wars. The disease is endemic in Central and East Africa and in Bolivia and Peru.
Tick-borne (endemic) relapsing fever (*Borrelia* spp) is transmitted to humans by infected soft-shelled ticks of the genus *Ornithodorus*. Infection occurs when saliva or coxal secretions are released by feeding ticks. The principal reservoirs are rodents and small animals as well as the ticks that pass the spirochete transovarially.
Lyme disease (*B. burgdorferi, B. garnii*, and *B. alzelii*) occurs worldwide and is transmitted primarily by the *Ixodes* species of ticks. The principal reservoirs are rodents and large mammals (e.g., deer). The disease can be spread by the adult, larval, and nymphal stage of the tick.
Leptospirosis is a zoonosis that occurs worldwide and affects many different species of animals. In the United States, the most common sources are dogs, livestock, rodents, wild mammals, and cats. Humans are indirectly infected by contact with urine or with contaminated water or soil or by direct contact with animals. Leptospirosis is an occupational hazard among farmers, meatpackers, sewer workers, and veterinarians and is a recreational hazard for campers and swimmers.

Diagnostic Procedures

Microscopy

In primary, secondary, and early congenital syphilis, the treponemes may be detected in serous fluid from the lesion by dark-field

microscopic examination (Fig. 51.22) or by performance of a DFA test. The dark-field examination is not appropriate for oral or rectal lesions because of the presence of morphologically similar nonpathogenic treponemes. The DFA test or silver stain can be used to detect treponemes in tissue.

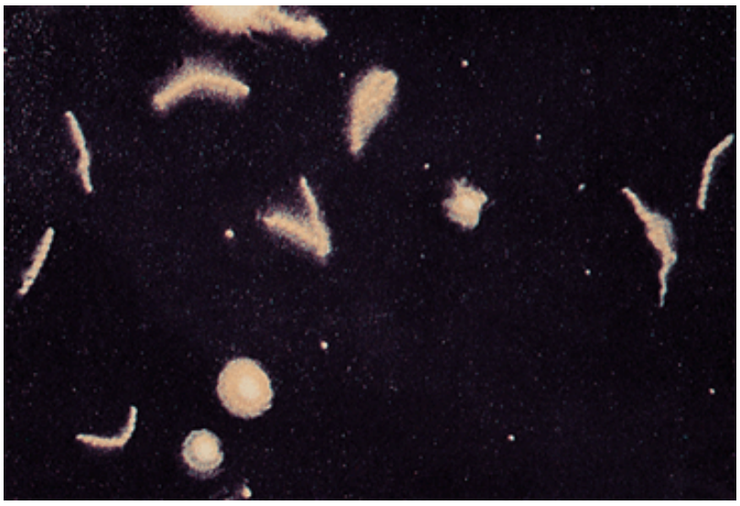

FIGURE 51.22. Appearance of *Treponema pallidum* in a dark-field preparation. (From Baron EJ, Finegold SM. *Bailey and Scott's diagnostic microbiology*. St. Louis: Mosby, 1990, with permission.)

The diagnosis of borreliosis is made in 70% of cases by examination of blood collected during a febrile episode by dark-field microscopy, Giemsa- or Wright-stained thick and thin smears (Fig. 51.23), or acridine orange–stained smears. Rarely, spirochetes are detected in the CSF of patients with central nervous system symptoms. Because of the scarcity of spirochetes in clinical specimens, direct examination is not recommended for the diagnosis of Lyme disease.

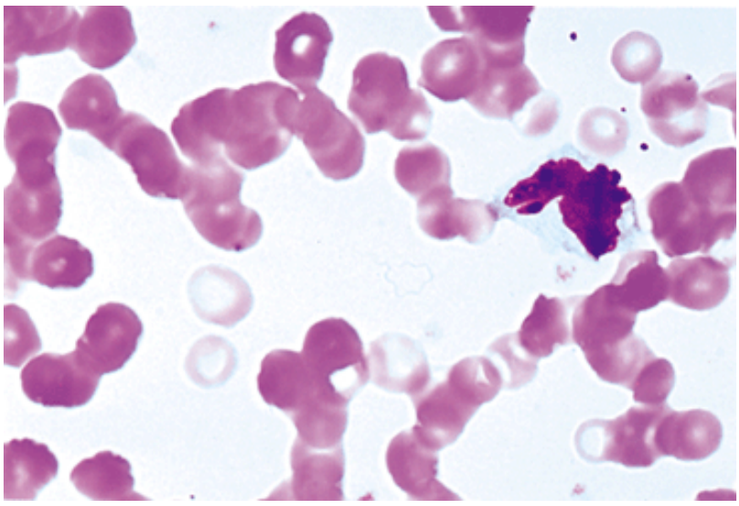

FIGURE 51.23. Wright-stained peripheral blood smear demonstrating *Borrelia*.

The direct examination of blood, CSF, or urine by dark-field examination has low sensitivity for samples with few leptospires, as has the DFA test or silver stain on tissue.

Culture Techniques

Isolation of *Borrelia* species in the routine clinical laboratory by *in vitro* cultivation is not recommended because of the low yield. Although improvements in the cultivation of *B. burgdorferi* from clinical specimens have occurred, the yield remains low and probably should not be attempted by the routine clinical laboratory.

Leptospira is cultivated in two types of media: those supplemented with bovine serum albumin and polysorbate 80 (Ellinghausen, McCullough, Johnson, Harris [EMJH] medium) or those enriched with rabbit serum (Fletcher or Stuart) or PLM-5TM, a proprietary medium similar to EMJH (108). The EMJH-based formulations are probably the best. Approximately two to three drops of blood (not citrated) or CSF collected during the first week of illness are added to each of three to five tubes of medium. One or two drops of undiluted and 1:10 dilution of urine collected after the first week is added to each of three to five tubes of medium with and without 200 µg/mL of 5-fluorouracil. The cultures are incubated in the dark for 6 weeks at 30°C. Tubes are examined weekly for growth in the form of a ring 1 to 3 cm below the surface, and organisms can be identified by dark-field microscopy.

Identification Methods

Diagnosis of syphilis depends on the observation of the organisms in lesions by dark-field examination or DFA test or by the serologic detection of antibodies.

Relapsing fever is diagnosed by the demonstration of organisms in peripheral blood by dark-field examination or by Giemsa- or Wright-stained smears. Lyme disease is recognized by serologic tests.

The isolation of *Leptospirra* in culture or the detection of antibodies by serologic tests aids in the laboratory diagnosis. Identification of *Leptosprira* species should be performed by a reference laboratory.

Direct Antigen or Nucleic Acid Detection

The DFA test is commercially available for the direct detection of *T. pallidum* in clinical specimens. Polymerase chain reaction tests for the diagnosis of Lyme disease, leptospirosis, and syphilis have been developed but are not generally available from commercial sources.

Serologic Procedures

Serologic tests for the diagnosis of syphilis measure two types of antibodies. The nontreponemal (nonspecific) tests measure both immunoglobulin G and M antilipid antibodies formed in response to lipoidal antigen released from damaged host cells and from the treponemes themselves. The treponemal (specific) tests measure antibodies directed against cellular components of the organism.

There are four standard nontreponemal tests: (a) Venereal Disease Research Laboratory (VDRL) slide, (b) rapid plasma reagin (RPR), (c) unheated serum reagin, and (d) toluidine red unheated serum test. All the nontreponemal tests have approximately the same sensitivity and specificity. Of these tests, the RPR is the most widely used in the United States, and the VDRL is the only accepted nontreponemal test for detection of antibodies

in the CSF of patients with suspected neurosyphilis. The nontreponemal tests are used primarily as screening tests and to follow patients on therapy. The sensitivity of the test varies with the stage of the disease (Table 51.30). In the early primary stage, the nontreponemal test usually becomes positive 1 to 4 weeks after appearance of the chancre (109). In congenital syphilis, a rising titer during a 6-month period is diagnostic, whereas passively transferred antibodies should not be detected after 3 months. The nontreponemal test becomes nonreactive in primary syphilis approximately 1 year after therapy and in secondary syphilis 2 years after treatment. A low titer may persist after 2 years in approximately 50% of patients treated in the latent or late stage of the infection (110). The specificity of these tests is approximately 98% overall but varies with the population. Causes of biological false positives include a variety of infectious diseases, injection drug use, pregnancy, and autoimmune disease.

TABLE 51.30. Reactivity of Serologic Tests in untreated syphilis

	Stage of Disease		
Test	**Primary**	**Secondary**	**Latent**
Nontreponemal			
(VDRL, RPR)	70–90[a]	100	70–90
Treponemal			
FTA-Abs	70–100	100	96–100
MHA-TP	70–90	100	96–100

[a] Percentage reactive.

VDRL, Venereal Disease Research Laboratory; RPR, rapid plasma reangin; FTA-Abs, fluorescent treponemal antibody absorbed; MHA-TP, microhem-agglutination assay-*Treponema pallidum*.

There are two principal treponemal tests: (a) the fluorescent treponemal antibody-absorbed and (b) the microhemagglutination assay for *T. pallidum*. These tests are used primarily to confirm a reactive nontreponemal test or to diagnose late-stage syphilis and usually remain positive for life. The range of sensitivity of the tests is shown in Table 51.30, and the specificity is 98% to 100%.

Several newer EIA tests for the diagnosis of syphilis are commercially available (109). They include nontreponemal, treponemal, and formats for the detection of immunoglobulin M in cases of congenital syphilis. In general, the sensitivity and specificity of these tests are similar to those of the older methods. The Western blot format is performed by the Syphilis Diagnostic Immunology Activity Laboratory at the CDC for diagnosis of adult and congenital syphilis.

Several different serologic tests are available for the serodiagnosis of relapsing fever. Unfortunately, these tests have limited success because of the antigenic variability observed with these organisms and the lack of test specificity.

The methods used to diagnose Lyme disease are the indirect fluorescent antibody (IFA) and EIA tests: the latter test appears to be easier to use and may be more sensitive. Both tests can be used to detect antibodies in serum, CSF, or synovial fluid. The problem with both tests is the low sensitivity early in the infection (within 3 weeks) and the lack of specificity. The Western immunoblot method is considered a necessary confirmatory test for positive EIA or IFA screening tests (111). Cross-reactivity among the *Borrelia* species and *T. pallidum* also occurs, but syphilis can be excluded with a nontreponemal test.

Diagnosis of leptospirosis is usually made by serologic tests that include the macroscopic agglutination, indirect hemagglutination, EIA, and dipstick tests for the detection of antibodies (108). Antibodies usually appear after 1 week and peak after 3 to 4 weeks. Titers may remain elevated for years. The microscopic agglutination test is sensitive and serovar specific. A rising titer or a single titer of 1:800 or greater with compatible clinical findings is indicative of the disease.

Interpretation of Results

The laboratory diagnosis of syphilis is based on the microscopic demonstration of spirochetes with the appropriate morphology in clinical specimens and a reactive serologic test. Problems in diagnosis occur if nonpathogenic spirochetes are present in the lesion or if the person has a biological false-positive test. The laboratory results need to be evaluated in light of the patient's symptoms.

A positive microscopic preparation is diagnostic for relapsing fever. The serodiagnosis of Lyme disease remains a problem mainly because of the lack of standardization of reagents and cutoff values. Inconsistent interlaboratory results occur.

Leptospirosis is diagnosed by the isolation of the organism or serodiagnosis. The possibility exists for a false-negative serologic test if the antigen pool used does not contain antigens to the infecting serovar.

Therapeutic Considerations

Penicillin remains the drug of choice for immunocompetent patients with syphilis. Alternatives include doxycycline, tetracycline, and ceftriaxone. In the immunocompromised patient, higher doses and longer duration of treatment may be required.

Relapsing fever can be treated with doxycycline or erythromycin. Penicillin is associated with slower clearance and more relapses. Lyme disease is treated with penicillin, doxycycline, amoxicillin, cefuroxime, or clarithromycin. The choice of therapy depends on the stage of the disease.

There is some controversy as to the efficacy of therapy for leptospirosis, but based on clinical and experimental data, the disease responds to treatment with doxycycline or intravenous penicillin.

Summary and Conclusions

Pathogenic spirochetes belong to three genera: *Treponema, Borrelia*, and *Leptospira*, which cause syphilis, relapsing fever and Lyme disease, and leptospirosis, respectively. Humans are the only reservoir for *T. pallidum*, whereas species of the other two genera are found primarily in rodents and larger mammals. Syphilis is transmitted through sexual contact or transplacentally; borreliosis via arthropod vectors (ticks); and leptospirosis via contaminated water and soil. With the exception of *Leptospira*, the other organisms cannot be isolated easily in the clinical laboratory. The diagnosis depends on demonstration of the spirochete in clinical specimens (e.g., dark-field microscopy,

DFA testing, and Giemsa or Wright stains) or antibodies by serologic tests. In general, spirochetal diseases can be treated with penicillin or tetracycline.

Fungi and Fungal Infections

Imaad Mujeeb

Deanna A. Sutton

Annette W. Fothergill

Michael G. Rinaldi

Michael A. Pfaller

Not long ago, fungal infections of humans were considered nuisance diseases—often irritating and cosmetically unappealing and affecting mainly the skin, mucous membranes, hair, and nails. Rarely, a patient might live in or pass through an area endemic for one of the classic dimorphic systemic pathogens and present with coccidioidomycosis, histoplasmosis, or blastomycosis. Even more rarely, an infection would occur after surgery or chemotherapy for cancer. For the most part, fungal infections were not regarded as significant entities for the clinician or laboratorian.

In contemporary medicine, the situation has changed significantly. Medical mycology has come into its own. With the ongoing discovery and more frequent use of the cutting-edge techniques of medical technology, i.e., more sophisticated surgical procedures used more aggressively, the advent of organ transplantation, the wider use of cytotoxic chemotherapy for malignancy, the application of broad-spectrum antibiotics, vaccines, indwelling catheters, lines, and devices, and, perhaps of most importance, the ever-escalating incidence of human immunodeficiency virus (HIV) infection and resultant acquired immunodeficiency syndrome (AIDS), fungi have become major agents of infectious diseases, particularly in hosts with abrogated immunity (1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29 and 30).

Persons whose immune systems are dysfunctional or nonfunctional are, in a genuine sense, “living Petri dishes.” Fungi that are ordinarily nonpathogenic, harmless saprobes, most often living in nature in soil or on plants, are able to take advantage of the situation in the immunocompromised host. Such organisms gain an opportunity to be pathogens, hence, the term opportunistic infections. The fungi have become some of the major agents of opportunistic infections of humans. The relative dearth of nontoxic therapies, the absence of diagnostic tests that permit early and correct diagnosis, and the general lack of training in mycology and mycotic diseases among health care professionals have resulted in a steady and consistent increase in both the number and significance of fungal infections over the past decade. Presently, mycotic infections pose one of the major threats to the health and life of immunocompromised patients (3,4,6,8,10,11,15,18,19,20,21 and 22,24,25,27,29,30).

As in most infectious diseases, the laboratorian is called on to assist the clinician in diagnosing and treating fungal infections. In the case of infections caused by fungi, the role of a good clinical mycology laboratory is paramount. Because many mycotic infections are caused by fungi that are not well known in human medicine, it becomes essential to have access to laboratory personnel with training and skills in classic botanical mycology. Likewise, with the advent of great numbers of new and efficacious antifungal drugs, the laboratory is increasingly called on to provide *in vitro* susceptibility data to assist the clinician in choosing optimal therapeutic regimens. It is unlikely that fungal infections will decrease in number or significance; in fact, it is quite the contrary. The role of the laboratory has never been greater or more important in the field of medical mycology than it is now.

FUNGI PATHOGENIC FOR HUMANS

Part of "52 - Fungi and Fungal Infections"

Fungi are eukaryotic organisms, both macroscopic and microscopic, that make up one of the major kingdoms of organisms. Contrary to definitions provided in many sources, fungi are not lower plants and are not properly classified in the plant world. Rather, fungi are classified in their own distinct taxon, the kingdom Fungi (or kingdom Mycota). Fungi are unique and merit being placed into their own kingdom for several reasons. Fungi, as noted, are true eukaryotes, having their DNA surrounded by a membrane, possess typical membrane structure and function, and have the typical array of eukaryotic organelles (e.g., ribosomes, mitochondria).

However, fungi have cell walls containing complex polysaccharides, the main ones being glucans and mannans. They also demonstrate *N*-acetylglucosamine or chitin in their walls. Fungi lack chlorophyll and are heterotrophic. Hence, they produce a plethora of enzymes that enable them to degrade almost any substrate known in nature. In fact, the major function of fungi in life is to degrade organic carbon. It is the fungi that degrade or decompose the bulk of organic carbon on the planet and return it to the atmosphere in the form of carbon dioxide.

Fungi reproduce both sexually and asexually and exist in literally

thousands of different morphologic expressions and multitudinous life cycles (31,32). Most relevant to medical mycology is the ability of fungi to produce asexual propagules of many types, shapes, and sizes. Such structures are often the means by which humans become infected through inhalation, contact with skin and mucous membranes, or after trauma. The two main growth forms of fungi consist of single-celled, budding forms called yeasts and multicellular, filamentous forms called molds. Among medical fungi, several possess the ability to convert from one morphology to another and back again, depending on the conditions of growth and the genetics of the specific organism. Such fungi are called dimorphic because of their ability to exist in two distinct morphologic forms. Other fungi, including many species of medical interest, demonstrate polymorphism: existence in many distinct morphologies. Once again, depending on growth conditions, such polymorphic fungi may transform from one form to another and back again. Given their genetic makeup, their ability to elaborate enzymes capable of powerful degradation, and their production of huge numbers of reproductive propagules, the fungi are clearly among the most versatile and successful of living creatures. The colonization, invasion, and use of human tissue as a growth medium are easy tasks for the fungi.

Few areas in biology have elicited more controversy and emotion than the taxonomy, nomenclature, and classification of the fungi. Table 52.1 indicates one current system of fungal classification, and Table 52.2 shows contemporary thinking as to the nomenclature of the actual fungal infections (mycoses). Most recently, the techniques of molecular biology have been employed to ascertain the relationships between fungi. Results of such early investigations show that a combination of classic morphologic study and molecular genetics will likely yield the most accurate data.

TABLE 52.1. CLASSIFICATION SCHEME FOR THE KINGDOM FUNGI

Group	Group Ending
Kingdom	
Division	-mycota
Subdivision	-mycotina
Class	-mycetes
Subclass	-mycetidae
Order	-ales
Family	-aceae
Genus	-no specific ending
Species	-no specific ending
Variety	-no specific ending
Example of the use of the taxonomic system presented in classifying a clinically significant, common dermatophyte: The organism is *Trichophyton mentagrophytes* var. *interdigitale*	
SUPERKINGDOM	Eukaryota
KINGDOM	Fungi
FORM-DIVISION	Fungi Imperfecti
FORM-CLASS	Hyphomycetes
FORM-ORDER	Hyphomycetales
FORM-FAMILY	Moniliaceae
FORM-GENUS	*Trichophyton*
FORM-SPECIES	*T. mentagrophytes*
FORM-VARIETY	*T. mentagrophytes* var. *interdigitale*

MYCOSES—THE DISEASES CAUSED BY FUNGI

Part of "52 - Fungi and Fungal Infections"

The gamut of fungal infections in humans is broad and ranges from the most superficial to the ultimate in tissue invasion and destruction. In discussing fungal infections, most authorities would employ the following scheme of mycotic infection classification or a variant thereof.

Superficial mycoses: These mycoses infect the superficial layers of the skin; most often the patient demonstrates little or no pathology except the cosmetic aspects. A very common example of superficial mycosis is pityriasis versicolor (tinea versicolor), caused by the yeastlike fungus *Malassezia furfur*.

Cutaneous mycoses: Although many mycoses may manifest as skin lesions, often secondary to disseminated disease or a primary cutaneous infection by a fungus that may cause deep disease, the cutaneous mycoses as discussed here really refer to skin infections caused by a specific group of fungi called dermatophytes. Dermatophytosis is among the most common of fungal infections throughout the world and affects the hair, skin, and nails. Dermatophytoses are caused by three genera of dermatophytes, *Trichophyton*, *Microsporum*, and *Epidermophyton*. Some dermatophyte-caused mycoses are not only among the most common of fungal infections but also among the most common of human diseases, e.g., tinea pedis or athlete's foot.

Subcutaneous mycoses: These mycoses affect not only the skin but also the subcutaneous tissues and even bone. Most often, these infections occur after an accidental and/or traumatic implantation of the fungus into the subcutaneous tissue. The fungi inciting these infections are dwellers in nature and do not require a human host. However, after inoculation, these organisms can precipitate a relentless, chronic disease, with the potential for great destruction of tissue. The span of subcutaneous mycoses is long, with many different fungi responsible for various clinical manifestations. Classic subcutaneous mycoses are sporotrichosis (*Sporothrix schenckii*), chromoblastomycosis (caused by at least six different species of darkly pigmented molds), and eumycotic mycetoma (caused by a wide variety of fungi).

Systemic (deep) mycoses: The traditional systemic agents are those fungi capable of inciting disease in the deep viscera after their acquisition. The classic systemic fungal pathogens are dimorphic (occur in both yeast and mold forms): *Coccidioides immitis* (coccidioidomycosis), *Histoplasma capsulatum* (histoplasmosis), *Blastomyces dermatitidis* (blastomycosis), and *Paracoccidioides brasiliensis* (paracoccidioidomycosis). *Penicillium marneffei* is a recently recognized dimorphic fungus endemic to Southeast Asia that causes systemic infections in HIV-infected individuals (9,33,34,35,36,37 and 38). Most deep fungal infections result after dissemination of the fungus from the lungs following its inhalation from nature. These infections occur quite regularly in the normal host, although, as with most infectious diseases, they are much more rampant and severe when present in the immunocompromised individual, e.g., histoplasmosis and coccidioidomycosis in those with AIDS.

Opportunistic mycoses: This group of mycoses is, in contemporary medicine, the most significant by far. Opportunistic mycoses are those occurring in the host with abrogated or altered immunity. It is now safe to say that given the right moment, in the correct “living Petri dish,” virtually any fungus may incite infectious

disease. There are virtually no fungal organisms that cannot cause serious disease in this patient population. These mycoses, more than any other factor, have changed the face of medical mycology and demonstrated the true power of those microbes to render horrific infections. In particular, patients who have neutropenia or leukemia, bone marrow transplant recipients, solid organ transplant patients, burn victims, those with genetic defects in their immune systems, among others, are all susceptible to infection by an ever-growing number of taxonomically diverse fungi. Of course, persons with AIDS have been victims of the opportunistic fungi in escalating numbers. Recognizing that any fungus may incite disease in this patient group, the classic opportunistic mycoses still remain: candidiasis (largely owing to *Candida albicans*, but with other species being more and more frequently implicated), cryptococcosis (*Cryptococcus neoformans*, particularly in the AIDS population), aspergillosis (*Aspergillus fumigatus* and *A. flavus* are the major agents, particularly in neutropenic patients), zygomycosis (mainly owing to *Rhizopus arrhizus* in the ketoacidotic diabetic), phaeohyphomycosis [caused by darkly pigmented (dematiaceous) molds and yeasts] and hyalohyphomycosis (caused by lightly pigmented, colorless, or hyaline molds). In large part, modern medical mycology has become the science of infections caused by opportunistic fungi (3,4,6,8,10,11,15,18,25,27,29,30).

TABLE 52.2. NOMENCLATURE OF MYCOTIC INFECTIONS

Nomenclature	Definition
Adiaspiromycosis	Mycosis owing to *Chrysosporium parvum*
African histoplasmosis (histoplasmosis duboisii)	Mycosis owing to *Histoplasma capuslatum* var. *duboisii*
Aspergillosis	Mycosis owing to *Aspergillus* spp
Black peidra	Mycosis owing to *Piedraia hortae*
Blastomycosis	Mycosis caused by *Blastomyces dermatitidis*
Candidiasis/candidosis	Yeast infection caused by *Candida* spp
Chromoblastomycosis	Sclerotic cells (bodies) in the dermis and/or in scales
Coccidioidomycosis, valley fever	Mycosis owing to *Coccidioides immitis*
Cryptococcosis	Yeast infection caused by *Cryptococcus* spp
Dermatomycosis	Mycosis of the skin and/or appendages
Dermatophytic mycetoma, pseudomycetoma, mycetomalike dermatophytosis (mycetomatoid dermatophytosis)	Mycosis caused by a dermatophytic fungus which clinically and histopathologically resembles eumycotic mycetoma
Dermatophytid	Skin allergic manifestation of a fungal infection
Dermatophytosis, tinea, ringworm	Mycosis caused by a dermatophyte
Epizootic lymphangitis (histoplasmosis farciminosi)	Mycosis owing to *Histoplasma capuslatum* var. *farcininosum*
Eumycotic mycetoma	Mycosis characterized by fistulae, granules in tissues, tumefaction, and often lesions of bone
Favus	Dermatophytosis of the skin/hair of the scalp with presence of crusty, purulent scutulae
Fungemia	Presence of fungi in the blood
Geotrichosis	Mycosis caused by *Geotrichum* spp
Histoplasmosis (histoplasmosis capuslati)	Mycosis owing to *Histoplasma capsulatum* var. *capsulatum*
Hyalohphomycosis	Opportunistic mycosis caused by various moniliaceous (light-colored, nondematiaceous) molds whose basic tissue form is in the nature of hyaline hyphal elements that are septate, branched or unbranched, and occasionally toruloid
Lobomycosis	Mycosis owing to *Loboa loboi*
Mycosis (plural, mycoses)	Parasitic disease caused by a fungus
Mycotic keratitis	Mycosis of the cornea
Onychomycosis	Mycosis of the nails
Opportunistic mycosis	Mycosis occurring in a host whose immune system has been/is compromised, either through innate disease or as result of medical intervention; often caused by fungi normally considered as harmless, contaminants, saprobes, or plant pathogens
Otomycosis	Mycosis of the external auditory canal
Paracoccidioidomycosis	Mycosis owing to *Paracoccidioides brasiliensis*
Phaeohyphomycosis	Mycosis caused by various dematiaceous fungi in which dematiaceous (dark) yeastlike cells, pseudohyphaelike elements, hyphae that may be short or elongate, regular, distorted to swollen shape, or any combination of these forms may be found in tissue
Pityriasis versicolor	Dermatomycosis caused by *Malassezia furfur*
Rhinosporidiosis	Mycosis owing to *Rhinosporidium seeberi*
Sporotrichosis	Mycosis owing to *Sporothrix schenkii*
Systemic mycosis	Mycotic infection of the viscera
Thrush	*Candida albicans* infection of the mucous membranes of the oral cavity
Tinea nigra	Phaeohyphomycosis (dermatomycosis) caused by *Phaeoannellomyces werneckii*
Torulopsosis	Yeast infection caused by *Torulopsis* spp
Trichosporosis	Yeast infection caused by *Trichosporon* spp
White piedra	Trichosporosis of the hair
Yeast infection	Mycosis caused by a yeast
Zygomycosis	Mycosis caused by members of the Zygomycetes

EPIDEMIOLOGY OF MYCOSES

Fungal infections are acquired in a variety of ways but mainly via acquisition of the etiologic fungus from its site in nature to the human host by accident or happenstance. In most cases, the fungus is living in nature, humans intervene through work or play, and the fungal inoculation is acquired. This can be by inhalation (very common), nontraumatic or traumatic inoculation (common), or ingestion (rare). Many of the mycoses are obtained by inhalation of the fungus from a geographic area of the world where the fungus is either wholly endemic or found much more frequently than elsewhere. For example, *H. capsulatum* var *capsulatum* and *B. dermatitidis* are global pathogens, but they are particularly prevalent in the Ohio-Mississippi River valley of the United States. Most cases of histoplasmosis and blastomycosis are diagnosed in individuals who either live or travel in, to, or from these areas. Similarly, *C. immitis* is endemic only to the lower Sonoran life zone regions of the earth (southwestern United States, parts of Mexico, and Central and South America). Coccidioidomycosis occurs after inhalation of the fungus while in one of the endemic regions. With the above-mentioned mycoses, there is no transmission from person to person; these are not communicable, contagious diseases. Another group of human fungal pathogens, the dermatophytic fungi, however, can be transmitted from person to person. With their skin fungal infections, it is possible to implement transmission from one human to another via indirect or direct contact (e.g., acquiring athlete's foot after using a shower stall in bare feet after its previous use by an individual with tinea pedis or the spread of ringworm of the scalp through a grade-school class when children have used a comb belonging to a classmate with tinea capitis). Likewise, humans are frequently infected by dermatophytes after handling their pet cat or dog or domestic cattle that are infected with various animal dermatophytic pathogens.

As has been mentioned, humans may acquire mycoses after traumatic implantation of the fungal agent from a source in nature. The classic example is rose-handler's or gardener's disease, sporotrichosis, acquired after the handling of rose thorns or sphagnum moss. Many contemporary cases of phaeohyphomycosis occur after traumatic implantation of soil or other materials from nature.

Of growing concern, however, are mycoses obtained in the hospital, often from the same fungi that comprise a part of the normal human flora. Although the array of fungal pathogens known to cause nosocomial infection is diverse, the vast majority of these infections are owing to *Candida* species. Recent studies confirmed the predominant role of candidiasis among the invasive mycoses (1,11,15,16,17,18,19,20,21,22,23,24 and 25,39). Among the species of *Candida* causing bloodstream infection in the United States, *C. albicans* accounts for 50% to 70% of all infections (15,24). As a group, *Candida* species are a part of the microbiota of the oral and gastrointestinal tracts of humans, and, in women, it is often found as normal vaginal flora. After surgery, antibiotic therapy, chemotherapy, and placement of indwelling devices, *C. albicans*, and other *Candida* species have become major bloodstream pathogens. The most recent epidemiologic figures show *Candida* to be the fourth most prevalent cause of hospital-acquired bloodstream infection (10,19,20,21,22 and 23). In surgical, medical, and neonatal intensive care units, *Candida* is a matter for critical concern in modern medicine (11,22). In fact, without question, candidiasis is the most prevalent and significant mycosis of humans (3,4,6,7,15,16,17,18,19,20,21,22,23,24 and 25).

Finally, in the setting of the neutropenic patient, fungi from among the environmental flora, found everywhere at all times, have become major killers. For example, in bone marrow and liver transplant services, the aspergilli are of concern (11,13,25,27,40,41,42,43 and 44). The mortality rate from invasive aspergillosis is unacceptably high, approximately 80% to 100% in most published studies (11,25,40). Often, outbreaks follow periods of hospital construction or renovation when the asexual spores (conidia) of aspergilli are prevalent in the air. Another opportunistic fungus that is widely dispersed in nature is *Fusarium*. Fusaria are among the most frequent of plant pathogenic fungi but now cause a higher rate of mortality in granulocytopenic patients than aspergilli (12,14,41,44,45 and 46). Such nosocomial opportunistic pathogenic fungi are on the rise, and constant vigilance must be exercised if mortality is to be minimized in the susceptible patient populations.

DIAGNOSTIC PROCEDURES (BY DISEASE TYPE)

Part of "52 - Fungi and Fungal Infections"

Superficial Mycoses

Agents of superficial mycosis are organisms that attack the keratinized outer layers of the skin, hair, and nails (47). Infections of this sort are usually of cosmetic concern only and cause little if any discomfort to the patient.

Pityriasis Versicolor

M. furfur is responsible for the condition known as pityriasis versicolor and can be found worldwide. Pityriasis versicolor presents as a series of darkened patches in very light-skinned individuals or as nonpigmented patches on individuals with darker skin. These areas will fluoresce yellow under a Wood's lamp. KOH (potassium hydroxide) examination reveals a characteristic “spaghetti and meatballs” appearance owing to the fragments of hyphae mixed with round yeast cells. *M. furfur* has also been implicated in fungemia in neonates and some adult patients receiving intralipid intravenously (16,31,48,49 and 50). Fungemic episodes usually resolve once the indwelling catheter is removed. *M. furfur* can easily be seen on Gram stain of positive blood culture broths but will not grow on Sabouraud agar when subcultured. The simple overlaying of the culture plate with olive oil will result in abundant growth within 48 hours. Any time a yeast is suspected but is not recovered, this simple method should be employed. At present, there are no direct antigen or DNA methods nor serologic procedures useful for detection of this yeast. The characteristic appearance of yeast cells resembling small bottles (this fungus was originally termed the “bottle bacillus”) seen in blood from patients receiving parenteral nutritional support with products containing oleic acid, coupled with lack of growth on routine laboratory media, should present a high index of suspicion to both the clinician and laboratorian for *M. furfur* fungemia.

Tinea Nigra

Phaeoannellomyces werneckii, previously called *Cladosporium werneckii*, is responsible for the superficial phaeohyphomycotic condition of tinea nigra. Tinea nigra appears as a dark brown to black patch, most often on the palms of the hands and soles of the feet. Although tinea nigra is also mainly of cosmetic concern, it must be differentiated from malignant melanoma before any treatment. Often extensive surgery can be avoided with a KOH examination of the affected area.

When fungal elements are determined to be present, skin scrapings should be placed on mycologic media with antibiotics. A dematiaceous yeastlike colony should appear within 3 weeks and may become velvety with age. The degree of hyphal growth depends heavily on the media and conditions under which the colony grows. Microscopic examination reveals two-celled cylindrical yeastlike cells and, depending on the age of the colony, toruloid hyphae.

P. werneckii is identified microscopically by seeing characteristic darkly pigmented annelloconidia (conidia possessing annellides or rings), which often slide down the sides of the conidiophore (Fig. 52.1) (31,32,51). Because no additional means, e.g., serologic tests, are currently available to identify this fungus or this disease, microscopic morphology, coupled with the characteristic lesions on the patient's skin, is the only satisfactory identification procedure.

FIGURE 52.1. Microscopic appearance of *Phaeoannellomyces werneckii* (Nomarski optics, original magnification ×1,250).

White Piedra

Trichosporon asahi (beigelii) (formerly *Trichosporon cutaneum*) is the causative agent for the condition called white piedra that affects the hair of the scalp, face, and body. This fungus surrounds the hair shaft and forms a white to brown swelling along the hair strand. By running a section of hair between the thumb and forefinger, the nodules can easily be removed. This condition is related to poor hygiene. When infected, the hair should be cut or shaved and kept clean. These steps usually negate the necessity of medical treatment.

When microscopic examination reveals hyphal elements or arthroconidia and/or budding yeast cells, infected hair may be placed on mycologic media without cycloheximide. Cream-colored, dry, wrinkled colonies should form within 48 to 72 hours at room temperature.

T. asahi (beigelii) can be identified in the same manner as other yeast isolates. Sugar assimilations, potassium nitrate (KNO_3) assimilation, urease production, and morphology on corn meal should be determined. *T. asahi (beigelii)* is KNO_3 negative and urease positive and grows at 37°C.

A most important microscopic characteristic is production of both arthroconidia (rectangular cells resulting from the fragmentation of hyphal cells) and blastoconidia (budding yeast cells). In *T. asahi (beigelii)*, one can see the arthroconidia and blastoconidia concurrently (31,32,50).

Black Piedra

Another condition affecting the hair, most often that of the scalp, is black piedra. The causative agent of black piedra is *Piedraia hortae*. Black piedra presents as dark, rocklike hyphal masses that surround and penetrate the hair shaft. Examination of the hyphal masses reveals branched hyphae tightly held together with a cementlike substance. Black piedra is also a condition of poor hygiene and is easily resolved with a haircut and proper regular washings.

P. hortae can be cultured on routine mycologic media. Very slow growth may be observed at 25°C and may begin as a yeastlike colony, later becoming velvety as hyphae develop. Asci may be observed microscopically, usually ranging from 4 to 30 μm and containing as many as eight ascospores. The characteristic cementlike material holding all the above-mentioned structures in place around hair shafts is typical of the group of fungi in which *P. hortae* is classified, namely, the Loculoascomycetes (31,32,51).

Cutaneous Mycoses

There are many species of dermatophytic fungi possessing the ability to cause disease in humans and animals. All have in common the ability to invade the skin, hair, or nails. In each case, these fungi are keratinophilic and keratinolytic, being able to break down the keratin surfaces of these structures. In the case of skin infections, the dermatophytes invade only the upper, outermost layer of the epidermis, the stratum corneum. Likewise, with hair and nails, being part of the skin, only the keratinized layers are invaded. Often the growth of dermatophytes in the skin per se is not the major reason for skin symptoms but rather the host immune response to the presence of the fungal elements. The outcome of acute versus chronic dermatophytoses is mainly the result of the host immune response rather than the invasiveness of the fungi.

The various forms of dermatophytosis are often referred to as tinea, e.g., tinea capitis (scalp infection), tinea corporis (infection of the trunk), tinea cruris (infection of the groin), tinea pedis (infection of the feet). A major clinical manifestation of dermatophytoses is infection of the nails (onychomycosis or tinea unguium). Three genera of dermatophytes are known (31,32,52): *Microsporum*, *Trichophyton*, and *Epidermophyton*. Without question, the most common pathogenic species observed by clinicians is *T. rubrum*. This species incites the bulk of athlete's foot

and nail infection seen by dermatologists and other clinicians. Other *Trichophyton* species frequently causing human diseases are *T. tonsurans* (infection of the hair and scalp) and *T. mentagrophytes*. Of the *Microsporum* species, *M. canis* and *M. gypseum* are most often seen in the United States. Infection owing to *M. canis* most often follows handling of cats and dogs, where the fungus resides naturally. Infections caused by *E. floccosum* most often affect the feet and the groin.

Dermatophytosis can manifest clinically in diverse ways, but most diagnoses are made based on clinical appearance and patient history. Cultures are always desirable and can be obtained from scraping the affected areas and placing the skin, hair, or nail tissue on any number of laboratory media such as Sabouraud agar, with and without antibiotics, or dermatophyte test medium. An alternative is employment of potato flakes agar, containing the color indicator bromthymol blue (53). With this medium, the dermatophytic fungi change the medium from yellow to blue but do not obscure the pigments produced by various dermatophytes that are often useful as adjuncts in identification. Also, this medium promotes sporulation of dermatophytes to enhance microscopic identification. As with dermatophyte test medium, many nondermatophytic fungi also grow on potato flakes agar and may turn the medium blue. The final identification lies with examination of the fungus under the microscope.

Microscopically, the genus *Microsporum* is identified by observation of its macroconidia, whereas with the genus *Trichophyton*, microconidia are the characteristic structures (Table 52.3). *E. floccosum* produces no microconidia, but its smooth-walled macroconidia borne in clusters of two or three are most distinctive. *M. canis* produces characteristic large, thick- and rough-walled macroconidia (Fig. 52.2). Its macroconidia are multicellular (five to eight cells per conidium). *Trichophyton rubrum* produces microconidia that are teardrop- or peg-shaped borne rough along the sides of hyphae, whereas *T. mentagrophytes* produces both single cigar-shaped macroconidia and grapelike clusters of spherical microconidia. *T. tonsurans* produces variably sized and shaped microconidia, with relatively large spherical conidia often being right alongside of small, parallel-walled conidia and other microconidia of various sizes and shapes (Fig. 52.3).

TABLE 52.3. CHARACTERISTIC FEATURES OF MACROCONIDIA AND MICROCONIDIA OF DERMATOPHYTES

Genus	Macroconidia	Microconidia
Epidermophyton	Smooth-walled, borne in cluster of two or three	Absent
Microsporum	Numerous, large, thick- and rough-walled[a]	Rare
Trichophyton	Rare, smooth, thin-walled	Numerous, spherical, teardrop- or peg-shaped[b]

[a] Except *M. audouinnii*.

[b] Except *T. schoenleinii*.

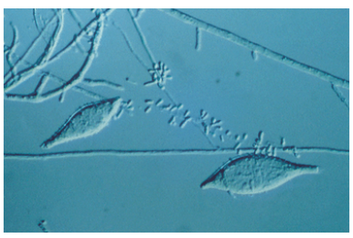

FIGURE 52.2. Macroconidia and microconidia of *Microsporum canis* (Nomarski optics, original magnification ×625).

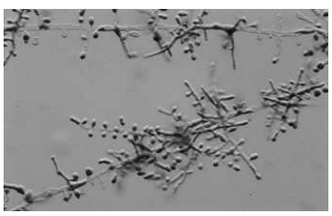

FIGURE 52.3. Microconidia of *Trichophyton tonsurans* (original magnification ×625).

Skin scraping, nail scraping, and observation of hairs directly by microscopy are also most helpful in diagnosing dermatophytic infections. Employing a drop of potassium hydroxide (15% KOH) on a glass slide over the surface of the specimen will often reveal filamentous, clear hyphal elements characteristic of dermatophytes (Fig. 52.4). Calcofluor white has been employed in examining specimens for fungal elements and has demonstrated excellent results.

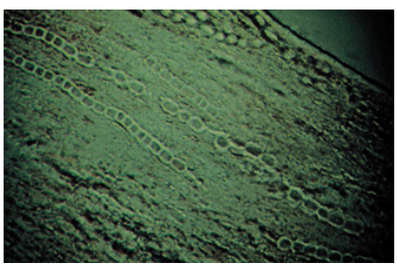

FIGURE 52.4. Potassium hydroxide preparation demonstrates hyphal elements characteristic of dermatophytes. *Trichophyton tonsurans* in hair shaft (original magnification ×600).

Identification of dermatophytes to genus is relatively straightforward, but species-level identification may be considerably more difficult.

Subcutaneous Mycoses

Many fungal pathogens can produce subcutaneous manifestations as part of their disease process; however, some fungi are commonly introduced traumatically through the skin and have a

propensity to involve the deeper layers of the dermis, subcutaneous tissue, and bone. Although they may ultimately be expressed clinically as lesions on the skin surface, they rarely spread to distant organs. In general, the clinical course is chronic and insidious, and, when established, the infections are refractory to most antifungal therapy. The most common subcutaneous mycoses are lymphocutaneous sporotrichosis, chromoblastomycosis, and eumycotic mycetoma (Table 52.4). Although lymphocutaneous sporotrichosis is caused by a single fungal pathogen, *S. schenckii*, the other subcutaneous mycoses are clinical syndromes caused by multiple fungal etiologies (31,54,55 and 56). The causative agents of subcutaneous mycoses are generally considered to have low pathogenic potential and are commonly isolated from soil or decaying vegetation. Exposure is largely occupational or related to hobbies (e.g., gardening, wood gathering). Infected patients generally have no underlying immune defect.

TABLE 52.4. COMMON AGENTS OF SUBCUTANEOUS MYCOSES

		Growth		
Disease	**Organism**	**Tissue**	**Culture (25°C)**	**Culture (37°C)**
Sporotrichosis	*Sporothrix schenckii*	Yeast (rare, cigar shaped)	Mold	Yeast
Chromoblastomycosis	*Cladosporium*	Hyphae[a]	Mold	Mold
	Fonsecaea	Hyphae[a]	Mold	Mold
	Phialophora	Hyphae[a]	Mold	Mold
Mycetoma	*Pseudallescheria*	Hyphae[b]	Mold	Mold
	Madurella	Hyphae[b]	Mold	Mold

[a] Dematiaceous, often blunted to form oval sclerotic bodies.

[b] May be in the form of microcolonies or granules.

Lymphocutaneous Sporotrichosis

Lymphocutaneous sporotrichosis is caused by *S. schenckii*, a dimorphic fungus that is ubiquitous in soil and decaying vegetation (31,32,54). Infection with this organism is chronic and is characterized by nodular and ulcerative lesions that develop along lymphatics that drain the primary site of inoculation. Dissemination to other sites such as bones, eyes, lungs, and central nervous system is extremely rare, occurring in less than 1% of all cases (31,32). Histopathologically, the organism stimulates both acute pyogenic and granulomatous inflammatory reactions. In tissues, the organism appears as a 3- to 5-µm cigar-shaped yeast (Fig. 52.5) but is rarely observed in human lesions. Thus, direct microscopic examination of infected material is usually unrewarding. Definitive diagnosis usually requires culture of infected pus or tissue. *S. schenckii* grows within 2 to 5 days on a variety of mycologic media and appears as a budding yeast at 37°C and as a mold at 25°C. The colonies at 25°C are initially white and moist, turning brown to black with prolonged incubation. Microscopically, the mold appears as delicate branching hyphae with numerous conidia developing in a rosette pattern at the ends of conidiophores (Fig. 52.6). Laboratory confirmation is established by converting the mycelial growth to the yeast form by subculture at 37°C. Alternatively, the organism may be identified immunologically by using the exoantigen test.

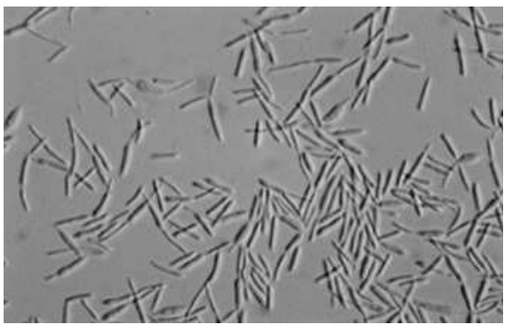

FIGURE 52.5. Microscopic appearance of *Sporothrix schenckii* yeast (original magnification ×1,250).

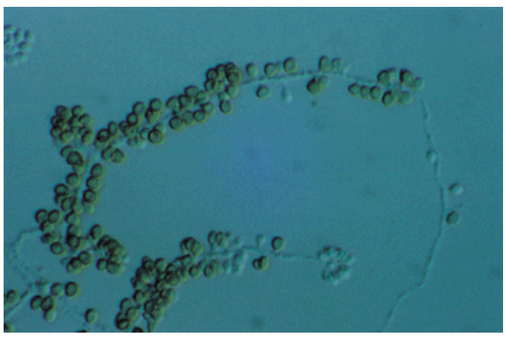

FIGURE 52.6. Microscopic appearance of the mold phase of *Sporothrix schenckii* demonstrates the rosette pattern of conidia at the end of a conidiophore, and dark sessile conidia along the hyphae (Nomarski optics; original magnification ×1,250).

Chromoblastomycosis

Chromoblastomycosis is most commonly seen in the tropics where the warm, moist environment coupled with the lack of protective footwear and clothing predisposes individuals to direct inoculation with infected soil or other organic matter. The organisms most often associated with chromoblastomycosis are dematiaceous (pigmented) fungi of the genera *Fonsecaea*, *Cladosporium*, and *Phialophora* (31,32,51). Multiple species of these genera have been implicated in this disease process. These organisms

are identified according to the pattern and type of sporulation, and in many cases more than one pattern may be observed for a given isolate. For this reason, there remains considerable confusion and controversy regarding the taxonomic placement of many of the dematiaceous fungi that cause chromoblastomycosis. Clinically, the disease is characterized by warty, cauliflowerlike lesions that develop slowly and extend via satellite lesions (31,32,51). The lymphatics are usually not involved and the lesions are painless unless they are involved with secondary bacterial infection. The diagnosis of chromoblastomycosis is generally made by histopathologic examination of infected tissue. Typical lesions demonstrate pseudoepitheliomatous hyperplasia and characteristic brown or copper-colored spherical cells or hyphae known as sclerotic or Medlar bodies (Fig. 52.7). These are the tissue forms of the fungus. The cultures grow as dematiaceous molds but may take weeks to appear and longer to develop the characteristic conidia. Treatment consists of surgery and antifungal therapy. Unfortunately, because most individuals present with advanced disease, therapy is frequently unsuccessful.

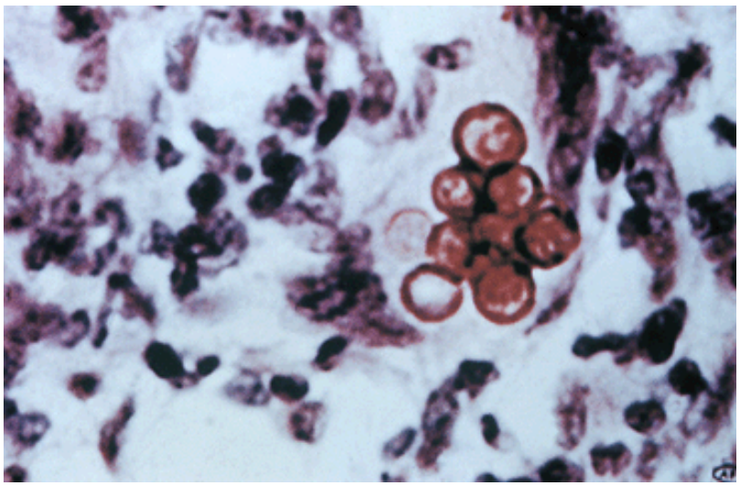

FIGURE 52.7. Histopathologic section of a lesion of chromoblastomycosis demonstrates the presence of sclerotic or Medlar bodies (original magnification ×1,200).

Eumycotic Mycetoma

As with chromoblastomycosis, most mycetomas are seen in the tropics. A mycetoma is defined clinically as a localized chronic granulomatous infectious process involving cutaneous and subcutaneous tissues (55). The process may be quite extensive and deforming with destruction of local bony structures. Most commonly mycetomas are localized to the feet and hands but may also involve other parts of the body such as the back, shoulders, and buttocks. The lesions consist of multiple granulomas and abscesses that suppurate and drain through sinus tracts. The etiologic agents of eumycotic mycetomas encompass a wide range of fungi, including *Pseudallescheria boydii* and *Madurella grisea* (31,32,51,55). Examination of the drainage from sinus tracts may reveal small granules or microcolonies of mycelial filaments. These granules may range from microscopic to 2 mm in diameter and vary according to the infecting species. Histopathologic examination of tissue may reveal hyphal elements and granules (Fig. 52.8). The precise microbiological features depend on the organism involved. Identification of the fungi causing eumycotic mycetomas is by morphology of the asexual conidia formed in culture. It is important to establish the etiology of the infection by culturing specimens because the clinical management depends on the causative organism. An identical picture to eumycotic mycetoma may be caused by various actinomycetes belonging to the genera *Actinomyces*, *Nocardia*, *Streptomyces*, and *Actinomadura* (31,55). These infections, known as actinomycotic mycetoma, may be treated with antibacterial agents, whereas eumycotic mycetomas respond poorly to antifungal therapy and frequently require excision or amputation.

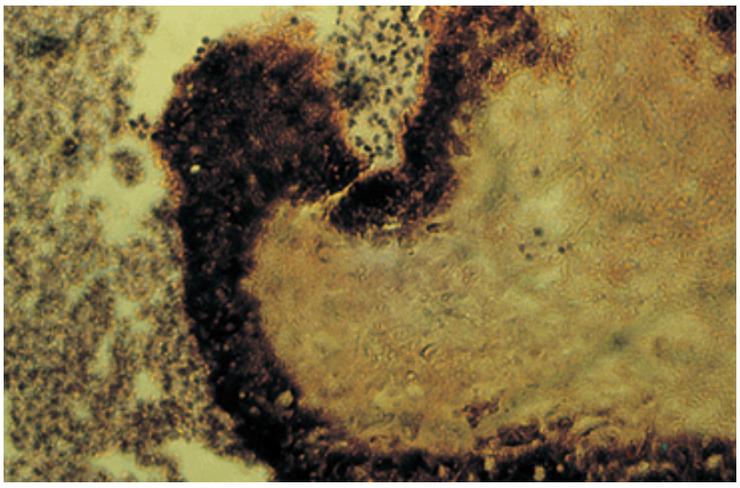

FIGURE 52.8. Tissue section taken from an eumycotic mycetoma illustrates a granule or microcolony (original magnification ×300).

Systemic Mycoses Owing to Dimorphic Fungal Pathogens

The dimorphic fungal pathogens are organisms that exist in a mold form in the natural environment or in the laboratory at 25° to 30°C and in the yeast or spherule form in tissues or when grown on enriched medium in the laboratory at 37°C (31,32,54). The organisms in this group are considered primary or systemic pathogens and include *H. capsulatum* var *capsulatum*, *H. capsulatum* var *duboisii*, *B. dermatitidis*, *C. immitis*, *Penicillium*

marneffei, and *Paracoccidioides brasiliensis* (Table 52.5). These organisms have also been termed endemic pathogens because susceptibility to infection with each organism is generally acquired by living in a geographic area constituting the natural habitat of the particular fungus. In the environment or at 25° to 30°C, these organisms all produce a mycelial form with hyaline, branching, septate hyphae. The tissue form of *H. capsulatum*, *B. dermatitidis*, and *P. brasiliensis* is a budding yeast that may be reproduced on enriched media at 37°C. *C. immitis* forms spherules in tissue or *in vitro* under appropriate conditions. Infection owing to these agents is usually acquired by inhalation of conidia from an environmental source. In recent years, infections with *H. capsulatum* and *C. immitis* have emerged as major opportunistic pathogens in individuals with AIDS (31,54,57). These infections are often acquired primarily but also may be due to reactivation of previous infection in these highly immuno-suppressed individuals.

TABLE 52.5. DIMORPHIC ENDEMIC FUNGAL PATHOGENS

				Growth	
Disease	**Organism**	**Geographic Distribution**	**Tissue**	**Culture (25°C)**	**Culture (37°C)**
Histoplasmosis	*Histoplasma capsulatum* var. *capsulatum*	Ohio and Mississippi River valleys	Intracellular yeast	Mold	Yeast
	Histoplasma capsulatum var. *duboisii*	Africa	Intracellular yeast	Mold	Yeast
Blastomycosis	*Blastomyces dermatitidis*	Ohio and Mississippi River valleys	Large, broad-based budding yeast	Mold	Yeast
Coccidioidomycosis	*Coccidioides immitis*	Southwestern U.S., Mexico, Central and South America	Spherule	Mold	Spherules
Paracoccidioidomycosis	*Paracoccidioides brasiliensis*	Central and South America	Multipolar budding yeast	Mold	Yeast
Penicillosis	*Penicillium marneffei*	Southeast Asia	Intracellular yeast that divide by fission	Mold	Yeast

Histoplasmosis

In 1905, Darling described the causative agent of histoplasmosis as a parasite, then later placed it in the fungal family (44,58). Histoplasmosis is distributed worldwide but is most noted from its endemic regions of the Mississippi-Ohio River valley. Human disease can be linked to either *H. capsulatum* var *capsulatum* (United States) or *H. capsulatum* var *duboisii* (Africa). Disease ranges from slight pulmonary involvement to disseminated disease and is known to involve cells of the reticuloendothelial system.

H. capsulatum var *capsulatum* is most often recovered from respiratory secretions or from blood or bone marrow. Appropriate specimens should be collected and transported to the laboratory as rapidly as possible. It is recommended that the specimen be placed directly on brain-heart infusion (BHI) medium with chloramphenicol and gentamicin to eliminate overgrowth by normal bacterial flora. When an organism is isolated, it should be transferred to potato flakes, Sabhi, or Gorman's media, which is specially formulated to enhance the growth of systemic pathogens and may provide optimum conditions for growth. Cultures incubated at 25°C grow very slowly, resulting in cottony white colonies in 7 to 28 days. The mold phase of *H. capsulatum* is characterized by thin, branching, septate hyphae that produce tuberculate macroconidia and microconidia (Fig. 52.9).

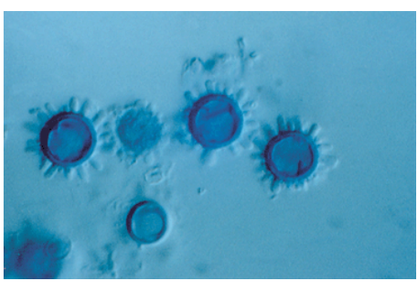

FIGURE 52.9. Microscopic appearance of the mold phase of *Histoplasma capsulatum* var. *capsulatum* demonstrates tuberculate macroconidia (Nomarski optics, original magnification ×1,250).

When *H. capsulatum* is suspected, further laboratory testing is required to differentiate it from saprobic fungi. *H. capsulatum* grows well on cycloheximide-containing medium. Conversion to the yeast form is achieved by incubating the culture at 37°C on BHI infusion agar. This process may take several weeks before conversion is observed. Saprobic fungi will not convert to the yeast form. Other more rapid means of identifying *H. capsulatum* from culture include the exoantigen test and the use of DNA probes (54,59,60 and 61). In the exoantigen test, antigens are extracted from culture material and reacted against anti-*Histoplasma* antibody in an immunodiffusion (ID) test. In the DNA probe test, nucleic acids are extracted from culture material and reacted against a probe specific for *H. capsulatum* ribosomal RNA. With these methods, definitive identification may be made in 2 hours (DNA probe) to 3 days (exoantigen) (54,59,60 and 61).

Additional means of diagnosing histoplasmosis includes histopathologic examination of infected tissue and serology. The tissue phase of *H. capsulatum* is a small budding yeast cell 2 to 5 mm in diameter found almost exclusively within macrophages (Fig. 52.10). It may be visualized with Giemsa or silver stains.

Serologic diagnosis employs both ID and complement fixation (CF) tests and has been quite useful (54,62). An assay to detect antigen in urine has also been developed that has excellent sensitivity and specificity for diagnosis of disseminated infection (54,63,64,65,66 and 67). Unfortunately, its availability is limited to only one laboratory.

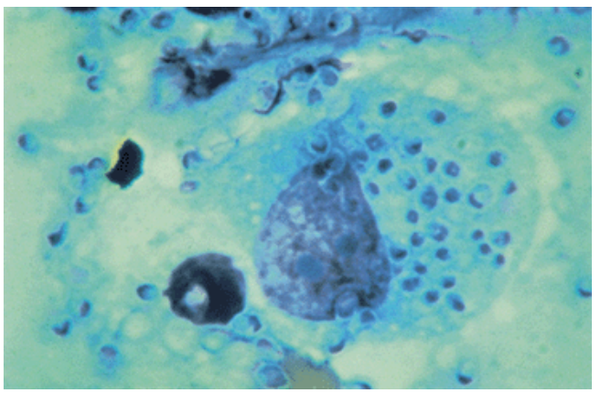

FIGURE 52.10. Microscopic appearance of the tissue phase of *Histoplasma capsulatum* var. *capsulatum* demonstrates intracellular yeast forms (original magnification ×1,000).

Blastomycosis

B. dermatitidis is another of the systemic fungi that become infective on inhalation of conidia. Like other systemic pathogens, *B. dermatitidis* is found in a specific region of the United States, most notably the Ohio-Mississippi River valley region. Disease begins with granulomatous lung involvement but may disseminate to other body sites. The most common form of dissemination is the appearance of cutaneous pustular lesions. Yeast cells can be recovered from biopsies and aspirates of the lesions. Less common involvement may be seen in bone and subcutaneous tissue.

When blastomycosis is suspected, clinical material (e.g., sputum, pus) should be placed on inhibitory media, without cycloheximide, such as BHI agar with chloramphenicol and gentamicin and incubated at 25°C for 7 to 28 days (31,32,54). Growth is very slow and ranges in appearance from a white to a tan fluffy mold. Microscopic examination at this point is not diagnostic. Probable *Blastomyces* isolates must be converted to the yeast phase by subculturing the isolate to a BHI blood agar slant and incubating at 37°C in CO_2 (a candle jar is sufficient). Yeast forms should be visible within a week. Microscopic examination at this point reveals characteristic broad-based budding yeasts.

Although microscopic examination of the yeast gives valuable information, a definitive identification may be made from mycelial phase cultures using the exoantigen test as described for *H. capsulatum*. A commercially available DNA probe assay also allows the rapid identification (2h) of this organism from culture (61). Additional means of diagnosing blastomycosis includes histopathologic examination of infected tissue. The tissue phase of *B. dermatitidis* is a large yeast with broad-based buds (Fig. 52.11). Serologic tests for diagnosing blastomycosis have not been particularly useful. Antigens for CF tests are available, but complement fixing antibodies are absent in as many as 50% of cases.

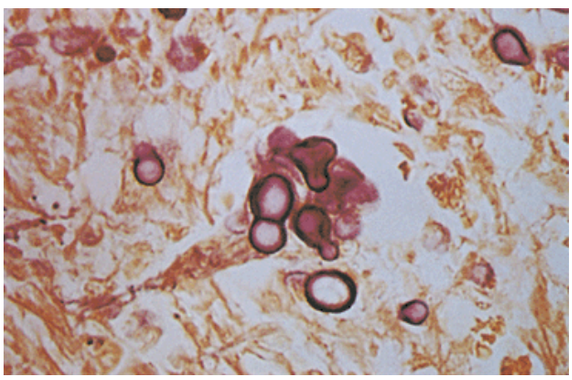

FIGURE 52.11. Microscopic appearance of the tissue phase of *Blastomyces dermatitidis* demonstrates a large, broad-based budding yeast (original magnification ×600).

Coccidioidomycosis

Coccidioidomycosis (Posadas disease, coccidioidal granuloma, valley fever, desert rheumatism, valley bumps, California disease) is commonly a self-limiting, mild to sometimes moderately severe respiratory disease, resulting from the inhalation of arthroconidia produced by the etiologic agent *C. immitis* (31,32,54,57). The organism resides in a narrow ecological niche known as the Lower Sonoran Life Zone, characterized by low rainfall and semiarid conditions. Highly endemic areas include the San Joaquin Valley in California, Maricopa and Pima counties in Arizona, and southwestern Texas. Outside the United States, areas of high endemicity are found in northern Mexico, Guatemala, Honduras, Venezuela, Paraguay, Argentina, and Colombia.

Because *C. immitis* is probably the most virulent of all human mycotic agents, the inhalation of only a few arthroconidia produces primary coccidioidomycosis, which may include asymptomatic pulmonary disease, allergic manifestations (toxic erythema, erythema nodosum or “desert bumps,” and erythema multiforme or valley fever and arthritis (“desert rheumatism”). Primary disease usually resolves without therapy and confers a strong, specific immunity to reinfection, which is detected by the coccidioidin skin test. In patients symptomatic for 6 weeks or longer, the disease progresses to secondary coccidioidomycosis, which may include nodules, cavitary disease, or progressive pulmonary disease; single or multisystem dissemination follows in approximately 1% of this population. Filipinos and blacks run the highest risk of dissemination, with meningeal involvement a common sequela. The gender distribution for clinically significant disease is approximately 9:1 (male:female). The exception is pregnant women among whom the dissemination rate equals or exceeds that for men.

After inhalation, barrel-shaped arthroconidia (2.5 to 4 × 3 to 6 μm) become more rounded as they convert to spherules (Fig. 52.12). At maturity, the spherules (30 to 60 μm in diameter)

produce endospores by a process known as progressive cleavage. Rupture of the spherule walls releases the endospores, which in turn form new spherules. Caution must be exercised with making a diagnosis by histopathology only, as small, empty spherules may resemble the yeast cells of *B. dermatitidis*, and endospores (2 to 5 μm in diameter) can be confused with cells of *C. neoformans*, *H. capsulatum* var *capsulatum*, and *Paracoccidioides brasiliensis*.

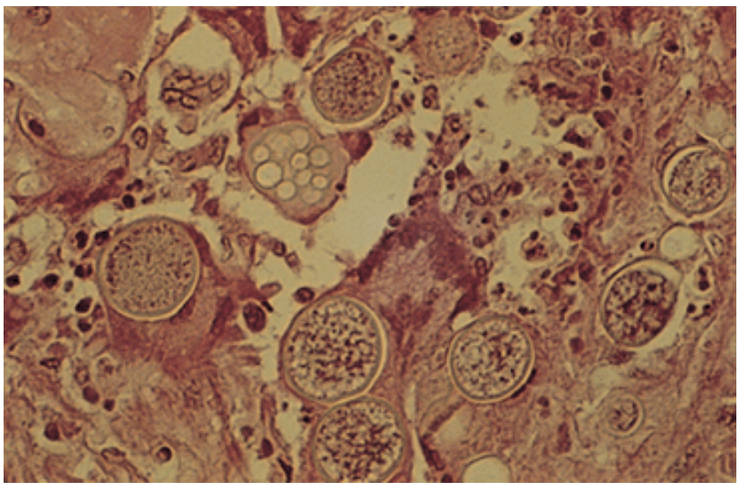

FIGURE 52.12. Tissue section taken from an individual with coccidioidomycosis demonstrates a spherule containing multiple endospores (original magnification ×320).

C. immitis (Rixford et Gilchrist, 1896) is a dimorphic fungus with a variety of mold morphologies at 25°C. Initial growth is white to gray, moist, and glabrous and occurs within 3 to 4 days. It rapidly develops abundant aerial mycelia, and the colony appears to enlarge in a circular "bloom." Mature colonies usually become tan to brown to lavender.

Microscopically, fertile hyphae arise at right angles to the vegetative hyphae and produce alternating (separated by a disjunctor cell) hyaline arthroconidia (Fig. 52.13). When released, conidia have an annular frill at both ends. As the culture ages, the vegetative hyphae also fragment into arthroconidia.

FIGURE 52.13. Microscopic appearance of the mold phase of *Coccidioides immitis* demonstrates arthroconidia (original magnification ×600).

Identification of *C. immitis* from culture may be accomplished by using the exoantigen or DNA probe tests (54,59,61). Additional means of diagnosing coccidioidomycosis include histopathologic examination of infected tissue for the presence of spherules and serologic testing. Several serologic procedures exist for initial screening, confirmation, and prognostic evaluation (31,32,54,62). For initial diagnosis, the combined use of the ID test and the latex particle agglutination test detects approximately 93% of cases. The CF and tube precipitin tests may also be employed for diagnosis as well as for confirmation. Prognostic studies frequently employ serial CF titers.

Paracoccidioidomycosis

Paracoccidioidomycosis (South American blastomycosis, Brazilian blastomycosis, Lutz-Splendore-Almeida disease, paracoccidioidal granuloma) is a chronic, progressive fungal disease endemic to Central and South America (31,32,54,68). Geographic areas of highest incidence (Holdridge plant classification zone) are typically humid, high rainfall areas with acidic soil conditions. As with other systemic mycoses, the gender distribution for clinically significant disease is approximately 9:1 (male:female).

Although the primary route of infection is pulmonary (usually inapparent and asymptomatic), subsequent dissemination leads to the formation of ulcerative granulomatous lesions of the buccal, nasal, and, occasionally, gastrointestinal mucosa; concomitant striking lymph node involvement is also evident. Although the causative agent *P. brasiliensis* has a rather narrow range of temperature tolerance [as evidenced by its predilection for growth in cooler areas of the body (nasal and oropharyngeal)], dissemination to other organs (particularly the adrenals) occurs with diminished host defenses.

Cutaneous and mucosal lesions typically show a pseudoepitheliomatous hyperplasia accompanied by a marked pyogenic and granulomatous response. As a similar tissue reaction is also seen in coccidioidomycosis, and particularly blastomycosis, a definitive diagnosis depends on the demonstration of characteristic yeast cells.

The typical budding yeast cells measure 12 to 40 μm in diameter, with multipolar budding around the periphery, resembling a "mariner's wheel" (Fig. 52.14). These "daughter" cells (2 to 5 μm in diameter) are connected by a narrow base, as contrasted

with the broad base attachment in blastomycosis. Many buds of various sizes may occur, or there may be only a few large buds, giving the appearance of a “Mickey Mouse cap” to the yeast cell. Caution must be exercised when making a diagnosis by histopathology only because the cells in their various sizes and configurations may mimic young spherules of *C. immitis*, the budding cells of *B. dermatitidis*, or the small yeast cells of *H. capsulatum* var *capsulatum*.

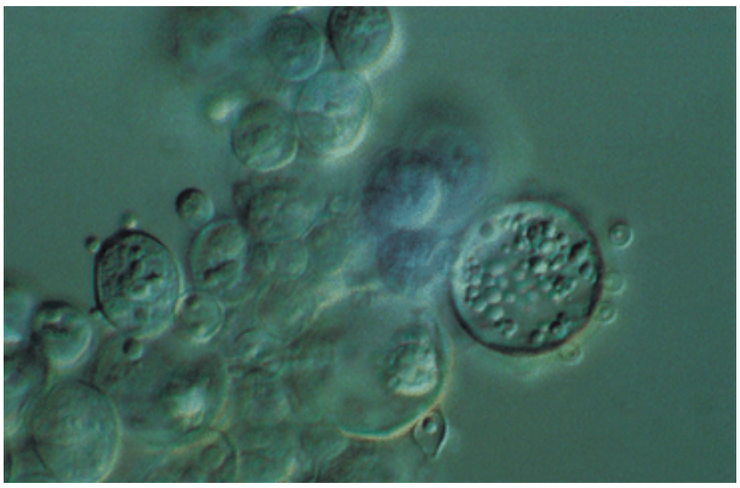

FIGURE 52.14. Microscopic appearance of the tissue phase of *Paracoccidioides brasiliensis* demonstrates multipolar budding yeast forms (Nomarski optics, original magnification ×1,250).

P. brasiliensis is a dimorphic fungus that produces a variety of mold morphologies when grown at 25°C (31,32,54,68). Flat colonies are glabrous to leathery, wrinkled to folded, floccose to velvety, pink to beige to brown, with a yellowish-brown reverse, and resemble those of *B. dermatitidis*. On BHI blood agar at 37°C, the mycelial phase rapidly converts to the yeast phase.

Microscopically, the mold form produces small (2 to 10 µm in diameter), one-celled conidia, generally indistinguishable from those observed with the mold phase of *B. dermatitidis* or the microconidia of *H. capsulatum* var *capsulatum*. When mycelial fragments are transferred to an enriched medium at 37°C, conversion to the characteristic yeast phase occurs.

Diagnosis may be made by culture, histopathologic examination of infected tissues, and serology (31,54,62,68). Both CF and agar gel ID procedures are available for serodiagnosis. The CF test, using yeast-derived antigen, is positive in 80% of active disease. Titers of 1:64 or higher are generally considered diagnostic. Although the CF titer usually decreases with therapy, it may persist in the range of 1:8 to 1:32. The ID test is positive in approximately 95% of active cases, has low cross-reactivity, and diminishes with successful therapy.

Penicillosis

Penicillium marneffei is a dimorphic fungus that appears to be endemic in Southeast Asia. Although infections have been reported in both normal and immunocompromised individuals, most of the cases occur in HIV-infected hosts (9,33,34,35,36 and 37,54). The environmental reservoir for the organism appears to be two species of rat and their burrows (33). Although the fungus does not appear to exist in other parts of the world, increasing international travel makes it likely that infections will be detected for beyond the endemic range of species (33,34 and 35).

Infection with *P. marneffei* is characterized by a variety of signs and symptoms, similar to those of other infections in patients with late-stage AIDS. These include fever, weight loss, generalized lymphadenopathy, anemia, productive cough, pulmonary infiltrates, subcutaneous abscesses and papule-like ulcers (34,35,37,38). The skin lesions may mimic those seen in other infectious processes such as tuberculosis, molluscum contagiosum, and histoplasmosis (36,38).

Detection of *P. marneffei* by histopathologic examination or by culture of blood, bone marrow, skin, and respiratory specimens is the most productive means of making a laboratory diagnosis of infection with this organism (9). In tissue, the presence of 4- to 8-µm diameter cells that divide by fission is characteristic of *P. marneffei* (9). When observed in histocytes, *P. marneffei* can resemble *H. capsulatum*; however, when observed outside of histiocytes, the cells of *P. marneffei* are considerably larger than those of *H. capsulatum* (9). In culture, *P. marneffei* produces a diffuse red pigment and grows as a mold at 25° to 30°C. When incubated at 37°C, it undergoes a phase transition and grows as a single celled yeast form. The red pigment is not produced by the yeast phase of the organism (9).

Opportunistic Mycoses

The opportunistic mycoses occur primarily in immunocompromised individuals, particularly those with malignancies and AIDS, and after major surgery, severe burn injury, and bone marrow and solid organ transplantation. The number and type of fungal pathogens included in this category are increasing rapidly (4,13,14,16,17,27,46,48,49,69,70,71,72 and 73) (Table 52.6). The most well-known causes of opportunistic mycoses include *Candida*, *C. neoformans*, and *Aspergillus* species. The estimated annual incidence of invasive mycoses owing to these pathogens is 73 infections per million population for *Candida*, 66 per million for *C. neoformans*, and 12 per million for *Aspergillus* species (25). In addition to these agents, of increasing importance is the steadily growing list of other opportunistic fungi (Table 52.6). These opportunistic fungi include yeasts other than *Candida* species, nondematiaceous or hyaline molds, agents of zygomycoses, and the pigmented or dematiaceous fungi (13,27,51,56,72,73). Infections caused by these organisms range from catheter-related fungemia and peritonitis to more localized infections involving lung, skin, and paranasal sinuses (13,27,51,56,72,73). Many of these fungi were previously thought to be nonpathogenic and now are recognized causes of invasive

mycoses in compromised patients. Estimates of the annual incidence of these less common mycoses have been virtually nonexistent, but recent data from a population-based survey conducted by the Centers for Disease Control indicate that zygomycosis occurs at a rate of 1.7 infections per million per year, hyalohyphomycosis at 1.2 per million per year, and phaeohyphomycosis at 1.0 per million per year (25).

TABLE 52.6. AGENTS OF OPPORTUNISTIC MYCOSES[a]

I.	*Candida* and other opportunistic yeasts
	Candida albicans
	Candida glabrata
	Candida tropicalis
	Candida parapsilosis
	Candida krusei
	Candida lusitaniae
	Candida dubliniensis
	Cryptococus neoformans
	Malassezia spp
	Rhodotorula spp
	Saccharomyces cerevisiae
	Trichosporon spp
II.	Agents of hyalohyphomycosis
	Aspergillus spp
	Fusarium spp
	Pseudallescheria boydii
	Scedosporium prolificans
	Scopulariopsis spp
III.	Agents of zygomycosis
	Absidia spp
	Mucor spp
	Rhizomucor spp
	Rhizopus spp
IV.	Agents of phaeohyphomycosis
	Alternaria spp
	Bipolaris spp
	Curvularia spp
	Exserohilum spp
V.	*Pneumocystis carinii*

[a] List is not all-inclusive.

The morbidity and mortality owing to infections caused by these opportunistic pathogens are extremely high, and the prevention, diagnosis, and therapy of these infections remain quite difficult (4,13,14,16,17,27,48,49,51,65,69,70,71,72 and 73). Increased recognition of the importance of the opportunistic mycoses has spurred efforts to develop new diagnostic and therapeutic approaches as well as to expand our knowledge of the epidemiology and pathogenesis of fungal infections (11,13,27,51,65,69,73,74 and 75).

Candida and Other Opportunistic Yeasts

The increased incidence of yeast and yeastlike fungi isolated from clinical specimens has magnified the importance of yeast identification to the species level. Gone are the days when *C. albicans*, *Candida* species (not *albicans*), and *Cryptococcus* species are acceptable yeast identifications (15,48,76). *Candida* species has become the number four cause of blood-borne infection in the United States (10,11,18,19,20,21 and 22,24). In addition to *C. albicans*, other *Candida* species such as *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, *C. krusei*, and *C. lusitaniae* are also being recovered more often than in the past and are responsible for more aggressive and refractory infections (1,5,6 and 7,15,20,39,48,71,76,77,78,79,80,81,82,83,84,85 and 86). Emergence of species other than *C. albicans* as causes of infection in some institutions has involved organisms such as *C. glabrata* and *C. krusei* (1,15,20,21 and 22,28,82,84,85 and 86), species that are either innately or relatively resistant to the triazole class of antifungal agents. Although species-specific differences in susceptibility to triazole agents such as fluconazole and itraconazole clearly exist (19,20,21 and 22,24,82,85,86), there are insufficient data to document precisely the role of antifungal drug pressure in the emergence of non-*albicans* species of *Candida* (6,15,24). Nevertheless, given the potential for selection of less responsive organisms by antifungal drug pressure (1,39,85,86), ongoing surveillance may be prudent (15,19,20,21 and 22,24). Clinical labor-atories may need to expand their yeast identification capabilities to facilitate these surveillance efforts (6,11,15,17,19,20,21 and 22,39,48,70).

The *Candida* species are not only frequently present as normal flora of the mucosa, skin, and digestive tract but are also the most notorious agents of yeast infection. These infections range from superficial skin infections to disseminated disease. *C. albicans* certainly reigns as the number one cause of yeast infection in the world today (15,24,28). This organism may be recovered from a variety of sites, including skin, oral mucosa and vagina, as normal flora, but when conditions are altered, it is capable of causing disease in virtually any site. *C. glabrata* is the second most common *Candida* species to incite disease (15,19,20,21 and 22,24,71). This organism is incapable of forming hyphae or pseudohyphae under usual laboratory conditions and assimilates only glucose and trehalose and therefore is easily differentiated from *C. albicans* and other species of *Candida* (50,71). Fungemia with *C. glabrata* is associated with a high rate of serious complications (e.g., endocarditis, endophthalmitis, liver abscess) and high mortality (39,71). Resistance of *C. glabrata* to fluconazole and other azoles has been documented and may contribute to increased colonization and infection with this organism in centers where azoles are used for antifungal prophylaxis (1,6,20,21,24,39,71,85,86). Other notable species of *Candida* include *C. parapsilosis*, *C. tropicalis*, *C. krusei*, and *C. lusitaniae* (15). These isolates are distinguished by differences in their carbohydrate assimilation patterns and by secondary testing (48,50). *C. parapsilosis* has become an important cause of hospital outbreaks of nosocomial infections (11,15,22,77,80,81,83). This organism has a propensity to form biofilms (77,81,83) and is a frequent colonizer of skin (22,87), characteristics that may explain its strong association with catheter-related bloodstream infections (1,77,80,83).

Yeasts are easily distinguished from molds. Macroscopically, they range in color from white to cream or tan, with a few species in the pink to salmon range. Yeasts that are darkly pigmented owing to melanin are associated with polymorphic dematiaceous fungi and are discussed elsewhere in the chapter. Textures vary per strain but can range from mucoid to butterlike to wrinkled to velvety.

Several tests are available to aid in yeast identification (Table 52.7) (48,50,79,88,89,90 and 91). The most basic and easiest test to perform is the germ-tube test. *C. albicans* is capable of forming germ tubes in 3 hours given the proper testing environment. This test requires the use of serum or plasma. Bovine serum can be purchased, but HIV and hepatitis B–negative fresh frozen plasma that has expired from the blood bank can be kept indefinitely at 4°C and used for this testing. A 0.5-mL aliquot of serum or plasma is placed in a disposable test tube. Using a sterile Pasteur pipette, a small portion of an isolated yeast colony is placed into the serum, gently shaken, and placed into a 35°C incubator for 2.5 to 3 hours but no longer. Other yeast isolates are capable of germ-tube formation with extended incubation periods. Care must be taken not to make too heavy a suspension, as this will inhibit germ-tube formation.

True germ tubes are not constricted at the point where they emerge from the blastoconidium (Fig. 52.15). One must take care when reading germ tubes because other isolates are capable of forming false or constricted germ tubes. *C. tropicalis* often germinates under these testing conditions, but germination structures are constricted at the point where they are formed on the yeast cell. After the incubation period, an accurate identification of *C. albicans* can be made when germ tubes are present. *C. dubliniensis* and *C. stellatoidea* are also capable of germ-tube production and may be difficult or impossible to differentiate from *C. albicans* without resorting to additional physiologic, immunologic, or nucleic acid–based testing (31,50,70,88,92). A known germ tube–positive *C. albicans* should be set up in conjunction with all patient testing as a positive control. *Cryptococcus* species should also be set up as the negative control. When test results are negative, the technologist must turn to other procedures for identification. Note that rare *C. albicans* isolates are not capable of germ-tube production.

TABLE 52.7. CHARACTERISTICS OF SELECTED MEDICALLY IMPORTANT YEASTS AND YEAST-LIKE FUNGI

Species	Blastoconidia	Arthroconidia	Chlamydoconidia	Germ Tubes	True Hyphae	Pseudohyphae
Candida albicans	+	–	+	+	+	+
Candida krusei	+	–	–	–	+	+
Candida parapsilosis	+	–	–	–	+	+
Candida tropicalis	+	–	–	–	+	+
Candida glabrata	+	–	–	–	–	–
Cryptococcus spp	+	–	–	–	–	–
Trichosporon spp	+	+	–	–	+	+

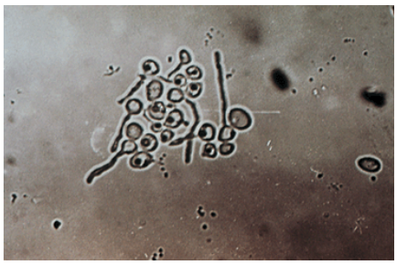

FIGURE 52.15. Germ tube of *Candida albicans* (original magnification ×600).

In addition to the germ-tube test, a rapid colorimetric test based on the detection of *C. albicans*–specific enzymes (L-proline aminopeptidase and ß-galactosaminidase) or the use of agar medium containing chromogenic substrates (CHROMagar Candida, Hardy Diagnostics, Santa Maria, CA) may be useful aids in rapid presumptive identification of yeasts (48,50,79,89,90). CHROMagar combined with observation of microscopic morphology on cornmeal–Tween 80 agar (see below) provides an excellent means of presumptive identification of *Candida* species, including *C. albicans*, *C. tropicalis*, and *C. krusei* (79,89,90). CHROMagar has proven particularly useful in detecting mixed infections with more than one species of *Candida* and formulations incorporating fluconazole into the agar have allowed investigators to simultaneously screen for infections owing to *Candida* and to detect potential fluconazole resistance (75,89,90). Although a single presumptive identification test cannot be used alone for identifying yeasts, a positive germ-tube or colorimetric test or characteristic appearance on CHROMagar medium is generally considered diagnostic for *C. albicans* and further identification is not indicated (48,79,90).

Although sugar fermentations are very valuable, they are very time and labor intensive, thus making them impractical for the routine microbiology laboratory. Sugar assimilations, however, are a series of tests that give significant identification information and can easily be incorporated into any laboratory (31,32,50). These tests identify which sugars a yeast is capable of using as a sole source of carbon. Assimilation results may be determined from means as sophisticated as the automated identification systems to simple manual procedures. Individual laboratories should assess which method is most practical for them.

Although many kits are available for yeast identification, the API 20C yeast identification strip (bioMérieux, Hazelwood, MO) remains a widely used commercial method for assimilation testing. A series of sugars is lyophilized and placed into wells on a plastic strip. Yeasts to be identified are suspended in an agar basal medium and pipetted into the wells. The strips are incubated at 30°C in a humidifier chamber and read at 24, 48, and 72 hours. As sugars are assimilated, the well becomes turbid with fungal growth. Wells in which the sugar is not assimilated remain clear. A code is derived from the assimilation pattern. This code is matched against a computerized database for identification. Identifications are accompanied by a percentage that indicates the probability that the identification is correct. Although this approach is very reliable, other auxiliary testing should accompany assimilation results before a final identification is made (31,32,50). Automated systems are available for yeast identification. Many of these systems use enzyme as well as assimilation reactions to aid in yeast identification.

One test that gives valuable information for separating the clinically significant yeasts is the KNO_3 assimilation (91). A positive KNO_3 assimilation test will turn the medium blue, whereas KNO_3-negative isolates will turn the medium yellow. *Cryptococcus albidus* works well as a positive control, whereas *C. albicans* is a suitable negative control.

Yeast isolates producing the enzyme urease can easily be detected by a simple urea agar. This is another fairly rapid, easily read test that aids in yeast identification. *Cryptococcus* and *Rhodotorula* species are positive, as are a few *Candida* and *Trichosporon* species. Media for detecting urea hydrolysis may be obtained commercially. Positive test results turn the media bright fuchsia pink, whereas negative results will cause little, if any, change in the medium. *C. albidus* works well as a positive control, whereas *C. albicans* functions well as a negative control.

Yeast morphology on cornmeal agar is extremely important when determining whether an isolate produces one or more of the following structures: hyphae, true pseudohyphae, arthroconidia or blastoconidia (31,32,50,88). The morphology is a very important key to yeast identification. As noted previously, when combined with appearance on CHROMagar, microscopic morphology on cornmeal agar allows the identification of a number of commonly encountered yeast isolates (79). A cornmeal plate is inoculated with two parallel 1-cm long streaks. The streaks are then covered with a coverslip and allowed to incubate at room temperature for 48 hours. The Petri dish can be placed on the microscope stage and viewed with a 20× objective. One or more of five morphology types should be observed (Table 52.7 and Fig. 52.16). Blastoconidia are the characteristic budding yeast forms most often seen on direct mounts. *C. albicans* also forms terminal thick-walled chlamydoconidia under some conditions. Pseudohyphae occur when the blastoconidia germinate

to form a filamentous mat. The cross walls are not true separations but rather constrictions, whereas true hyphae remain parallel at cross walls with no indentation. The fifth morphologic type seen with yeasts is arthroconidia. This type begins as true hyphae but begins to break apart at the cross walls as the structures mature. Rectangular fragments of hyphae should be accompanied by blastoconidia to consider an isolate a yeast.

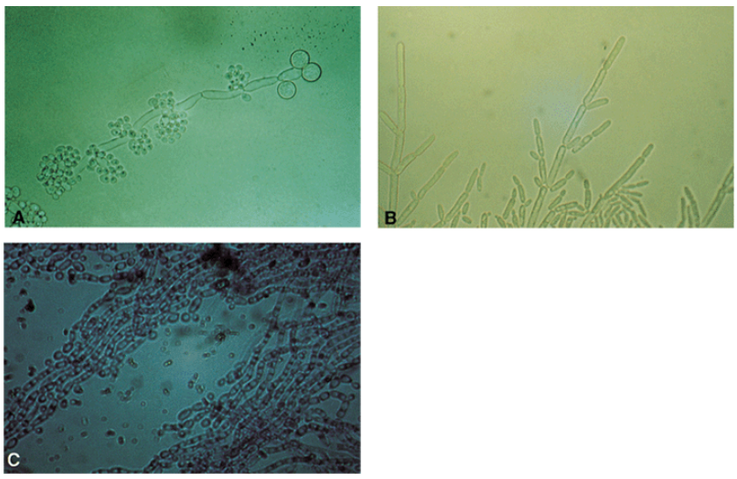

FIGURE 52.16. Yeast morphologies observed on cornmeal agar (original magnification ×600). **A:** True hyphae, blastoconidia, and chlamydoconidia. **B:** Pseudohyphae. **C:** Arthroconidia.

Temperature studies also offer additional information for yeast identification. *Cryptococcus* species have weak growth at 35°C and no growth at 42°C. Several *Candida* species have the ability to grow well at temperatures as high as 45°C. The inability to grow at temperatures of 42° to 46°C is one of the characteristics used to distinguish *C. dubliniensis* from *C. albicans* (92).

Any one of these tests alone, with the exception of the germ-tube test, is not sufficient for proper identification, but when tested in concert, proper identification is often easily accomplished. Armed with the above procedures, the technologist should be able to identify the most commonly encountered yeast isolates.

Among the opportunistic yeasts that merit special mention are the *Cryptococcus* species, which are important causes of meningitis and pulmonary disease (16,31,32,48,50,93,94). These organisms are surrounded by a capsule that causes the characteristic mucoid appearance common with this genus. The capsule can be detected surrounding the budding yeast in spinal fluid with the aid of India ink. The ink stains the cerebrospinal fluid (CSF) while leaving clear halos around each individual yeast cell (Fig. 52.17). *C. neoformans* is the most noted pathogen in this group. This has become one of the major causes of opportunistic infection in AIDS patients. This organism is commonly found in soil contaminated with pigeon droppings and is most likely inhaled before infection. *Cryptococcus* species are noted for not producing true hyphae or pseudohyphae on cornmeal agar (Table 52.7). Some are nitrate positive, whereas all are urease positive. Sugar assimilations vary with each species. The diagnosis of infection owing to *C. neoformans* may be made by culture of blood, CSF, or other clinical material; however, it is most commonly made by detecting capsular antigen (cryptococcal

antigen) in CSF or serum. Detection of cryptococcal antigen is accomplished by using one of several commercially available latex agglutination or enzyme immunoassay (EIA) kits. These assays have been shown to be highly sensitive and specific for the diagnosis of cryptococcal disease (31,32,50,94).

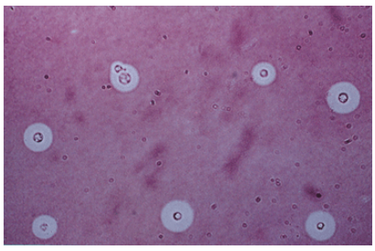

FIGURE 52.17. India ink preparation demonstrates the capsule of *Cryptococcus neoformans* (original magnification ×600).

Rhodotorula species are closely related to the cryptococci in that they bear a capsule and are urease positive. Some species are also nitrate positive. This group of yeasts are remarkable for their bright salmon pink color. They are less common agents of disease but have been known to cause opportunistic infection.

T. asahi (beigelii), a common cause of white piedra, is an emerging agent in disseminated infection (95). This organism has been the culprit in several outbreaks of infection in cancer patients. Its treatment is complicated by the fact that this organism tends to be resistant to amphotericin B, the one antifungal drug known to kill most fungi (95). Amphotericin B is the number one choice for treatment of life-threatening fungal infection but often is not able to clear these infections. *Trichosporon* species are noted for their production of arthroconidia on cornmeal agar (Table 52.7). This, along with the other testing, will ease the identification of this organism. *T. asahi (beigelii)* shares antigenic determinants with *C. neoformans*, and thus serum and CSF from patients with disseminated trichosporonosis may give a positive reaction with tests for cryptococcal antigen (31,32).

There is one last yeast that bears mentioning. It will be negative for all tests. *M. furfur* is a lipophilic organism that requires long-chain fatty acids to live. This organism is a common skin colonizer and when present may cause a condition known as tinea versicolor (52). This condition occurs as hyperpigmented or hypopigmented areas on the skin. It usually causes no discomfort but is undesirable cosmetically. *M. furfur* is also known to cause more serious infections such as fungemia and catheter-related infections (49). Outbreaks of infection were noted in neonatal intensive care units where premature infants were receiving intravenous lipid supplementation. The growth of the organism is favored by the lipid-rich formula, and the organism gains access to the bloodstream via the catheter, thereby causing fungemia (48,49). Treatment usually is not necessary because infection subsides when the lipid infusion is stopped and the intravascular lines are removed. Since the first reports in neonates, this organism has also caused similar syndromes in anorexic patients also receiving lipid infusions through vascular catheters. This organism should be considered when yeasts are seen microscopically in blood culture bottles or clinical material but no organisms are recovered when cultured on routine agar medium. To isolate this organism on agar medium, the plates must be inoculated and then overlaid with sterile olive oil (48,49 and 50).

Aspergillosis

Aspergillosis encompasses a broad spectrum of diseases caused by members of the genus *Aspergillus*. The range of pathologic processes include (a) toxicity owing to ingestion or inhalation of mycotoxins produced by aspergilli, (b) allergies (allergic bronchopulmonary aspergillosis, extrinsic allergic alveolitis), (c) colonization in preformed cavities in the lung (fungus ball), (d) invasive, inflammatory, granulomatous, necrotizing disease of the lungs and other organs, and (e) in the host with abrogated immunity and systemic and fatal disseminated disease (4,11,13,14,16,25,27,31,32,40,41,42 and 43,96,97).

Clinical manifestations, apparently related to the immune status of the host and fungal exposure, are ear infections (incited primarily by *A. niger*), mycotic keratitis (keratomycosis), sinusitis, cutaneous aspergillosis (often sequelae of disseminated disease), pulmonary aspergillosis, central nervous system involvement, bone disease, endocarditis, and fatal disseminated aspergillosis (in organ transplant and leukemic patients) (13,14,16,31,32,40,41,97).

As with other ubiquitous fungi, the diagnosis of aspergillosis necessitates caution when evaluating the isolation of an *Aspergillus* species from clinical specimens. Recovery from surgically removed tissue or sterile sites, accompanied by positive histopathology (moniliaceous, septate, dichotomously branching hyphae) should always be considered significant; isolation from normally contaminated sites requires closer scrutiny.

Although approximately 19 *Aspergillus* species have been documented as agents of human disease, the major clinical entities are caused by *A. fumigatus*, *A. flavus*, *A. niger*, and *A. terreus* (Table 52.8). The increased, clinically significant isolation of *A. nidulans* merits its recognition as a possible emerging pathogen.

TABLE 52.8. DIFFERENTIAL CHARACTERISTICS OF SOME CLINICALLY SIGNIFICANT *ASPERGILLUS* SPECIES

Species	Colonial Morphology	Microscopic Morphology
A. fumigatus	White to gray-green; slate gray with age; reverse yellow to variable; growth at 45–50°C	Smooth-walled conidiophore terminates in dome-shaped vesicle bearing uniseriate phialides from the upper portion only; conidial heads strongly columnar; conidia echinulate
A. flavus	Yellow to lime-green; reverse pinkish; brown to black sclerotia may be present	Rough; thick-walled conidiophores bear globose vesicles; uniseriate or biseriate phialides cover the majority of the vesicle; conidial heads radiate; conidia echinulate
A. nidulans	Dark green to yellow-green; reverse pinkish	Short, sinuous, pale brown conidiophores bearing hemispherical vesicles; biseriate phialides cover upper half of vesicle; globose, rough-walled conidia from short columns; cleistothecia and Hulle cells present
A. niger	White to carbonaceous black; reverse pale yellow	Large, smooth, thick-walled conidiophores bearing globose vesicles; biseriate phialides cover entire vesicle; conidial heads are radiate; conidia thick-walled, echinulate
A. terreus	Cinnamon-buff to brown; reverse dull yellow to brown	Delicate fruiting head compared with above species; short, flexous conidiophores terminate in small, domelike vesicles; biseriate phialides cover most of the vesicle; small conidia to elliptical; single aleurioconidia formed on submerged hyphae; conidial heads columnar

Culture Methods and Identification

Most etiologic agents of aspergillosis grow readily on routine mycologic media lacking cycloheximide, at both 25° and 35°C; *A. fumigatus*, a thermotolerant species, has a maximum growth temperature of 45° to 50°C. Species-level identification of the major human pathogens can usually be made by observing cultural and microscopic characteristics from growth on potato dextrose agar, whereas the less commonly seen isolates require standardized media (Czapek-Dox and 2% malt agar) to utilize identification keys (31,32,41). Microscopic morphology [conidiophores, vesicles, metulae, conidiogenous cells (phialides), conidia] is best observed with the aid of a slide culture (Table 52.8 and Fig. 52.18).

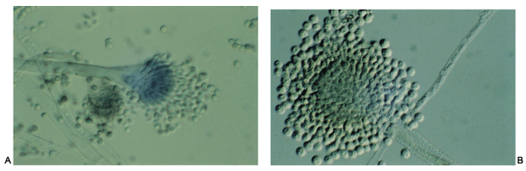

FIGURE 52.18. Microscopic appearance of *Aspergillus* species. **A:** *Aspergillus fumigatus* (Nomarski optics, original magnification ×625). **B:** *Aspergillus flavus* (original magnification ×1,250).

Serologic Diagnosis

Both immunodiffusion and countercurrent immunoelectro-phoresis tests are available for the detection of antibodies to *Aspergillus* antigens, as these antibodies are generally uncommon in sera from healthy individuals (62,96,97). They have limitations, however, in the setting of the immunocompromised host, who is frequently unable to mount an antibody response. Recent efforts for serodiagnosis have been directed toward demonstration of the *Aspergillus* antigen galactomannan employing countercurrent immunoelectrophoresis, radioimmunoassay (RIA), latex agglutination, and enzyme immunoassay methodologies (42,43,47,96,97). Although antigen detection appears promising, further evaluation is needed to establish its utility in diagnosing invasive disease early enough to permit efficacious therapy.

Zygomycosis

Zygomycetes causing human disease encompass several genera in the division of Zygomycota (Table 52.9). The principal human pathogens in the class Zygomycetes are encompassed by two orders: the Mucorales and the Entomophthorales. In the order Mucorales, pathogenic genera include *Rhizopus*, *Mucor*, *Absidia*, *Rhizomucor*, *Saksenaea*, *Cunninghamella*, *Syncephalastrum*, and *Apophysomyces* (31,32,56). As with other saprobic mold-fungi, immunosuppression and trauma are frequent predisposing factors in zygomycosis. Metabolic acidosis, induced by several conditions, appears to be the foremost predisposing factor in classic rhinocerebral zygomycosis caused primarily by *Rhizopus arrhizus*. The predilection of these fungi for the vascular system with resulting infarction and necrosis, combined with their rapid growth rate, makes them some of the most fulminant agents of mycotic disease. The order Entomophthorales contains two pathogenic genera, *Conidiobolus* and *Basidiobolus*. These agents generally incite a more chronic, granulomatous infection of subcutaneous tissues.

TABLE 52.9. PREDOMINANT AGENTS OF ZYGOMYCOSIS

Superkingdom	Eukaryota
Kingdom	Fungi
Division	Zygomycota
Class	Zygomycetes
Order	Mucorales
Family	Mucoraceae
Genera/species	*Rhizopus arrhizus*
	Rhizopus rhizopodiformis
	Mucor circinelloides
	Absidia corymbifera

Family	Cunninghamellaceae
	Cunninghamella bertholletiae
Family	Saksenaeceae
	Saksenaea vasiformis
Family	Thamnidiaceae
	Cokeromyces recurvatus
Order	Entomophthorales
Family	Ancylistaceae
	Conidiobolus coronatus
Family	Basidiobolaceae
	Basidiobolus ranarum

Histopathology

Histopathologically, fungi in the order Mucorales are seen as ribbonlike, aseptate or sparsely septate moniliaceous hyphae (Fig. 52.19).

In contrast to Hyphomycetes, their diameter often exceeds 10 µm. Because the Zygomycetes are an extremely ubiquitous group of fungi, demonstration of characteristic fungal elements in tissue merits considerably more importance than the mere isolation of a mucoraceous fungus. The tissue presentation seen by members of the Entomophthorales is that of more regularly septate hyphae, often, but not consistently, accompanied by an eosinophilic halo termed the Splendore-Hoeppli phenomenon. The isolation of these agents always merits attention because they have not been found to be laboratory contaminants.

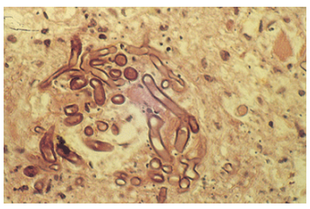

FIGURE 52.19. Tissue section from an individual with zygomycosis demonstrates ribbonlike, aseptate hyphae (original magnification ×600).

Culture Methods

Specimens for culture may be obtained from various sites, but biopsies at the edges of necrotic sites are the most rewarding. As hyphal elements are fragile, tissue should be minced, rather than ground, and processed immediately. If a delay in transport is unavoidable, store at room temperature because Zygomycetes rapidly lose viability when refrigerated.

Growth of most genera of pathogenic Mucorales is readily visible (within 12 to 18 hours) on standard mycologic media lacking cycloheximide and occurs at either 25° or 37°C. It is easily recognized by the rapid growth rate (filling the tube or Petri dish in a matter of days) and gray to brown woolly colonies. Further identification to the genus and species level is based primarily on microscopic morphology (Table 52.10 and Fig. 52.20) because as no practical biochemical or serological methods exist (31,32,56).

TABLE 52.10. DIFFERENTIAL CHARACTERISTICS OF SOME CLINICALLY SIGNIFICANT ZYGOMYCETES GENERA

Genus	Colonial Morphology	Microscopic Morphology
Rhizopus	Rapid growth, cottony, white; becoming gray to brown	Long, unbranched sporangiophores, solitary or in clusters arising from rhizoids; sporangia dark, globose; containing mostly angulated, striated sporangiospores; columella hemispheric
Mucor	Rapid growth, cottony, white; becoming gray to brown	Rhizoids absent; branched or simple sporangiophores arise from hyphae; sporangia globose; sporangiospores globose to cylindrical; columella variable
Absidia	Rapid growth, cottony, gray to olive	Finely branched sporangiophores arise from stolons between rhizoids; pear-shaped sporangia contain globose sporangiospores; conspicuous apophysis merges with round columella; septum usually present in sporangiophore below apophysis
Rhizomucor	Rapid growth, white, becoming gray-brown, low aerial mycelium	Sporangiophores arise from branched aerial hyphae or stolons; rhizoids poorly developed; globose sporangia contain small, round sporangiospores; thermotolerant, growth at 50–55°C
Cunninghamella	Rapid growth, white, becoming dark gray	Erect sporangiophores terminate in globose vesicles; additional smaller, whorled branches of sporangiophores occur beneath primary vesicle; vesicles bear one-spored sporangiola on short stalks (denticles)
Syncephalastrum	Rapid growth, white, becoming gray to black	Branched sporangiophores terminate in globose vesicles; tubular sporangia (merosporangia) contain single row of globose sporangiospores; rhizoids usually present
Saksenaea	Rapid growth, white, woolly	Induce sporulation on nutritionally deficient media; flask-shaped sporangia on short sporangiophores; rhizoids at base of sporangiophore
Apophysomyces	Rapid growth, white, cottony	Induce sporulation on nutritionally deficient media; sporangiophores arise from hyphae, with supporting ‘foot-cells’; pear-shaped sporangia, pronounced dark apophysis; sporangiospores oblong
Mortierella	Rapid growth, white, cottony, garlic-like odor; colonies appear as overlapping “rosettes”	Short tapering sporangiophores arise from rhizoids; small, multispored sporangia rapidly deliquesce; sporangiospores kidney-shaped with double wall
Cokeromyces	Moderate growth, tan, flat, tenacious, becoming brown-gray	Dimorphic; yeast at 37°C; sporangiole stalks arise from vesicle and recurve backward, terminating in multispored sporangiola; zygospores abundant

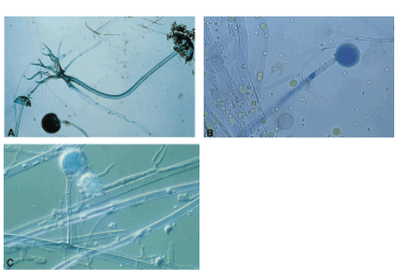

FIGURE 52.20. Microscopic appearance of selected Zygomycetes. **A:** *Rhizopus* species (original magnification ×300). **B:** *Mucor* species (original magnification ×600). **C:** *Absidia* species (Nomarski optics, original magnification ×625).

The Entomophthorales generally require 3 to 4 days before growth is apparent and are characterized by thin, flat, gray to pale yellow waxy colonies adhering to the agar. As they mature, conidia are forcibly expelled onto the Petri dish lid, giving it a ground-glass appearance.

Hyalohyphomycosis

The term hyalohyphomycosis includes all infections owing to nondematiaceous molds that appear as colorless, septate, branched or unbranched hyphal elements in tissue (Fig. 52.21) (27,31,32,41). Numerous genera of moniliaceous (hyaline) Hyphomycetes

are documented agents of hyalohyphomycosis, and the list continues to grow (Table 52.11).

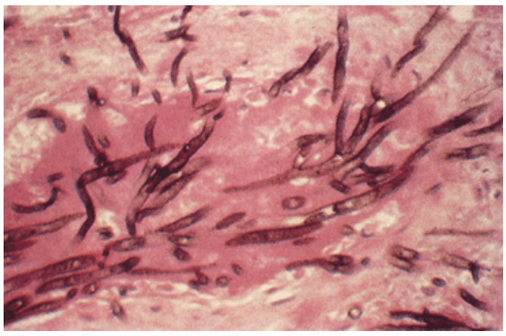

FIGURE 52.21. Tissue section from an individual with hyalohyphomycosis owing to *Fusarium* species (original magnification ×600).

TABLE 52.11. DOCUMENTED AGENTS OF HYALOHYPHOMYCOSIS[a]

Acremonium	*Graphium spp*
falciforme	*Lecythophora*
kiliense	*hoffmannii*
recifei	*mutabilis*
restrictum	*Paecilomyces*
Beauveria bassiana	*variotii*
Chrysosporium spp	*Penicillium*
Cylindrocarpon spp	*chrysogenum*
Fusarium	*citrinum*
chlamydosporum	*commune*
dimerum	*expansum*
moniliforme	*lilacinum*
napiforme	*marneffei*
oxysporum	*spinulosum*
proliferatum	*Scedosproium*
semitectum	*apiospermum*
solani	*inflatum*
sporotrichoides	*Scopulariopsis*
Geotrichum	*brevicaulis*
candidum	*candida*
penicillatum	

[a] This list is not all-inclusive.

Although infections caused by most of these fungi are relatively rare, they appear to be increasing in incidence (12,13 and 14,16,17,27,44,45 and 46,72,73). Most disseminated infections are thought to be acquired by the inhalation of spores or by the progression of previously localized cutaneous lesions. In this chapter, the discussion of specific genera is limited to selected clinically important hyaline mold-fungi, including *Fusarium*, *Pseudallescheria*, *Scedosporium*, and *Scopulariopsis*.

Histopathology

Most agents of hyalohyphomycosis have the same tissue morphology and elicit a similar pathologic response (Fig. 52.21). Consequently, it is impossible to make a correct diagnosis of the etiologic agent based on histopathology alone, and all suspected

material should be submitted for fungal culture and identification (27,31,32,41,47).

Culture Methods and Characteristics of Selected Medically Significant Hyphomycetes

The common etiologic agents of hyalohyphomycosis grow readily on routine mycologic media at both 25° and 35°C. Growth on cycloheximide-containing media shows considerable variability, and this criterion should not be used when determining the potential pathogenicity of an isolate. Although the isolation of moniliaceous agents presents few problems, their identification is occasionally hampered by lack of the production of characteristic structures, e.g., asexual propagules. Growth on potato dextrose agar (PDA) or potato flakes agar generally promotes profuse conidiation and produces the characteristic macroscopic morphologies necessary for separation of genus- or species-level identification. Microscopic morphology is best observed with the aid of a slide culture.

Fusarium species have been recognized with increased frequency as causes of disseminated infection in immunocompromised patients (12,41,44,45 and 46). The most common species isolated from clinical specimens include *F. moniliforme*, *F. oxysporum*, and *F. solani* (41,44,46). The hallmark of disseminated fusariosis is the appearance of multiple purpuric cutaneous nodules with central necrosis. Biopsy of these nodules generally reveals branching, hyaline, septate hyphae invading dermal blood vessels (Fig. 52.21). Cultures of the biopsy material and of blood are useful in establishing the diagnosis of *Fusarium* infection. Although blood cultures are virtually always negative in invasive infections owing to *Aspergillus* species, approximately 75% of patients with fusariosis will have positive blood cultures. In culture, colonies of *Fusarium* species are rapidly growing, cottony to woolly, flat, and spreading. Colors may include blue-green, beige, salmon, lavender, red, violet, and purple. Macroscopic identification should only be made from colonies grown on PDA, as color may be quite variable and is highly medium dependent (31,41,45,46). Microscopically, *Fusarium* species are characterized by the production of both macroconidia and microconidia (Fig. 52.22) (8,27,31,41,45,46). Microconidia are single- or double-celled, ovoid to cylindrical, and generally borne as mucous balls or short chains. Macroconidia are fusiform or sickle shaped and many celled (Fig. 52.22). *Fusarium* species may be misidentified as *Acremonium* when macroconidia are not observed.

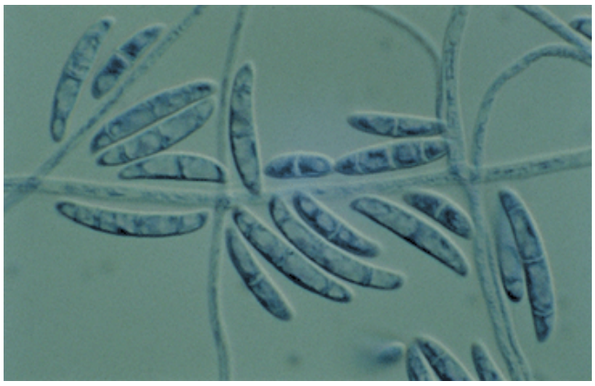

FIGURE 52.22. Microscopic appearance of two-celled microconidia and multicelled, sickle-shaped macroconidia of *Fusarium solani* (original magnification ×625).

Pseudallescheria boydii may be readily isolated from soil and is an occasional cause of mycetoma worldwide; however, it is also the cause of serious disseminated and localized infection in immunocompromised patients (31,32,51,55). In addition to widespread disseminated disease, *P. boydii* has been reported to cause corneal ulcers, endophthalmitis, sinusitis, pneumonia, endocarditis, meningitis, arthritis, and osteomyelitis. *P. boydii* is indistinguishable from *Aspergillus* species and other agents of hyalohyphomycosis on histopathologic examination. Such distinction is important clinically, as *P. boydii* is resistant to amphotericin B and susceptible to miconazole, intraconazole, and voriconazole (31,32,98). Thus, appropriate cultural and mycologic identification is necessary for optimal therapy. The taxonomy and nomenclature of this fungus have caused a tremendous amount of confusion. *P. boydii* (earlier names are *Allescheria boydii* and *Petriellidium boydii*) is a homothallic fungus, i.e., it does not require two mating strains to produce the teleomorph or sexual form. Hence, some strains may produce cleistothecia containing ascospores in culture. More commonly, the anamorph (asexual form) is seen (i.e., *Scedosporium apiospermum*). Macroscopically, colonies are moderately rapidly growing, woolly to cottony, and initially white, becoming smoky brown to green. Microscopically, conidia are one celled, elongate, and pale brown and are borne singly or in balls on either short or long conidiophores (31,32,51).

Scedosporium prolificans (formerly *Scedosporium inflatum*) is a potentially virulent and highly aggressive emerging agent of hyalohyphomycosis (31,73). Although far less important than *Fusarium* or *P. boydii*, infections owing to *S. prolificans* are associated with soft-tissue trauma and are characterized by widespread local invasion, tissue necrosis, and osteomyelitis (73). *S. prolificans* resembles *P. boydii* (*S. apiospermum*) in macroscopic and microscopic morphology. The formation by *S. prolificans* of annelloconidia in wet clumps at the apices of annellides with swollen bases is the most useful characteristic in differentiating this organism from *P. boydii* (*S. apiospermum*) (Fig. 52.23).

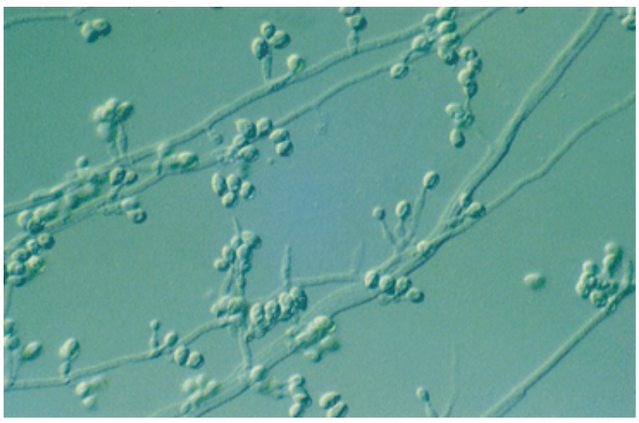

FIGURE 52.23. Microscopic appearance of *Scedosporium prolificans* demonstrates characteristic annellides with swollen bases (Nomarski optics, original magnification ×625).

Scopulariopsis species are ubiquitous soil saprobes that have been rarely implicated in invasive human disease. *S. brevicaulis* is

the most frequently isolated species. Infection is usually confined to the nails; however, serious deep infection has been noted recently in neutropenic leukemia patients and after bone marrow transplantation (31,32,41). Both local and disseminated infections have been described with involvement of the nasal septum, skin and soft tissues, blood, lungs, and brain. Diagnosis is made by culture and histopathology. *Scopulariopsis* species grow moderately to rapidly at room temperature on virtually all laboratory media. Colonies are initially glabrous (smooth), becoming granular to powdery. Young colonies are white and become very pale buff to buff brown depending on the species. Conidiophores are simple or branched; the conidiogenous cells are annellides that form solitarily or in clusters, or may form a scopula, e.g., a "broomlike" structure similar to that seen with *Penicillium* species. Annelloconidia are smooth initially, become rough at maturity, are shaped like light bulbs, and form in basipetal chains (Fig. 52.24).

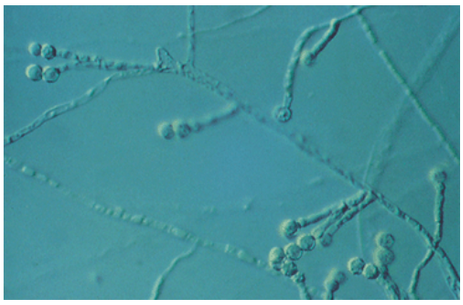

FIGURE 52.24. Microscopic appearance of *Scopulariopsis* species shows anneloconidia in basipetal chains (Nomarski optics, original magnification ×625).

Phaeohyphomycosis

Phaeohyphomycosis is defined as tissue infection caused by dematiaceous (pigmented) hyphae and/or yeasts (31,32,51). Infections owing to dematiaceous fungi constitute a significant and increasingly prevalent group of opportunistic fungal diseases and may take the form of disseminated disease or become localized to the lung, paranasal sinuses, or central nervous system (27,31,32,51). Primary inoculation, resulting in a localized subcutaneous infection, occurs commonly in underdeveloped countries. The dematiaceous fungi that have been documented to cause human and animal infection encompass a large number of different species; however, most human infections have been caused by *Alternaria*, *Bipolaris*, *Cladosporium*, *Curvularia*, and *Exserohilum* species (31,32,51).

Histopathology

In tissue, hyphae with or without yeast forms are present. Because the pigmentation (owing to the presence of melanin in hyphal walls) may not be readily apparent, these fungi may be confused with *Aspergillus* species on histopathologic examination. Staining with the Fontana-Masson technique (a melanin-specific stain) may help visualize the dematiaceous elements (Fig. 52.25). Alternatively, the pigmented hyphae/yeasts may be detected by examining an unstained tissue section by bright-field microscopy (51).

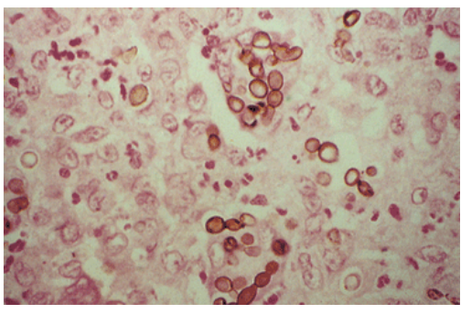

FIGURE 52.25. Tissue section from an individual with phaeohyphomycosis caused by *Bipolaris spicifera*. Stains for melanin, such as Fontana-Masson, may be used to accentuate and confirm the presence of melanin in the fungal cell walls (Fontana-Masson stains, original magnification ×260).

Clinical and Mycologic Characteristics of Selected Medically Important Phaeohyphomycetes

The dematiaceous fungi differ considerably in the clinical spectrum of infection and response to therapy (31,51). Furthermore, the different genera are not readily distinguished on histopathologic examination. Thus, an accurate microbiologic diagnosis based on culture of the infected tissue is important for optimal clinical management of infections attributable to these fungi.

Alternaria species are important causes of paranasal sinusitis in both healthy and immunocompromised patients. Other sites of infection include skin and soft tissue, cornea, lower respiratory tract, and peritoneum. *A. alternata* is the best documented human pathogen in this genus. In culture, *Alternaria* colonies are rapidly growing, cottony, and gray to black. The conidiophores are usually solitary and simple or branched. The conidia develop in branching chains and are dematiaceous, muriform, and smooth or rough and taper toward the distal end with a short beak at their apices (Fig. 52.26) (31,51).

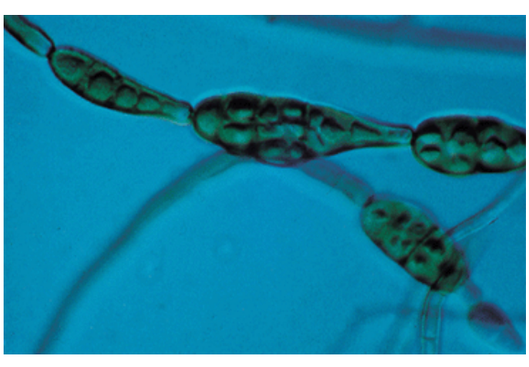

FIGURE 52.26. Microscopic appearance of *Alternaria alternata* (Nomarski optics, original magnification ×1,250).

Cladosporium species are occasionally isolated from cutaneous, eye, and nail infections. These fungi are rapidly growing with a velvety, olive gray to black colony. The conidiophores arise from the hyphae and are dematiaceous, tall, and branching. The conidia may be smooth or rough and single to several celled and form in branching chains at the apex of the conidiophore (31,51). The conidia at the branch points of the chains may have a shieldlike shape and are referred to as shield cells.

Curvularia species are ubiquitous inhabitants of the soil and have been implicated in both disseminated and local infection. Sites of infection include endocarditis, local catheter infection, nasal septum and paranasal sinuses, lower respiratory tract, skin and subcutaneous tissue, bones, and cornea (31,32,51). In clinical specimens, the hyphae may appear nonpigmented (hyaline). Common species causing disease in humans are *C. geniculata*, *C. lunata*, *C. pallescens*, *C. senegalensis*, and *C. verruculosa*. In culture, *Curvularia* colonies are rapidly growing, woolly, and gray to grayish black or brown. Microscopically, the conidia are dematiaceous, two to several celled, and curved (Fig. 52.27). The conidiophores are dematiaceous, solitary or in groups, septate, simple or branched, sympodial, and geniculate (31,32,51).

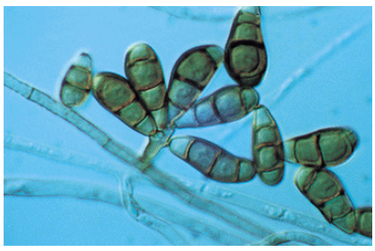

FIGURE 52.27. Microscopic appearance of *Curvularia* species demonstrates conidia and geniculate conidiophore (Nomarski optics, original magnification ×1,250).

Infections caused by the genera *Bipolaris* and *Exserohilum* present similarly to those owing to *Aspergillus* species, except that disease progresses more slowly. Clinical presentations include dissemination with vascular invasion and tissue necrosis, involvement of the central nervous system and paranasal sinuses, and association with allergic bronchopulmonary disease. Most commonly, these organisms cause sinusitis in “normal” (atopic/asthmatic) hosts and more invasive disease in immunocompromised hosts. Marijuana smoking may be a risk factor for infection with these organisms. In culture, *Bipolaris* and *Exserohilum* both form rapidly growing, woolly, gray to black colonies. Microscopically, the conidiophores are sympodial and geniculate. The conidia are dematiaceous, oblong to cylindrical, and multicelled.

Pneumocystosis

Pneumocystis carinii is an organism that causes infection almost exclusively in debilitated and immunosuppressed patients, especially those with HIV infection. It is the most common opportunistic infection among the AIDS population; however, the incidence has decreased in recent years because of the prophylactic use of trimethoprim/sulfamethoxazole and other antimicrobial agents including Highly Active Anti-Retronal Therapy (HAART). Although previously considered to be a protozoan parasite, recent molecular and genetic evidence suggests that *P. carinii* is closer phylogenetically to the fungi (99,100,101,102,103 and 104). Ultrastructurally, both fungi and *P. carinii* have similar cell-wall and mitochondrial structure as well as the presence of intracytoplasmic bodies resembling ascospores (102,105,106). There is homology of the conserved domains of the 16S rRNA with that of the Ascomycetes (99,104,105), the 5S rRNA with the primitive Zygomycetes (103), and the ß-tubulin gene with that of the filamentous fungi (58,107). In addition, the protein synthesis elongation factor EF-3 and thymidylate synthetase are similar to those of the Ascomycetes (99,100). Conversely, there are several factors favoring a protozoan origin including the different morphologic forms found in human tissue and the presence of cholesterol and other unique sterols, instead of ergosterol, in the cell membrane (103,108).

The life cycle of *P. carinii* may include both sexual and asexual components (102,105). During the course of human infection, *P. carinii* may exist as free trophic forms (1.5 to 5 µm in diameter), as a uninucleate sporocyst (4.0 to 5.0 µm), or as a cyst (5 µm) containing as many as eight ovoid to fusiform intracystic bodies (Fig. 52.28) (108,109). After rupture of the cyst, the cyst wall may be seen as an empty collapsed structure (Fig. 52.29).

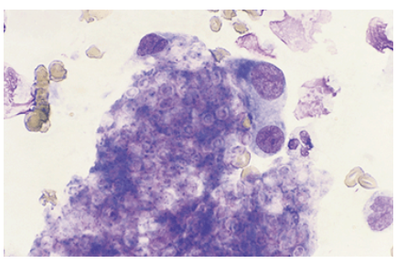

FIGURE 52.28. Microscopic appearance of *Pneumocystis carinii* stained with Giemsa stain (original magnification ×1,000 oil).

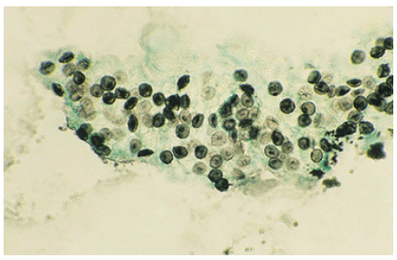

FIGURE 52.29. Microscopic appearance of *Pneumocystis carinii* stained with Gomori methenamine silver stain (original magnification ×1,000 oil).

The reservoir for *P. carinii* in nature is unknown. Although airborne transmission has been documented experimentally among rodents (110,111), it is unlikely that rodents serve as a reservoir for human disease given the fact that rodent strains of *P. carinii* are genetically distinct from those of humans (112,113).

The respiratory tract appears to be the main portal of entry for *P. carinii*. Pneumonia is clearly the most common clinical presentation of *P. carinii* infection; however, among AIDS patients, extrapulmonary sites of infection including lymph nodes, spleen, bone marrow, liver, small intestine, genitourinary tract, heart, eyes, ears, skin, bone, and thyroid have been reported (108,114,115). The high rate of seropositivity among young

children has led to the assumption that most infections were secondary to reactivation of latent infection; however, recent evidence suggests that both reactivation and primary infection occur (116,117,118,119,120,121 and 122). Malnourished, debilitated, and immuno-suppressed patients, especially AIDS patients with low CD4 counts (less than 200/µL), are at high risk.

The hallmark of *P. carinii* infection is an interstitial pneumonitis with a mononuclear infiltrate composed predominantly of plasma cells. The onset of disease is insidious with signs and symptoms including dyspnea, cyanosis, tachypnea, nonproductive cough, and fever. The radiographic appearance is typically one of diffuse interstitial infiltrates with a ground-glass appearance extending from the hilar region but may appear normal or show nodules or cavitation. The mortality rate is high among untreated patients and death is owing to asphyxia.

Histologically, a foamy exudate is seen within the alveolar spaces with an intense interstitial infiltrate composed predominantly of plasma cells. Other patterns including diffuse alveolar damage, noncaseating granulomatous inflammation, and infarctlike coagulative necrosis may also be seen (109).

The diagnosis of *P. carinii* infection is almost entirely based on microscopic examination of clinical material including bronchoalveolar lavage fluid, bronchial brushings, induced sputum, and transbronchial or open lung biopsy specimens. Examination of bronchoalveolar lavage fluid has been shown to have a sensitivity of 90% to 100% and in most instances alleviates the need for transbronchial or open lung biopsy (123,124). Although examination of induced sputum may be useful in some AIDS patients with a high organism load, it has a 20% to 25% false negative rate (123,124). Several stains have been used to detect *P. carinii* including Giemsa, Giemsa-like, toluidine blue, Gomori's methenamine silver, periodic acid–Schiff, Gram-Weigert, calcofluor, and immunofluorescence (108). Giemsa and Giemsa-like (e.g., Wright's) stains demonstrate the trophozoites and do not stain the cell wall (Fig. 52.28). Immunofluorescent techniques stain both trophic forms and the cyst walls (108). *P. carinii* cysts are often stained with Gomori's methenamine silver and demonstrate intact cysts, helmet-shaped forms and cuplike structures as well as the presence of two focal thickenings resembling commas in the cyst wall that are apparently unique to *Pneumocystis* (Fig. 52.29). Generally, a combination of stains is used in most laboratories.

Other diagnostic modalities, including serologic testing, have not proven useful in the diagnosis of *P. carinii* infection (108,125). Although polymerase chain reaction (PCR)-based methods are more sensitive than microscopy in detection of *P. carinii* (126,127,128 and 129), they are generally less specific and more labor intensive (129,130).

ANTIGENIC, BIOCHEMICAL, AND MOLECULAR MARKERS FOR DIAGNOSIS OF INVASIVE FUNGAL INFECTION

Part of "52 - Fungi and Fungal Infections"

The need for more rapid, sensitive and specific nonculture methods for diagnosis of fungal infections is acute. Tests for detection of antibodies, fungal antigens, metabolites, and fungus-specific nucleic acid sequences all have the potential to yield rapid diagnostic information that can guide the early and appropriate use of antifungal therapy (65,76,97,131,132,133 and 134). Some progress has been made in these areas (Table 52.12); however, with few exceptions, these tests have yet to make a significant impact on the diagnosis of fungal infections.

TABLE 52.12. ANTIGENIC, BIOCHEMICAL, AND MOLECULAR MARKERS FOR DIRECT DETECTION OF INVASIVE FUNGAL INFECTIONS

Organism	Cell Wall or Capsule Components	Cytoplasmic Antigens	Metabolites	Genomic DNA Sequences[a]
Candida spp	1. Mannans a. RIA b. ELISA 2. 1,3-B-glucans a. Amebocyte lysate assay 3. Chitin synthase a. Spectrophotometric	1. Enolase a. ELISA b. Immunoblot 2. Antienolase antibody a. ELISA 3. 47-kD breakdown product of HSP-90 a. Enzyme-linked dot immunobinding assay	1. D-Arabinitol a. Rapid enzymatic b. GLC/FID c. Mass spectroscopy/GLC	1. C-14-lanosterol demethylase 2. Ribosomal RNA genes 3. Chitin synthase
Cryptococcus neoformans	1. Capsule-glucuronoxylomannan a. Latex agglutination b. GLC		1. D-Mannitol a. Mass spectroscopy b. ELISA	1. Ribosomal RNA genes
Trichosporon asahi (beigelli)	1. Cell wall a. Cross reactivity in assays for cryptococcal glucuron-oxylomannan			1. Ribosomal RNA genes
Blastomyces dermatitidis	1. Cell wall a. RIA for 120-kD cell wall adhesion protein			1. Ribosomal RNA genes
Histoplasma capsulatum	1. Cell wall a. RIA and ELISA for polysaccharide antigen			1. Ribosomal RNA genes
Aspergillus spp.	1. Galactomannan a. Latex agglutination b. ELISA c. RIA 2. 1,3-B-glucans a. Amebocyte lysate assay 3. Chitin a. Spectrophotometry		1. D-Mannitol a. GLC/FID b. Mass spectroscopy/GLC	1. C-14 lanosterol demethylase 2. Ribosomal RNA genes 3. Alkaline protease

[a] All sequences detected by polymerase chain reaction.
RIA, radioimmunoassay; ELISA, enzyme-linked immunosorbent assay; GLC, gas-liquid chromatography; FID, flame ionization detector.
Adapted from Walsh TJ, Chanock SJ. Diagnosis of invasive fungal infections: advances in nonculture systems. *Curr Clin Topics Infect Dis* 1998;18:101–153.

Determination of antibody and/or antigen titers may be useful in diagnosing fungal infections and when performed in a serial fashion also provide a means of monitoring the progression of disease and the patient's response to therapy (62,66,67,76,94,96,97,135,136). With the exception of antibody tests for histoplasmosis and coccidioidomycosis, however, most tests designed to detect an antibody response as a means of diagnosing invasive fungal infections lack sensitivity and specificity, are poorly standardized and are not widely available (62). Antibody tests for *Candida* and *Aspergillus* are often unable to distinguish active from past infection and colonization from transient fungemia. In addition, a negative test for fungus-specific antibodies does not rule out infection because immunocompromised patients, and some individuals with disseminated infection may not mount an antibody response to the infecting organism (62).

Detection of fungal antigens or metabolites in serum or other body fluids represents the most direct means of providing a serologic diagnosis of invasive fungal infection (42,43,63,66,67,94,96,97). Although significant advances have been made in recent years (Table 52.12), most methods for rapid detection of fungal antigens are available only in research laboratories (97). Notable exceptions are the tests for detection of the polysaccharide antigens of *C. neoformans* and *H. capsulatum* (63,66,67,94,97). The commercially available latex agglutination and EIA tests for cryptococcal antigen are well standardized and widely available and detect more than 95% of cryptococcal meningitis and approximately 67% of disseminated cryptococcal infections (94,97). Both the latex agglutination and EIA tests have supplanted the India ink test (sensitivity of less than 40%) for the diagnosis of cryptococcal meningitis (94). The test for *Histoplasma* antigen is available from a reference laboratory (Histoplasmosis Reference Laboratory, Indianapolis, IN) and is widely used for the diagnosis of disseminated histoplasmosis (63,66,67,97). The test employs either a RIA or EIA format and detects *H. capsulatum* polysaccharide antigen in urine and serum (63). Both the

RIA and the EIA tests have been shown to be rapid (less than 24 hours), sensitive (55% to 99%), specific (more than 98%), and reproducible (63,66,67). In addition to urine and serum, the antigen may be detected in the spinal fluid of 42% to 67% of patients with *Histoplasma* meningitis and in bronchoalveolar lavage fluid of 70% of patients with AIDS and severe pulmonary histoplasmosis (64,66,67,97).

In contrast to the success achieved with the antigen test for cryptococcosis and histoplasmosis, immunoassays for antigens of *Candida* and *Aspergillus* have been disappointing (42,43,76,96,97,133). Efforts to develop tests to detect *Candida* mannan and enolase antigens have been promising but have failed to produce a commercially available product because of problems in achieving optimal sensitivity and specificity (76,97,132,135,136). Likewise, both EIA and latex agglutination assays for detecting *Aspergillus* galactomannan in serum have shown promise but are not widely available (42,43,96,97). Further research is needed in this area to determine both the diagnostically relevant antigens and the testing format necessary to establish a clinically useful assay.

The detection of fungal metabolites is a potential method for the rapid diagnosis of both candidiasis and aspergillosis (41,65,97). The detection of arabitol in serum appears to be an indicator of hematogenously disseminated candidiasis (65,76,97). The diagnostic specificity of arabitol detection may be improved by correcting for renal function (arabitol:creatinine ratio) or by detection of specific isomers (D-arabitol) (76,97). Similarly, the detection of elevated levels of D-mannitol in bronchoalveolar lavage fluid may be useful in the diagnosis of pulmonary aspergillosis (97). The diagnostic utility of metabolite detection remains uncertain owing to significant method-dependent variation in the sensitivity and specificity (97,133).

The use of the PCR to detect fungal nucleic acids directly in clinical material offers great promise for the rapid diagnosis of fungal infections (43,65,97,131,134,137,138,139 and 140). At present, most of the research has concentrated on the diagnosis of invasive

candidiasis (65,76,97); however, PCR has also been applied to the diagnosis of aspergillosis and other fungal infections (Table 52.12) (43,131,134,139).

The amplification and detection of *Candida*-specific DNA from blood and other body fluids are now well established in the research setting (76,137,138) but have yet to gain wide application in the clinical laboratory (65). Amplification targets include the lanosterol demethylase gene, mitochondrial DNA, ribosomal RNA sequences, the actin gene, and a chitin synthetase gene to name a few (65,76,131,133). Detection of as few as two to 10 cells per milliliter has been reported, although most assays do not approach this level of sensitivity in clinical samples. The true sensitivity of PCR for diagnosis of invasive candidiasis is unknown, but sensitivities of 76% to 96% have been reported (65,76,131,133). PCR for detection of *Aspergillus* and other fungal pathogens also shows great promise and the number of studies documenting its utility in this regard is growing steadily (43,97,131,134,139). Current PCR-based approaches to the diagnosis of fungal infections are cumbersome, yet promising prototypes. The distinction between PCR results involving normal flora, colonization, contamination, and truly invasive isolates must be resolved.

In addition to detection of fungal pathogens in clinical material, immunologic and molecular approaches have been applied successfully to the identification of fungi in culture (47,54,59,60 and 61,97,140). Nucleic acid probe–based methods offer great promise for the identification of both common and uncommon clinical isolates (140). Exoantigen and nucleic acid probe–based methods are now well established in the clinical laboratory for the identification of the dimorphic pathogens *H. capsulatum*, *B. dermatitidis*, and *C. immitis* (54,59,60 and 61). In the commercially available nucleic acid probe tests (GenProbe, San Diego, CA), nucleic acids are extracted from culture material and reacted with a chemiluminescent-labeled probe specific for *H. capsulatum*, *B. dermatitidis*, *C. immitis*, or *C. neoformans* rRNA (54,60,61). These tests may be completed within 2 hours and have an accuracy of 99% to 100%.

TABLE 52.13. ANTIFUNGAL AGENTS WITH SYSTEMIC ACTIVITY

Drug	Route	Mechanism	Comments
Amphotericin B	IV	Binds to ergosterol causing direct membrane damage	Established agent; broad spectrum; toxic
Lipid formulations (amphotericin B lipid complex or colloidal dispersion, liposomal formulation)	IV	Same as amphotericin B	Recently licensed agents with broad spectrum activity and decreased toxicity; used for refractory severe infections not responding to conventional therapy
Miconazole	IV	Inhibits membrane sterol synthesis	Toxic agent with modest activity against *Candida* and other yeasts; active against *Pseudallescheria boydii*
Ketoconazole	Oral, topical	Same as miconazole	Established agent with modest broad-spectrum activity
Fluconazole	Oral, IV, topical	Same as miconazole	Triazole with broad-spectrum activity; good central nervous system penetration; good *in vivo* activity against *Candida* and *Cryptococcus neoformans*
Itraconazole	Oral, IV, topical	Same as miconazole	Triazole with broad-spectrum activity including *Aspergillus;* excellent *in vivo* activity against endemic mycoses
Voriconazole, Posaconazole, Ravuconazole	Oral, IV, topical	Same as miconazole	Investigational agents with broad-spectrum activity against species resistant to established agents; used for treatment of aspergillosis
Caspofungin, Anidulafungin	IV	Inhibition of fungal cell wall glucan synthase	Investigational agent with broad-spectrum *in vitro* activity, except against *C. neoformans* and *T. asahi (beigelii)*; used for treatment of aspergillosis
5-Fluorocytosine	Oral	Inhibition of DNA and RNA synthesis	Toxicity and resistance are problems; used in combination with amphotericin B

IV, intravenous.

THERAPY

Part of "52 - Fungi and Fungal Infections"

The emergence of fungal pathogens as important agents of human infection has resulted in an increase in the use of systemic antifungal agents worldwide and the introduction of a number of new antifungal agents with systemic activity (69,74,98,141,142,143,144,145,146,147,148,149,150 and 151). Several antifungal agents are now available for the treatment of fungal infections. Fourteen of these compounds are discussed briefly in this chapter (Table 52.13). They include representatives of the polyene macrolide class (amphotericin B, amphotericin B lipid complex, liposomal amphotericin B, and amphotericin B cholesterol dispersion), the azoles (miconazole, ketoconazole, fluconazole, itraconazole, voriconazole, posaconazole, and ravuconazole), glucan synthesis inhibitors (caspofungin and anidulafungin), and an inhibitor of pyrimidine synthesis (5-fluorocytosine). In addition, the rationale for and limitations of *in vitro* susceptibility testing are discussed with a description

of the current efforts to develop a standardized *in vitro* testing method and to establish clinical correlations for *in vitro* test results.

Antifungal Agents

Amphotericin B and the liposomal and lipid complex formulations of amphotericin B are polyene macrolide antibiotics used primarily in the treatment of systemic and life-threatening fungal infections. These compounds act by binding to ergosterol in the fungal cell membrane, causing loss of membrane integrity and osmotic instability (74). Amphotericin B is the drug of choice for the treatment of aspergillosis, disseminated candidiasis, cryptococcosis, and zygomycosis (69,74,98,142). It is also effective in the treatment of coccidioidomycosis, histoplasmosis, and blastomycosis (Table 52.14). Unfortunately, the therapeutic efficacy of amphotericin B is limited by significant toxicity, specifically nephrotoxicity. The liposomal and lipid complex formulations of amphotericin B were designed to increase the therapeutic index (increase efficacy and decrease toxicity) for amphotericin B therapy and to maximize the delivery of amphotericin B to patients with deep-seated fungal infections such as hepatosplenic candidiasis and invasive pulmonary aspergillosis (74,98). Three different formulations have been evaluated in clinical trials and have been approved for treatment of invasive fungal infection in patients for whom conventional therapy has failed: amphotericin B lipid complex, a 1:1 molar complex of phospholipids and drug; ambisome, a phospholipid/cholesterol liposome formation; and amphocil, a 1:1 molar complex of cholesterol sulfate and amphotericin B. The resultant liposomal and lipid complex preparations have selective toxicity for fungal cells but not for mammalian cells and theoretically promote delivery of the drug to the site of infection, while avoiding the toxicity of supramaximal doses of amphotericin B. The available clinical data indicate that these formulations allow the administration of higher doses of amphotericin B with no increase in acute toxicity and no chronic toxicity (74,98). Importantly, there is no evidence of dose-limiting nephrotoxicity. Unfortunately, the therapeutic efficacy of these formulations does not appear to be significantly better than that of conventional amphotericin B.

TABLE 52.14. ANTIFUNGAL THERAPY FOR DEEP MYCOSES

	Agents	
Infection	**First Choice**	**Alternatives[a]**
Aspergillosis	Amphotericin B (± 5-FC)	Itraconazole
	Lipid formulations of amphotericin B	Caspofungin
Blastomycosis	Amphotericin B	Ketoconazole[b]
	itraconazole[b]	
Candidiasis	Amphotericin B (± 5-FC) fluconazole	Caspofungin
Chromoblastomycosis	Itraconazole	5-FC
Cocciodioidomycosis	Amphotericin B	Ketoconazole[b]
	Fluconazole	Itraconazole[b]
		Intrathecal amphotericin B[c]
Cryptococcosis	Amphotericin B (± 5-FC)	Fluconazole
Fusariosis	Amphotericin B	Lipid formulation of amphotericin B
Histoplasmosis	Amphotericin B	Ketoconazole[d]
	Itraconazole[d]	Fluconazole[d]
Phaeohyphomycosis	Amphotericin B	Itraconazole
Pseudallescherosis	Itraconazole	Miconazole, ketoconazole, or voriconazole
Sporotrichosis	Oral iodides[e]	
	Itraconazole[e]	
Trichosporosis	Amphotericin B[f]	Fluconazole
Zygomycosis	Amphotercin B	None established

[a] Limited data exist for most alternative agents.

[b] Indolent, nonmeningeal.

[c] Meningeal.

[d] Chronic pulmonary or indolent, nonmeningeal disseminated infection.

[e] Lymphocutaneous.

[f] Extracutaneous.

5-FC, 5-fluorocytosine.

The azole class of antifungal compounds consists of a large number of agents with systemic antifungal activity, including the imidazoles (miconazole and ketoconazole) and the newer triazoles (itraconazole, fluconazole, voriconazole, posaconazole, and ravuconazole) (Table 52.13) (74,98,142,145,147,148,150). The azole antifungals interact with cytochrome P-450–dependent enzymes with resulting impairment of ergosterol synthesis and depletion of ergosterol in the fungal cell membrane (150). This results in inhibition of fungal cell growth. The imidazoles miconazole and ketoconazole are established broad-spectrum agents active against a variety of fungal pathogens, including yeasts, dimorphic organisms, dermatophytes, and opportunistic pathogens (Table 52.13 and Table 52.14). The triazoles all show promise as broad-spectrum, orally active, systemic agents with less potential for toxicity than the currently available imidazoles (74,98,142,145,147,148,150). Both fluconazole and itraconazole currently have important roles as

agents of first choice or as major alternatives in the treatment of deep mycoses (Table 52.14) (74,98,152,150). Ongoing and future clinical trials will more clearly define the specific roles of the triazoles in the treatment of systemic mycoses (74,98,142,145,147,148,152,150).

Another target of antifungal activity has been the inhibition of glucan synthesis in the fungal cell wall. This approach takes advantage of the fact that human cells lack the enzyme glucan synthase and thus increases the selectivity for fungal cells. The echinocandins caspofungin and anidulafungin are inhibitors of 1,3-β-D-glucan synthesis, which leads to the lysis of fungal cells. Caspofungin and anidulafungin both have demonstrated potent *in vitro* and *in vivo* activities against a variety of yeasts (including fluconazole- and itraconazole-resistant strains) and molds (141,143,146,151). Notably, both agents lack activity against *C. neoformans* and *T. beigelii* (144).

5-Fluorocytosine is a water-soluble fluorinated pyrimidine antimetabolite used orally (intravenous formulation is investigational) in the treatment of systemic infections caused by susceptible pathogenic or opportunistic yeasts and fungi. The spectrum of susceptible fungal pathogens is narrow and includes *Candida* species, *C. neoformans*, and some agents of chromoblastomycosis (Table 52.14). 5-Fluorocytosine acts as a competitive antimetabolite for uracil in the synthesis of fungal RNA and also inactivates thymidylate synthetase (98). These activities can be antagonized by a variety of purine and pyrimidine bases and nucleosides.

Antifungal Susceptibility Testing

The field of antifungal susceptibility testing has progressed considerably over the past 10 to 15 years. *In vitro* susceptibility tests with antifungal agents are performed for the same reasons that tests with antibacterial agents are performed (98,153,154,155,156,157,158 and 159). Ideally, *in vitro* susceptibility tests will (a) provide a reliable estimate of the relative activities of two or more antifungal agents, (b) correlate with *in vivo* antifungal activity and predict the likely outcome of therapy, (c) provide a means with which to monitor the development of resistance among a normally susceptible population of organisms, and (d) predict the therapeutic potential of newly discovered investigational agents.

At present, the state of the art for susceptibility testing of yeasts is comparable with that of bacteria (158). Standardized methods for performing antifungal susceptibility testing are reproducible, accurate, and available for use in clinical laboratories. The development of quality control guidelines and interpretive criteria for a limited number of antifungal agents (Table 52.15) provides a basis for application of this testing in the clinical laboratory (Table 52.16) (158,159).

TABLE 52.15. INTERPRETIVE GUIDELINES FOR *IN VITRO* SUSCEPTIBILITY TESTING OF YEAST ISOLATES TO FLUCONAZOLE, ITRACONAZOLE, AND 5-FLUOROCYTOSINE USING NATIONAL COMMITTEE FOR CLINICAL LABORATORY STANDARDS APPROVED METHODS[a]

Antifungal Agent	Interpretive Category	MIC (μg/mL) Interpretive Breakpoint	Clinical Outcome (% Success)[b]
Fluconazole	Susceptible	≤8.0	97
	Susceptible-dose dependent	16–32	82
	Resistant	≥64	60
Itraconazole	Susceptible	≤0.12	90
	Susceptible-dose dependent	0.25–0.5	63
	Resistant	≥1.0	53
5-FC	Susceptible	≤4.0	NA[c]
	Intermediate	8.0–16	NA
	Resistant	≥32	NA

[a] Macrodilution and microdilution broth methods as described by Pfaller et al. (158), Rex et al. (159), and NCCLS (155).

[b] Clinical outcome for treatment of candidemia (fluconazole only) and oropharyngeal candidiasis in patients with acquired immunodeficiency syndrome (both fluconazole and itraconazole) as described by Rex et al. (159)

[c] Clinical data not available.

5-FC, 5-fluorocytosine.

Although establishing a correlation between *in vitro* susceptibility tests and clinical outcome has been difficult, it is now clear that antifungal susceptibility testing can predict outcome in several clinical situations, the most notable of which is fluconazole and itraconazole treatment of oropharyngeal candidiasis in AIDS patients (159). The establishment of interpretive breakpoints for *in vitro* susceptibility of yeasts to these antifungal agents has now been accomplished (Table 52.15). The National Committee for Clinical Laboratory Standards Subcommittee on Antifungal Susceptibility Tests has also developed and published a proposed reference method for broth dilution testing of filamentous fungi that cause invasive infections (98,153,156). Studies are now ongoing to further refine this approach and to evaluate the *in vivo* correlation with the *in vitro* data for molds (98,160).

Despite this progress, it remains to be seen how useful antifungal susceptibility testing will be in guiding therapeutic decision making. Guidelines for the use of susceptibility testing in the laboratory have been developed (Table 52.16) and include routine identification of fungi to species level and only selective application of *in vitro* susceptibility testing (158). Future efforts must be directed toward establishing and validating interpretive breakpoints for currently available antifungals as well as those new antifungals under development. In addition, procedures must be optimized for testing non-*Candida* yeasts (e.g., *C. neoformans*) and molds (93,98).

SUMMARY AND CONCLUSIONS

Our understanding of the epidemiology and pathogenesis of fungal infections has improved considerably over the past decade. By weight of the sheer numbers of cases, we have the best understanding of candidal infections; however, there is little doubt that newer fungi previously considered nonpathogens have now emerged as significant human pathogens, particularly in the immunocompromised host. Recognition of these emerging fungal pathogens has resulted in improved understanding of their clinical presentation and response to available therapeutic measures. Clearly, additional efforts are necessary to improve diagnosis and management and to understand better the pathogenesis of infection owing to this diverse group of fungal pathogens. Future studies should include clinical trials of prophylactic agents to prevent colonization, of empiric agents for early treatment of suspected infections, and of therapeutic agents to treat documented infections. Advances in diagnostic methods may provide earlier diagnosis and thus encourage earlier and potentially more effective therapeutic interventions. Finally, epidemiologic studies documenting the rates of colonization and infection owing to these emerging fungal pathogens, as well as studies of the effectiveness of various components of infection control and antibacterial drug use, and optimal guidelines for insertion and management of vascular catheters are urgently needed.

TABLE 52.16. RECOMMENDATIONS FOR STUDIES OF FUNGAL ISOLATES IN THE CLINICAL LABORATORY

Recommendation	Clinical setting
• Species level identification of all *Candida* isolates from deep sites	Routine
• Genus level identification of molds	
• Routine antifungal susceptibility testing not recommended	
• Periodic batch susceptibility testing of *Candida* spp	Epidemiologic survey
• Establish antibiogram for an institution	
• Relevant drugs: fluconazole, itraconazole, 5-FC	
• Routine antifungal susceptibility testing not required	AIDS and oropharyngeal candidiasis
• Susceptibility testing may be useful for patients unresponsive to azole therapy	
• Relevant drugs: fluconazole, itraconazole	
• Isolates of *Candida* (especially non-*albicans*) from deep sites	Invasive candidiasis
• Susceptibility testing offered on request for selected patients	
• Relevant drugs: fluconazole, itraconazole, 5-FC	
• Testing not recommended	Cryptococcosis
• Interpretive criteria have not been established	
• Testing not recommended	Mold infections
• Interpretive criteria have not been established	

5-FC, 5-fluorocytosine; AIDS, acquired immunodeficiency syndrome.

- MYCOPLASMA
- RICKETTSIA

CHLAMYDIA

Part of "53 - Chlamydia, Mycoplasma, and Rickettsia"

Chlamydiae are obligate intracellular bacterial parasites of eukaryotic cells. Once called *Bedsonia* species (for Sir Samuel Bedson, who first isolated and described the causative agent of psittacosis), trachoma-inclusion conjunctivitis (TRIC) agents, and *Miyagawanella* species, these organisms were once considered viruses because of their inability to synthesize ATP or to grow on artificial media. They are dissimilar to the viruses, however, in that they contain both RNA and DNA, are susceptible to antibacterial agents, have cell walls similar to Gram-negative bacteria, synthesize protein utilizing their own ribosomes, and divide by binary fission. First isolated in embryonated eggs in 1957 and in cell culture in 1963, these organisms have been described as "energy parasites" (1).

Because of their unique developmental cycle, the chlamydiae are taxonomically classified in a separate order, Chlamydiales (from the Greek *chlamys*, a cloak draped around the shoulder, in reference to the intracytoplasmic inclusions "draped" around the infected cell's nucleus) and family Chlamydiaceae. The family recently was divided into two genera: *Chlamydia* and *Chlamydophila*, which contain three species pathogenic for humans: *Chlamydia trachomatis* (18 serovars), *Chlamydophila* (formerly *Chlamydia*) *psittaci*, and *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* (2). Several distinct clinical syndromes are caused by the specific chlamydial serotypes (Table 53.1). *C. trachomatis* can be differentiated from *C. psittaci* based on its ability to form glycogen inclusions detectable in infected cell cultures with an iodine staining technique and its susceptibility to sulfonamides. Laboratory properties differentiating the chlamydial species are outlined in Table 53.2. Cellular infection with *C. trachomatis* results in a single inclusion that tends to displace the nucleus, whereas the inclusions of *C. psittaci* typically rupture early, resulting in a perinuclear distribution that fails to displace the nucleus. In addition, species can be distinguished definitively using monoclonal antibody stains.

TABLE 53.1. HUMAN CLINICAL DISEASE CAUSED BY CHLAMYDIAL SPECIES

Species	Serotypes	Disease	Major Symptoms	Infection Site	Mode of Transmission
C. pneumoniae	One	Pneumonia	Diffuse lung disease	Pulmonary	Person to person
C. psittaci	Several	Psittacosis (ornithosis)	Subclinical; mild respiratory illness or overt pneumonia	Pulmonary	Birds (including fecal droppings) to man; rarely human to human
C. trachomatis	A, B, Ba, C	Endemic trachoma	Chronic conjunctivitis; may result in blindness	Ocular	Human to human
	L1, L2, L3	Lymphogranuloma venereum	Transient genital ulcers, inguinal (males), pelvic or retroperitoneal (women) lymphadenopathy	Lymph nodes, rectum	Sexual
	D–K	Adult inclusion conjunctivitis	Acute follicular conjunctivitis	Ocular	Genital to eye
		Genital tract infection	Nongonococcal urethritis, cervicitis, epididymitis, proctitis, salpingitis	Genital tract, rectum	Sexual
		Inclusion conjunctivitis of the newborn	Acute mucopurulent conjunctivitis	Ocular	Genital to eye during passage through birth canal
		Pneumonitis/pneumonia of the newborn	Afebrile, chronic diffuse pulmonary disease; pneumonia	Pulmonary	Aspiration during passage through birth canal

C. trachomatis and *C. psittaci* possess a common group-reactive lipopolysaccharide antigen (3), have a similar small genomic size, and demonstrate approximately 10% DNA homology. *C. pneumoniae*, by comparison, lacks significant DNA homology with either of the other species, has different restriction endonuclease patterns, and appears to generally lack extrachromosomal DNA as is typically demonstrable in strains of *C. trachomatis* and the majority of *C. psittaci* isolates (4, 5). DNA homology generally is high within each species.

All three recognized chlamydial species exhibit two distinct forms during their unique developmental cycle. The 300-nm elementary body is especially adapted for extracellular survival and represents the infectious form in the life cycle. The elementary bodies of *C. pneumoniae* are pleomorphic but typically pear-shaped, although under some conditions they are round, similar to the elementary bodies of *C. trachomatis* and *C. psittaci* (2, 6). Upon contact with and attachment to a susceptible cell, the elementary body is actively taken into a phagosome by endocytosis, where the entire replication cycle takes place. Lysosomal fusion, however, fails to occur.

Over the next 6 to 8 hours, the elementary body undergoes reorganization into the metabolically active but noninfectious reticulate or initial body. For 18 to 24 hours, the reticulate body synthesizes new material and divides continuously by binary fission within a membrane-bound vacuole. Adapted for intracellular functions, reticulate bodies cannot survive in the extracellular milieu and are incapable of infecting other cells. After this period of synthesis and division, the reticulate bodies reorganize and condense into compact elementary bodies still bound within the phagocytic vesicle. Depending on the strain, somewhere between 48 and 72 hours after the cellular infection was initiated, the vacuoles release their contents and the cell lyses, releasing infectious elementary bodies.

Chlamydia trachomatis

Spectrum of Disease

Once designated the lymphogranuloma-venereum-trachoma inclusion conjunctivitis (LGV-TRIC) agent, *C. trachomatis* now is recognized as an important cause of cervicitis and pelvic inflammatory disease in women, nongonoccocal urethritis (NGU) and epididymitis in men, and inclusion conjunctivitis and interstitial pneumonia in neonates. The host range of *C. trachomatis* is restricted to humans. *C. trachomatis* is reportedly the most common

sexually transmitted disease in developed countries (7), causing an estimated 4 million infections per year in the United States alone, with resulting annual estimated direct and indirect costs totaling $1.4 billion (8).

TABLE 53.2. LABORATORY CHARACTERISTICS OF HUMAN CHLAMYDIAL SPECIES

Characteristic	*C. trachomatis*		*C. psittaci*	*C. pneumoniae*
	LGV Biovar	Trachoma Biovar		
Inclusions				
Refractile, vacuolar	+	+	0	0
Iodine staining glycogen	+	+	0	0
Intracerebral injection lethal for mice	0	+	+	0
Sulfadiazine susceptibility	+	+	0	0
Cell culture				
L-cell plaques	0	+	+	0
Enhanced recovery following				
Cell treatment with diethylaminoethyl-dextran	+	0	0	+

Inclusion Conjunctivitis

Ocular infections have been documented in approximately one third of neonates treated prophylactically with silver nitrate whose mothers were infected with *C. trachomatis* at parturition (9). Therefore, neonatal chlamydial conjunctivitis may be seen in up to 2 to 6% of infants born in areas where the prevalance of sexually transmitted infection is high.

Typically appearing 2 to 25 days after delivery (earlier in the setting of premature rupture of membranes), inclusion conjunctivitis is characterized by edematous, inflamed conjunctivae with a copious mucopurulent discharge. In cases of chronic or relapsing infection, conjunctival follicles may develop. The infection is usually self-limited, resolving spontaneously over a period of several months with no significant sequelae even without antimicrobial therapy.

Inclusion conjunctivitis in the adult, albeit relatively rare, presents acutely with a foreign body sensation, mucopurulent discharge, photophobia, and follicular conjunctivitis with or without keratitis. Except in cases of reinfection, symptoms disappear spontaneously over a period of several months to 2 years. Adult ocular infection usually occurs in patients whose sexual partner(s) show signs of genital chlamydial infection (10).

Trachoma

Endemic trachoma is a chronic disease characterized by recurrent corneal and conjunctival infection with *C. trachomatis*. Pannus formation and conjunctival scarring occur as sequelae to the chronic follicular keratoconjunctivitis. Historically, trachoma represented the single greatest cause of blindness in the world and probably remains today the single most common cause of preventable blindness (11). In 1973, approximately 400 million people worldwide were afflicted with trachoma, which resulted in blindness in 2 million (12). Although the number and size of endemic areas have been significantly reduced since 1950, trachoma continues to occur, mainly among the impoverished, in less developed regions of the world, especially of northern Africa, the Middle East, and northern India. It is still occasionally seen

in Native Americans in the southwestern United States. In endemic areas, children are often infected with serotypes A to C of *C. trachomatis* during the first 3 months of life. Transmission is not genital but by close contact with infected persons or from flies carrying infectious ocular material from eye to eye (13). Although relatively unusual, acute disease in adults over 20 years of age is much more common in women than in men, apparently due to closer contact with children.

Typically, trachoma begins acutely with inflammation of the bulbar and palpebral conjunctivae. Although initially a mixed cellular response is seen in the ocular exudate, macrophages and lymphocytes coalesce within a few weeks, forming soft, necrotic subconjunctival follicles. At this stage the disease may resolve spontaneously, unless reinfection occurs. Upon repeated infection, however, corneal vascularization begins and progresses concomitantly with conjunctival scarring. Repeated bacterial superinfections contribute to this process. The synergistic combination of bacterial infection, corneal vascularization, and conjunctival scarring results in blindness.

Lymphogranuloma venereum

C. trachomatis serovars L1, L2, L2a, and L3 cause a venereally transmitted disease, lymphogranuloma venereum (LGV), endemic to regions of South America, Africa, and Asia. Climatic bubo, tropical bubo, and estiomene are all synonyms for this disease referred to on occasion in 18th century literature (14). Although uncommon in the United States, with fewer than 500 cases typically reported yearly to public health departments, it is seen more frequently in the warmer, more humid regions of the country, especially the southeast, in people of lower socioeconomic status, in male homosexuals, and in individuals returning from other endemic regions. The disease is reported three times more frequently in men than in women. Transmission following laboratory accidents during aerosolization of the agent without appropriate biosafety measures and through fomites has reportedly occurred and resulted in pulmonary infection with pleural effusion, pneumonitis, and hilar and/or mediastinal lymphadenopathy. Probable reservoirs in the population include persons ignoring symptoms of cervical, urethral, or anorectal infection and individuals with asymptomatic disease.

LGV is the only chlamydial infection resulting in multisystem disease and causing constitutional symptoms. During the primary phase of the illness, 3 days to 3 weeks following exposure, a small painless herpetiform vesicle or ulcer develops, which heals without scarring. The lesions are only infrequently noticed by infected individuals on the affected sexual organ. In gay men and sometimes in women, the primary lesion may be an anorectal ulcer with associated symptoms of diarrhea, tenesmus, and a bloody, mucopurulent rectal discharge resulting from ulceration of the rectosigmoid colon. In such cases, fever and other constitutional symptoms are frequent, and perirectal or inguinal lymphadenopathy may result. A diffuse inflammatory response with mucosal ulceration, crypt abscesses, and granuloma formation is seen upon histologic examination of a rectal biopsy during this stage of the disease.

The primary phase of illness is followed 2 to 6 weeks later by a secondary stage characterized by suppurative regional lymphadenopathy and pronounced constitutional symptoms, including chills, fever, anorexia, headache, and arthralgias. Characteristic small, stellate abscesses surrounded by histiocytes are noted upon histologic examination of affected nodes. Other laboratory abnormalities commonly seen during this period include a leukocytosis, an elevated erythrocyte sedimentation rate, and abnormal liver function tests. During this phase, sequelae resulting from anorectal infection may include perirectal abscesses and rectovaginal or ischiorectal fistulas. Less frequently observed symptoms include hepatitis, erythema nodosum, “aseptic” meningitis, meningoencephalitis, and arthritis with a culture-negative effusion.

The late phase of the disease results from the sequelae caused by fibrotic changes and interference with normal lymphatic drainage. Chronic and progressive, infiltrative or ulcerative involvement of the scrotum, penis, or urethra with fistula development, ulcers, and posterior urethral strictures is not uncommon in men with untreated genital infection. Rectal strictures may result in “pencil stools.” Rarely, lymphedema may cause genital elephantiasis, with vulvar or penile enlargement and disfigurement. Chronic ulceration of the vulva and pedunculated perianal protrusions (lymphorrhoids) also may occasionally occur.

Nongonococcal Urethritis and Prostatitis

Isolated in 30% to 50% of all cases, *C. trachomatis* serovars D to K are the microorganisms, most commonly associated with male nongonococcal urethritis (NGU). Up to one third of men with urethral chlamydial infection may be without symptoms, and the organism can be isolated from a significant percentage of asymptomatic sexually active males. Although the symptoms of NGU are generally less acute than in cases of gonorrhea, the two cannot be reliably differentiated based on symptomology alone. In NGU, the urethral discharge is typically less purulent and smaller in volume than in gonococcal infection and results in less dysuria. Signs of NGU include erythema and tenderness of the meatus and a urethral exudate often demonstrable only upon urethral stripping in the morning prior to urination. One to two percent of chlamydial urethral infections have been reported to evolve into epididymitis.

C. trachomatis is the most frequently isolated agent in young heterosexual men with this disease in whom structural genitourinary tract abnormality is absent (15). *C. trachomatis* also has been reported to be associated with “venereal” Reiter syndrome (16) and has been isolated in up to 80% of cases of postgonococcal urethritis. Among homosexual men, it may cause proctitis or proctocolitis, depending on the serotype of the infecting strain.

Gynecological Infections

Genital infection with *C. trachomatis* is more prevalent in women than in men, but often escapes clinical detection. The adult female may have asymptomatic endocervical infection (17) or may present with mucopurulent cervicitis with vaginal discharge, urethritis, bleeding cervical erosions, proctitis, pelvic inflammatory disease, and/or salpingitis. Vaginitis does not occur. *C. trachomatis* has been isolated from the cervix of 30% to 60% of women with a history of sexual contact with a partner with NGU or gonorrhea or who diagnosed themselves with gonococcal infection, from 10% to 20% of women presenting to sexually

transmitted disease (STD) clinics without a history of contact with parties with urethritis, and from 5% to 10% of young women visiting family planning centers, prenatal clinics, or gynecologic clinics (18). Detection rates are higher in sexually active teenagers, particularly those who are pregnant and those attending STD clinics. The prevalence of infection with *C. trachomatis* also is higher in those of lower socioeconomic status, of black race, residing in urban areas, of divorced marital status, and with increased numbers of sexual partners. It also appears to be higher in users of oral contraceptives (19). In most studies, *C. trachomatis* is several times more prevalent than *Neisseria gonorrhoeae*.

The consequences of chlamydial infection in young women are significant. Up to 10% of women with genital infection show signs and symptoms of acute salpingitis. Among women with ascending infection, important sequelae include chronic pelvic pain, infertility resulting from occlusion of the fallopian tubes, and ectopic pregnancy. Asymptomatic cervical infection is common, and most women with involuntary infertility resulting from bilateral tubal damage fail to give a history of prior pelvic infection. Accordingly, it is highly probable that the proportion of women with ascending chlamydial infection is much higher than 10%. *C. trachomatis* has been detected in approximately two thirds of women with mucopurulent cervicitis. Over 80% of women with chlamydial genital infection demonstrate this syndrome upon gynecologic examination (20).

Acute endometritis resulting from *C. trachomatis* can progress to salpingitis following insertion of an intrauterine device, dilatation and curettage, hysterosalpingography, and subsequent to abortion or parturition. In a number of reported studies, *C. trachomatis* has been isolated from the urethra or cervix of approximately one third of women with laparoscopically documented acute pelvic inflammatory disease and from a comparable portion of women with clinical evidence of salpingitis, symptoms of which include low abdominal pain, discomfort during sexual intercourse, and abnormal vaginal bleeding. Serologic studies have demonstrated that *C. trachomatis* infection has occurred in up to 60% of women with salpingitis. In addition, the agent can be isolated more frequently than *N. gonorrhoeae* from women with this disease, although symptoms typically appear to be less severe. Serologic detection of IgM or high titers of IgG antibodies to *C. trachomatis*, both suggestive of recent or active infection, have been reported in up to 87% of women with acute perihepatitis or peritonitis (Fitz-Hugh Curtis syndrome) (21). Related intraperitoneal disease reportedly associated with chlamydial infection include perisplenitis and periappendicitis.

The risk for developing involuntary infertility as a result of tubal occlusion increases with the severity and number of episodes of salpingitis. The overall risk of infertility reportedly approximates 10% following a single episode of salpingitis, 30% with two episodes, and over 50% following infection on three or more occasions. Supporting this association, *C. trachomatis* has been isolated from a large porportion of peritubal and tubal specimens cultured from infertile women with tubal obstruction (22).

The dysuria-pyuria (urethral) syndrome also has been ascribed to *C. trachomatis* (23). In young women with frequency and dysuria, *C. trachomatis* often can be isolated. The agent also has been detected in pus expressed from the Bartholin's gland in cases of bartholinitis and occasionally from the rectum in women with chlamydial genital infection. Conflicting evidence exists on the importance of *C. trachomatis* as a cause of chorioamnionitis, premature rupture of membranes, premature delivery, spontaneous abortion, and stillbirth and on the influence of prior infection on the success of *in vitro* fertilization procedures.

Neonatal Pneumonia

Onset of classic chlamydial interstitial pneumonia in infants is gradual, with a range from 2 weeks to 3 months. The majority of cases are detected within 3 to 6 weeks of birth. Although the course of illness is protracted, the majority of infants remain consistently afebrile. In most cases, serum IgG and IgM levels are elevated, and the peripheral blood eosinophil count exceeds 300/mm^3 (24). Precedent conjunctivitis and/or ear abnormalities have been noted in many cases (25). Rhinitis with nasal obstruction, typically without nasal discharge, often represents the initial clinical manifestation.

A sequence of closely spaced staccato coughs each separated by a brief inspiration, tachypnea, hyperinflation, and rales with diffuse interstitial involvement typify the illness. Roentgenographic findings usually include pulmonary infiltrates, peribronichial thickening, and focal consolidation. A specific antibody response to the infecting strain of *C. trachomatis* is often demonstrable. A pronounced eosinophilic exudate is observed upon examination of tracheal secretions. Clinical illness usually lasts for several weeks, but rales and radiologic abnormalities may persist for months.

Epidemiology

The basic epidemiology of *C. trachomatis* infection was defined early in this century. The associaton between neonatal conjunctival infection, the maternal cervix, and infection among siblings, suggesting transmission by mucous membrane contact, was described as early as 1942 (26). Although the etiologic agent was thought to be a virus, the full spectrum of disease including female cervical infection, neonatal inclusion conjunctivitis, urethritis, and ophthalmitis in adults was comprehensively delineated prior to the advent of the antibiotic era. Although the role of *C. trachomatis* in NGU is still unclear, the agent can be isolated from a large proportion of men with this syndrome as well as from a significant number of female contacts with these men. Likewise, the majority of fathers of infants with inclusion conjunctivitis are positive for *C. trachomatis* upon urethral culture. Concomitant chlamydial infection at several body sites also is relatively common, and the majority of individuals with chlamydial conjunctivitis have simultaneous pharyngeal or genital colonization and/or infection.

Several conditions are associated with an increased prevalence of female chlamydial infection. *C. trachomatis* cervical infection appears to be more common in women with a history of other sexually transmitted disease. In addition, there appears to be an increased culture recovery rate from specimens collected during the first and fourth weeks of the female menstrual cycle. Risk factors in adolescent women include a younger age at first sexual intercourse, increased number of years of sexual activity, and use of

oral contraceptives. Although contact with infected mucosal membranes represents the most common route of exposure, ocular trachoma may be acquired via fomite inoculation and by swimming in contaminated water. Trachoma also has been acquired during ocular tonometry from equipment improperly sterilized between each procedure.

C. trachomatis also can cause sexually transmitted disease in children. When vaginal, rectal, or pharyngeal chlamydial infection occurs in children outside of the neonatal period, an investigation should be conducted to determine whether sexual abuse has occurred. Although infection with *C. trachomatis* in children does not prove that they are victims of sexual abuse, it should alert caretakers to the possibility of such a problem. Similarly, children undergoing medical evaluation for sexual abuse should be cultured for chlamydiae from pharyngeal, rectal, and vaginal sites, as appropriate.

Diagnostic Procedures

Specimen Selection Collection

Specimens collected for the detection of chlamydiae should be handled with care. Such specimens may contain other agents of potential risk to the health care worker. Following aerosolization and inhalation of LGV strains of *C. trachomatis* in a laboratory setting, accidental infection resulting in pneumonitis and mediastinal lymphadenitis has been reported (27).

All samples collected for chlamydial isolation should be stored at refrigerator temperature prior to processing and inoculated to appropriate cell lines within 48 hours. If specimen processing is expected to be delayed for more than 48 hours after collection, specimens should be frozen at -70°C or below.

Although LGV strains of *C. trachomatis* have been isolated from clotted whole blood, blood culture is not recommended for routine diagnosis of infection. The specimen most frequently submitted to the laboratory for chlamydial isolation is the genital swab. Scrapings are preferred, but specimens from the conjunctivae and the genital tract are most easily collected with a swab. Cervical specimens also may be collected with a cytologic sampling brush. Materials utilized for some swabs have been shown to be toxic to the cell lines used to support the *in vitro* replication of chlamydiae and to inhibit chlamydial multiplication.

Swabs prepared with dacron, rayon, or cotton fibers should be used for specimen collection. Likewise, swabs with plastic or metal shafts are superior to toxic wooden-shaft varieties. Confusing artifacts may result with some dacron swabs when iodine staining techniques are used to demonstrate *C. trachomatis* inclusions. Similarly, alginate swabs can result in the formation of confusing artifacts when dark-field microscopy is utilized to reveal chlamydial inclusions by Giemsa stain.

Removal of mucus and pus prior to obtaining an endocervical sample reduces the rate of bacterial contamination and the frequency of cytotoxicity in inoculated cell cultures and results in better smears for direct fluorescent antibody staining. Infected cells, required for the detection of chlamydiae by cell culture techniques, are also increased in number in samples collected following removal of excess cervical mucus. Concomitant culture of the cervix and the urethra with subsequent specimen pooling increases the culture positivity rate substantially at minimal added expense.

Specimens submitted for diagnosis of chlamydial infection include scrapings or swabs from the conjunctivae, urethra, cervix, and rectum, bubo pus, sputa, throat washings, and tissue. Because epithelial cells, as opposed to mucus or pus, must be collected, vigorous rubbing of the swab against the involved site is required for optimal specimen acquisition. When collecting eye specimens, the eyelid should be everted and the swab rolled directly over the surface of the conjunctivae. In cases of urethritis in the male, the swab should be inserted 3 to 5 cm into the urethra and withdrawn using a rotating motion. In cases of cervicitis in the female, the endocervical specimen should always be collected from the squamocolumnar junction.

Deep posterior nasopharyngeal specimens are required for the diagnosis of chlamydial respiratory tract infection. Techniques used for the collection of samples for the detection of *Bordetella pertussis* are appropriate for this purpose. In suspected cases of lymphogranuloma venereum, pus from an affected lymph node should be apsirated with a syringe needle following insertion through apparently healthy tissue rather than directly into the bubo. Infected fluctuant nodes usually contain frank pus. If none is aspirated, sterile nonbacteriostatic saline should be injected into the node and drawn back into the same syringe in an attempt to collect material for diagnostic testing. Collection of specimens in cases of proctitis or lower gastrointestinal tract infection is best accomplished using direct anoscopic visualization of the suspected sites, optimally from ulcerative or hypertrophic lesions. Isolation of chlamydiae from the upper genital tract represents the only valid technique for documenting *C. trachomatis* involvement in cases of endometritis and acute salpingitis. Optimal gynecologic techniques for the collection of clinical specimens include laparoscopically directed fallopian tube biopsy or needle aspiration and/or guarded endometrial biopsy or washing (28).

No single transport medium has yet been accepted as optimal for the recovery of *C. trachomatis* from clinical specimens. Although labile at temperatures above 6°C, the organism is relatively stable at refrigeration temperatures. A single freeze-thaw cycle results in at least a 1-log loss in infectivity. If a specimen requires storage for less than 72 hours, it is therefore recommended that the sample be maintained at 4 to 6 rather than be frozen. Some laboratorians, however, recommend that all specimens be frozen at less than or equal to -70°C until processing. Two commonly employed transport media are a sucrose-phosphate-glutamate medium and a cell culture medium supplemented with 10% fetal bovine serum. Most chlamydial infections occur in body sites normally colonized with bacterial flora. As a result, specimens collected for the isolation of *C. trachomatis* usually must be treated with antibiotics prior to cell culture inoculation. Antibiotics without chlamydial activity but active against the organisms commonly encountered at the collection site usually are incorporated into the transport medium itself. Aminoglycosides such as gentamicin, uniformly inactive against chlamydiae, have proven to be particularly useful for this purpose. Formulations commonly include vancomycin (100 g/mL) and gentamicin (10 g/mL) as antibacterial agents and nystatin (25 to 50 g/mL) or amphotericin B (2.5 to 4.0 g/mL) to suppress the growth of

yeasts. Tetracyclines, erythromycin, and penicillins should not be used because they interfere with chlamydial isolation procedures. Specimens such as homogenized tissue, semen, and bubo aspirates should be diluted 1:10 and 1:100 in cell culture medium prior to shell vial inoculation because they are often toxic to cells in culture.

Direct Microscopy

An adequate specimen for cytologic examination should include at least 1,000 epithelial cells spread evenly over the surface of the slide such that the cells can be examined individually. Although historically the Giemsa stain proved useful for the detection of chlamydial inclusions, the technique is no longer recommended for routine diagnosis of *C. trachomatis* infection because direct fluorescent antibody and culture systems have proven to be significantly more sensitive. The Giemsa-stained smear may still represent the diagnostic technique of choice in cases of inclusion conjunctivitis of the neonate when large numbers of infected inclusion-containing cells usually can be detected in a rapid and cost-effective manner (Fig. 53.1).

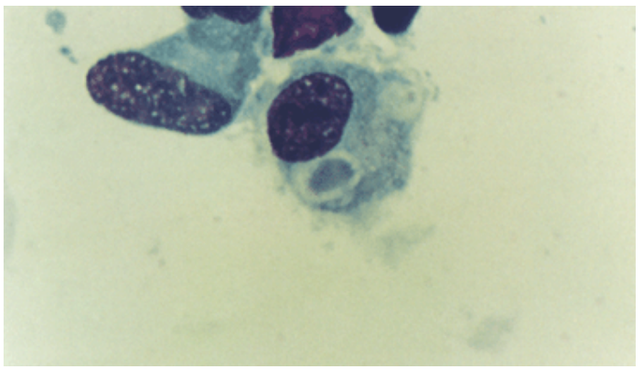

FIGURE 53.1. Giemsa-stained chlamydial inclusion in cell scraping from a case of neonatal conjunctivitis.

Direct visualization of chlamydial elementary bodies using fluorescein-conjugated monoclonal antibodies on urethral, endocervical, conjunctival, and rectal specimens and in respiratory tract or nasopharyngeal aspirates from infants with pneumonitis has proven to be a rapid and sensitive technique for the diagnosis of *C. trachomatis* infection. This technique obviates the need for transport media, and fixed slides are stable for up to 1 week at either room or refrigeration temperature.

Although relatively time-consuming in the laboratory, the method is especially useful in low-volume settings and when specimens must be transported from distant collection sites prior to testing. A distinct advantage of direct fluorescent antibody testing over antigen detection and culture techniques is the capability to evaluate the adequacy of the specimen during slide examination. Columnar epithelial cells attest to the fact that the sample was collected properly, whereas excessive cervical mucus and/or a preponderance of squamous epithelial cells indicate inadequate site preparation or specimen collection. Murine monoclonal antibodies directed against the major outer membrane proteins (MOMP) of all known human serovars of *C. trachomatis* and in both forms of the organism (the infectious elementary body and the replicating, metabolically active reticulate body) are generally felt to be superior to antibody preparations specific for chlamydial lipopolysaccharide (LPS) because the fluorescence is more intense with MOMP preparations. Bacteria other than chlamydiae, however, may sometimes stain with anti-MOMP antibodies either through nonspecific immunoglobulin binding or from cross-reactivity with shared epitopes. This phenomenon is observed frequently with rectal specimens, possibly because of the large numbers of bacteria normally present in such specimens or resulting from cross-reacting antigens in *Peptostreptococcus productus* (29). In specimens from other body sites, cross-reacting bacterial species are less common and can reliably be differentiated from fluorescing elementary bodies on a morphologic basis. Because common epitopes exist between chlamydial and other Gram-negative bacterial lipopolysaccharides, direct fluorescent antibody reagents directed against chlamydial LPS have the potential for cross-reactivity with bacterial species. This would not be expected with antibody preparations directed against the chlamydial MOMP.

A high-quality fluorescence microscope is essential for proper examination of clinical specimens using direct fluorescent antibody (DFA) techniques. Differences in optical alignment, illumination power, and filter quality and wavelength will cause variability in the fluorescent intensity of elementary bodies. To control for these variables, positive and negative controls should be tested routinely with patient samples to substantiate satisfactory reagent and microscope performance. Slides are typically scanned under 400× total magnifiication, and suspicious structures are confirmed using a 1,000× oil immersion objective. The sensitivity of DFA methods when compared with culture is a function of the sensitivity of the comparative cell culture technique, the patient population examined, and the number of elementary bodies required for interpretation of a smear as positive. The sensitivity of DFA in studies of female cervical specimens has ranged from 70% to 100%, whereas the specificity typically exceeds 95% for both men and women. In studies that have employed a third technique to resolve discrepant results between DFA and culture for the diagnosis of chlamydial infection in women, false-negative cultures have been reported for endocervical specimens. DFA appears to be more sensitive for the detection of elementary bodies in female endocervical samples than in male urethral specimens (approximately 70%), probably because of the discomfort associated with specimen collection. Because lower numbers of elementary bodies are typically observed in urethral samples than in endocervical specimens, the number required for the interpretation of a test as positive may have to be lowered for urethral specimens to achieve adequate test sensitivity.

Culture Techniques

McCoy cells, a heteroploid mouse cell of uncertain origin, are most frequently used for the isolation of chlamydiae from clinical specimens. Although a number of other cell lines have proven satisfactory for this purpose, extensive research has been done, and all standard procedures have been developed using this line. Regardless of the cell line used, the most critical step in enhancing chlamydial replication is increased contact between the infectious elementary bodies and the cell monolayer. This can be accomplished mechanically (centrifugation) or by changing the

surface charge of the cell (treating with DEAE-dextran). Cell irradiation or treatment with an antimetabolite (5-iodo-2-deoxyuridine, cytochalasin B, or cycloheximide) further enhances chlamydial replication. Specimen centrifugation onto cycloheximide-treated McCoy cell monolayers, either on coverslips in 1-dram shell vials or in microtiter wells is the method of choice for the culture of chlamydiae at this time.

To process the specimen for cell culture, all cell-containing fluid should be expressed from the swab into the transport medium container, the swab is discarded, and the specimen is vortexed in a centrifuge tube containing glass beads. Coarse debris may be removed from the specimen by centrifuging at a low speed for a brief period of time. Cell monolayers should then be inoculated with the clinical specimen by centrifuging at 2,500 to 3,000 g (centrifugation of microtiter plates is limited to approximately 1,500 g) for 1 hour at 30°C to 35°C.

Controlled temperature centrifuges assist in maintaining a constant acceptable temperature during centrifugation. The inoculum should be removed after 1 to 2-hours (immediately following centrifugation for specimens likely to be toxic to the McCoy cells), and fresh medium containing 1 g/mL of cycloheximide should be added. Cells then should be incubated at 35°C to 37°C in air with 5% CO_2 (CO_2 is unnecessary for stoppered vials) and stained to detect chlamydial inclusions at times appropriate for the staining system employed. Cells should be methanol-fixed prior to staining. The optimal incubation time for both the Giemsa and the iodine (Fig. 53.2) staining techniques is 60 to 72 hours, when glycogen concentrations are at a maximum. Immunofluorescent and immunoperoxidase (Fig. 53.3) procedures are capable of detecting chlamydial inclusions as early as 18 hours after cell culture challenge, but cultures inoculated in duplicate are typically incubated and stained after 24 hours and after 48 hours incubation. Immunoperoxidase and immunofluorescent staining techniques also are more sensitive than the iodine stain, but are more expensive to perform and require more attention to staining.

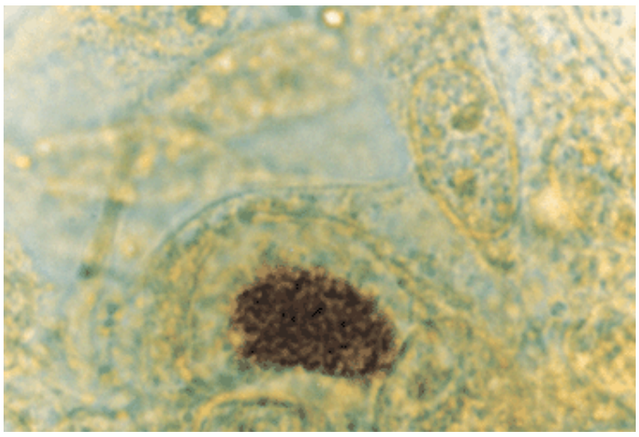

FIGURE 53.2. Iodine-stained *Chlamydia trachomatis* inclusion in infected MyCoy cell culture.

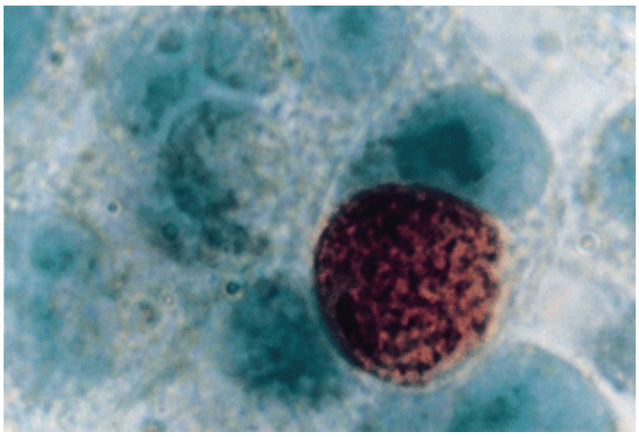

FIGURE 53.3. Immunoperoxidase-stained chlamydial inclusion in infected McCoy cell culture.

The use of 96-well microdilution plates for the isolation of chlamydiae affords considerable cost savings both for media and plastic disposables and expedites the simultaneous processing of multiple specimens. Two possible problems with this technique are the potential for cross-contamination as a result of the proximity of the microtiter wells and the possibility that the decreased cell surface may result in lower isolation rates. Equivalent isolation rates are seen with vials and microtiter plates when specimens are collected from symptomatic individuals. When asymptomatic populations are screened, however, shell vials are clearly superior. Blind passage is required in this setting for maximal recovery rates (approximately 25% of asymptomatic individuals and 10% of symptomatic persons will be positive only when specimens are tested by this technique), and subculture from microtiter wells is considerably more difficult and less efficient than from shell vials. To accomplish the passage, an inoculated cell culture incubated for 72 to 96 hours should be homogenized and the suspended cells used to challenge a second cell monolayer.

Enzyme-Linked Immunoassays

Screening tests based on enzyme-linked immunosorbent assay (EIA) technology were introduced shortly after the commercial availability of DFA tests. In general, EIAs are highly useful for screening symptomatic and asymptomatic women in high- and moderate-risk groups, but they have lower sensitivity for screening women in low-risk populations (30,31,32,33,34,35 and 36). Likewise, these assays are satisfactory for screening symptomatic males for chlamydial infection but demonstrate relatively low positive and negative predictive values when asymptomatic men are tested (37). In a multicenter study, this procedure showed an 87.2% sensitivity and 98.9% specificity compared to urethral swabs tested by cell culture. When screening female urine specimens, however, the current assay appears to lack specificity.

Investigators also have generally found EIA to perform in a satisfactory manner when testing ocular specimens, but limited data suggest that EIA may not perform as well when examining specimens from the respiratory tract (38, 39). Studies also have shown that false-positive results occur when testing clinical specimens for chlamydiae using EIA tests, particularly with samples from the lower gastrointestinal tract. As a result, commercially available EIA kits are not currently approved for the testing of rectal specimens.

Other available techniques include filtration EIA procedures.

In these assays, chlamydiae are trapped in nitrocellulose membranes and detected using monoclonal antibodies directed against the chlamydial LPS using a radiometric or colorimetric antibody detection technique. These tests may offer increased sensitivity over earlier assays and clearly decrease the time required to test an individual specimen. Relatively inexpensive, these procedures also lend themselves to rapid nonbatch testing of multiple specimens as they are received into the laboratory.

Nucleic Acid Probes

An acridinium-ester-labeled DNA probe complementary to *C. trachomatis* ribosomal RNA is commercially available for direct detection of *C. trachomatis* in endocervical, urethral, and conjunctival swab specimens. Instrumentation required for test performance includes a water-bath and luminometer. Test results are available in 2 to 3 hours. The sensitivity of the DNA probe test compared to conventional cell culture as the reference method varies from about 75% to 97% for both endocervical and urethral swab specimens (40,41,42,43,44 and 45). The specificity of the probe test is ≥97% for all specimen types, and it can be improved with a probe competition assay (46).

Nucleic Acid Amplification

Nucleic acid amplification tests for direct detection of *C. trachomatis* in clinical specimens are available from a few manufacturers. Acceptable specimens include endocervical and male urethral swab specimens and male and female urine samples. Total processing time is 4 to 5 hours. Data from several studies indicate that the nucleic acid amplification tests are highly specific and are more sensitive than conventional cell culture (47,48,49,50,51 and 52). However, given that the amplification assays are more expensive than the other commercial nonculture tests, laboratory directors must determine whether the tests will be cost effective in their particular patient population.

Serology

Serologic techniques are not recommended for diagnosis of chlamydial genital tract infection. Although most individuals with documented chlamydial infection have detactable antibodies to *C. trachomatis*, there also appears to be a high prevalence of antibody positivity in uninfected individuals in sexually active populations. This is because chlamydial genital and respiratory tract infection is common, and antibodies to chlamydiae persist following the resolution of infection. In addition, considering the chronic nature of the disease, it is often difficult to demonstrate a diagnostic fourfold rise in antibody titer in persons with active infection.

Skin tests for the diagnosis of LGV, however, have been available since 1938 (53). Originally, skin test antigen was prepared from sterilized bubo or genital exudate material collected from individuals with LGV. The widespread application of the “Frei test” became possible when it was found that large quantities of LGV antigen could be prepared in the yolk sac of developing chick embryos (54). Because the test lacks acceptable sensitivity and specificity (55), serologic techniques have, for the most part, supplanted it. A single titer of 256 or higher by complement fixation generally is considered diagnostic of infection with LGV. This technique lacks sensitivity for diagnosing other infections caused by *C. trachomatis*.

The microimmunofluorescence test (MIF) for the detection of antibodies to chlamydiae was developed in the early 1970s. It is highly reliable in detecting IgG-class antibodies in individuals previously infected with chlamydiae, and, as a result, has proven useful for epidemiologic investigations examining rates of infection with *C. trachomatis* (56, 57). The MIF test also detects IgM antibodies. Its primary use is in the clinical diagnosis of chlamydial pneumonitis in neonates. Although the MIF test primarily detects serotype-specific antibody, chlamydial genus reactivity can be measured if reticulate body antigen is incorporated into the test reagent (58).

Interpretation of Laboratory Results

Most currently available laboratory tests for the diagnosis of *C. trachomatis* infection are relatively expensive and labor-intensive. The U.S. Centers for Disease Control and Prevention (CDC) recommended in 1985 that symptomatic individuals at high risk for sexually transmitted chlamydial infection be treated with appropriate antibiotics empirically (18). This approach is both cost-effective and rational in clinical settings serving high-risk populations for patients willing to acquiesce to treatment for an unproven infection.

Nonculture techniques for the diagnosis of *C. trachomatis* infection generally are highly sensitive but lack specificity, particularly in low-risk populations. As a result, positive screening tests in low-risk patients with nonspecific symptoms should be confirmed with more specific tests, such as culture, before initiation of antimicrobial therapy.

Specific test selection for the diagnosis of infection with *C. trachomatis* usually is based on cost, public health, and laboratory expertise. Culture techniques are generally considered cost-effective for the diagnosis of chlamydial infection in high-risk women presenting to STD clinics, whereas empiric antibiotic therapy appears to be more cost-effective for men in the same setting (59). In populations with chlamydial cervical infection prevalences from 2% to 7%, antigen detection tests have proven cost-effective for screening purposes (60, 61).

Because of the limitations of all of the current testing techniques, the selection of specific test methods for the diagnosis of chlamydial infection by the laboratory should take into account the test cost, the projected number of tests to be performed, personnel requirements, potential problems with specimen transport, and the patient population to be examined. Cell culture techniques are 100% specific, allow for characterization of isolated strains, and are applicable to all types of clinical specimens. They currently represent the methods of choice when unequivocal specificity is required. Demanding somewhat less technical expertise, antigen detection procedures, by comparison, offer the advantages of ease of specimen transport, decreased hazard to the laboratory worker, and generally are less labor-intensive. DFA, ELISA, nucleic acid probe, and culture methodologies appear to be fairly comparable in terms of sensitivity. Nucleic acid amplification tests offer the highest sensitivity.

The lower specificities of direct antigen detection tests in low-risk populations generally preclude their use for screening purposes in such settings. Considerable social stigma is still attached to the presence of sexually transmitted disease. To minimize the emotional cost associated with a report of a positive result, clinicians

should communicate to their patients the predictive value of a positive test with the specific technique employed by the laboratory.

Therapeutic Considerations

Sulfonamides, macrolides, and tetracyclines are all highly active *in vitro* against *C. trachomatis*. In cases of inclusion conjunctivitis, topical therapy with tetracycline, erythromycin, or sulfonamide for 2 to 3 weeks will often suppress signs of infection but will not necessarily eradicate the infecting agent from the nasopharynx or conjunctiva. This is of particular import in infants at risk for the development of chlamydial pneumonia. *C. trachomatis* colonization of the conjunctivae has been shown to persist for up to 40 weeks and nasopharyngeal carriage up to 18 months or more in the face of topical therapy. Therefore, systemic treatment of neonatal inclusion conjunctivitis with erythromycin, or, in older infants, with sulfonamides is indicated to eradicate the ocular infection as well as to prevent pneumonia. Systemic therapy with a tetracycline is recommended for adult disease. In chronic trachoma, therapy is more difficult. Extended treatment with doxycycline appears to be the most effective regimen. Surgical correction of trachoma-associated lid deformities reduces the incidence of blindness.

The best approach to the prevention of neonatal chlamydial infection is prenatal diagnosis and treatment of infected parents. Ocular prophylaxis with silver nitrate does not prevent the establishment of chlamydial infection in the infant, whereas prophylaxis with erythromycin appears to be at least somewhat effective. It does not, however, decrease the overall acquisition of *C. trachomatis* (62) and is ineffective if application to the infant's eyes is delayed.

The recommended antimicrobial agent for the treatment of LGV is tetracycline. Alternative regimens include courses of erythromycin, doxycycline, or sulfamethoxazole. All of these regimens rapidly improve constitutional symptoms, but have little impact in the duration of healing buboes (63). Late complications are not generally affected by antibiotic therapy. Surgical intervention is often required to repair strictures and fistulas and to address elephantiasis.

The most effective agents for the treatment of genital tract infection with *C. trachomatis* are azithromycin and the tetracyclines. Chloramphenicol, rifampin, and oral ampicillins (administered in high doses) and the newer fluoroquinolones such as ofloxacin have all been reported to be effective for treatment of infection with *C. trachomatis* (64,65 and 66), but they are not recommended as first-line agents for chlamydial infection. Optimal treatment during pregnancy for *C. trachomatis* infection has not been established. A regimen of erythromycin (stearate, base or ethylsuccinate; not estolate) or azithromycin is probably the best approach.

With the exception of azithromycin, single-dose therapy with any antibiotic does not reliably eradicate *C. trachomatis* from genital tract sites. Therapy for an extended period of time, at least 10 days, is recommended for complicated infections. All attempts to treat pelvic inflammatory disease on an outpatient basis should include intramuscular injection of a third-generation cephalosporin (such as cefotaxime or ceftriaxone) to provide coverage for *N. gonorrhoeae* as well as tetracycline for chlamydiae. The fluoroquinolones as a group have significant activity against gonococci and some, especially ofloxacin, are highly active against *C. trachomatis*. Further clinical trials will help define the role of these agents for the treatment of chlamydial genital tract infections.

Chlamydophila (Formerly Chlamydia) psittaci

Psittacosis (parrot fever, ornithosis) is a zoonotic disease primarily infecting birds that is accidentally transmitted to man. First described in psittacine birds (parrots and parakeets), *C. psittaci* has been shown to infect most avian species as well as many nonprimate mammals, causing varying degrees of illness. In Switzerland in 1879, Ritter described several human cases of unusual pneumonia associated with tropical bird exposure. Morange named the disease (from the Greek word for parrot, psiittakos) following an outbreak in 1894 in which he attributed the source of the disease to parrots. Meyer chronicled outbreaks in several countries from 1929 to 1930 following large-scale importation of infected South American parrots to the United States and Europe (67). During the investigation of an outbreak at the London Zoo in 1930, Bedson isolated the causative agent from avian and human tissues. Rivers and his associates explained that the probable route of transmission to man was via the upper respiratory tract following inhalation of dried excreta from birds shedding the agent. During ecologic studies on infection in Australian wild birds, Burnet proved that fledglings acquired the infection in the nest from asymptomatic parents. Between 1965 and 1980, 40 to 160 human cases were reported annually in the United States (68) with a 1% to 5% mortality rate.

Pathogenesis and Spectrum of Disease

In man, following inhalation into the respiratory tract, *C. psittaci* migrates to the reticuloendothelial cells of the spleen and liver, where it replicates intracellularly within macrophages. Invasion of the lung and other organs then follows by hematogenous seeding. This two-step process explains the relatively long incubation period (7 to 15 days or longer) observed in this disease. A predominantly lymphocytic inflammatory response occurs in both the alveolar and interstitial spaces of the lungs, particularly in the dependent lobes. This results in alveolar wall thickening, edema, and sometimes necrosis. Small hemorrhages may occur, accounting for the hemoptysis sometimes seen clinically. Mucus plugging of the brochioles contributes to the dyspnea and cyanosis often observed in severe disease. The epithelial lining of the bronchial tree typically remains intact. Liver, spleen, and hilar node enlargement may occur, and focal splenic and hepatic necrosis can result. In fatal cases, meningeal, pericardial, brain and adrenal changes have been noted upon histologic examination of tissues collected at autopsy.

Although the lung is the organ most prominently involved, *C. psittaci* causes a systemic illness in man. The course of clinical disease, however, varies widely. The infection generally manifests itself with sudden onset of chills and high fever (38°C to 40.5°C), but may present insidiously with slowly increasing malaise and fever over a 2- to 4-day period. Severe headache is often the patient's major complaint. Arthralgias and painful myalgias (especially in the back of the neck), anorexia, and malaise are other

common symptoms. A pale macular rash (Horder spots) has been described. Jaundice is noted only in very severe cases.

A persistent dry hacking cough, which can appear at any time during the course of infection, is a prominent feature of the disease. Small amounts of mucoid, occasionally blood-streaked sputum may be produced. Gastrointestinal symptoms are experienced by only a minority of patients and, when present, include diarrhea, nausea, vomiting, and abdominal bloating. Other uncommon complaints include epistaxis and mild sore throat. Changes in mental status, associated with hypoxia, may be observed toward the end of the first week of illness and occasionally progress to lethargy, delirium, and even coma.

Epidemiology

Virtually any species of bird can serve as a host to *C. psittaci*. As a result, psittacosis is truly a cosmopolitan disease. Although psittacine birds remain the major reservoir for human infection, cases associated with exposure to infected ducks, cockatiels, sparrows, canaries, pigeons, and occasionally, various mammalian species have all been reported. Many cases in recent years have occurred in persons processing carcasses of domestic fowl, especially turkeys (69). Usually a sporadic disease, approximately one-half of all cases occur in pet bird owners. The disease is considered an occupational hazard for pet shop employees, zoo workers, veterinarians, and others who capture or raise psittacine birds for sale and profit.

A dramatic drop in the incidence of cases of psittacosis in the United States has been noted over the past few decades. Factors contributing to this decline include the use of tetracycline-containing poultry feed and the federal requirement that all commerically imported psittacine birds be treated for 30 days with antichlamydial drugs prior to transport into the country. Although antibiotics do not totally eradicate the agent from infected birds, they greatly reduce the transmission rate of the organism. Imported and domestic birds often are housed together or in close proximity in commercial settings. Because birds rapidly become infectious under stressful and crowded conditions, the potential for the spread of the organism in such settings always remains a real possibility.

C. psittaci is found in relatively high titer in the excreta, feathers, blood, and tissues (particularly the kidneys, spleen, and liver) of infected birds. Although birds can show signs of overt illness and die from infection, more frequently they demonstrate only minor symptoms such as lethargy, diarrhea, failure to feed, and ruffled feathers. This often results in close contact with the owner investigating the cause for the bird's altered behavior. Asymptomatic birds and those that have recovered from illness often continue to shed the organism for several months.

The agent can survive in dried bird excreta for long periods of time, and aerosolization of such contaminated materials with subsequent inhalation usually results in human infection. Bird bites, mouth-to-beak intimate contact, and manipulation of contaminated tissues and feathers have also led to infection. Prolonged, close contact with infected birds is not required for acquisition of the organism. Well-documented cases in which individuals have had only momentary contact with potentially contaminated environments have been reported. This may explain why approximately 20% of cases have no known route of exposure. No documented cases exist from ingestion or handling of dressed, eviscerated poultry.

Several reported instances of direct person-to-person transmission, primarily involving hospital personnel, have been recorded. Disease in these cases has reportedly been more severe than that following exposure to infected avians. The reasons for these observations are speculative, but include theoretical alterations in strain virulence following human passage and a dose effect.

Diagnostic Procedures

Culture

Although the diagnosis of psittacosis can be confirmed by isolation of the organism, attempts to isolate *C. psittaci* from clinical or animal specimens may be hazardous to laboratory personnel, and such procedures should be offered only by facilities with specialized training in the handling of the etiologic agent under laboratory conditions. Cell culture probably is the most sensitive technique for primary isolation of *C. psittaci*. Several cell lines have been used to cultivate *C. psittaci*. L cells efficiently support the growth of the agent, most strains forming cytopathic plaques that result in additional cycles of chlamydial replication, and eventually infecting the entire monolayer. Specific identification can be made by staining infected cells with commercially available genus-specific immunofluorescent antibody reagents. *C. trachomatis* can be differentiated from *C. psittaci* with species-specific immunofluorescent antibody preparations or based on the failure of *C. psittaci* intracellular inclusions to stain with iodine.

Serology

Because of the high titers of complement-fixing antibody produced in cases of psittacosis, complement fixation tests are used by public health laboratories to confirm the diagnosis of the disease. Although a single titer of 32 or higher is consistent with a presumptive diagnosis of psittacosis, a fourfold rise in titer between acute and convalescent serum specimens collected a minimum of 3 weeks apart is interpreted as definitive evidence of *C. psittaci* infection. Antibody titers generally rise by the second week of illness. Antimicrobial therapy inititated early in the disease can delay or diminish production of complement-fixing antibodies and, as a result, decrease the sensitivity of the test (70).

Technically demanding, the accuracy of the complement fixation test is highly dependent upon the quality of available test antigen. Unfortunately, satisfactory reagents are not always available commercially. Because *C. psittaci* is a common cause of inclusion conjunctivitis in guinea pig colonies, all lots of guinea pig-derived complement must be carefully tested for the presence of interfering antibodies before being placed in service (71).

Interpretation of Laboratory Results

Routine laboratory tests usually are of little value in establishing diagnosis of psittacosis. White blood cell counts typically fall within the normal range, although an unremarkable leukocytosis or leukopenia may be observed. Occasionally, patients become anemic during the course of the disease. During acute stages of the illness, protein may be detectable in the urine. Despite the fact that hepatomegaly is common, results of liver function

tests are usually within normal limits. Analysis of cerebrospinal fluid is unrewarding.

The diagnosis, therefore, usually is dependent upon the results of serologic testing. False-positive rises in antibody are rare, but have been reported in some patients with legionellosis. Although infrequently necessary, clinical specimens may be shipped, upon approval of the state public health laboratory, to the CDC for attempts to isolate the agent.

Therapeutic Considerations

The tetracyclines are extremely effective agents for the treatment of psittacosis. Following initiation of antimicrobial therapy, clinical improvement can usually be observed within 48 to 72 hours. Relapses, however, are common unless treatment continues for 10 days to 2 weeks after defervescence. Case fatality rates ranged from 20% to 40% in the preantibiotic era, but today the prognosis is good with appropriate therapy. All suspected cases should be reported promptly to public health authorities.

Chlamydophila (Formerly Chlamydia) pneumoniae

Spectrum of Disease

C. pneumoniae was originally designated the TWAR agent, a name constructed by combining the laboratory identifiers from the first two isolates, TW-183 and AR-39. The organism generally causes a mild self-limited pneumonia in teenagers and young adults. Early symptoms including pharyngitis, with or without laryngitis, may represent the only clinical evidence of infection. Other individuals may develop bronchitis, which in turn may further progress to a pneumonia lacking any distinguishing clinical or roentgenographic characteristics. The organism is being recognized increasingly as a cause of serious respiratory infection in persons with AIDS (72) and in other immunocompromised individuals. Fever, cough, and sore throat are the most common symptoms. Young individuals with mild pneumonia typically fail to show abnormalities in white blood cell counts or leukocyte differentials. In older adults with other chronic illnesses, disease is often more severe and may result in hospitalization. Such patients are more apt to show a leukocytosis.

The erythrocyte sedimentation rate is typically elevated. Some patients have a biphasic illness where an initial episode of pharyngitis and laryngitis resolves spontaneously, but is followed in 2 to 3 weeks by bronchitis and pneumonia. Although the first isolate of *C. pneumoniae* was recovered from a conjunctival specimen, no further association with ophthalmic infection has been reported. Data from several studies suggest that the organism *C. pneumoniae* might be a factor in the pathogenesis of cardiovascular disease (73, 74).

Epidemiology

Unlike *C. psittaci*, no avian or other animal reservoirs have been identified for *C. pneumoniae*. Human-to-human transmission appears to be the only significant mechanism for spread of the agent. Although the mode of transmission has not been specifically identified, it is presumed to be via a respiratory route. *C. pneumoniae* does not appear to be sexually transmitted (75).

Antibody prevalence is generally low during the childhood years, rising rapidly in teenagers. In adults, the prevalence of *C. pneumoniae* antibodies reportedly ranges from 25% to 50%. Antibody persistance in the elderly suggests repeated infection with resulting periodic boosts in titer. The prevalence of antibody is reportedly higher in males than in females. In several outbreaks among military recruits, boarding school students, and in the general population, retrospective serologic studies have demonstrated that *C. pneumoniae* was the cause of pneumonia. Prospective studies have since incriminated *C. pneumoniae* in similar outbreaks among college students. One recent investigation indicated that *C. pneumoniae* was an important cause of hospital-acquired pneumonia in intubated patients having undergone some type of surgical procedure (76). Reported outbreaks have occurred throughout the world during all seasons of the year.

Diagnostic Procedures

Culture

HeLa-229 cells are more susceptible to infection with *C. pneumoniae* than the McCoy cells utilized in most laboratories for the isolation of *C. trachomatis*. Multiple cell passage may be required to recover the organism. Egg cultivation, however, may be necessary for the isolation of the agent from some specimens. If HeLa-229 cells are used for the isolation of *C. pneumoniae*, pretreatment of the monolayers with diethylaminoethyl-dextran increases the susceptibility of the cells to infection.

Serology

Two patterns of antibody response to *C. pneumoniae* are seen. During primary infection, complement-fixing antibodies appear early, followed in 10 days to a month by IgM antibodies measurable by microimmunofluorescence techniques. Typically, IgG-class antibodies are not detected until 6 to 8 weeks after onset of illness. In the second pattern, attributed to reinfection, complement-fixing antibody is not detectable, and IgM antibody occurs in low titer or cannot be detected at all. A rapid anamnestic IgG antibody response occurs upon reinfection. Whole inclusion immunofluorescent testing and ELISA tests utilizing broadly cross-reactive LGV antigen appear to be of limited value because of cross-reactivity with *C. trachomatis*.

Therapeutic Considerations

Few comparative antibiotic trials have been conducted to determine clinical efficacy in the treatment of *C. pneumoniae* infection. *In vitro* clarithromycin has been reported to be more active on a weight basis than other macrolides, tetracyclines, and ciprofloxacin. Limited clinical experience suggests that erythromycin may be inadequate for the treatment of serious infection, resulting in prolonged symptoms or relapse. Based on clinical experience in other types of chlamydial infections, tetracyclines currently appear to be the drugs of choice.

MYCOPLASMA

Part of "53 - Chlamydia, Mycoplasma, and Rickettsia"

Mycoplasmas, the smallest organisms capable of self-replication, were first isolated by Roux and Nocard from cattle with contagious

bovine pleuropneumonia in 1898. Subsequent isolates from other sources were termed pleuropneumonialike organisms. Members of the class Mollicutes (Latin: *mollis*, soft; *cutis*, skin), they are characterized by the absence of a cell wall and are, therefore, refractory to treatment with ß-lactam class antibiotics. All mycoplasmas require lipids and lipid precursors for plasma membrane synthesis.

Like viruses, they pass through filters that retain bacteria but, except for cell wall, possess all other cellular constituents of bacteria. Unlike cell wall-deficient bacteria (L forms), they fail to revert to bacteria when cultured under appropriate conditions.

Microbiology and Taxonomy

Despite superficial cultural similarities, the mycoplasmas comprise a heterogenous group of microorganisms differing from each other in DNA composition, metabolic reactions, nutritional requirements, antigenic composition, and host species specificity. The differentiating characteristics of the various human mycoplasmas are outlined in Table 53.3. They are divided into three taxonomic families: The Mycoplasmataceae and Spiroplasmataceae (both requiring cholesterol for growth), and the non–cholesterol-dependent Acholeplasmataceae. Included in the family Mycoplasmataceae are the *Mycoplasma* species, which do not hydrolyze urea, and the genus *Ureaplasma*, strains of which produce abundant quantities of urease.

TABLE 53.3. CHARACTERISTICS OF HUMAN MYCOPLASMAS

Species	Frequency of Isolation	Usual Site of Isolation	Nature of Disease	Metabolic Activity			Optimum pH	Growth-Enhanced in Gaseous Environment			Days to Detection of Colonial Growth
				Arginine	Urea	Glucose		Aerobic	Anaerobic	CO_2	
M. orale	Frequent	Oropharynx	Unknown	+	0	0	7.0	+	+ +	LD[a]	3–10
M. salivarium	Frequent	Oropharynx	Unknown	+	0	0	6.0–7.0	+	+ +	+	2–5
M. buccale	Rare	Oropharynx	Unknown	+	0	0	7.0	+	+ +	LD	3–10
M. faucium	Rare	Oropharynx	Unknown	+	0	0	7.0	+	+ +	LD	3–10
M. lipophilium	Rare	Oropharynx	Unknown	+	0	0	7.3	LD	LD	LD	LD
Acholeplasma laidlawii	Extremely rare	Oropharynx	Unknown	0	0	+	6.0–8.0	+ +	+ +	+ +	1–5
M. fermantans	Infrequent	Genitourinary tract	Unknown	+	0	+	7.3	+	+ +	LD	3–20
M. primatum	Rare	Genitourinary tract	Unknown	+	0	0	LD	LD	LD	LD	LD
M. genitalium	Rare	Genitourinary tract	Nongonococcal urethritis	0	0	+	7.3	LD	0	+ +	Slow
M. hominis	Frequent	Genitourinary tract	Septicemia, abscesses, arthritis, endometritis, other reproductive disorders	+	0	0	5.5–8.0	+ +	+ +	+ +	1–4
Ureaplasma urealyticum	Frequent	Genitourinary tract	Nongonococcal urethritis, arthritis, other reproductive disorders	0	+	0	5.5–6.5	+ +	+ +	+ +	1–4
M. pneumoniae	Frequent	Oropharnyx, respiratory tract	Tracheobronchitis, pneumonia	0	0	+	6.5–7.5	+ +	0	+ +	3–20

There are 51 recognized species in the genus *Mycoplasma* and two, *Ureaplasma urealyticum* and *Ureaplasma diversum*, in the genus *Ureaplasma*. Ten Mycoplasma species have been detected in the clinical laboratory. *Mycoplasma pneumoniae* is the cause of primary atypical pneumonia. *Mycoplasma salivarium* and *Mycoplasma orale* are common inhabitants of the oropharynx, particularly in individuals with poor oral hygiene, whereas *Mycoplasma buccale*, *Mycoplasma faucium*, *Mycoplasma primatum*, and *Mycoplasma lipophilum* are less frequent oropharyngeal colonizers. *Mycoplasma fermentans* is a rare isolate from genital tract and oropharyngeal specimens. *Mycoplasma hominis*, generally considered a genital tract mycoplasma, also can cause infection at other body sites. *Mycoplasma genitalium*, which may cause some cases of nonspecific urethritis, and *U. urealyticum* also are isolated from genital tract specimens. An additional, probably pathogenic, mycoplasma has been identified recently and is tentatively termed *Mycoplasma incognitos* (77).

Mycoplasmas are ubiquitous in nature as saprophytes and/or parasites of plants and animals. *Mycoplasma* species also cause contamination of cell cultures used for research and diagnostic purposes, interfering with their metabolic processes and slowing their rate of growth. The spiroplasmas that infect insects and plants have a helical structure, whereas most other mycoplasmas are spherical. The morphology of individual organisms, however, varies based on differences in growth conditions and the stage of the cell cycle. Some mycoplasmas form branching filaments 0.3 to 0.4 µm in diameter and up to 1,500 µm long, which divide to form new spherical bodies. Most mycoplasmas are facultative anaerobes. Strains isolated from cattle and sheep rumen that grow only under strict anaerobiosis, however, are termed anaeroplasmas. Most mycoplasmas divide by binary fission. The genomes of ureaplasmas and mycoplasmas approximate 500 kd, whereas those of the acholeplasmas and the spiroplasmas are about 1000 kd. The morphology of *M. pneumoniae*,

M. genitalium, *M. pulmonis*, and *M. gallisepticum* is characterized by specialized structures at one or both poles of the organisms. *M. genitalium* and *M. pneumoniae* have a tapered, filamentous tip containing a dense, central rodlike core.

Specialized structures also have been observed in strains of *M. pulmonis*, and pear-shaped polar blebs have been reported in *M. gallisepticum*. These structures may assist the organisms in attachment to the respiratory or genital mucosa, as they usually represent the points of intimate contact by the mycoplasmas with the membranes of the host cells. They also may be involved in locomotion because these four mycoplasmas demonstrate a gliding motility in which the organisms move tip first.

Mycoplasmal cells do not Gram-stain, but may be stained, albeit poorly, with a Giemsa technique. Because of their plasticity, mycoplasmas all have a tendency to grow down into solid media. This may result in the production of colonies with a characteristic "fried egg" appearance (an opaque central zone of growth in the agar surrounded by a translucent peripheral surface zone). These "typical" colonies, however, do not always develop. Colonial morphology is a function of the medium constituents and degree of hydration, and atmospheric conditions. Mycoplasma colonies vary in size from 50 to 600 µm and consequently are best visualized through a clear medium with a dissecting microscope. On primary isolation, colonies of *M. pneumoniae* typically appear mulberrylike without translucent peripheral growth, although larger colonies with the characteristic zone of peripheral growth do sometimes develop. Ureaplasmas usually produce small colonies (15 to 30 µm in diameter), but on media buffered to pH 6.0, colonies up to 300 µm in size often develop. Because of the tiny colonies characteristically produced in culture, ureaplasmas were originally designated T strains or T mycoplasmas.

Mycoplasmas are highly fastidious organisms, requiring enriched media, typically containing peptones, yeast extract (supplying preformed nucleotide precursors), and animal sera (10% to 20%). The serum provides a complex of lipoprotein and cholesterol, which is incorporated into the lipid membrane of sterol-requiring mycoplasmas. Because acholeplasmas synthesize saturated long-chained fatty acids and carotenoids, which substitute for cholesterol in the plasma membrane, they have no need for exogenous cholesterol. Multiplication rates for mycoplasmas are generally lower than those for bacteria, ranging from as short as 1 hour to as long as 6 to 9 hours (*M. pneumoniae*). The microbial yield from broth cultures is low (1 to 20 mg of protein/L). Cells are visualized best in broth culture using phase-contrast or dark-field microscopy. *Mycoplasma* species usually utilize either glucose or arginine as a major energy source, although some strains are capable of using both. The carbohydrate-metabolizing species break down glucose by glycolytic pathways, mainly to lactic acid. In most mycoplasmas, the respiratory pathways are flavin-terminated, and heme compounds, catalase, and cytochromes therefore are absent. Species that metabolize arginine use a three-enzyme system to convert it to ammonia via ornithine, the process providing the organism with ATP. By comparison, the ureaplasmas utilize neither glucose nor arginine, but convert urea to ammonia by means of urease, although their requirement for urea as an energy source has not been proven.

Mycoplasma pneumoniae

Spectrum of Disease

M. pneumoniae (once termed the Eaton agent) is a human pathogen that primarily causes acute respiratory disease including pneumonia. Tracheobronchitis is the most common clinical syndrome resulting from *M. pneumoniae* infection. The organism also accounts for up to 10% of radiographically proven cases of pneumonia. Serious disease is seen principally in older children and young adults, whereas milder disease typically occurs in infants and young children. Although it occurs sporadically in all seasons and in epidemics, lasting months to years, some reports indicate that infection is more common in the fall and winter months. Following exposure, the incubation period to illness is approximately 3 weeks, with the majority of cases occurring within 15 to 25 days. Onset of disease is typically insidious, and constitutional symptoms including headache, fever, and malaise are usually noted 2 to 4 days before disease localization. Pneumonia, pharyngitis, and tracheobronchitis all clearly are caused by infection with this organism. A variety of complications associated with these syndromes also have been described. It has been further suggested that even in the absence of respiratory disease, some cases of otitis media, erythema multiforme and other skin diseases, pericarditis and myocarditis, and neurological disease may result from *M. pneumoniae* infection. Clinical manifestations attributed to *M. pneumoniae* infection are outlined in Table 53.4.

TABLE 53.4. CLINICAL ILLNESS ATTRIBUTED TO *MYCOPLASMA PNEUMONIAE* INFECTION

	Primary illness		Complications	
Definite Causation	**Possible Association**	**Reported Association**	**Definite or Probable Association**	**Reported**
Pneumonia	Otitis media	Arthritis	Pleural effusion	Pleuritis
Tracheobronchitis	Myringitis	Pancreatitis	Atelectasis	Pneumatocele
Bronchiolitis	Erythema multiforme (major and minor)	Fever of unknown origin	Respiratory insufficiency	Lung abscess
Pharingitis			Relapse	Bronchiectasis
Rhinitis	Myocarditis		Sinusitis	Bronchiolitis obliterans
	Pericarditis		Otitis media	Bacterial superinfection
	Meningoencephalitis		Myringitis	Cavitary disease
	Neuritis		Maculopapular rash	Nephritis
	Meningitis		Vesicular rash	Hepatitis
			Urticaria	Pancreatitis
			Erythema nodosum	lgA nephropathy
			Erythema multiforme	Pediatric nephrotic syndrome
			Intravascular erythrocytic hemolysis	Thrombocytopenic purpura
				Pelger-Huet anomaly
			Intravascular coagulation	Hemophagocytosis
			Raynaud's syndrome	Transverse myelitis
			Myocarditis	Leukencephalitis
			Pericarditis	Optic neuritis
			Arthritis	Cerebrovascular accident
			Meningoencephalitis	Hearing loss
			Neuritis	Polymyositis
			Meningitis	Pediatric benign myositis
			Cerebellar ataxia	
			Changes in mentation	

Although in cases of tracheobronchitis, tracheitis with frequent bouts of paroxysmal coughing and substernal pain may be conspicuous, basic bronchitis with frequent cough is more commonly noted. Respiratory illness in infants or older children accompanied by wheezing suggests bronchiolitis. Bronchitic patients tend to have fewer and milder systemic symptoms, a shorter duration of cough and fever, and a lower frequency of high-titered serum cold agglutinins than patients with pneumonia.

Pharyngitis often accompanies lower respiratory tract infection with *M. pneumoniae*, but it may be the predominant symptom in the disease (78). In such cases, symptoms usually are indistinguishable from pharyngitis caused by other bacteria or by viruses. The onset is usually insidious with headache and fever, but sore throat appears early and becomes the chief complaint. Coryza and cough also may be present. The posterior pharynx usually is diffusely erythematous, and tonsillar and pharyngeal exudates may be observed. Tender anterior cervical nodes usually are noted.

Isolation of *M. pneumoniae* from respiratory secretions in such cases does not necessarily establish it as the cause of the pharyngitis. Two studies in children have shown that *M. pneumoniae* may be isolated as frequently from asymptomatic patients as from those with pharyngitis and that a rise in antibody titer only rarely correlates with organism isolation and/or clinical pharyngitis (78, 80).

Rhinitis is reported to be the major clinical finding in children less than 1 year of age with *M. pneumoniae* infection. Isolated cases of bullous myringitis, with associated severe ear pain, may complicate *M. pneumoniae* respiratory tract infection, but the previously held theory that most isolated cases of bullous myringitis are caused by this organism is probably invalid.

Lower respiratory illness caused by *M. pneumoniae*, once called “walking pneumonia,” usually is mild. Hospitalization generally is not required; only about 2% of children and 10% of adults with *M. pneumoniae* illness are admitted to hospitals. Prodromal headache is more common in teenagers and adults than in children. Before cough appears, headache, fever, and malaise increase in severity over a 2- to 4-day period. A cough (nonproductive) then becomes the major manifestation of illness, and its absence makes the diagnosis of *M. pneumoniae* infection unlikely. Diffuse or substernal soreness in the chest that increases on inspiration is common, but pleuritic pain is rare. Mild sore throat, laryngitis, coryza, and earache may be seen. Fever is sustained unless altered by antipyretics, and maximum temperature may reach 104°F, but is typically less than 102°F. Shaking chills are uncommon. Tender anterior cervical nodes are often reported. Muscle tenderness is common, and nausea, vomiting, anorexia, and arthralgias may occur. Skin rash develops in approximately 15% of cases a few days after onset. Usually maculopapular in nature, it also may be vesicular or bullous. Clinically inapparent sinusitis is common.

Although the course of pneumonia is variable, recovery is the rule. Death has been reported, but is rare. In untreated cases, fever lasts from 2 days to 2 weeks. Slow, progressive, symptomatic improvement is typical. Cough, malaise, and radiographic abnormalities frequently persist for 2 to 6 weeks. The most common complications of *M. pneumoniae* infection are pulmonary in nature. Extensive lung involvement with lobar consolidation may result in respiratory insufficiency. In mild cases, significant pleural effusion and transient atelectasis may occur. In patients with sickle cell disease, severe illness with significant pleural effusion is common.

Clinical relapse occurs within 2 to 3 weeks of the initial illness in approximately 10% of all cases and may be accompanied by a radiographically confirmed infiltrate in the lung segment initially involved or in another segment of the same or opposite lung. Residual pleural abnormality and subsequent pneumatocele development, lung abscess, cavitation, bronchiolitis obliterans, secondary bacterial infection, and bronchiectasis all have been reported following pneumonia caused by *M. pneumoniae*, although the role of the organism in these sequelae is unclear. Myringitis may be seen, and secondary bacterial ear infections in children are not uncommon.

Illness caused by *M. pneumoniae* may be complicated by urticaria, erythema nodosum, or more commonly by erythema multiforme or Stevens-Johnson syndrome. Erythema multiforme major may be primarily caused by *M. pneumoniae* and, although a history of preceding illness usually exists, it can occur in the absence of associated respiratory disease. The organism has been cultured from vesicular fluid of these patients. Significant intravascular hemolysis can occur in association with high-titer cold agglutinins, but clinically inapparent hemolysis is probably more common. In patients with clinical hemolysis cold agglutinin titers in excess of 1:500 typically are seen and hemagglutinins also are usually demonstrable at 37°C. Intravascular hemolysis usually occurs late in the illness and may coincide with return of the body temperature to normal. Other occasionally reported hematologic complications include Raynaud's phenomenon and disseminated intravascular coagulation.

Neurological complications of *M. pneumoniae* infection have been reported in up to 10% of hospitalized patients (81, 82). The most commonly described syndromes are meningitis, encephalitis, meningoencephalitis, and mono- or polyneuritis. Less commonly reported complications include cerebrovascular accident, “toxic” psychosis, cerebellar ataxia, transverse myelitis, and

several types of mononeuropathy including cranial nerve palsy, phrenic nerve paralysis, and sudden deafness. *M. pneumoniae* has been reported to be the possible cause of up to 6% to 8% of all cases of aseptic meningitis (83) and many cases of meningitis, neuritis, and meningoencephalitis attributed to *M. pneumoniae* are not associated with antecedent respiratory illness. Although the course of such infections has not been well characterized, residual neurological deficits and death have been described, and *M. pneumoniae* has been isolated from the cerebrospinal fluid (CSF). In cases of meningitis and meningoencephalitis, various types of leukocytic CSF responses have been observed, but mononuclear cells usually predominate. The CSF protein level is usually elevated, and the glucose concentration is normal or low.

Reported cardiac complications range from clinically inapparent changes in electrocardiograms to significant peri- and myocarditis with prominent pericardial effusion. Marked arthralgia is common, but overt arthritis is rare. Other reported complications include juvenile benign myositis, polymyositis, hepatitis, thrombocytopenic purpura, hemophagocytosis, Pelger-Huët abnormalities, pancreatitis, nephritis, IgA nephropathy, and nephrotic syndrome in children (84).

Epidemiology

M. pneumoniae is a cosmopolitan cause of respiratory disease, but epidemics have been best documented in temperate climates. In large urban areas, the organism is endemic, and infection and disease occur year-round. During the summer months, it may cause up to 50% of all pneumonias. Some evidence suggests that epidemics occur at 4- to 8-year intervals both in military and civilian populations and, during such periods, disease is most prevalent in the late summer and early fall months. Typical epidemics start in the fall, are slow in onset, and may persist in the community for as long as 2 years. Infection during epidemic periods is three to five times more frequent than in nonepidemic years, with overt disease being most common in older children and young adults. Smaller outbreaks, however, can be observed at any time. The proportion of all pneumonias attributable to *M. pneumoniae* varies with the population studied. Frequencies have ranged from 4% in an indigent civilian population to 44% in a population of military personnel. In a large community study in Seattle, Washington, approximately 15% of all documented pneumonias were attributed to *M. pneumoniae* (85). This is probably representative of communities throughout the developed world. The relatively mild nature of typical *M. pneumoniae* infection is underscored by the fact that less than 5% of resultant pneumonia cases are severe enough to require hospitalization.

M. pneumoniae infection rates are highest in school-age children and young adults. It is the most common etiologic agent of pneumonia in children 5 to 15 years of age. In the Seattle survey, this organism was responsible for 30% to 60% of all pneumonias in the 5- to 20-year-old age group. Although pneumonia attributable to *M. pneumoniae* is less common in adults, it remains a significant pulmonary pathogen throughout life. In addition, *M. pneumoniae* is reported to be the most common cause of tracheobronchitis and lower respiratory disease, with wheezing in children 5 to 15 years of age (86). Pneumonia appears to be somewhat more common and illness more severe in young males than in young females. Higher infection rates are seen, however, in women 30 to 39 years old than in men of comparable age, probably reflecting increased exposure to school-aged children. Although data are somewhat conflicting, both day care center and family studies have shown that symptomatic *M. pneumoniae* infection is also common in children less than 5 years of age, although the disease is typically mild (87,88 and 89). Despite common complaints of coryza and wheezing, most children with *M. pneumoniae* infection are afebrile.

M. pneumoniae transmission between school-aged children is frequently followed by introduction into and slow but extensive spread within families. The limiting factor determining whether an exposed family member will acquire the organism appears to be immunity resulting from previous infection. Transmission in institutionalized and school populations is generally slow, requiring close contact with an infected individual. Spread between playmates appears to be more efficient than among classmates in a schoolroom setting. High transmission rates also have been observed in college populations and in military recruits where close contact in dormitories and barracks appears to play an important role (90,91,92 and 93). Transmission by individuals with asymptomatic infection has not been documented. Because of the evidently low communicability, the requirement for close contact for efficient transmission, and the relatively long incubation period, the spread of *M. pneumoniae* in the community is slow, and infections appear endemic in nature. Epidemics, however, have occurred, and point-source outbreaks lacking characteristics of prolonged close contact have been reported, implying that small-particle aerosol transmission may occur. Risk of clinical disease from *M. pneumoniae* infection is low among children less than 5 years of age, high for those in the 5 to 20-year-old range, and again, lower among adults over 20 years of age. When it occurs, though, illness usually is more severe in middle-aged and elderly individuals.

Diagnostic Procedures

Specimen Selection/Collection

M. pneumoniae infects the entire respiratory tract and, as a result, may be isolated from throat swabs or washings, nasopharyngeal swabs, tracheal aspirates, lung biopsies, and sputum. Since the organisms attach to epithelial cells of the respiratory mucosa, specimens should contain cellular material for optimal yield. *M. pneumoniae* has, on rare occasions, also been isolated from nonrespiratory sites including blood, CSF, and internal abdominal organs. Because the natural course of infection lasts for 6 to 8 weeks, the collection time is not critical, although specimen collection prior to initiation of antimicrobial therapy should be accomplished whenever possible. Because *M. pneumoniae* is relatively fastidious and very susceptible to drying, direct specimen inoculation onto growth media as soon as possible after acquisition of the specimen is strongly encouraged. Vials of liquid SP-4 medium or trypticase soy broth with 0.5% bovine albumin may be inoculated at the patient's bedside with swab specimens and transported expeditiously to the laboratory at room temperature. Antibiotics, such as penicillin, usually are incorporated in transport media to suppress bacterial overgrowth. Sputum, throat washings and other liquid specimens, and tissue samples can be

transported to the microbiology laboratory in sterile leak-resistant containers, preferably on ice, for processing. If delay in processing (more than 24 hours) is anticipated, specimens should be frozen at -70°C or below. Organisms survive indefinitely under these storage conditions. Likewise, if specimens are to be transported over long distances, shipment on dry ice is recommended. Containers placed on dry ice should be tightly sealed to prevent absorption of CO_2 by specimens. Short-term storage of specimens at -20°C is acceptable, but longer-term storage at this temperature (more than a few weeks), results in loss of *M. pneumoniae* viability. Provided the medium contains protein, mycoplasmas are unique in their ability to withstand repeated episodes of freezing and thawing.

Currently, there are no useful staining techniques for the direct microscopic detection of *M. pneumoniae* in clinical specimens. As a result, laboratory diagnosis of mycoplasmal infection usually depends upon recovery of the organism in culture, detection of its presence using genetic probes, or on the results of serologic assays.

Culture Techniques

Media for the isolation of mycoplasmas usually contain a base of soybean or beef protein supplemented with serum (10% to 20%) as a source of mandatory sterols and yeast extract to provide peptides and other growth factors including preformed nucleic acid precursors. Because *M. pneumoniae* replicates more slowly than most bacteria and many fungi commonly encountered in clinical specimens, antimicrobial agents are generally added to make the media selective, preventing overgrowth by more rapidly growing microorganisms. Exploiting the fact that mycoplasmas lack the cell walls characteristic of most bacteria and therefore are intrinsically resistant to cell-wall active agents, ß-lactam antibiotics such as penicillin and polymyxins (typically active against most Gram-negative species) are commonly employed for the inhibition of contaminating bacteria. Thallium acetate also is used sometimes to inhibit the growth of contaminating bacteria. Because it interferes with the growth of *U. urealyticum* and *M. genitalium*, it should be avoided when attempting to isolate these species. Care should be taken when handling this compound because it is also toxic to humans. Likewise, the addition of antifungal agents such as amphotericin B is useful in preventing overgrowth by contaminating yeasts. Methylene blue also is utilized sometimes as a medium supplement to inhibit other species of mycoplasma.

Because the *Mycoplasmatales* represent a heterogeneous group of organisms, no single medium will provide optimal conditions to accomplish the isolation of all species. A pH of 6.0 is required by *U. urealyticum* for optimal replication, and little growth is observed above pH 7.0. By contrast, most other species grow well in media with a 7.0 pH. *M. pneumoniae* is the most pH-tolerant species, growing in media with a pH range from 5.5 to 8.0. For pH to be monitored visually, inclusion in the medium of a pH indicator, such as phenol red, is recommended. The incubation atmosphere is also an important growth factor. *M. genitalium* and *M. pneumoniae*, both obligate aerobes, are stimulated by atmospheric CO_2. *M. salivarium*, *M. orale*, *M. buccale*, and *M. faucium* grow best under anaerobic conditions and grow poorly on H agar aerobically. *M. fermentans*, *U. urealyticum*, and *M. hominis* appear to be minimally affected by incubation atmosphere.

Quality control testing should be performed on all prepared media to demonstrate that optimal growth of mycoplasmas can be achieved. For this purpose, it is highly recommended that laboratories use recent clinical isolates of all species being sought in culture. Stock strains adapted to culture conditions often grow readily on media that fail to support the growth of organisms from clinical specimens. Artifacts also are a major problem in the detection of mycoplasmas in clinical materials because debris and host cells can resemble fried-egg colonies. It is therefore imperative that all laboratories prove that observed colonies represent transferable entities with specific properties before issuing a report indicating that a mycoplasma has been isolated from a clinical specimen. Some lots of serum induce the formation of pseudocolonies, whorls of magnesium and calcium soap crystals appearing on the surface of agar plates. Although transferable, these crystals can be differentiated from true colonies of mycoplasmas because they fail to produce metabolic products.

To isolate *M. pneumoniae*, a 0.1-mL volume of transport medium in which a swab has been extracted should be simultaneously inoculated onto a solid medium, such as H agar or SP-4 medium, and into a biphasic broth medium. Isolation of the agent is best accomplished from sputum or tracheal aspirate, but nasopharyngeal and oropharyngeal swab specimens also often prove fruitful. Body fluids, sputa, and disrupted tissue specimens should be diluted 1:10 and 1:100 before media inoculation to lower the concentration of inhibitory substances commonly found in tissue samples. Agar plates should be incubated aerobically at 35°C to 37°C in a sealed container and examined for the presence of characteristic colonies with a stereoscopic microscope under oblique light at 20× to 40× total magnification after 2, 10, 15, and 21 days' incubation. This provides the best working distance and resolution for observation of colonies on an agar surface through the bottom of an unopened plate. This technique prevents contamination of the media surface with microorganisms, including mycoplasmas, during the multiple-plate examinations. Biphasic cultures should be observed for a pH decrease as indicated by a color change of the phenol red indicator from red to yellow-green from acid production by *M. pneumoniae* resulting from glucose fermentation. They also should be examined microscopically by viewing the broth through the side of the container for the presence of spherules, fluid medium colonies appearing as early as 5 days after medium inoculation. *M. pneumoniae* does not produce turbidity in liquid media, and cloudy culture medium is usually indicative of bacterial or fungal contamination. Bacterial overgrowth also sometimes will result in an acidic pH change in the medium, but typically within the first couple of days of incubation. A color change resulting from *M. pneumoniae* in the biphasic system tends to occur 1 to 2 days after the appearance of characteristic colonies on agar plates. Both systems require a minimum of 5 days of incubation and sometimes as long as 14 to 21 days for growth detection. Because mycoplasmas grow down into agar media, subculture of colonies to a broth medium is best accomplished by excising the agar around a colony and transferring it to broth. For subculture to an agar medium, colonies are first emulsified in broth and then transferred to a plate. Broth from biphasic systems should be subcultured to solid media after 21 days' incubation, and these cultures should be observed for an additional 21 days. The

majority of positive specimens will yield typical small colonies on agar and spherules in broth as well as cause a detectable pH change within 10 to 12 days. Some strains may require up to 30 days for primary isolation.

Recovery of *M. pneumoniae* in culture has little immediate clinical diagnostic value, because of the length of time required for primary isolation. It is useful, though, for epidemiologic purposes and in outbreaks of infection in settings where close physical contact has occurred between possible patients. The recovery of *M. pneumoniae* in culture, however, is always significant clinically because the organism is never part of the “normal” flora.

Identification Methods

A presumptive positive report for *M. pneumoniae* can be issued if an organism has been recovered that grows slowly on agar, forms spherules in broth, and ferments glucose. With the exception of *U. urealyticum*, which can be identified with special strains, definitive differentiation of species cannot be based on colonial morphology. A potential confounding factor, albeit uncommon, is the isolation of cell wall-deficient bacteria, which, in many cases, resemble mycoplasmas.

Ordinarily forming large fried egglike colonies, these organisms transfer poorly and usually revert to typical bacterial morphologies on ß-lactam-free media. Confirmation is accomplished using a test for hemolysis (94). To perform the hemolysis test, suspect colonies are overlaid with a thin layer of 8% guinea pig red blood cells in saline agar, incubated overnight at 37°C, and examined for clear zones of ß-hemolysis surrounding individual or groups of colonies.

M. pneumoniae can be differentiated from the only other two mycoplasmas isolated from respiratory specimens under recommended culture conditions based on colony size and growth rate. *M. hominis* forms larger colonies and grows more rapidly than *M. pneumoniae*. *Acholeplasma laidlawii*, which hemolyzes guinea pig erythrocytes, also grows more rapidly than *M. pneumoniae* and forms large colonies within several days of subculture. Unequivocal identification of an isolate as *M. pneumoniae* can be accomplished using growth inhibition assays with specific antibody. Aliquots of serial 10-fold dilutions of broth cultures are spread uniformly over H agar plates and allowed to adsorb. Paper discs soaked with specific antisera then are placed on the agar plates which are incubated for 4 to 6 days and examined for zones of growth inhibition.

Serology

There is considerable confusion and disagreement in the literature and among physicians regarding the clinical utility of the serum cold agglutinin assay for the diagnosis of *M. pneumoniae* infection. A simple and inexpensive procedure, it appears to be of some value in serious lower respiratory tract infections, when more specific assays are not available. It is of particular value in hospitalized patients because it is positive early enough in the course of disease to assist the clinician in the choice of appropriate antimicrobial therapy and more frequently is positive in patients seriously ill with *M. pneumoniae* infection. The presence of cold agglutinins, however, is not specific for *M. pneumoniae* infection (95). Serum cold agglutinins at a titer of 1:32 or greater have been reported in 50% to 90% of patients with confirmed *M. pneumoniae* lower pulmonary tract infections. In general, the intensity of the cold agglutinin response directly correlates with the severity of pulmonary involvement. Although elevated cold agglutinin titers have been reported in 18% of cases of adenovirus pneumonia in a military population (96), as a rule, the higher the cold agglutinin titer, the more likely a particular respiratory infection is caused by *M. pneumoniae*. Only a fraction of cold hemagglutinin-positive nonbacterial pneumonias are caused by *M. pneumoniae*, but the majority of infections in patients with titers of 1:128 or higher are caused by this organism.

A useful rapid screening “bedside” test for the presence of serum cold agglutinins may be performed by adding blood to a tube containing an equal volume of an anticoagulant such as sodium citrate. The tube then is placed in ice water (0°C to 4°C) for 15 to 30 seconds, removed, and immediately examined for coarse agglutination by tilting the tube on its side. On warming, the agglutination should disappear and should form again upon recooling. A positive screening test correlates with a standard test result of 1:64 or above. In the standard cold agglutinin test, blood should be allowed to clot at 22°C to 37°C before removal of the serum. The test is then performed by making a serial dilution of the patient's serum, mixing each dilution with a suspension of standardized human group O erythrocytes, and incubating the test overnight at 4°C. IgM-class antibodies directed against *M. pneumoniae* react with the I antigen on the red blood cells membrane at 4°C. Hemagglutination disappears on warming to 37°C. Cold agglutinins appear during the first and second week and disappear by the sixth week of illness. A single titer of 1:128 or higher generally is considered significant. Because cold agglutinins appear in only about half of all patients with proven *M. pneumoniae* infection, a negative result is of little value.

Like many other infectious diseases, the specific serologic diagnosis of illness caused by *M. pneumoniae* can be based on a significant change in IgG antibody titer between timed acute and convalescent serum samples. The acute phase specimen should be collected as early as possible in the illness, and the convalescent sample should be collected 2 to 4 weeks later. The two specimens should be tested concomitantly. Complement fixation (CF), ELISA, and immunofluorescent assays are commonly employed for this purpose. A fourfold increase in antibody titer, demonstrable in 50% to 85% of patients tested with immunofluorescent or CF techniques, is diagnostic of acute *M. pneumoniae* infection. CF antibodies, typically develop during the second and third weeks of illness and persist for 6 to 12 months.

Because CF antibodies often are relatively short-lived, a fourfold decrease in titer can also be helpful in establishing etiologic significance in a specific patient. Although CF titers of 1:256 or higher usually are indicative of recent infection, unequivocal causation of infection with *M. pneumoniae* should not be assumed under such conditions. Infection with *M. pneumoniae* is typically associated with a prolonged incubation time. As a result, antibody development has often already begun at the time of clinical presentation. Fourfold changes in titer can thus occur over a very short period of time (in as few as 5 days), and serum samples collected 5 to 7 days apart will often demonstrate a significant rise in antibody titer. False-positive results, however, have been reported in patients with *M. genitalium* infection, patients with documented bacterial meningitis (97), and in some

cases of acute pancreatitis. Reports based on CF tests that implicate *M. pneumoniae* in various neurological syndromes must, therefore, be interpreted with caution as they may be the result of these cross-reacting antibodies.

Both immunofluorescent and ELISA techniques, comparable in sensitivity and specificity to CF assays, offer the advantage of permitting separate detection of IgG and IgM class antibodies. ELISA techniques using solubilized whole organisms and unfractionated extracts lack sensitivity because the active components are represented in such small quantities in the antigenic mixture that they are undetectable. By comparison, the use of purified adhesion P1 protein in ELISA system appears to offer acceptable levels of sensitivity while increasing the specificity of the test significantly over techniques using whole lysed *M. pneumoniae* organisms.

Interpretation of Diagnostic Test Results

Roentgenographic chest examination typically reveals unilateral infiltrates that appear diffusely reticulonodular or interstitial. Bilateral involvement, however, occurs in about 25% of patients. Although small pleural effusions are noted in approximately one fourth of cases, significant pleural effusion is rare. Peripheral white blood cell counts are typically within normal range, but may be elevated. Leukocyte differentials usually demonstrate 60% to 85% polymorphonuclear leukocytes with occasional bands. Erythrocyte sedimentation rates are typically strikingly elevated. Gram-stained sputum specimens usually reveal large numbers of leukocytes, but no predominant bacterium. Usual upper respiratory flora generally is reported on sputum culture. Standard blood cultures are negative.

In the setting of a compatible clinical syndrome, isolation of *M. pneumoniae* in culture should be considered diagnostic. Because carriage of *M. pneumoniae* often can be demonstrated for 6 to 8 weeks after recovery from illness, the potential for confusion does exist in cases of subsequent but unrelated illness. Under optimal conditions, only 85% of patients demonstrating a four-fold rise in antibody titer to *M. pneumoniae* are typically culture-positive. The precise value of a negative probe or culture, therefore, is not known.

Therapeutic Considerations

M. pneumoniae is susceptible *in vitro* to many broad-spectrum antimicrobial agents including tetracyclines, macrolides, chloramphenicol and the aminoglycosides but are resistant to inhibitors of cell wall syntheseis such as the ß-lactams, because they lack typical bacterial cell walls. Although *in vitro* susceptibility testing of *M. pneumoniae* usually is not performed and standardized procedures for such testing have not been developed, erythromycin-resistant strains have been reported. Untreated, illness caused by *M. pneumoniae* typically resolves in 2 to 3 weeks, but symptoms resolve more rapidly with appropriate antimicrobial therapy. Recommended antibiotics for treatment of pneumonia caused by *M. pneumoniae* in adults are tetracycline and its analogues as well as erythromycin. Tetracyclines must not be given to children or pregnant women. Use of other therapeutic modalities including antitussives, antipyretics, assisted ventilation, and oxygen therapy should be based on assessment of individual patient needs. Because illness is clinically indistinguishable from that caused by any number of viruses, routine treatment of individuals with pharyngitis and tracheobronchitis is not recommended unless a specific diagnosis has been made based on laboratory findings. If, however, prolonged illness is observed and *M. pneumoniae* has been established as the etiologic agent, either tetracycline or erythromycin therapy may be indicated. Because antibiotic-treated individuals continue to harbor organisms in the posterior pharynx for up to 2 to 3 months, antimicrobial therapy does not appear to decrease transmission rates to close contacts.

No method has proven uniformly effective in preventing infection and disease with *M. pneumoniae*. As a result, patients probably should be isolated, and attempts should be made in home settings to discourage close contact with infected individuals.

Mycoplasma hominis and Ureaplasma urealyticum

Spectrum of Disease

Mycoplasma hominis

M. hominis colonizes the genitourinary tract (20% to 40% of women and a smaller percentage of adult males) and, occasionally, the oropharynx. It has, however, been reported in infections following facial and transpharyngeal oral surgery (98) and in cases of exudative pharyngitis (99,100 and 101). In addition, it has been isolated sometimes in pure culture, from the upper urinary tract of patients with acute pyelonephritis. In many such infections, antibody to *M. hominis* has been demonstrable in both urine and serum. Data from several studies suggest that the organism is an infrequent cause of acute pyelonephritis and acute exacerbations of chronic pyelonephritis. Likewise, *M. hominis* is frequently recovered, when appropriate culture procedures are utilized, from tubo-ovarian and pelvic abscesses as well as from inflamed fallopian tubes. In both Swedish and British studies (102), the organism was isolated directly from the fallopian tubes of approximately 10% of women with acute salpingitis using laparoscopic techniques to collect specimens. In these studies, antibody was detectable in the serum of approximately 50% of patients with salpingitis compared to 10% of healthy women. Seroconversion also was demonstrable in approximately one half of women from whom *M. hominis* was isolated from the lower genital tract. Other studies, however, have reported that women with gonococcal pelvic inflammatory disease were not more likely to demonstrate detectable serum antibodies to *M. hominis* than those without *N. gonorrhoeae*, suggesting that damage caused by other agents may be important in such antibody responses, thereby obfuscating the true importance of *M. hominis* in this disease.

M. hominis also is commonly seen in association with postpartum fever. It can be isolated from the blood of approximately 10% of febrile women following abortion but not from nonfebrile postabortal women or following normal pregnancies. Rises in antibody titer are demonstrable in approximately 50% of febrile women following abortion, whereas only a small fraction of women without fever show detectable antibody to *M.*

hominis. Bloodstream infection with *M. hominis* typically is a transient and often asymptomatic sequela of uncomplicated vaginal delivery. Immediately postparturition, *M. hominis* can be recovered for a short period of time from the blood, but in less than 10% of women tested. This compares to women with postpartum fever in whom the agent reportedly has been isolated more than 24 hours after delivery in many cases and in whom a rise in antibody titer has been demonstrated. Presumably, *M. hominis* induces postpartum fever by causing endometritis. Typically, such patients have low-grade fever for 24 to 48 hours after delivery, show minimal symptoms, and recover uneventfully without antimicrobial therapy.

Although isolated from up to 30% of patients with nongonococcal urethritis, results of several studies have failed to incriminate *M. hominis* as a cause of this disease. Some hypogammaglobulinemic patients have, however, developed a chronic urethrocystitis, which, failing to isolate other potential etiologic agents, is apparently caused by persistent ureaplasmal or *M. hominis* infection. Less frequently, *M. hominis* causes extragenital infections including meningitis, brain abscess, septicemia, and arthritis. *M. hominis* has been isolated from the synovial fluid of hypogammaglobulinemic patients with nonbacterial septic arthritis and should be considered as a potential etiologic agent of arthritis in these patients. Likewise, *M. hominis* occasionally has been isolated after childbirth from otherwise normal mothers who develop sudden-onset arthritis. Response to tetracyclines and other agents to which mycoplasmas are typically susceptible further supports the belief that *M. hominis* was responsible for this arthritis. Immunosuppression also may predispose an individual to proliferation with *M. hominis* and resultant peritonitis and septicemia have been reported.

Because neonates are also relatively hypogammaglobulinemic, they appear to be at increased risk of infection with *M. hominis*. In one report, *M. hominis* was the sole organism recovered from purulent material collected from a neonate following incision and drainage of several supraclavicular abscesses (103) and in another reported neonatal infection, *M. hominis* was the etiologic agent in a case of submandibular lymphadenitis (104). Likewise, a neonate with severe burns reportedly developed septicemia from *M. hominis*. The organism also has been isolated from amniotic fluid in a case where the infant subsequently died with respiratory distress syndrome (105). An interstitial pneumonia was observed on postmortem examination of lung tissue. *M. hominis* also is clearly the cause of some ocular infections in neonates. Other *M. hominis* infections reported include a scalp abscess complicating placement of an intrapartum monitoring device (106) and a massive pericardial effusion in a newborn (107). In cases of neonatal meningitis and brain abscess when *M. hominis* has been recovered from CSF or abscess material, the neonate probably either became infected *in utero* or became colonized at birth, subsequently developing infection. In cases of *M. hominis* meningitis, CSF examination usually reveals a pleocytosis with a predominance of neutrophils, an increased protein, and a decreased concentration of glucose. Because CSF generally is not cultured for mycoplasmas, *M. hominis* should be considered in the differential diagnosis of cases of culture-negative neonatal CNS infection.

Ureaplasma urealyticum

Recent studies suggest a fairly strong association between *U. urealyticum* and certain reproductive and genitourinary infections, including nongonococcal or nonspecific urethritis, prostatitis, and, in women, acute urethral syndrome. Having been isolated from the epididymis in association with an antibody response, recent studies also indicate that the organism may be a rare cause of acute epididymitis (108). *U. urealyticum* also may play a role in involuntary infertility, habitual spontaneous abortion and stillbirth, low birth weight, and premature delivery associated with silent chorioamnionitis The agent also has been isolated from aspirates of scarred renal tissue in patients with reflux nephropathy (109), but their role in this disease is not known. Current data do not support a role for *U. urealyticum* in cervicitis, vaginitis, postabortal or postpartum fever (although on rare occasions it has been isolated from the blood of women with low-grade postpartum temperature increases), or Bartholin gland abscess.

Nongonococcal urethritis is more common than gonococcal urethritis in most developed nations, and *U. urealyticum* accounts for 20% to 30% of such infections (110). At least two studies have shown that infants colonized with *U. urealyticum* have statistically lower mean birth weights than babies in whom colonization was not detected (111, 112). The association with low birth weight, however, was not related to a shortened gestational period. Although *U. urealyticum* was recovered significantly more often from babies whose placentas demonstrated histologically confirmed chorioamnionitis than from babies whose placentas were read as normal in one study (113), no adverse effects could be attributed to either colonization of the neonates or the placental lesions. The organism has, however, been recovered from fetal tissues following spontaneous abortion. *U. urealyticum* also has been isolated more often from neonates with pneumonia than from asymptomatic controls (21% versus 4%) and from a significant proportion (16%) of infants less than 3 months of age hospitalized with pneumonitis (114, 115). Fatal neonatal pneumonia resulting from an intrauterine infection with *U. urealyticum* also has been reported (116). Like *M. hominis*, in adult patients with hypogammaglobulinemia, *U. urealyticum* has been shown to cause invasive disease (117). *M. hominis* and *U. urealyticum* also have been the sole organisms recovered from the CSF of neonates with meningitis (118, 119) and, in prospective studies, represent the most common microbiological isolates in preterm neonates undergoing lumbar puncture for suspected sepsis or hydrocephalus (120, 121). The significance of these findings, however, is unclear because many such CNS infections resolve without specific antibiotic therapy, and the long-term sequelae following such infections have yet to be determined.

Epidemiology

The major reservoir for both *M. hominis* and *U. urealyticum* is the genital tract of adult women and men. Following puberty, colonization with genital mycoplasmas occurs primarily as a function of sexual contact, and antibodies are first detectable at this time. *U. urealyticum* has been isolated from up to 81% of adult women, while 9% to 50% are culture-positive for *M. hominis* (122).

U. urealyticum is isolated more frequently from the vagina than from the cervix, endometrium, and upper genital tract, whereas *M. hominis* is recovered more often from the cervix than from endometrium or the vagina (123). Although the incidence of colonization is lower in men than in women, from 30% to 50% of sexually active males are colonized with *U. urealyticum* (124). The majority of individuals colonized with these organisms are without associated symptoms. When infection does occur, however, it appears to be caused by a person's endogenous flora. The frequency with which *U. urealyticum* and *M. hominis* are recovered from the cervix and vagina of sexually active women implies that in these body sites they represent part of the usual bacteria flora. These two organisms reportedly have been isolated more frequently from blacks than whites but, because genital mycoplasma colonization also appears to be related to socioeconomic status, the extent to which this reflects differences in susceptibility is not clear. Genital mycoplasmas also tend to be recovered more often from pregnant than nonpregnant women. By comparison, they are isolated significantly less frequently following menopause. These findings suggest that sex hormones may have some influence on colonization with these organisms.

Colonization of infants with genital mycoplasmas generally occurs during passage through the birth canal. As with adults, most neonates have no associated clinical manifestations of infection, although *U. urealyticum* can cause a clinically silent amnionitis which, despite the lack of symptoms, can persist and result in premature delivery (125). Infants delivered vaginally are much more frequently colonized with these agents than babies delivered by cesarean section. *U. urealyticum* has been isolated from at least one body site in 30% to 62% of all infants born to women positive by cervical culture for the agent and, likewise, *M. hominis* can be recovered from 18% to 45% of babies born to women harboring the organism (126, 127). Ureaplasmas have been recovered from genital specimens of approximately one third of infant females. *M. hominis* is isolated somewhat less often from these same specimens. These organisms are recovered significantly less frequently from genital specimens of infant boys. This is probably because of the decreased exposure of their genital mucosal surfaces.

Persistence of neonatal colonization with genital mycoplasmas generally ends by 2 years of age (128), although the organisms occasionally persist to puberty in young girls. In one reported study, up to 20% of prepubertal females remained colonized with *U. urealyticum* and approximately 6% with *M. hominis*. Genital mycoplasmas have only rarely been isolated from prepubertal males outside of the neonatal period. Both organisms are found considerably more often in sexually abused children (129).

Diagnostic Procedures

Specimen Selection/Collection

With appropriate collection and culture techniques, genital mycoplasmas can often be recovered from the urine and from cervical, vaginal, or urethral swabs of asymptomatic individuals. *U. urealyticum* also has been isolated in pure culture from several usually noncolonized sites including (i) the blood of patients with low-grade temperature elevations; (ii) lung tissue of infants with neonatal pneumonia; (iii) prostatic secretions of patients with prostatitis; (iv) the upper urinary tract of patients with renal calculi and upper urinary tract disease; (v) fluid from arthritic joints of hypogammaglobulinemic individuals; and (vi) fetal membranes or tissues. *M. hominis* likewise has been isolated from several normally noncolonized body specimens including the blood of postpartum patients with fever, the CSF of neonates with signs and symptoms of meningitis and sepsis, surgical drainage, mediastinal and abdominal fluids, joint fluid of arthritic persons with hypogammaglobulinemia, bronchoalveolar lavage, throat swabs, abscesses, prostatic secretions, semen, and tissue specimens.

These organisms appear to represent usual flora in the female genital tract. As a result, care must be exercised when collecting samples from internal sites not to contaminate specimens with cervical, vaginal, or urethral secretions. Swabs should be suspended in a suitable transport medium (such as 0.5% albumin in 2 mL of soybean-casein digest broth containing 200 to 400 U.S. units of penicillin per milliliter). Transport media should contain both protein and a peptone to provide maximum protection to the cell wall-deficient mycoplasmas. A transport medium is not required for submission of fetal tissues and membranes, but such specimens should be maintained in a moist environment until culture inoculation can be accomplished. Although swabs with wooden shafts should not be used for specimen collection (plastic and aluminum are acceptable), the tip composition (cotton, rayon, or calcium alginate) does not appear to be a factor in the recovery of these organisms. Ideally, specimens should be transported to the laboratory without delay and inoculated to an appropriate culture system. Specimens may, however, be held up to 24 hours at 4°C without significant loss of organism viability. For longer delays, specimens should be frozen at -70°C.

Urine specimens should be transported to the laboratory on ice (specimen transport devices containing boric acid preservatives are not recommended) and centrifuged at 600× g to sediment epithelial cells and other debris. The pellet from the centrifuged urine specimen should be diluted 1:2 in transport medium prior to culture inoculation. Because urine protein concentrations are typically low, a urine sample submitted for recovery of mycoplasmas should not be frozen unless the specimen pellet is reconstituted with transport media containing a protein supplement. Body fluids, sputa, and tissues should be diluted 1:10 or 1:100 in transport media prior to culture inoculation to remove inhibitory substances. Specimen storage for more than several days at -20°C is not recommended because the organism is known to lose viability at this temperature.

Blood specimens for the isolation of genital mycoplasmas should be collected in a syringe without anticoagulant because *M. hominis* and *U. urealyticum* are inhibited to some degree by these compounds. Blood should be inoculated into an appropriate blood culture medium at the patient's bedside. Because *M. hominis* will replicate in most blood culture systems (but does not alter the appearance of the media), blood for the isolation of this organism can be inoculated directly into routine blood culture bottles, but must be subcultured blindly on a daily basis for 5 days to detect growth of the organism. Alternatively, a medium specifically formulated for isolation of *M. hominis* from blood (28)

may be used. Blood should be diluted at least 1:10 in medium to prevent inhibition by factors normally present in clinical specimens. In automated blood culture systems, the instrument may detect the organism's metabolism and respond with a positive growth signal (130). Although Gram stains of the media will be negative, the organism can be visualized using the acridine orange staining procedure, and the organism can be recovered upon subculture of the broth medium.

Culture Techniques

The four mycoplasmas commonly encountered in genital tract specimens have substantially different growth properties. *M. hominis* and *U. urealyticum*, the two most important clinically, grow rapidly and can be readily isolated. *M. fermentans* and *M. genitalium* are more difficult to detect in culture. Because *M. hominis* tends to overgrow *U. urealyticum* when isolated concomitantly, separate culture systems are required for the recovery of the two organisms. *M. hominis* grows over a pH range from 6 to 8, but *U. urealyticum* fails to grow at a pH greater than 7.0 and multiplies optimally in a pH range from 5.5 to 6.5. As a result, *M. hominis* can replicate in media designed for the isolation of *U. urealyticum*, but the converse is not generally true. *M. hominis* is susceptible to lincomycin, whereas *U. urealyticum* is not. Thus, inclusion of 20 to 50 g/mL of lincomycin in the medium effectively selects for *U. urealyticum*. Erythromycin has likewise been used successfully as a selective agent in media designed to recover *M. hominis*. Two media systems commonly used are U agar and U broth for the isolation of *U. urealyticum* and H agar and H broth for the recovery of *M. hominis*. Because the final pH of both H agar and H broth is greater than 7.0, they effectively select for *M. hominis*. A number of other media have been used successfully for isolation of these organisms (131,132,133 and 134).

Because of the steep death phase resulting from exhaustion of urea and the elevated pH of the medium from urease activity, *U. urealyticum* presents unique problems during isolation attempts. In both broth and solid media it is essential that the culture system be properly buffered and that a sufficient quantity of urea be supplied. After a color change in broth medium, *U. urealyticum* may remain viable for as few as 12 hours, whereas colonies survive for approximately 2 days after detection on solid media. 2-(N-morpholino) ethanesulfonic acid (MES) at a pH of 6.3 is a very effective buffer for this purpose. Molar ratios of buffer to urea for broth cultures are 2:1 to 4:1. In agar, a 10:1 buffer to urea ratio can prevent inhibitory pH increases at the site of colonial growth, preventing resulting loss of organism viability. In broth systems the addition of a reducing agent, such as 1mM sodium sulfite, reduces the lag phase for many strains of *U. urealyticum*. The organism is detected in culture by its production of a readily recognizable pH change resulting from urea hydrolysis.

Of the potentially pathogenic mycoplasmas, *M. hominis* is the least fastidious. In addition to H agar and H broth, nonhemolytic colonies may be observed on many routine blood-containing bacteriologic media. The most productive are those with an enriched base such as Columbia CNA, supplemented anaerobic blood agar, and chocolate agar; growth on standard sheep blood agar is inconsistent. On these media, *M. hominis* grows fastest under conditions of anaerobiosis and somewhat slower under hypercapneic incubation. Colonies are so small that they usually are only detectable when present in large numbers on these media and when plates are carefully examined. The organism may be observed on plates incubated anaerobically after 48 hours; but some isolates may require 72 hours before growth is visible. Growth is typically noted 24 hours later with cultures incubated in 5% CO_2. In either environment, *M. hominis* colonies are approximately 0.05 mm in diameter and may be interpreted as specimen debris or water condensation when plates are examined with the unaided eye. Debris, however, is seldom observed outside of the area of primary inoculation. Strong light assists in plate examination. Colonies may be noted only when media are examined under light at an oblique angle. Plate examination under a dissecting microscope also assists in colony recognition.

Whereas *U. urealyticum* produces no discernible turbidity in broth culture, *M. hominis* can cause a faint, yet distinct haze. For optimal isolation of both organisms, 0.1-mL aliquots of the clinical specimen should be inoculated with a loop or pipette to both agar and broth media. Both U and H agar plates should be streaked for isolation. Plates may be incubated at 35°C to 37°C under aerobic, anaerobic, or hypercapneic conditions. Anaerobic incubation of these media does not appear to increase recovery rates for either *M. hominis* or *U. urealyticum*, but such conditions may discourage the growth of aerobic bacteria and fungi. Strict anaerobic conditions, however, enhance growth of *M. fermentans* and prevent the growth of *M. genitalium*. Care should be exercised to avoid drying of agar plates under all incubation conditions. Aliquots of specimen (0.1 mL) also should be inoculated into H broth and a U diphasic medium system and incubated aerobically. Plates should be examined for growth after 1, 2, 3 and 4 days' incubation with a stereoscopic microscope at 40 to 60× total magnification, with the agar surface viewed through the bottom of the plate to avoid media contamination. Oblique lighting enhances colony visibility. Standard compound microscopes work poorly because of the short working distance of the lenses and poor contrast. The U broth must be examined twice daily to detect a color change indicative of mycoplasmal growth.

Nearly all isolates of both *M. hominis* and *U. urealyticum* will be detected within 5 days of inoculation in broth media. Cultures rapidly decline in viability after peak growth, which occurs prior to any observable pH shift. This complicates choosing an optimal time for subculture. Aliquots from all positive broth cultures should be immediately subcultured to both a fresh U broth and a U agar plate. *U. urealyticum* colonies can be identified using a $CaCl_2$ staining technique (0.1 M $CaCl_2$ and 0.1 M urea) or with the single-reagent test of Shepard (135, 136). Upon addition of a drop of reagent to the plate, colonies of *U. urealyticum* produce a brown halo discernible under transmitted light within 1 to 5 minutes, whereas colonies of *M. hominis* demonstrate no such reaction. Positively staining transferable isolates that hydrolyze urea may be definitively reported as *U. urealyticum*.

M. hominis produces relatively large colonies (200 to 300µm in diameter) on both U and H agars, unless lincomycin is included in the medium as a selective agent. Although most large-colony isolates recovered on H agar are *M. hominis*, bacteria-producing colonies similar to *M. hominis* are sometimes recovered. *M. hominis* can be distinguished from cell-walled bacteria based

on its failure to Gram stain. *M. hominis* colonies recovered on blood-containing media will stain, however, using the traditional Dienes technique. Subculture to a penicillin-containing medium, such as A-7 agar, which inhibits some bacteria, may in some case clarify whether an isolate is indeed a mycoplasma. Large-colony isolates may be presumptively identified as *M. hominis* if they are transferable and utilize arginine (in H broth supplemented with 50 mM arginine). A commercially available arginine broth containing penicillin, erythromycin, polymyxin, and amphotericin (Remel, Lenexa, Kansas) originally formulated for the isolation of *M. hominis* from contaminated urogenital specimens, prevents false-positive reactions that can occur if organisms being tested are arginine-utilizing bacteria other than mycoplasmas. The medium can be inoculated with a few drops of a saline suspension of growth from either the primary or the subculture plates. The inoculum can be prepared by transferring a small block of colony-bearing agar to a tube of saline and vortexing the tube vigorously. Both the inoculated tube and an uninoculated control should be incubated overnight and read for a color change from salmon to red, indicating arginine hydrolysis. A final examination of a Gram-stained smear of positive arginine broths assures that the reaction is not the result of contaminating bacteria.

Colonies may be transferred with an inoculating needle, but an agar block method generally is considered more convenient. With this technique, a small piece of medium bearing the colonies is cut from the agar plate and transferred face down to the medium of choice. The block is then rubbed over the first quadrant of the plate to transfer the colonies, and the remainder of the plate is streaked in a conventional manner using a needle or loop. The inoculated medium is incubated and examined after 24 and 48 hours. Colonies should have the characteristic “fried-egg” appearance commonly associated with mycoplasmas. Upon subculture, colonies are typically larger than on primary isolation media, and, as a result, more easily detectable with the unaided eye. Attempts to isolate *Mycoplasma* and *Ureaplasma* species are, unfortunately, commonly hampered by the presence of confounding artifacts on culture media. Mammalian cellular debris may closely resemble colonies on agar plates. Debris, however, does not transfer.

Serology

Serologic assays for detection of antibodies to either *U. urealyticum* or *M. hominis* have been used in certain research laboratories (137, 138). These tests, however, are not commercially available and, therefore, are rarely useful for clinical diagnosis.

Interpretation of Laboratory Results

Interpretation of the significance of recovery of either *U. urealyticum* or *M. hominis* from a clinical specimen is sometimes difficult. Under most circumstances, isolation of *U. urealyticum* from cervical specimens has little significance because of the high colonization rate in apparently healthy women. Although reported colonization rates with *M. hominis* are somewhat lower, its recovery from cervical specimens must likewise be interpreted with caution. Isolation of either organism from usually sterile cites such as blood, amniotic fluid, fallopian tube, upper urinary tract, and other internal sites has greater significance. Recovery of *U. urealyticum* in large numbers from the urethra of a male with nongonococcal urethritis is probably significant.

Positive culture results should be interpreted only in conjunction with other laboratory results and clinical findings.

Therapeutic Considerations

Mycoplasmas are characteristically susceptible to many broad-spectrum antibiotics including fluoroquinolones, chloramphenicol, tetracycline, and clindamycin. At clinically achievable levels, tetracycline inhibits most strains of *M. hominis* and *U. urealyticum*. By comparison, erythromycin demonstrates only moderate activity against *U. urealyticum* and lacks activity against *M. hominis*. In part because standardized procedures are not currently available, *in vitro* susceptibility testing usually is not performed on clinical isolates of these organisms.

Both *C. trachomatis* and *U. urealyticum* apparently cause NGU. A 100-mg dose of a tetracycline, such as doxycycline, given twice daily for 7 days, represents standard therapy for this syndrome. About 10% of ureaplasmas are resistant to tetracyclines, however, and patients with infections caused by such strains typically fail to respond to treatment with a tetracycline. Most strains of tetracycline-resistant *U. urealyticum* appear to be susceptible to erythromycin.

When cases of prolonged postabortal or postpartum fever are presumed to be caused by *M. hominis*, treatment with a tetracycline should be considered, realizing that tetracycline-resistant strains may be involved. In other more serious illnesses in which *M. hominis* is thought to be responsible, such as arthritis in a hypogammaglobulinemic person and neonatal infections, tetracycline resistance always should be considered.

AIDS-Associated Mycoplasma (Mycoplasma incognitos)

A previously unrecognized pathogenic human mycoplasma tentatively designated *M. incognitos* was first recognized by Lo and coworkers (139). The organism, initially thought to be a large DNA virus, was isolated as the result of an experiment in which purified DNA derived from Kaposi's sarcoma tissues of persons with AIDS was introduced into NIH3T3 cells by transfection. Cells were monitored for transforming foci, and a transformant, designated sb51, was recovered. The agent, which passed through a 0.22 m-pore-size filter, was subsequently shown to infect normal cells. Electron microscopic examination of infected cells demonstrated nearly spherical viruslike particles 140 to 280 nm in diameter. The agent, detected in the cytoplasm, along the cell membrane, and occasionally in the nuclei of infected cells, showed minimal or no cytopathic effect. The small size of the membrane-bound intracellular particles, their capability to result in persistent cell infection, and their ability to transfect susceptible cells resulted in the conclusion that the particles were viral in nature. Southern blot analysis, however, revealed that no cross-hybridization existed with any known virus tested. Ribosomal RNA analysis, using *Escherichia coli* probes, revealed significant homology, suggesting that the VLIA particles were procaryotic in nature. Because the agents were filterable, subsequent testing with DNA from several *Mycoplasma* species was attempted. Results

indicated that the particles were related to mycoplasmas.

Biochemical, antigenic, and DNA analysis demonstrated that *M. incognitos* was distinct from all other recognized human *Mycoplasma* species, but very closely related to *M. fermentans*. The organism can be grown in SP-4, a cell-free medium designed to support the growth of fastidious mycoplasmas. It is also similar to *M. fermentans* in that it utilizes glucose both anaerobically and aerobically, metabolizes arginine, and is susceptible to tetracycline, but resistant to erythromycin (140).

Several differences between the "Lo mycoplasma" and *M. fermentans*, however, do exist and may justify assigning the organism to a new species, *M. incognitos*. The organism is capable of intracellular parasitism, a trait not reported with *M. fermentans*, and individual colonies and particles are smaller than those of *M. fermentans*. It also appears to be somewhat more fastidious than *M. fermentans* and has not been isolated directly from infected human or experimental animal body fluids or tissues. In addition, monoclonal antibodies directed against *M. incognitus* fail to cross-react with *M. fermentans*. Restriction enzyme digests also differ between the two organisms. Finally, the pathogenic properties of *M. incognitos* are quite different from those described for *M. fermentans*.

The Lo mycoplasma was originally detected in peripheral blood mononuclear cells and autopsy tissues of persons with AIDS. The organism since has been visualized in brain, liver, and spleen tissues of infected patients using electron microscopy. Histopathologic tissue examination reveals a variety of results ranging from little change to occasional extensive necrosis, with or without evidence of an inflammatory response. No other known infectious agents were demonstrable in the lesions. Whether *M. incognitos* represents a cofactor, an opportunist, or a primary etiologic agent in the lesions described in these immunocompromised patients remains unclear. The organism is clearly infectious, and is apparently responsible for disease progression in some individuals. In one recent report, six geographically separated, previously healthy non–HIV-positive patients with acute influenza-like symptoms died with fulminant *M. incognitos* infection with multisystem involvement 1 to 7 weeks after onset of illness. The organism was found extracellularly and intracellularly in necrotizing lesions of spleen, lung, liver, and adrenal gland tissues in all six patients, as demonstrated by electron microscopic, immunoserologic, *in situ* hybridization, and polymerase chain reaction (PCR) techniques. No other potential infectious agents were demonstrable.

Monoclonal antibodies directed against epitopes of *M. incognitos* also have been used to immunohistochemically demonstrate the organism in liver, spleen, lymph node, thymus, or brain in 22 patients with AIDS, as well as in two placentas delivered by patients with AIDS. A 33S-labeled DNA probe specific for *M. incognitos* and an *in situ* hybridization technique also have detected *M. incognitos*-specific genetic material in these tissues. Likewise, ultrastructural analysis of the specific areas of tissue highly positive for *M. incognitos* antigens has revealed characteristic organisms both intracellulary and extracellularly. The organism is, therefore, apparently cytopathic and cytocidal. *M. incognitos* also has been shown to cause fatal systemic infection in experimental silver leaf monkeys. Experimentally infected animals showed only a transient immune response and developed wasting syndromes, resulting in death within 7 to 9 months. Progressive weight loss, tissue necrosis, and a minimal inflammatory cellular and antibody response were noted in all infected animals. The organism was found in the nuclei and the cytoplasm of infected tissues in the absence of other possible etiologic agents. The organism apparently has little specific tissue tropism.

Neither the prevalence nor the significance of *M. incognitos* in human disease is known. The organism appears to be invasive in some immunocompromised patients and capable of inducing immunosuppression in previously healthy persons. The functional deficit of various organ systems, in the absence of other etiologic agents, is apparently associated with cryptic infection with *M. incognitos*, therein the proposed species name. The high prevalance of *M. incognitos* infection in persons with AIDS has led to conjecture that it plays a significant disease-promoting role in HIV-infected individuals. Independently, French investigators have reported that tetracycline analogs inhibit the cytopathic effects of HIV in T-lymphoblastoid tumor cell lines without suppression of virus production (141). Consistent with this theory, *M. incognitos* infection has been shown to accentuate the cytocidal effects of HIV in CD4-positive human cell lines (142). Because the Lo mycoplasma is potentially susceptible to antimicrobial therapy, this possibility warrants in-depth investigation. *In vitro*, ciprofloxacin appears to be the most active antibiotic against *M. incognitos*. Carefully controlled and matched clinical trials in appropriate persons with AIDS using antibiotics to which the Lo mycoplasma is highly susceptible *in vitro* should help to clarify this issue.

The suggestion that a procaryotic cell can be generated by transfection of a eucaryotic cell is highly controversial. Other plausible explanations exist for this reported finding, including contamination of the cell line with the Lo mycoplasma during laboratory manipulations or introduction of the organism from an unidentified source during routine passage of the cells in culture or during early transfection cycles. Alternatively, *M. incognitos* may have been present in the Kaposi's sarcoma cells that served as the source of transfecting DNA. This process would involve the transcription and translation of the entire *M. incognitos* genome (approximately 500 megadaltons) by the genetic apparatus of a eucaryotic cell and the final assembly of a functional procaryotic cell. Although highly unlikely, further research is likewise justified to investigate this possibility.

RICKETTSIA

Part of "53 - Chlamydia, Mycoplasma, and Rickettsia"

Agents of rickettsial disease were originally grouped together based on the concept that arthropods are an important part of the organisms' life cycle and in part based on the presumed obligate intracellular associations of these agents. Thorough studies of these organisms were greatly hindered because most were difficult or impossible to cultivate; therefore, classification based strictly on this schema is flawed. The advent of molecular taxonomic classification has confirmed a close genetic and phenotypic relationship between some of the genera (*Rickettsia* and *Ehrlichia*) and proved that convergent evolution has yielded characteristics that led to the inclusion of other more diverse genetic and phenotypic genera and species such as *Coxiella* and *Rochalimaea* (now reclassified as *Bartonella*) (143). The species previously known as *Rickettsia tsutsugamushi* has been determined significantly divergent to be classified into a new genus, *Orientia* (144). In general, four genera are now considered to include important human pathogens in the family Rickettsiaceae: *Rickettsia*, *Orientia*, *Ehrlichia*, and *Coxiella*. *Bartonellaceae* remain a separate family in the order Rickettsiales.

The members of these genera are true bacteria that contain DNA and RNA and divide by binary fission. By ultrastructure, these bacteria have gram negative-type cells walls, and when examined by light microscopy they appear as small gram-negative intracellular bacteria. Aside from *Bartonella* spp., none have been successfully cultivated on artificial, cell-free medium; cultivation in tissue culture has been accomplished for many of these species. Members of the genus *Rickettsia* and *Orientia* live in the cytoplasm of the host cell, those in the genera *Ehrlichia* and *Coxiella* live in membrane-bound vacuoles, whereas *Bartonella* spp. may reside in either extracellular or intracellular niches depending upon the host. Ehrlichiae grow to form a cytoplasmic aggregate of bacteria called a morula. Conversely, *C. burnetii* actively proliferates within the acidified phagolysosome to form aggregates containing in excess of 100 bacteria.

Rickettsia species contain lipopolysaccharide (LPS) as in other related Gram-negative bacteria, and some epitopes in this LPS convey group and genus serologic cross-reactivity. *O. tsutsugamushi* lacks both LPS and peptidoglycan in its cell wall, and *Ehrlichia* species have no detectable LPS, but apparently do contain peptidoglycan in their cell walls (145, 146). *C. burnetii* undergo an LPS "phase variation" similar to that described for smooth and rough strains of the Enterobacteriaceae. Immunoblot analysis and gene cloning has demonstrated the presence of highly conserved proteins as well as species- or genus-specific proteins among genetically related species. Evidence is now accumulating to suggest that some of the major outer membrane proteins of *Rickettsia*, *Ehrlichia*, *Coxiella*, and *Bartonella* species function as cellular ligands to promote host cell attachment and invasion, while others serve as structural components (147,148 and 149). Owing to the inability to achieve gene deletion and supplementation for some of these species, definite virulence factors with proven in vivo significance have yet to be identified.

Rickettsial diseases of humans are separated into groups on the basis of clinical characteristics, etiologic agent, insect vectors, and epidemiology, including geographic distributions (Table 53.5). With the exception of *C. burnetii* and possibly some *Bartonella* spp., rickettsiae usually are transmitted among mammalian reservoirs by arthropod vectors. Humans are not an essential link in their natural cycle but become chance hosts when they are bitten by an infected vector, scratch or rub infectious arthropod feces into the skin, inhale or ingest the organism, or have the infectious agent inoculated into the skin via cat scratch or bite. The presence of indigenous reservoirs and vectors, plus the continuous possibility that new strains of rickettsiae may be introduced from other parts of the world, make the threat of new outbreaks and continued low prevalence, high morbidity infections in the United States a continuing concern.

TABLE 53.5. SUMMARY OF FEATURES IN HUMAN RICKETTSIAL DISEASES

Disease	Agent	Arthropod Vector-Transmission	Hosts	Diagnostic Tests[a]
Spotted fever				
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Tick bite	Dogs, rodents	IFA, DFA, IH

Carrion's disease and Oroya fever	*B. bacilliformis*	Sandflies	?Humans	Culture, Wright or Giemsa-stained blood smear

DFA or IH test can be used to detect *Rickettsia* in tissues samples. PCR may be performed to detect *Ehrlichia, Coxiella*, or *Bartonella* nucleic acids in acute-phase blood using specific oligonucleotide primers. The preferred confirmatory serologic tests are IFA or ELISA (where available). Cultivation of *Bartonella* may be accomplished in a BHL2 laboratory, whereas cultivation of other rickettsiae should be attempted only in specialized BHL3 health laboratories.

Although grouped together under the name "rickettsial diseases," the pathogenetic mechanisms of each of the various genera in the family Rickettsiaceae are different. Members of the genus *Rickettsia* are vasculotropic and infect endothelial cells, whereas both ehrlichiae and *Coxiella burnetii* reside within phagocytes, which accounts for some of the clinicopathologic differences encountered. Although patients with human monocytic and granulocytic ehrlichiosis often present with an illness similar to the vasculotropic rickettsioses, the pathogenesis is clearly different because endothelial cell infection and vasculitis are rare events. In contrast to these rickettsial infections, humans acquire *C. burnetii* predominantly after inhalation of infectious aerosols.

Rickettsiae, ehrlichiae, and *Coxiella burnetii* have been cultivated in tissue culture cells; a specific diagnosis may be rendered within as few as 48 hr. for RMSF and Q fever. Culture for *E. chaffeensis* may take up to 1 month to achieve, while culture for the HGE agent usually is more rapid. *Bartonella* species are fastidious but can be cultivated by prolonged routine axenic culture. Some consider rickettsial cultivation hazardous; however, given the widespread application of standard precautions, such methods should be reconsidered for early and specific identification of rickettsial infections.

Spotted Fever Group Rickettsioses

Rickettsia rickettsii

Rocky Mountain spotted fever (RMSF) is the most frequent rickettsial disease in the United States. Systemic endothelial cell infection by the obligate intracellular bacterium *Rickettsia rickettsii* leads to disease after proliferation of the rickettsia within the cytoplasm of endothelial cells, vasculitis, microvascular leakage, tissue hypoperfusion, and end-organ damage (150). This potentially rapidly fatal infection is infrequently diagnosed, but often is considered in the differential diagnosis of patients after tick exposure who present with fever, headache, and rash.

Epidemiology

RMSF occurs in almost every state of the continental United States, southwestern Canada, Mexico, Central America, and South America. However, most cases are diagnosed in North Carolina, Georgia, Virginia, Tennessee, Oklahoma, and Maryland. Despite this, the geographic prevalence varies over years and decades potentially influenced by changes in ecology of tick vectors and climate. RMSF incidence varies cyclically over decades peaking last in 1981 with the last nadir in 1996. Since 1996, the incidence of RMSF has risen, suggesting yet another peak of cases and attendant fatalities within the next decade. Despite the name, only a small proportion of all cases occur in the Rocky Mountain regions. Habitats that favor activity of *Dermacentor variabilis* (American dog tick, in the Eastern United States and Canada) or *Dermacentor andersoni* (wood tick in the Western United States), including wooded areas or coastal grassland and salt marshes are where the highest incidence rates are documented. However, well documented foci of infection are observed in both rural and urban settings, including the South Bronx (151). Most cases in the United States occur during April through October with peak tick activity and human exposure. The incidence of disease is highest in children 5 to 9 years of age. Ticks are the natural hosts, reservoirs, and vectors of *R. rickettsii*. Ticks naturally maintain infection by transovarial transmission (passage of the organism from infected ticks to their progeny),

but natural maintenance also requires transient infection of small and medium size animals from which uninfected tick lines derive infection (152). Humans are infected only accidentally and are generally considered dead-end hosts. Rarely, RMSF is acquired by inhalation of infectious aerosols in laboratory workers propagating the infectious agent; only one case of transfusion-transmitted RMSF has been documented (153).

Pathology and Clinical Manifestations

Vasculitis results after infection of endothelial cells and direct rickettsia-mediated cellular injury (150). Perivascular lymphohistiocytic infiltrates and edema without significant endothelial damage are the first findings and coincide with the appearance of macules and maculopapules. The characteristic lymphohistiocytic or leukocytoclastic vasculitis of small venules and capillaries (Fig. 53.4) leads to erythrocyte extravasation and skin petechiae (154), but also the more serious consequences of widespread vascular leakage, hypoperfusion and ischemic injury of organs. Rarely, vessels become completely thrombosed and cause infarction or hemorrhagic necrosis of organs, digits, or extremities. The most significant complications of RMSF result from microvascular leakage leading to noncardiogenic pulmonary edema or cerebral edema after meningoencephalitis (150).

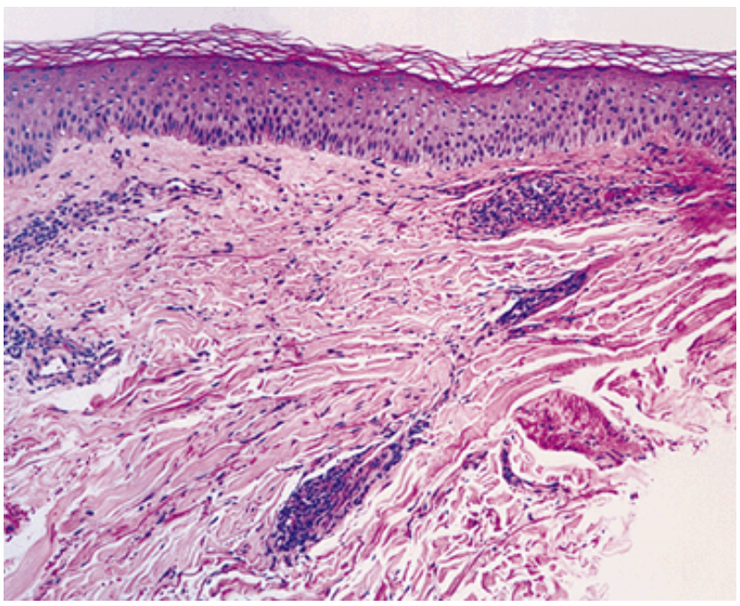

FIGURE 53.4. Cutaneous histopathologic changes in Rocky Mountain spotted fever. The skin biopsy, obtained from a petechial lesion, demonstrates superficial and mid-dermal lymphohistiocytic and leukocytoclastic vasculitis. H&E, original magnification 400×.

After the infectious agent is inoculated via tick bite into the dermis, the rickettsiae attach to endothelial cells via rickettsial

protein adhesins (147). Rickettsial phospholipase activity initiates focal host cell membrane injury that induces phagocytosis for repair (155). The engulfed rickettsia then gains access to the cytoplasm by continued membrane lysis. *R. rickettsii* initiates directional movement via intracellular actin polymerization allowing easy invasion of neighboring cells (156). While proliferating, the rickettsiae damage host cell membranes by peroxidative reactions and continued phospholipase activity (155, 157). Infection initiates an inflammatory cascade with cytokine release, including tumor necrosis factor-α (TNF-α), interleukin-1ß (IL-1ß), and interferon gamma (IFN-γ) from recruited mononuclear phagocytes and lymphocytes and from infected endothelial cells (158). Although these inflammatory and immune responses have been suspected to contribute to vascular injury, the beneficial effects of inflammation and immunity outweigh inflammatory damage since depletion of TNF-α and IFN-γ in animal models diminishes survival and increases morbidity (159). The *Rickettsia*-mediated injury associated with upregulated procoagulant activity on infected endothelial cells may promote platelet adhesion, leukocyte emigration, and coagulation factor consumption, a clinical syndrome similar to but distinct from disseminated intravascular coagulation (160).

After a median incubation period of 7 days (range 2 to 14 days), an initially nonspecific illness with headache, fever, and anorexia ensues. Symptoms that reflect gastrointestinal involvement, such as nausea, vomiting, diarrhea, or abdominal pain occur often early in the disease. The skin rash is observed usually after 3 days of illness, but the typical clinical triad of headache, fever, and rash is absent in 97% of all patients at first presentation (161). Approximately 10% of patients, predominantly adults, lack or have an atypical rash. The rash may spread rapidly over the entire body, including soles and palms, and may later become petechial. Severe myalgia and malaise may accompany the persistent fever and headache. Meningoencephalitis may lead to changes in sensorium, delirium, or coma. Additional central nervous system involvement is manifested by ataxia, meningismus, or auditory deficits. Other severe complications may include pneumonitis with noncardiogenic pulmonary edema, myocarditis, acute renal failure, and vascular collapse. Clinical findings associated with death include hepatomegaly, jaundice, stupor, acute renal failure, respiratory distress, and a disseminated intravascular coagulation-like syndrome (161, 162).

Thrombocytopenia, minimal leukopenia or the lack of leukocytosis with a marked left shift in a severely febrile patient, and hyponatremia are observed in about 50% of patients and may facilitate early consideration of the diagnosis. Most other laboratory findings are unhelpful and vary only with involvement of specific organs. The CSF in RMSF meningoencephalitis usually is characterized by a mononuclear cell pleocytosis.

Delayed diagnosis and treatment are important reasons for the high case fatality (2% to 7%) and morbidity rates of RMSF (163). Thus, the diagnosis of RMSF initially must be based upon clinical suspicion so that early therapy can be initiated in suspected cases. Prompt therapy in uncomplicated infections leads to defervescence within 1 to 3 days and recovery within 7 to 10 days.

Diagnostic Procedures

No laboratory test definitively establishes an early diagnosis of RMSF. Therefore, treatment should not be withheld while awaiting *R. rickettsii*-specific laboratory tests. With the availability of skin biopsy of a typical rash lesion in 85% of patients, RMSF can be diagnosed as early as day 3 to 4 of illness by demonstrating spotted fever group rickettsial antigens within endothelial cells using immunofluorescence or immunoenzymatic methods (Fig. 53.5) (164, 165). The sensitivity of these methods is not greater than 70% and is diminished with prior antimicrobial therapy, biopsy of suboptimal lesions, or limited tissue examination owing to the focality of infection. Evaluation of blood for *R. rickettsii* nucleic acids by PCR has been disappointing because of the very low levels of rickettsemia in most patients (166). Most diagnoses are established in convalescence by demonstration of a fourfold or greater rise in antibody titer by

indirect fluorescent antibody (IFA) assay; a single elevated convalescent IFA titer ≥ 64 supports the diagnosis in a clinically compatible case (167). Antibodies usually do not develop before day 10; thus, serologic tests in the active phase of infection will be unhelpful. A variety of older, less frequently used serologic tests have been described, but are rarely used and do not merit further discussion. Commercially available ELISA and solid-phase immunoassays have shown promise for objective, sensitive, and specific serologic confirmation (168). Weil-Felix testing should not be performed because of the lack of both sensitivity and specificity.

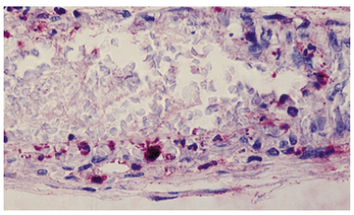

FIGURE 53.5. Immunoperoxidase demonstration of *Rickettsia rickettsii* in a large dermal vessel from a patient with Rocky Mountain spotted fever. Note the presence of small red-stained coccobacilli within endothelial cells and a background of lymphocytes and histiocytes infiltrating the vessel wall. Immunoperoxidase, original magnification 630×.

Therapy and Prevention

Effective therapy for RMSF requires either a tetracycline antibiotic or chloramphenicol. Alternatives such as fluoroquinolones or new the macrolides have not been evaluated and other broad-spectrum antibiotics such as ß-lactams or aminoglycosides are not effective. A high degree of morbidity and mortality are associated with sulfonamide use. Because both the tetracyclines and chloramphenicol are rickettsiostatic, recovery depends upon induction of appropriate immune responses. As a result, prophylactic therapy of tick bites to prevent RMSF will only serve to delay the onset and confound diagnosis. Because vaccines are not available, prevention relies on eliminating tick infestations of dogs, avoiding tick-habitats, the use of insect repellents and special protective clothing, and careful inspection of body surfaces after tick exposures.

Other Spotted Fever Rickettsioses

There are many human pathogens among the spotted fever group aside from *R. rickettsii*, including *R. conorii* (Boutonneuse fever), *R. sibericus* (North Asian tick typhus), *R. japonica* (Oriental spotted fever), *R. australis* (Queensland tick typhus), *R. honei* (Flinders Island spotted fever), the unnamed Israeli spotted fever rickettsia, and *R. africae* (African tick bite fever). As opposed to tick transmission for most members of the spotted fever group, *R. akari*, which causes rickettsialpox, is transmitted by mite bites. Boutonneuse fever (Mediterranean spotted fever, Kenya tick typhus, or Indian tick typhus), caused by *R. conorii*, occurs in much of southern Europe, south western and central Asia, the middle East, Morocco, Ethiopia, Kenya, and South Africa. The illnesses caused by other spotted fever group rickettsiae are distributed regionally and cause clinically similar infections with occasional characteristic features (169). *R. sibericus* occurs mostly in Russia, China, Mongolia, and Pakistan, *R. australis* or *R. honei* occur in Australia, *R. japonica* in Japan, and *R. africae* is found in South Africa. By antigenic and genetic analyses, these species are closely related to *R. rickettsii*. The recently described *R. felis* that is transmitted by cat fleas (*Ctenocephalides felis*) in the Southern United States, Mexico, and potentially Central America and causes a murine typhuslike illness, has attributes most like a spotted fever group rickettsia as well (170, 171).

Boutonneuse fever has been steadily increasing in incidence in southern Europe since 1980. The seroprevalence may be as high as 11% to 26% in some regions (172). *R. conorii* is transmitted by *Rhipicephalus sanguineus*, the brown dog tick, or by *Dermacentor*, *Haemaphysalis*, *Amblyomma*, *Hyalomma*, or *Ixodes* spp. ticks. As for RMSF, incidence is highest in summer months in the Mediterranean basin, but may occur at any time in warm regions with year-round tick activity. Imported infections are frequent in travelers to endemic regions, particularly those with recent exposures via safaris and bush land (173).

R. akari, the causative agent of rickettsialpox, is transmitted by *Allodermanyssus sanguineus*, the mouse mite. Despite the mouse host's wide distribution in urban environments, the disease is infrequently diagnosed (174). Recent investigations suggest that a major target of infection in humans may be macrophages as well as endothelial cells (175).

Pathology and Clinical Manifestations

Fever, headache, myalgias, and a maculopapular rash with onset 3 to 5 days after symptoms typically are observed with Boutonneuse fever (169). An eschar (*tache noire*) at the initial site of tick attachment and regional lymphadenopathy will be detected in about 70% of patients. The clinical illness is severe and similar to RMSF in up to 6% of infected individuals and death occurs in 1.4% to 5.6%. Severe manifestations include purpura, neurologic involvement, respiratory insufficiency, acute renal failure, and severe thrombocytopenia. A particularly malignant form occasionally is observed in glucose-6-phosphate dehydrogenase deficient patients and in individuals with alcoholic liver disease or diabetes mellitus. Most spotted fever group rickettsioses present with similar manifestations and laboratory findings; an eschar is present in many at the site of initial tick bite. A form of spotted fever that occurs in Israel has a more severe course including pediatric fatalities (176). It is important to recognize that diagnosis should be rendered based upon the clinical presentation, but since some patients do not recall a tick bite, and others do not have rash or an eschar, initial diagnosis may be very difficult.

Rickettsialpox, caused by *R. akari* infection, usually is mild and often recognized when a varicelliform rash is observed. Most patients with rickettsialpox experience a typical macular or maculopapular rash as seen in other rickettsioses prior to the appearance of vesicles associated with fever, headache, and chills (174). Spontaneous resolution even in the absence of antirickettsial therapy is the norm and complications are rare.

Laboratory confirmation of other spotted fever group rickettsioses is similar to that for RMSF and is achieved with immunohistologic studies that demonstrate spotted fever group rickettsiae in skin biopsies (Fig. 53.6 and Fig. 53.7) or in circulating endothelial cells (177), *in vitro* cultivation in shell vial tissue culture (178), and most often by the serologic studies that demonstrate a four-fold increase in spotted fever group antibodies during convalescence. Fortunately, many reagents used for RMSF diagnosis can be used for diagnosis of most spotted fever group infections. Therapy and prevention are similar to that for RMSF and also may include the use of fluoroquinolone antibiotics.

Typhus Group Rickettsioses

Rickettsia typhi

The causative agent of murine typhus is *Rickettsia typhi*, a rickettsia in the typhus group transmitted to man by fleas (179). The

rickettsia is not maintained in the flea by transovarial transmission; thus, flea to rat (or opossum) to flea (vertical transmission) is an important mechanism for natural maintenance. The new rickettsia, *Rickettsia felis*, that is genetically related to *R. typhi* and *R. rickettsii*, has been identified in south Texas and Mexico; it is maintained by transovarial transmission in cat fleas (*Ctenocephalides felis*) (180). Humans are accidentally infected when rickettsia-infected flea feces contaminate flea-bite wounds.

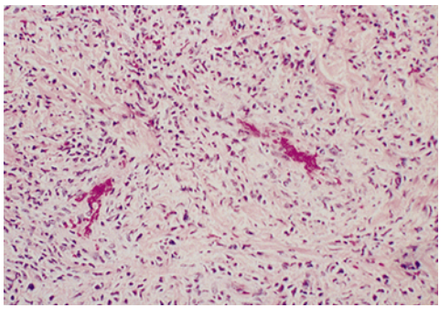

FIGURE 53.6. *Tache noire* (*eschar*) of Boutonneuse fever (*Rickettsia conorii*) acquired by a patient who traveled to Africa. Note the lymphohistiocytic infiltrate, marked edema, fibrin deposition, and vascular injury. H&E, original magnification 400×.

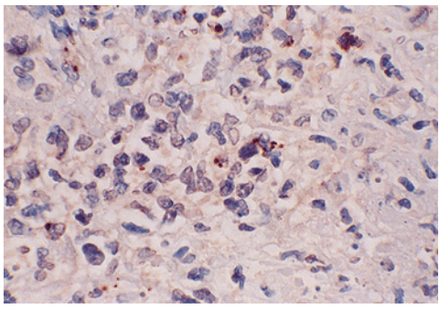

FIGURE 53.7. *Tache noire* (*eschar*) of Boutonneuse fever (same patient as in Fig. 3) with demonstration of *Rickettsia conorii* by immunoperoxidase staining. Note the intracellular location of the rickettsiae presumably limited to endothelial cells and potentially macrophages.

Epidemiology

Although murine typhus occurs worldwide in warm, coastal environments, in the United States it is most prevalent in southern Texas and southern California. Two distinct ecologies exist, one involving rat fleas (*Xenopsylla cheopis*) and rats (*Rattus* species) and another involving cat fleas and opossums (181). As expected, the disease occurs most often during spring, summer, and other times when flea vectors are active.

Pathology and Clinical Manifestations

R. typhi causes disease in a way similar to that of *R. rickettsii* in RMSF, by primary infection of endothelial cells and induction of vasculitis and vascular injury (182). Other important pathologic findings include interstitial pneumonitis, interstitial nephritis, myocarditis, meningitis, and mild hepatitis. With severe vasculitis and widespread inflammatory injury, multi-organ damage may result and death may result.

Flea feces that contain *R. typhi* are inoculated into the flea-bite wound after the flea defecation-feeding reflex. The rickettsia proliferate locally, spread to lymphatics and venous blood to infect endothelium in many tissues. Although typhus group rickettsiae infect endothelial cells, unlike spotted fever group organisms, actin is poorly polymerized and cellular injury is probably induced by mechanical lysis after large numbers of rickettsiae accumulate (156). Infection and endothelial cell injury lead to vasculitis and significant vascular barrier dysfunction.

As for other vasculotropic rickettsioses, murine typhus is moderately severe in adults and mild in children (183). After an incubation period of 1 to 2 weeks, a nonspecific febrile illness develops. Important clues for rickettsiosis include headache, rash, and myalgias; other findings that occur in under half of patients include vomiting, cough, and diarrhea or abdominal pain. Neurologic involvement is infrequent in adults, but may include confusion, stupor, coma, seizures, meningismus, and ataxia. Macules or maculopapules on the trunk, extremities, including soles and palms, are observed early, but a petechial rash is infrequent. Complications include relapse, stupor, dehydration, and CSF pleocytosis, multiorgan damage, and death.

Nonspecific laboratory findings include mild leukopenia with left shift, thrombocytopenia, hyponatremia, hypoalbuminemia, and elevations in serum hepatic transaminase levels.

Diagnostic Procedures

As for RMSF, delayed therapy increases morbidity and mortality, and early diagnosis must be based on clinical suspicion (183). Diagnostic confirmation is usually achieved by IFA serologic testing in convalescence. Other tools now being evaluated include PCR amplification of *R. typhi* nucleic acids in acute phase blood, culture by the shell vial assay, and skin biopsy with immunohistology.

Therapy and Prevention

Murine typhus is treated similar to RMSF by the use of tetracyclines or chloramphenicol. A single patient successfully treated with ciprofloxacin has been reported (184); *in vitro* data suggest that azithromycin and clarithromycin may be effective therapeutic agents as well (185). Prevention of murine typhus depends on control of mammalian and flea reservoirs in urban and suburban areas alike.

Rickettsia prowazekii

It has long been considered that humans are the only reservoir of *Rickettsia prowazekii*, the causative agent of epidemic typhus and a member of the typhus group. *R. prowazekii* represents perhaps the most virulent of all of the vasculotropic rickettsiae and is responsible for a significant degree of historical morbidity and

mortality associated with wars prior to the 20th century (186). The infection results when infected human body or head lice feed on uninfected persons. Rickettsiae that infect the lice midgut epithelial cells are defecated into the host abrasions in the skin, into the conjunctivae, or are inhaled. Once established, rickettsemia allows blood-feeding uninfected lice to acquire the infection which is then passed on to other uninfected individuals during times of poor hygiene, crowding, war, etc., and allows epidemic spread. The most recent major outbreak of typhus was discovered in the war-torn parts of Burundi, where nearly 60,000 persons were infected and nearly 6,000 people died (187). Other recent epidemic have been identified in Africa, Mexico, Central America, South America, eastern Europe, Afghanistan, northern India, and China. Epidemic typhus is not always severe; a mild form, caused by a genetic variant of *R. prowazekii* has been identified and associated with exposure to flying squirrels that harbor infected fleas or lice (188). Primary infection results in non-sterile immunity and recrudescence or Brill-Zinnser disease, a mild form of typhus, may occur years later when debility or immunocompromise supervenes.

Clinical Manifestations. Epidemic typhus may be mild or severe. After an incubation period of usually fewer than 14 days, fever, severe headache, abdominal tenderness, and rash are observed in most patients; chills, myalgias, and arthralgias are present in most, while gastrointestinal, respiratory, and central nervous system involvement are seen in a decreasing proportion of patients. The rash starts as pink or erythematous blanching macules and maculopapules and may evolve to petechiae predominantly involving the trunk. The case fatality rates ranges between 3.8% and 20% during outbreaks.

Orientia (Rickettsia) tsutsugamushi

Scrub typhus is caused by the rickettsial pathogen *Orientia tsutsugamushi* (formerly *Rickettsia tsutsugamushi*) (144). The causative agent is genetically and antigenically distinct from spotted fever and typhus group rickettsiae. These small obligate intracellular bacteria likely occupy an intra-endothelial niche; however, members of this monospecific genus lack both lipopolysaccharide and peptidoglycan in their cell envelopes (146). Scrub typhus is predominantly found in the Far East in areas bounded by Korea, Pakistan, and northern Australia. Imported infections to the United States also occur. The rickettsia is transmitted after bites of trombiculid mites in the genus Leptotrombidium, which are both vectors and reservoirs. The infectious agent is maintained by highly efficient transovarial transmission; rodent hosts of mites are probably not involved in natural maintenance. Multiple serotypes are known, many of which share antigenic cross-reactivity, but may represent unique separate species.

Clinical Manifestations. The incubation period for scrub typhus varies from 6 to 21 days before the onset of a mild to severe febrile disease. An eschar appears at the chigger (mite) bite site in less than half of cases. In addition to fever, the illness is characterized by headache, myalgia, cough, lymphadenopathy, maculopapular rash, and gastrointestinal symptoms. Infection can be complicated by meningoencephalitis or interstitial pneumonitis, and fatalities may occur in as many as 7% of untreated patients. Diagnosis is usually confirmed by serology using the indirect fluorescent antibody or immunoperoxidase serologic tests with *O. tsutsugamushi* as antigen.

Treatment

Therapy, as for other vasculotropic rickettsioses, includes doxycycline or chloramphenicol, after which defervescence occurs within 24 to 48 hours. Recently, highly virulent doxycycline-resistant strains have been reported (189). *In vitro* susceptibility tests show that azithromycin may be an effective alternative for scrub typhus.

Ehrlichioses

Although *Ehrlichia* spp are well-recognized etiologic agents of disease in dogs and ruminants, it wasn't until 1987 that human infection in the United States was identified (190). That first case was erroneously attributed to infection by *Ehrlichia canis*; however, subsequent evaluations have shown similar infections transmitted by ticks to be caused by several distinct species of *Ehrlichia* (191,192 and 193). *Ehrlichia* infections are characterized by undifferentiated fever, and peripheral blood examination may sometimes demonstrate the infectious agent as clusters of small, coccoid to coccobacillary bacteria sequestered within a vacuole in either monocytes or neutrophils. After its identification in humans in 1990, *Ehrlichia chaffeensis*, a new species, was cultivated from an infected patient and identified as the main cause of this infection (191). Since then, seroepidemiologic studies indicate that *E. chaffeensis* infections are more frequent than RMSF in some geographic regions (194).

Another *Ehrlichia* spp was implicated in 1994 as the cause of disease in the upper Midwest that was characterized by intracellular inclusions, called morulae, that were only in blood neutrophils (192, 195). Serologic and molecular studies showed that the cause was not *E. chaffeensis*, and molecular studies identified DNA sequences nearly identical to veterinary ehrlichiae known to infect horse or ruminant neutrophils. These findings were confirmed by serologic tests, and data now indicate that the causative agent and the veterinary neutrophil pathogens, *E. equi*, and *E. phagocytophila*, represent variants of a single species. The disease was called human granulocytic ehrlichiosis or HGE, to distinguish it from infection with *E. chaffeensis*, then designated human monocytic ehrlichiosis (HME), that most often involved monocytes in blood. Recently, another *Ehrlichia* spp., *E. ewingii*, previously known as a canine pathogen, has been implicated as a cause of febrile illness in humans (193). It is a serologic and close genetic relative of *E. chaffeensis*, but resides in neutrophils. It is likely that other *Ehrlichia* species yet to be discovered may contribute to fever that occurs after tick bites.

Although these small obligate intracellular bacteria have a gram negative-type cell wall by ultrastructure, gram-staining is not useful for identification. Phylogenetic analysis of 16S ribosomal RNA and groesl genes, serologic and protein investigations, as well as vector relationships can be used to divide the *Ehrlichia* genus into three distinct clades, noted here as the *E. canis*, *E. sennetsu*, and *E. phagocytophila* groups (196). These bacteria parasitize specific derivatives of mammalian bone marrow-derived cells; *E. chaffeensis* and *E. sennetsu* infect mononuclear

phagocytes, and the *E. phagocytophila* group and *E. ewingii* infect neutrophils.

Epidemiology

Distributed mostly in southeastern and south central states, *E. chaffeensis* infections are found wherever the Lone Star tick, *Amblyomma americanum* may bite humans (197). Moreover, infections identified in California, Washington, New York, Massachusetts, and Connecticut, as well as potential infections in Europe, Africa, and the Far East suggest a wider array of potential vectors or serologically similar agents. HGE has been documented mostly in the upper Midwest and northeast United States, but infected patients have been found in California, the mid-Atlantic, south Atlantic, and south central United States, and broadly across Europe (197,198 and 199). *Ixodes persulcatus* group ticks, including *I. scapularis* (black-legged or deer tick) in the eastern United States, *I. pacificus* (western black-legged tick) in the west, and probably *I. ricinus* (sheep tick) in Europe are important vectors (198). Consequently, co-transmission and co-infections with *Borrelia burgdorferi* (Lyme disease) and *Babesia microti* (human babesiosis) are well recognized. The geographic distribution of *E. ewingii* is incompletely documented, but transmission by *A. americanum* ticks would predict human infections to occur in the same regions where HME is identified (193).

The mean age of patients with HME and HGE is more than 44 years in most series, unlike the situation for RMSF or Lyme disease (198). In spite of this, severe and fatal infections have been documented in the pediatric age group. As expected, most infections are identified during May through September when the small nymphal stage ticks are at peak activity and human outdoor exposure is maximal; a second peak of HGE occurs in late October through December when the adult stages of the vector ticks are most active.

Unlike the situation for *Rickettsia* spp., *Ehrlichia* species are maintained by horizontal transmission (tick to mammal to tick). For *E. chaffeensis*, the white-tailed deer (*Odocoileus virginianus*) is a major reservoir host (200), while a major reservoir for the *E. phagocytophila* group in the eastern United States is the white-footed mouse, *Peromyscus leucopus* (201,202). The role that white-tailed deer and domestic ruminants play in the ecology of these infectious agents is not clear.

Because of this horizontal transmission, persistent mammalian infection is important and is well recognized in dogs (*E. canis*, *E. ewingii*, and *E. chaffeensis*), white-tailed deer (*E. chaffeensis*), ruminants (*E. phagocytophila*), and hosts for other ehrlichial species. However, persistent infections appear to be very infrequent in humans.

Pathology and Clinical Manifestations

Despite the clinical similarities with the vasculotropic rickettsioses, the pathogenesis of human monocytic and granulocytic ehrlichiosis does not involve endothelial cell infection or vasculitis (198). Pathologic findings show mild perivascular lymphohistiocytic infiltrates, hepatocyte apoptoses, mild lobular hepatitis, increases in mononuclear phagocytes in spleen, lymph node, liver, and bone marrow, occasional erythrophagocytosis, and granulomas of liver and bone marrow with *E. chaffeensis* infections. Despite the frequency of leukopenia, anemia, or thrombocytopenia, most bone marrow samples are normocellular or hypercellular. In HME, a mononuclear cell CSF pleocytosis can be identified. Gastrointestinal and pulmonary hemorrhages, diffuse alveolar damage with organizing pneumonia, and nosocomial or opportunistic infections may occur as severe complications of HME or HGE.

The underlying pathogenetic factor in HME and HGE appears to involve diffuse increases in mononuclear phagocytes with granuloma formation (in HME) or infiltrates of histiocytes that are activated for increased nonspecific phagocytic activity. As a result, moderate to profound leukopenia and thrombocytopenia are frequent manifestations that can not be explained on the basis of destruction of infected cells. Hepatic or other organ-specific injury probably is not related to direct infection and may result from poorly regulated release of deleterious cytokines at sites of inflammatory cell recruitment. A similar mechanism may underlie diffuse alveolar damage that occasionally is seen and that results in adult respiratory distress syndrome (ARDS) (203). Inflammation and edema with meningoencephalitis is a serious complication that seems restricted to HME.

HME, HGE, and infection by *E. ewingii* are distinct processes caused by different *Ehrlichia* species that present with similar clinical features (193, 198). After a post-tick bite incubation period of approximately 7 to 10 days, the usual presentation is undifferentiated fever, with headache, myalgia, and malaise. Other findings attributable to involvement of the gastrointestinal, respiratory, renal, or central nervous systems occur in the minority of patients, but are not rare. Rash, including macular or maculopapular, and rarely petechial lesions, occurs infrequently in HME and rarely in HGE. Ordinarily, illness lasts approximately 4 to 12 days, and hospitalization is often required. The high prevalence of *E. phagocytophila* group antibodies and asymptomatic seroconversions after intense tick exposure for *E. chaffeensis* suggest that frequent mild or subclinical infections may occur.

Patients with HME and HGE often present with leukopenia, lymphopenia, neutropenia, or thrombocytopenia during the first 7 days of illness (204, 205). Thereafter, leukocyte components normalize while platelet counts may remain depressed for 2 weeks or longer. Bone marrow examinations often reveal cellular or reactive bone marrows despite pancytopenia (206). In HME, 75% of bone marrows contain granulomas and granulomatous inflammation, a finding not identified in patients with HGE. Mild to moderate elevations in hepatic aminotransferase activities are frequently found as evidence of underlying hepatic injury. Adult patients infrequently develop acute renal failure associated with concurrent rises in serum urea nitrogen or creatinine levels. A syndrome similar to disseminated intravascular coagulation (DIC) characterized by both prolonged activated partial thromboplastin time/prothrombin time and hypofibrinogenemia can occur in HME and HGE.

Diagnostic Procedures

Many patients with HME and HGE are identified presumptively by the recognition of typical *Ehrlichia morulae* in peripheral blood leukocytes. While some view this as too infrequent to be useful for diagnosis of HME, an intense search will sometimes

identify a very small number of infected cells (Fig. 53.8). By comparison, between 20% and 80% of HGE patients have peripheral blood neutrophils with typical *Ehrlichia morulae* (Fig. 53.9) that are found in between 0.5% and 40% of cells (198). However, morphologic analyses can be difficult and misleading; thus, an experienced microscopist is required for this evaluation. A more definitive study and identification can be achieved by PCR amplification of nucleic acids specific for each species or by demonstrating an increasing titer of *E. chaffeensis* or *E. phagocytophila* group antibodies during convalescence (197, 198, 207, 208). Currently, a diagnosis is based upon a clinically compatible disease with laboratory evidence of *Ehrlichia* spp. infection by (i) seroconversion using specific *E. chaffeensis* or *E. phagocytophila* group serologic tests, (ii) PCR identification of specific *E. chaffeensis* or *E. phagocytophila* group nucleic acids and specific serologic evidence of infection by a valid serologic method, or (iii) PCR identification or specific serologic evidence of infection and identification of morulae in appropriate peripheral blood leukocytes. Patients with HGE and HME develop cross-reactive serologies in between 12% and 30% of cases; thus, serodiagnosis mandates tests using both *E. chaffeensis* and *E. phagocytophila* group antigens. PCR amplification performed during the acute phase may be as sensitive as 86% under optimal circumstances (207, 208). Culture of *Ehrlichia* spp. has been performed only in research and public health laboratories with a strong interest. However, the ease of cultivation of *E. phagocytophila* group ehrlichiae (Fig. 53.10) and recent improvements in *E. chaffeensis* cultivation (Fig. 53.11) suggest a diagnostic role in the future. No evidence exists to classify *E. chaffeensis* or *E. phagocytophila ehrlichiae* as highly biohazardous. Because both HME and HGE have caused fatalities, therapy should be instituted based upon clinical evaluation and not withheld while awaiting laboratory confirmation.

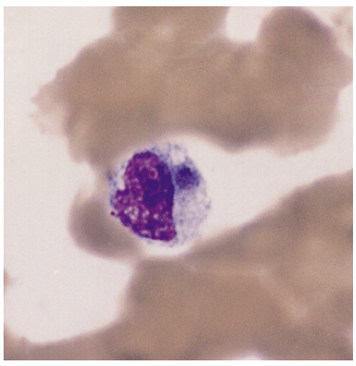

FIGURE 53.8. *Ehrlichia chaffeensis* in a peripheral blood monocyte from a patient with fatal human monocytic ehrlichiosis (HME) in Illinois. Note the round intracytoplasmic inclusion with stippling. Photograph courtesy of Joan Barenfanger, M.D.; Wright stain, original magnification 1,000×.

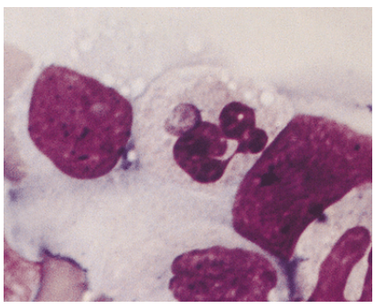

FIGURE 53.9. Peripheral blood neutrophil from a Wisconsin patient with human granulocytic ehrlichiosis (HGE). The organism that causes HGE is almost identical to *Ehrlichia phagocytophila* and *Ehrlichia equi*. Note the intracytoplasmic inclusion with stippling. Wright stain, original magnification 1,000×.

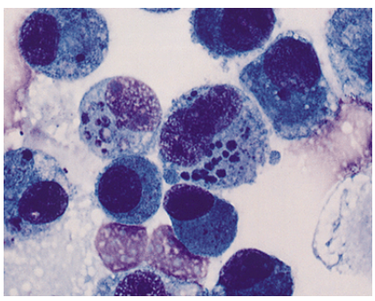

FIGURE 53.11. *Ehrlichia chaffeensis* cultivated *in vitro* in a macrophage cell line (canine DH82 cells). Note the multiple, large, round intracytoplasmic aggregates of bacteria. Romanowsky stain, original magnification 1,000×.

Fatalities with HME and HGE occur in between 0.5% and 2% of all infections documented (209). Worrisome complications include respiratory distress, meningoencephalitis, a toxic-shock or septic-shock like illness, and multiorgan failure. Long term neurologic injury may be a consequence of severe or untreated infections. Immune compromise, including infection with HIV, corticosteroid therapy, pre-existing malignancies, or transplantation seem to predispose to more severe or fulminant infection and the potential for a fatal outcome.

Therapy

As for RMSF, HME and HGE can be effectively treated with tetracyclines, and most patients improve significantly within 48 hours. Although chloramphenicol therapy was associated with a significantly shorter interval of fever and hospitalization than

non-tetracycline treated patients with HME, both *E. chaffeensis* and *E. phagocytophila* group ehrlichiae are resistant to its effects *in vitro* (204, 210, 211). Rifampin has been used with success in individual HGE cases, but no comprehensive studies have proven its clinical utility for HME or HGE. Other broad-spectrum antibiotics such as ß-lactams, aminoglycosides, and macrolides are not effective *in vitro*, and current *in vivo* data do not support a role for their therapeutic use. Antimicrobial prophylaxis after tick bite for HME and HGE has not been evaluated.

Coxiella burnetii

Coxiella burnetii is the causative agent of Q fever, a febrile disease that often lacks rash, and may present in acute or chronic forms. The acute form of the disease often begins as an influenza-like illness, occasionally with interstitial pneumonitis, or granulomatous hepatitis (212). Chronic Q fever usually is culture-negative endocarditis (213). Although prevalent on a worldwide basis, Q fever is diagnosed infrequently in the United States. The usual mechanism for transmission is via aerosols or ingestion of contaminated dairy products; arthropod vectors are rarely implicated. Persons at risk include those who are immunocompromised, those with underlying cardiac valve or vascular damage or cardiac prostheses, farmers, abbatoir workers, and others who are exposed to farm animals or products (213, 214). The relative risk for infection increases with age.

Epidemiology

It is likely that many more cases of Q fever occur each year than are diagnosed in the United States owing to the nonspecific clinical manifestations and lack of availability of specific laboratory diagnostic tests. Regardless, *C. burnetii* is implicated in 0.5% to 3% of cases of serologically investigated acute respiratory illnesses or hepatitis in some areas of the United States, and may account for 40% of atypical pneumonias in Japanese pediatric patients (215, 216). Cattle, sheep, goats, parturient cats, and wild animals such as rabbits, are reservoirs for *C. burnetii*. This bacterium is more closely related to *Legionella pneumophila* and the arthropod symbiont *Francisella* (formerly *Wolbachia*) *persica* than to *Rickettsia* and *Ehrlichia* spp. (143). The organism is considered highly contagious for humans and animals, as even a single organism may establish infection. *C. burnetii* is highly stable under a variety of environmental conditions owing to a spore-like form. It is transmitted by inhalation of aerosols generated by dust, straw, or cloth contaminated with birth tissues, by processing of contaminated animal products, or by consuming raw dairy products. Although animal exposure is the major risk factor in Europe, the United States, and Australia, urban acquisition, without concomitant animal exposure, occurs at a high rate in France (213). Transmission from infected human products of conception places obstetric health care workers at high risk in endemic regions (217). Immunocompromise after cancer therapy, HIV infection, organ transplantation, hemodialysis, cirrhosis, or chronic granulomatous disease is a risk factor in over 20% of patients with acute or chronic Q fever (218).

Pathology and Clinical Manifestations

In contrast to other rickettsial infections, humans acquire *C. burnetii* predominantly after inhalation of infectious aerosols. The most frequent presentations of acute Q fever include an influenza-like respiratory illness, a granulomatous illness with hepatitis, and an undifferentiated febrile illness. Pulmonary infection elicits a mild interstitial lymphocytic pneumonitis with dense macrophage-rich intraalveolar exudates heavily infected with *C. burnetii* (219). The infection may elicit granulomas in liver, bone marrow, and other organs, all signs of an acute and usually self-limited infection (220). Chronic Q fever endocarditis is characterized by macrophage and lymphocyte-rich infiltrates in necrotic fibrinous valvular vegetations (Fig. 53.12) and by the absence of granulomas (221).

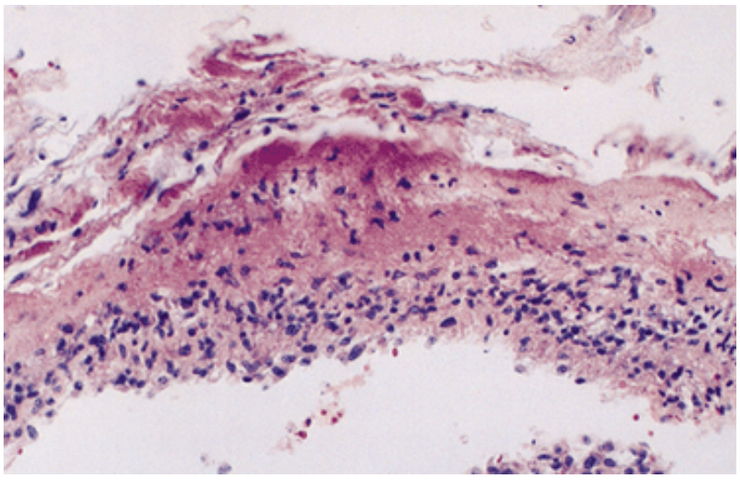

FIGURE 53.12. Histopathology of Q fever endocarditis reveals focally dense lymphohistiocytic infiltrates associated with fibrin deposition and necrosis. Note the scarcity of purulent inflammation that can also accompany *Coxiella burnetii* infection of cardiac valves. H&E, original magnification 400×.

As with many other obligate intracellular pathogens, recovery from acute infection may result in nonsterile immunity. It is

likely that development of debilitating chronic Q fever occurs after recovery from mild or inapparent acute Q fever after which the agent is not cleared (221). The persistence of *C. burnetii* in tissue macrophages at sites of pre-existing tissue damage (Fig. 53.13) causes a low-grade smoldering inflammation, which eventually leads to irreversible cardiac valve damage or persistent vascular injury.

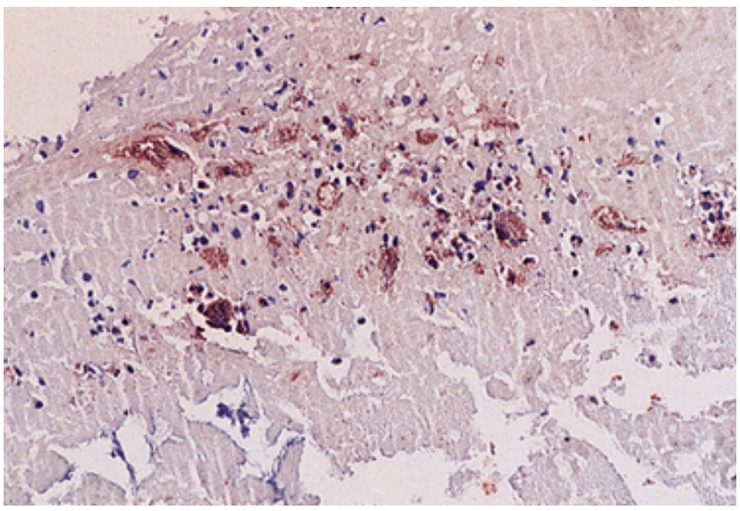

FIGURE 53.13. Immunoperoxidase demonstration of *Coxiella burnetii* in Q fever endocarditis. Note the presence of coccoid bacteria within histiocytes associated with the necrotic vegetation. Immunoperoxidase, original magnification 400×.

Acute Q fever develops approximately 3 weeks (range, 14–39 days) after exposure to the causative agent (212). The severity of illness ranges from subclinical infection to a febrile systemic illness with severe frontal headache, arthralgia, and myalgia often accompanied by respiratory symptoms. In adults, the pneumonia usually resembles primary atypical or viral pneumonitis or legionnaires' disease with a nonproductive cough. Other prominent clinical findings that may lead to diagnostic confusion include fatigue, vomiting, abdominal pain, and meningismus. Hepatomegaly and splenomegaly may be detected in some patients. Laboratory findings may reveal leukopenia with a left shift (>5%) in 50% of patients and thrombocytopenia, which is infrequent. In a review of 170 adult French patients with acute Q fever, 81.8% had fever, and of these patients 62% had elevated serum hepatic transaminase levels, 46% had respiratory involvement, 18% had cutaneous findings, and 11% had neurologic findings that required lumbar puncture for evaluation. Nearly 20% of these patients were afebrile and presented with one or more of hepatic, pulmonic, cutaneous, and/or neurologic findings (212). Other series of patients indicate that pulmonary involvement is the most frequent manifestation. Radiographically, the pulmonary consolidations become round and resolve slowly. Acute Q fever is a self-limited illness that lasts for 2 to 3 weeks. Severe infections including acute encephalopathy with impairment of consciousness and an abnormal pattern on electroencephalogram and computed tomographic scans of the brain have been reported.

Risk for development of chronic Q fever is strongly correlated with advancing age. Chronic Q fever tends to be recalcitrant to therapy and often (23% to 65%) results in death. Endocarditis, usually seen in damaged or prosthetic valves, may occur months to years after acute Q fever or in the absence of any history of Q fever (221). Chronic Q fever less frequently presents as infections of vascular prostheses and aneurysms, osteomyelitis, myocarditis, undifferentiated fever, pneumonia, hepatitis, or an isolated purpuric rash. In Q fever endocarditis, fever may be absent in up to 15% of cases, and more than 75% of all identified patients have congestive heart failure (213). Other frequently observed features include marked clubbing of the fingers, hepatomegaly, and splenomegaly.

Frequent laboratory abnormalities in chronic Q fever include an erythrocyte sedimentation rate greater than 20 mm/hour in 80% of cases, hypergammaglobulinemia in 54% of cases, and hyperfibrinogenemia in 67%. Leukocytosis, leukopenia, thrombocytopenia, or anemia are seen in a minority of patients (212, 213). The presence of rheumatoid factor in more than 50% of cases, circulating immune complexes in nearly 90%, and the frequent findings of anti-platelet antibodies, anti-smooth muscle antibodies, anti-mitochondrial antibodies, circulating anticoagulants, and positive direct Coombs test may suggest an autoimmune process (222). A variety of other syndromes have been associated with Q fever, including meningoencephalitis, inflammatory pseudotumor of the lung, glomerulonephritis, immune complex vasculitis, hemolytic anemia, and autoimmune disorders.

Diagnostic Procedures

Although infrequently diagnosed, Q fever should be considered in patients with fever of unknown origin or culture-negative endocarditis who live in rural areas or who are in close contact with domestic livestock, cats, or their products of conception. The diagnosis of Q fever can be confirmed serologically by significant increases in indirect fluorescent antibody titers to phase I and phase II antigens (223). The inability of the complement fixation test to discriminate between recent and remote infection diminishes its usefulness when acute-phase sera are not available. Elevated or rising titers of phase II antibody alone are characteristic of acute Q fever, and the appearance and persistence of elevated titers of phase I and phase II antibody are indicative of chronic Q fever. Elevated titers of phase I immunoglobulin (Ig) A antibody are reported to be diagnostic for Q fever endocarditis (224); however, one evaluation showed that a phase II IgG titer of 200 or greater is indicative of *C. burnetii* infection and that a phase I IgG titer of less than 800 is inconsistent with chronic Q fever (223).

Cultivation and antimicrobial susceptibility testing of *C. burnetii* is not difficult and requires a traditional virology laboratory (225); however, some consider *C. burnetii* to be highly biohazardous and recommend cultivation only by trained personnel in specialized biohazard facilities. Diagnosis by culture can be performed using a variety of cell lines and primary cultured cells. Alternative methods for diagnosis include PCR amplification of *C. burnetii* genomic or plasmid targets in blood, valve tissues, and perhaps other infected tissues such as placenta (226). Immunohistologic demonstration of *C. burnetii* by using polyclonal or a monoclonal antibody has a sensitivity of approximately 67% as compared with culture, and is useful when only fixed tissues are available (221).

Therapy

Most patients with Q fever experience a self-limited illness that should be empirically treated within 3 days of onset with tetracycline or doxycycline if suspected (227). Later therapy has little effect on the course of the acute infection. Ofloxacin and pefloxacin are effective and success with a combination of pefloxacin and rifampin is achieved with prolonged (16 to 21 days) therapy. ß-lactams are not effective, but some success with chloramphenicol, trimethoprim-sulfamethoxazole, and ceftriaxone have been reported for individual cases. Prednisone was reported to provide additional clinical benefit in cases of hepatitis with “autoimmune” laboratory findings.

For chronic Q fever, especially endocarditis, prolonged therapy is mandatory. This usually requires the bacteriostatic drugs tetracycline or doxycycline in combination with bactericidal drugs such as rifampin, ofloxacin, or pefloxacin. The use of lysosomotropic alkalinizing agents such as hydroxychloroquine may aid in maintaining activity of pH-sensitive antimicrobial agents in the phagolysosomal environment of *C. burnetii* (228). For patients with heart failure, valve replacement may be warranted and should be accompanied by an effective antibiotic regimen to avoid reinfection of the prosthetic valves (213). Therapy should be monitored by serologic evaluation every 4 months; phase I titers less than 200 for IgG and the absence of an IgA titer indicate cure. Even with this evaluation, cure of chronic Q fever in less than 2 years is unlikely, and thus therapy should be continued for at least 3 years.

Bartonelloses

Perhaps few other bacterial genera have undergone as much change in nomenclature, description of new species, recognition of clinical manifestations, and discovery of zoonotic potential than the genus *Bartonella*. 10 years ago, the genus *Bartonella* contained only a single species, Bartonella bacilliformis, the agent of an intriguing vector-borne infection with two clinical phases, hemolytic anemia and cutaneous vascular proliferations, and found only at certain altitudes in parts of the Andes mountains. Similarly, the genus *Rochalimaea* contained only a single human pathogen, *R. quintana*, the cause of trench fever. With the application of molecular phylogenetic methods, the emergence of AIDS, rigorous examinations of tissues from patients with cat scratch disease (CSD), and the recovery of previously reemerging and newly emerging bacterial pathogens, the number of species classified in the genus *Bartonella* now is approximately 15 (229, 232). In parallel, the clinical consequences of infection also have markedly broadened to include febrile bacteremia, chronic lymphadenopathy, cutaneous and visceral vascular lesions, multifocal abscesses and tissue inflammatory lesions, and endocarditis, among other less frequently cited abnormalities (233).

Bartonella species are members of the α_2-subgroup of *Proteobacterium*. They are closely related to the mammalian pathogens in the genera *Afipia* and *Brucella*, and to the plant pathogens *Agrobacterium* (234). Molecular studies led to the reclassification of the genera *Rochalimaea* and *Grahamella* as *Bartonella*, and the removal of the family Bartonellaceae from the order Rickettsiales (235). This genus *Bartonella* is characterized by small Gram-negative rods that are fastidious, aerobic, and in some cases, facultative intracellular organisms. Unlike members of the order Rickettsiales, *Bartonella* spp. can be cultivated axenically on agar supplemented with blood or hemin in air or 5% to 10% CO_2. Flagella have been identified in *B. bacilliformis* and *B. clarridgeiae*, but pili that may be important mediators of host cell attachment are present in both *B. henselae* and *B. quintana*. Bacteriophage-like particles have been found associated with both *B. bacilliformis* and *B. henselae*.

The pathogenetic mechanisms of these species are incompletely described. Erythrocyte invasion by *B. bacilliformis* depends upon propulsion from the flagellum and bacterial production of the protein deformin (236). Inhibition of deformin's ability to mediate attachment to and deformation of host erythrocytes does not inhibit lysis. *Bartonella henselae* apparently attaches to endothelial cells via its 43 kDa surface porin protein (237). After attachment, *B. bacilliformis* and perhaps other *Bartonella* spp., invade host cells by virtue of invasion-associated locus (ialA and ialB) proteins (149). Hemin is required for growth, and its acquisition in *B. quintana* is mediated by a tail-specific protease, encoded by ctpA that apparently renders the cell highly permeable to hemin and hemin-like molecules (238). ialA, ialB, ctpA, and filA (a gene encoding the filament-A protein) are clustered together akin to virulence gene pathogenicity islands observed among Enterobacteriaceae (239). Both *B. bacilliformis* and *B. henselae* produce proteins that are angioproliferative (240).

Bartonella spp. often occupy an intra-erythrocytic location in felids, canids, rodents, birds, fish, etc., and may establish persistent bacteremia in the absence of overt clinical signs. Arthropod vectors may be important in maintenance of naturally infected vertebrate hosts or in transmission to man. *B. bacilliformis* and *B. quintana* are transmitted to humans via sandflies (*Lutzomyia* spp.) and body lice (*Pediculus humanus*), respectively, and humans are the only known reservoirs for these bacterial pathogens (241, 242). In addition, cat fleas (*Ctenocephalides felis*) often are naturally infected and are proven vectors of *B. henselae* among cats (243). The association of some *Bartonella* spp. with cats, rodents, or other animals in the absence of clinical signs, and the detection of *Bartonella* spp. in a variety of ectoparasites such as fleas, lice, and ticks, suggest a role for horizontal (mammal-arthropod-mammal) transmission in the natural maintenance cycle (244,245,246 and 247).

Epidemiology

Domestically acquired *Bartonella* spp. infections are relatively prevalent. It is estimated that approximately 20,000 cases of CSD occur in the United States per year or approximately 10 cases per 100,000 population nationally (248). Infection in immunocompromised individuals seems to be less frequent, but good statistical data are lacking. Cat exposure, in particular kitten bites and scratches, are common variables among *Bartonella henselae* infections of immunocompetent and immunodeficient persons (249, 250).

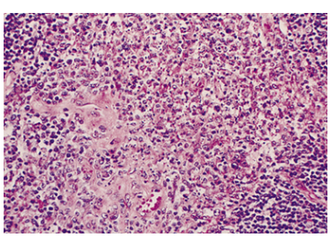

FIGURE 53.14. Early histologic lymph node changes in cat scratch disease caused by *Bartonella henselae*. Note the vague rim of granulomatous inflammation surrounding a region of karyorrhexis and necrosis. Bacilli are most likely to be detected by staining techniques in early lesions such as this. H&E, original magnification, 400×.

Specific epidemiologic associations are dependent upon the *Bartonella* spp. For example, *B. bacilliformis* has been identified only in association with sandfly bites in South America. Previously, infections had only been documented at specific altitudes

in the Peruvian, Colombian, and Ecuadorian Andes mountains; however, recent investigations have clearly shown disease acquisition in the low jungle and adjacent areas and the likely existence of mild or subclinical disease forms (251).

B. quintana long has been associated with lice and conditions of poor hygiene (246, 247, 252). Homeless persons, alcoholics, persons with HIV infection, and injection drug users are at increased risk for infection, bacteremia, and endocarditis. A role for cats has been speculated as some patients with *B. quintana*-associated bacillary angiomatosis or *peliosis hepatis* have been cat owners or had cat exposures; however, transmission of *B. quintana* to cats and fleas has not yet been demonstrated. In contrast, ample evidence exists to show that *B. henselae* is flea-borne among cats and that persons with *B. henselae*-associated CSD, bacillary angiomatosis, bacillary peliosis, febrile bacteremia, and endocarditis have significantly high rates of cat exposure, including cat bites and scratches (233, 249, 250). CSD has a bimodal seasonal distribution with peaks in the fall and early winter, perhaps corresponding to peak flea seasons for cats (253). Up to 40% of infections may occur in adults and a slight male predominance is recorded (253). Occupational exposure (veterinarians) may be a risk factor; however, the high frequency of cat ownership and exposure among the general population precludes more definitive study (254). The highest risk factors for CSD, most frequently caused by *B. henselae*, are ownership of pet kittens, a kitten scratch or bite, and ownership of at least one kitten with fleas (250). Chomel showed that kittens, seropositive cats, and flea-infested cats were more likely to be bacteremic, and prolonged bacteremia in cats has been associated with acquisition of CSD (255, 256). Human infection by other species of *Bartonella*, such as *B. elizabethae*, *B. clarridgeiae*, or *B. vinsonii*, is infrequent enough that specific epidemiological associations cannot be made.

Pathology and Clinical Manifestations

Bartonelloses present with diverse pathologic and clinical findings depending upon species and host immunocompetence. However, infections often share some features owing to similarities in pathogenetic mechanisms and niches. For example, pathogenic species have been shown capable of invasion and survival in erythrocytes of various mammalian species. The three major pathogenic species, *B. bacilliformis*, *B. quintana*, and *B. henselae* will be discussed briefly here.

Bartonella Bacilliformis, Oroya Fever, and Verruga Peruana

After inoculation into the dermis from *Lutzomyia* spp. sandflies, *B. bacilliformis* gains access to the blood. Following an interval of approximately 21 days (1 to 30 weeks) the clinical presentation of febrile hemolytic anemia (Oroyo fever) or Carrion's disease, a condition with cutaneous angioproliferative lesions (*verruga peruana*), may develop (257). Ordinarily, Oroya fever precedes the verrucous stage by about 2 to 20 weeks. Oroya fever results from the direct invasion of erythrocytes and subsequent hemolysis; systemic manifestations include malaise, somnolence, anorexia, myalgia, headache, arthralgia, chills, dyspnea, and fever. Examination of blood smears shows that up to 100% of erythrocytes may contain intracellular bacilli. Severe complications include pericardial effusion, myocarditis, coma, convulsions, delerium, acute respiratory distress, anasarca, or abortion. The case fatality rate ranges from 88% in epidemics to 8% in hospital-managed patients (257). Opportunistic infections, especially salmonellosis, account for many of the fatalities. Simultaneous with the hemolytic process, the bacteria infect endothelial cells (258). Their persistent presence may later lead to the secondary verruga peruana that result from the stimulation of vascular proliferations by a *B. bacilliformis* angioproliferative factor (240).

Bartonella Infections in Immunocompetent Hosts

Cat Scratch Disease. The most frequent Bartonella infection is cat scratch disease. This most often results from *B. henselae* infection after cat exposure. CSD generally is a benign self-limited condition, characterized by prolonged lymphadenopathy, with or without fever (233, 259). However, severe complications may occur including Parinaud's oculoglandular syndrome, encephalitis/encephalopathy and febrile seizures, myelitis, peripheral neuropathy, neuroretinitis, granulomatous hepatitis or splenitis, erythema nodosum, disseminated abscesses, and osteolytic bone lesions (233). In Arkansas children, 5% of all fevers of unknown origin were found to be caused by *Bartonella henselae*, and *B. henselae* has been implicated as a cause of status epilepticus in CSD complicated by encephalopathy (260, 261).

Approximately 1 week after inoculation of *Bartonella* into a scratch or bite wound, a papule develops and persists for 1 to 3 weeks. At about 2 weeks post-inoculation, adenopathy develops in the draining lymph nodes, most often axillary, cervical, and submandibular regions. Adenopathy may occur in other sites, but generalized adenopathy is rare. Ordinarily, adenopathy resolves within several months, but may persist for 12 to 24 months.

The pathologic manifestations of CSD include dermal and epidermal necrosis associated with a dense neutrophil and macrophage-rich infiltrate in which numerous bacilli can be demonstrated at the inoculation papule (262). Initially, lymph nodes show necrosis (Fig. 53.14), followed with infiltration by neutrophils (stellate microabscesses), and later by a rim of granulomatous inflammation surrounding a suppurative center (231). Similar pathology may be observed in other tissues and organs, occasionally leading to misdiagnoses such as tuberculosis, histoplasmosis, toxoplasmosis, tularemia, and brucellosis. Bacilli are most often observed in early lesions (Fig. 53.15).

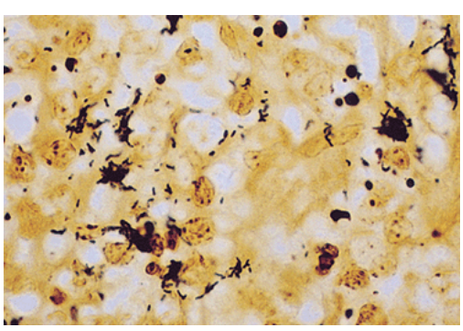

FIGURE 53.15. *Bartonella henselae* in cat scratch disease demonstrated by silver impregnation. This region corresponds to the region of necrosis and karyorrhexis shown in Fig. 11. The organisms were proven *B. henselae* by PCR. Wharthin-Starry stain, original magnification 1,000×.

Bacteremia, Febrile Bacteremia, and Endocarditis

Trench fever is a form of bacteremia caused by *B. quintana* that was first recognized during World War I (252). It occurs 9 to 25 days after inoculation of infected louse feces into skin wounds or abrasions, and leads to a relapsing fever that is accompanied by severe headache and bone pain. Patients who are bacteremic with *B. quintana* but do not have classical trench fever are often afebrile but also may have headache and bone pain. In Brouqui's report, 5 of 10 bacteremic patients had positive blood cultures for 2 to 6 weeks (247). Bacteremia with *B. quintana* and *B. henselae* may occur with or without simultaneous endocarditis.

Endocarditis caused by *B. quintana* is most often associated

with homelessness and alcoholism in patients with no history of valvular injury; however, *B. henselae* endocarditis is observed most often in patients with previously damaged valves and cat exposure (252). Echocardiographic evaluation frequently is unrevealing. The pathology of endocarditis is similar to that observed with other bacterial causes, including fibrin deposition, necrosis, and inflammatory cell infiltrates (Fig. 53.16) (263); however, most valve vegetations have large numbers of bacilli identified by Wharthin-Starry stains (Fig. 53.17). Specific bacterial identification can be achieved by immunohistologic studies (264).

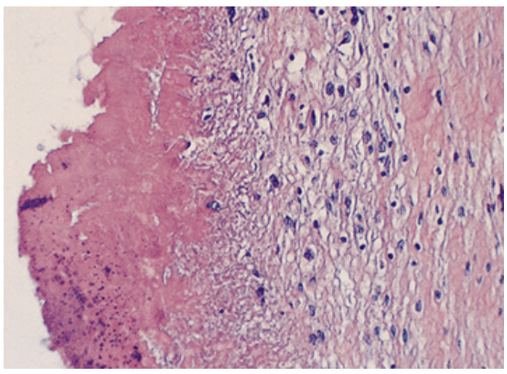

FIGURE 53.16. Histologic findings in *Bartonella quintana* endocarditis. Note the typical features of endocarditis with vegetations that contain fibrin, mixed inflammatory cells, and necrotic tissue. The majority of the acellular vegetation corresponds to the location of the bacilli by special stains. H&E, original magnification 400×.

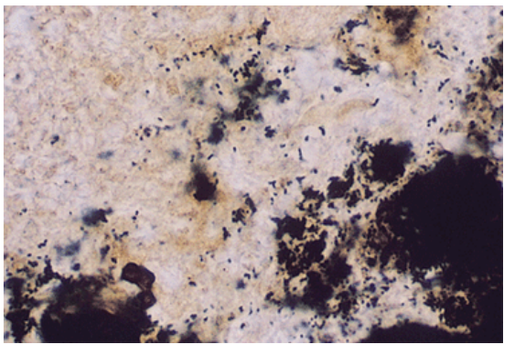

FIGURE 53.17. *Bartonella quintana* in a cardiac valve vegetation with endocarditis. Note the abundant bacilli that cluster in regions corresponding to the fibrinous necrotic acellular material in Fig. 13. Wharthin-Starry stain, original magnification 1,000×.

Bartonella Infections in Immunocompromised Hosts

Bacillary Angiomatosis (BA) and Peliosis

Both *B. quintana* and *B. henselae* may cause unique lesions when patients with HIV infection or other immunocompromising conditions exist. A frequent and dominant manifestation is the development of angioproliferative lesions similar to those in *verruga peruana*, but called bacillary angiomatosis (BA) (Fig. 53.18) (265). Vascular lacunes called peliosis may occur in visceral organs (liver, spleen) or in bone (ostelytic lesions), each of which contain abundant bacilli in the interstitium in close proximity to endothelial cells when stained by the Wharthin-Starry method (Fig. 53.19) (266, 267). BA in HIV-infected patients typically occurs when CD4 counts fall below 100 cells/mm^3 (268). Rare consequences of *Bartonella* infection in immunocompromised hosts include febrile bacteremia, endocarditis, involvement of bone marrow, parenchyma of brain, abdominal cavity, cervix, or vulva, and potentially dementia (233).

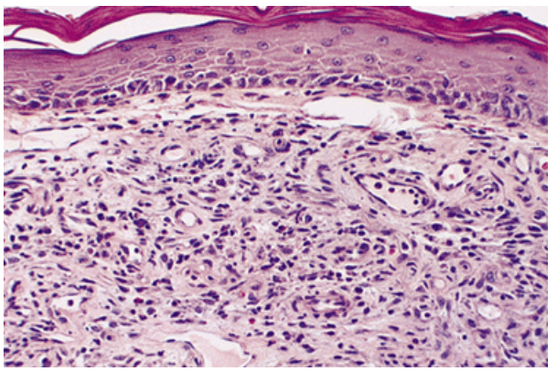

FIGURE 53.18. Histopathology of bacillary angiomatosis caused by *Bartonella henselae* infection in an HIV-infected person. Note the vascular proliferations associated with interstitial mixed inflammation and edema. The histopathologic findings are distinct from those of Kaposi's sarcoma, but do resemble pyogenic granuloma. H&E, original magnification 200×.

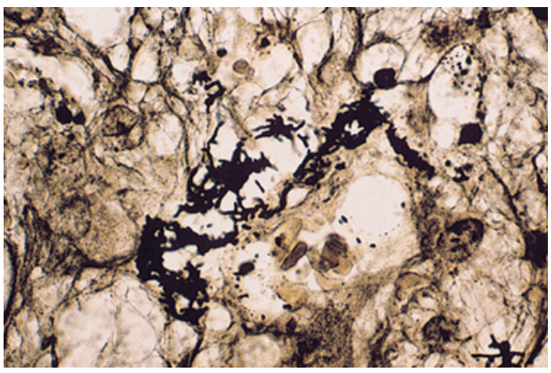

FIGURE 53.19. *Bartonella henselae* in the interstitial spaces of bacillary angiomatosis, corresponding to Fig. 53.18. Note the distinct clusters of bacilli. Wharthin-Starry stain, original magnification 1,000×.

Laboratory Findings

Laboratory evaluation in patients with CSD usually is unremarkable with the exception of an erythrocyte sedimentation

rate that is elevated in 60%. Organ-specific abnormalities (elevated liver enzymes, etc.) may belie focal bacillary involvement. The leukocyte, erythrocyte, and platelet counts are usually normal. In HIV-infected persons, CD4 lymphocyte count and hematocrit are lower than case controls, whereas alkaline phosphatase and aspartate aminotransferase are higher (268).

Diagnosis

Because of the diversity of clinical manifestations and organ involvement, the differential diagnosis for *Bartonella* spp. infections is very wide. However, bartonelloses should be suspected in several characteristic situations in immunocompetent individuals that include persistent lymphadenopathy, fever of unknown origin, encephalopathy with febrile seizures, granulomatous hepatitis, and optical neuritis. Immunocompromised or debilitated patients may develop these findings and should be evaluated for bartonellosis when evidence of cutaneous or visceral organ vascular proliferations, osteolytic bone lesions, or culture-negative endocarditis is detected. Particularly important clinical clues are cat or kitten exposure or louse infestation.

Culture

The diagnosis of *Bartonella* spp. infection is definitively confirmed with *in vitro* cultivation of the bacterium from blood or tissues. Blood samples may be inoculated directly into commercially available vials provided for automated blood culture; however, success has been achieved most frequently using the centrifugation-lysis method (Isolator tubes, Wampole, Cranbury, NJ) or by first freezing EDTA-anticoagulated blood prior to isolation attempts (230, 269,270,271,272,273,274 and 275). A variety of liquid, agar, and cell culture systems have been used for primary isolation and cultivation of *Bartonella* spp. The most frequently recommended method is direct plating of frozen or lysed blood onto agar medium that is enriched for hemin, including Columbia blood, CDC anaerobic blood, chocolate, sheep blood, heart infusion blood, and buffered charcoal yeast extract agars. A chemically defined broth-based medium supplemented with 15 mg/mL hemin has been reported to be more sensitive for primary isolation as compared with solid agar (271). Endothelial cell cultures are also efficient means for isolating *B. henselae* and *B. quintana* (267). In a comparison of methods for isolation of *Bartonella* spp., blind subculture from blood culture broth (BACTEC Plus, Becton Dickinson Microbiology Systems) into endothelial cell shell vial cultures was superior to direct agar inoculation or subcultivation from broth to agar-based medium for recovery of *Bartonella* spp. in endocarditis (269). The same authors also demonstrate that subculture of blood culture broth to agar was 98% sensitive in recovering *B. quintana* in homeless patients with endocarditis, and that recovery of *B. henselae* from lymph nodes in CSD was poor (9% to 13%) regardless of the method used. Because it is impractical to subculture all negative blood cultures, some groups have used acridine orange staining of negative or growth index-suspicious cultures to screen for those that would benefit from further subcultivation (246, 273). Regardless, patients in whom a high degree of suspicion for *Bartonella* infection exists should have cultures held for at least 21 days after which small dry colonies may appear (Fig. 53.20).

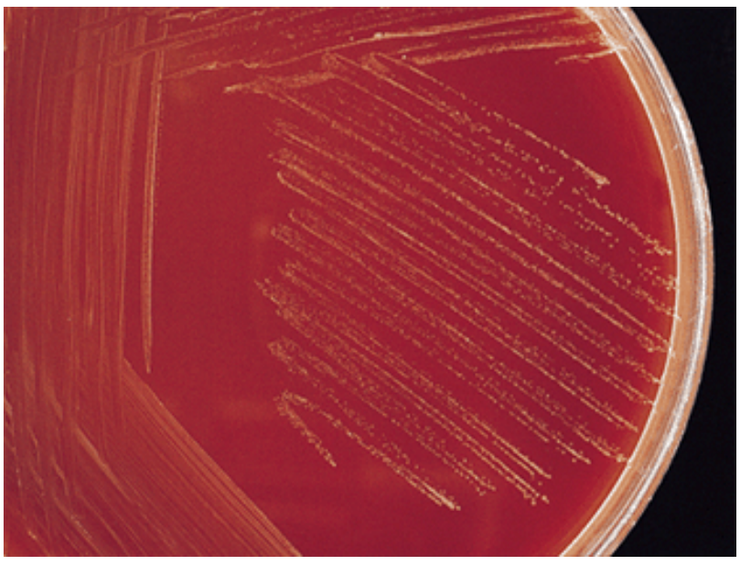

FIGURE 53.20. *Bartonella henselae* cultivated on blood agar usually requires 3 weeks or more to develop small white colonies that adhere to the plate and may be difficult to disperse.

With conventional bacterial identification systems, most *Bartonella* spp. are inert. However, supplementation of the suspension medium with 100 µg/mL hemin has allowed the biochemical differentiation of many *Bartonella* spp. in routinely used laboratory identification systems (276). Other methods for identification and differentiation of suspected *in vitro* isolates include gas-liquid chromatography analysis of cell wall fatty acids, PCR, PCR-RFLP, or sequence analysis of citrate synthase (gltA) or 16S ribosomal RNA genes, and immunofluorescence or other antigenic analyses.

Molecular Diagnosis

The most frequently used molecular method for diagnosis of the bartonelloses is PCR. In general, PCR is a more sensitive diagnostic method than culture and may identify infection in seronegative patients (252). PCR sensitivity tends to be very high for blood obtained from patients with endocarditis (approximately 80%) and in skin biopsies of patients with BA (up to 100%); however, reported sensitivity in lymph nodes from CSD

patients is variable (between 30% and 96%) (252, 269, 277). Little data exist on the utility of direct amplification of *Bartonella* spp. DNA from blood of bacteremic patients, but quantitation of CFUs from patients suggests that sufficient numbers of bacteria circulate to allow sensitive detection in many cases (230).

Serology

The preparation of specific serologic reagents has revolutionized the diagnosis of CSD and *Bartonella* infections (253). The most frequently used assay is the indirect fluorescent antibody (IFA) test, but enzyme immunoassays and western immunoblotting have also been applied for diagnosis (232, 248, 253, 277,278,279 and 280). Several studies now confirm that IFA for detection of *B. henselae* IgG antibodies is sensitive (84% to 95%) and specific (93% to 97%), and has a high positive predictive value (62% to 91%) in patients with clinically diagnosed CSD (253, 281, 282). More limited studies of *Bartonella* spp. ELISA indicate similar performance characteristics (279). In CSD, 78% of patients have IgG antibodies detected within the first week after onset of illness, and peak titers were found 8 weeks after onset (253). The IFA test is incapable of differentiation between *B. henselae* and *B. quintana* antibodies (252, 253); insufficient data are available to show an ability to differentiate among infections in humans by other *Bartonella* spp. However, significant titers of anti-*Chlamydia pneumoniae* antibodies are detected in *Bartonella* spp., endocarditis, and high titers of anti-*Bartonella* spp. antibodies can be detected in patients with Q fever endocarditis, potentially leading to misdiagnoses (283, 284).

Although many immunocompromised patients with *Bartonella* infections have detectable antibody titers, there is still controversy about the use of serodiagnosis in this group. Moreover, well-documented cases continue to show a low level of seronegativity in infected individuals.

Histopathology

The typical histopathologic findings of adenopathy in CSD, proliferative and vascular lesions in BA and peliosis, as well as in endocarditis are described above. Necrotizing, stellate microabscesses are no longer required for the diagnosis of CSD (253). When bacilli are identified in characteristic lesions by nonspecific staining methods, a definitive identification cannot be rendered; however, these morphologic features provide strong evidence of *Bartonella* spp. infections in the correct clinical and epidemiological situations. An immunohistologic method for *in situ* antigenic identification of has been described (264).

Therapy

With the exception of Oroya fever caused by *B. bacilliformis*, *Bartonella* spp. infections are rarely fatal. For Oroya fever, chloramphenicol, penicillin, and fluoroquinolones are effective and streptomycin is often used for *verruga peruana*, but *B. bacilliformis* is susceptible to a very broad range of antibiotics *in vitro* (285). Similarly, *B. henselae*, *B. quintana*, *B. elizabethae*, and *B. vinsonii* are highly susceptible to many antibiotics *in vitro*, with some variance in susceptibility to fluoroquinolones (233, 286). Whether *in vitro* susceptibility can be used to predict in vivo efficacy has yet to be determined.

Preferred antimicrobial regimens for BA and peliosis include erythromycin and doxycycline; alternative second-line drugs are tetracycline, minocycline, and azithromycin (233). It is recommended that therapy continue for at least 2 months in immunocompromised persons with BA and for at least 4 months for persons with peliosis or osteomyelitis. If relapse occurs, life-long therapy is advocated.

Despite the success of antimicrobial therapy in immunocompromised patients, the only drugs that provide clinical benefit for CSD include rifampin, ciprofloxacin, gentamicin, sulfamethoxazole/trimethoprim, and azithromycin (259, 287). The length of therapy is not clearly established, and the majority of cases of typical CSD will resolve spontaneously regardless of therapy.

For patients with bacteremia or endocarditis, too little data exist to make well-supported recommendations. Some authors prefer to use doxycycline, erythromycin, azithromycin, or tetracycline for 14 and 6 months in patients with febrile bacteremia and endocarditis, respectively (233). Often, sufficient injury is present to require valve replacement in those with endocarditis.
