Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

In the preface to the second edition of this book, two major changes in the practice of clinical biochemistry were noted. The first was the increasing integration between the pathology disciplines, driven largely by shared technology and now reflected in the multi-disciplinary training for many healthcare scientists. The second was the increasing tendency for medically qualified clinical biochemists to have direct responsibility for the management of patients with metabolic diseases. Both these trends have continued, and we have recognized them in preparing this third edition. The sections on haematology and immunology have been expanded so that, while not attempting to provide detailed accounts of these subjects, we believe that we have provided sufficient information to allow clinical biochemists to familiarize themselves with both their laboratory and clinical aspects, and to be in a position to seek greater knowledge from specialist textbooks as required.

The aspects of metabolic disease for which medical clinical biochemists may have responsibility include nutritional disorders, diabetes, inherited metabolic disease (particularly in adults), metabolic bone disease, renal calculi and dyslipidaemias, and we have encouraged our authors to provide sufficient detail to convey the general principles of the diagnosis and management of these conditions. We believe that this material will also be of interest to scientist clinical biochemists, by helping to set the more scientific material in its clinical context.

The overall aim of the book remains unchanged: to provide, in a single volume, a textbook of clinical biochemistry both for senior trainees and for established practitioners. We have not included details of analytical methodology, which are well covered in other books, but have included a new chapter devoted to quality management, since this is such an important topic: laboratory data are useless – and potentially dangerous – if their quality cannot be assured. Although the processes of quality management are to a considerable extent centred on the laboratory, they start and finish with patients and their medical attendants.

Comments from reviewers of the previous edition have encouraged us to include material that is usually outside the scope of textbooks of clinical biochemistry. New chapters on the metabolic response to stress and forensic aspects of clinical biochemistry increase the breadth of

coverage in a way that we hope readers will find useful, informative and relevant.

We thank our numerous contributors, old and new, for their commitment to this project, their (in most cases) adherence to deadlines and their tolerance of our editorial input. No one writes book chapters for the money; we are grateful to them all for their ready acceptance of our invitations and for their time.

The greatest change with this edition has been the recruitment of three new editors – Ruth Ayling, Andrew Day and Marta Lapsley (lead editor) who have joined William Marshall in place of Stephen Bangert, whose other commitments precluded his being involved. Two editors took the main responsibility for each chapter, but all of us read and commented on all the material, and approved the final versions. We hope that we will thereby have produced an error-free manuscript and apologize for any errors that may have slipped through. Will any reader who spots one please let us know, so that it can be corrected at reprinting?

At Elsevier, Jeremy Bowes commissioned the project, but day-to-day management has once again been in the capable hands of Ailsa Laing. We are indebted to her for her constant encouragement and for liaising with our authors with regard to the delivery of their manuscripts. Not to have had to do this in addition to sorting out editorial matters has been a huge help. Our thanks also go to the in-house team, particularly Beula Christopher, who coordinated the typesetting and proof corrections, and the designers and the copy editor, who have transformed the multitude of different styles of documents and images into a coherent finished product that is a pleasure to handle and read.

Most importantly of all, we would also like to mention the long suffering families, friends and colleagues who have listened to endless discussions about the work involved in editing the book and have provided practical support over many months to relieve us of more mundane tasks. In particular we would like to thank Wendy (Marshall), Michèle (Day) and Michael (Lapsley) who have contributed significantly, albeit indirectly, to the final publication.

Screening 4

Other uses of biochemical investigations 5

CONCLUSION 5

INTRODUCTION

The science of biochemistry is fundamental to the practice of clinical medicine. Many diseases have long been known to have a biochemical basis and research in biochemistry is increasingly providing descriptions of pathological processes and explanations for disease at a molecular level.

As a result of the application of biochemical principles and techniques to the analysis of body fluids and tissues, clinicians have an extensive and ever-increasing range of biochemical investigations that can be called upon to aid clinical decision-making. Such investigations can provide information vital to the diagnosis and management of many conditions, including both those with an obvious metabolic basis (e.g. diabetes mellitus) and those in which metabolic disturbances occur as a consequence of the disease (e.g. renal failure). On the other hand, many conditions are successfully diagnosed and treated without recourse to any biochemical investigation, while there remain conditions in which it might be expected that biochemical investigations should be of value but for which appropriate tests are not yet available. For example, there are, as yet, no practical biochemical investigations to assist in the diagnosis and management of the major affective disorders (see Chapter 35), although there is considerable evidence that biochemical disturbances are involved in the pathogenesis of these conditions.

Biochemical analysers range from large, automated instruments capable of performing multiple tests on single serum samples to relatively simple instruments designed to measure only one or a few analytes. In general, they generate results quickly, reliably and economically. However, some tests, often more complex and expensive ones, are performed manually and may take longer to complete. Biochemical data are thus readily available to support clinical decision-making. Ordering a biochemical investigation is a simple procedure and there is no doubt that such investigations are

often requested automatically, without regard for their potential value in the specific clinical setting. Clinical biochemists decry this but do themselves no favour by their use of the term, widely employed by clinicians, 'routine investigations' (usually meaning relatively simple investigations that are performed frequently) and even 'routine laboratories' (meaning the places where they are done).

Ideally, investigations should always be performed because there is a specific indication for them, that is, because it is anticipated that their results will provide information of benefit to the management of the patient. However, it cannot be denied that investigations requested for no specific reason can sometimes provide valuable information. Most clinicians are able to recall occasions when an unexpected result from a 'routine test' has provided the essential clue to the diagnosis in a difficult case. More often, the finding of an unexpectedly abnormal result may engender considerable anxiety and involve further investigations to elucidate its cause, only for it to transpire that the biochemical abnormality is of no clinical significance.

The potential range of investigations available to support the clinician is considerable, from simple low cost urine dip-stick tests to magnetic resonance imaging using hugely expensive equipment. There is an understandable tendency for clinical biochemists to think that biochemical investigations are pre-eminent among special investigations. In some conditions they are, in others they have no role, while in many, their value is greatly increased when their results are considered alongside those of other investigations, for example imaging. The clinician should be aware of the whole range of investigations that are available, but needs also to be able to appreciate their various advantages and limitations. The clinical biochemist, too, needs to be aware of the role of other investigations, so that he or she can view biochemical tests in context and advise on their suitability and the interpretation of their results in specific clinical circumstances.

It has been the editors' aim to ensure that this information is provided where relevant in this book.

The processes of acquiring and interpreting biochemical data are complex. Correct interpretation requires that the clinical context and reason for requesting the test are properly understood, otherwise the result has little value. This chapter explores the variety of potential ways in which biochemical data can be used in clinical practice.

SPECIFIC USES OF BIOCHEMICAL TESTS

Diagnosis

It has been said that diagnosis in medicine is an art, not a science, yet the process of diagnosis is amenable to scientific analysis. Making a diagnosis is the equivalent of propounding a hypothesis. A hypothesis should be tested by experiment, the results of which may support or refute the hypothesis, which can then be extended, modified or discarded in favour of an alternative, as appropriate. The validity of a clinical diagnosis is tested by observation of the natural history of the condition or its response to appropriate treatment or by the results of definitive investigations: the diagnosis will be confirmed if these are as expected from knowledge of previous cases. If they are not, it must be reviewed.

Clinical diagnosis is based on the patient's history and clinical examination. Taking general and hospital practice together, it has been estimated that, in more than 80% of cases, a confident diagnosis can be made on the basis of the history or the history and clinical findings alone. Even when this cannot be done, it should be possible to formulate a differential diagnosis, that is, a list of diagnoses that could explain the clinical observations. The results of investigations may then lead to one of these being considered the most likely and providing a rational basis for treatment. Subsequent observation will indicate whether the diagnosis was correct.

Although not necessarily required for the management of an individual patient, it may be possible to extend the clinical diagnosis by further investigation to determine the pathogenesis of the condition and ultimately, its underlying cause. For example, measurement of serum troponin concentration may confirm a clinical diagnosis of myocardial infarction in a patient with typical chest pain and electrocardiographic abnormalities; angiography could be used to demonstrate coronary atherosclerosis prior to surgery or angioplasty; the finding of hypercholesterolaemia would indicate a causative factor for the atherosclerosis; a family history of premature heart disease would suggest that the hypercholesterolaemia was familial and DNA mutation analysis might reveal the underlying genetic defect.

The ideal diagnostic investigation would be 100% sensitive (all cases of the condition in question would be correctly diagnosed) and 100% specific (no individual without the condition would be wrongly diagnosed as having it). The concepts of specificity and sensitivity are examined fully in Chapter 2. In practice, the capacity of biochemical investigations to provide precise diagnostic information is extremely variable. At one end of the spectrum, the techniques of genetic analysis are making it possible to reliably diagnose inherited metabolic diseases

in utero; at the other end of the spectrum, to take just one example, a decrease in plasma sodium concentration can occur in many different conditions and is, on its own, diagnostic of none of them.

Molecular genetic analysis has become a separate discipline in its own right and is a special case for the use of biochemical investigations for diagnosis. It is used to detect the presence of a mutation responsible for a specific disease. Even when possession of a mutation does not inevitably result in the development of a disease, its presence can indicate increased susceptibility to a condition. However, even individuals with the same genotype for a characteristic may differ in their phenotypes. But, although molecular genetics is a rapidly developing field, many genetically determined conditions, including inherited metabolic diseases, are still diagnosed on the basis of their biochemical phenotype.

With the exception of genetically determined diseases, the number of conditions in which biochemical investigations alone provide a precise diagnosis is very small. There are several reasons for this. First, biochemical changes are often a consequence of a pathological process that is common to many conditions. Thus, although tissue destruction leads to the release of intracellular enzymes into the plasma, few such enzymes are specific to any one tissue and tissue destruction can occur for many reasons, for example with ischaemia, exposure to toxins etc. Second, it also frequently happens that a biochemical variable can be influenced by more than one type of process. To cite a familiar example, plasma albumin concentration can be influenced by changes in the rates of synthesis and degradation of the protein and by changes in its volume of distribution, and the rate of synthesis in turn depends on substrate supply and hepatic function, among other factors. Third, even when a biochemical change is specific to one condition, it may not indicate its cause and this may need to be established before the condition can be treated appropriately. For example, the demonstration of a high plasma concentration of the thyroid hormone, tri-iodothyronine, is characteristic of hyperthyroidism, but this can be a result of several different thyroid diseases, and treatment appropriate for one of these may not be appropriate for another.

When a biochemical investigation is used for diagnosis, the result obtained from the patient will usually be compared with a reference range, that is, the range of values that can be expected in comparable apparently healthy individuals. The theory of reference ranges is discussed further in Chapter 2, but two points require particular emphasis here.

First, the natural variation of biochemical parameters is such that the ranges of concentrations of constituents of the plasma are likely to be narrower in an individual than in a group (even if well-matched to the individual). Second, for many biochemical variables, there is overlap, often considerable, between the range of values seen in healthy individuals and those characteristic of disease. Thus, a test result in a patient with a disease may fall into the range typical for healthy people and vice versa. This overlap stems in part from the fact that some organs have considerable reserve capacity. The liver, kidneys, pancreas and small intestine exemplify this. For example, in chronic kidney disease, renal function may still be sufficient to

maintain normal homeostasis with respect to body fluid composition, even when half the functional capacity of the kidneys has been lost. It should not, therefore, be surprising that simple measurements of function can yield normal results in patients with kidney disease. In chronic pancreatitis, biochemical evidence of functional disturbance (e.g. of malabsorption) usually only becomes apparent when at least 80% of the functional capacity of the pancreas is lost, although the characteristic of severe pain often occurs at an earlier stage. Similarly, disease of the small intestine by no means always results in malabsorption.

When previous measurements are available in an individual, test results can be compared with these values, rather than with a reference range. Indeed, biochemical investigations are sometimes requested to provide a 'baseline' against which to assess future results, particularly if there is risk of a particular complication developing or if a change can be anticipated from the natural history of the disease or the expected response to treatment. A change in a biochemical variable in relation to a previous result may be of significance, even if both results are within the reference range. Thus, a rise of creatinine concentration within the reference range may indicate a significant loss of kidney function, and may even indicate acute kidney injury if the rise has occurred rapidly. The concept of the critical difference between two results is discussed further in Chapter 2.

The capacity of a biochemical test to provide diagnostic information can be quantified by the calculation of a mathematical function known as the predictive value. As will be discussed in Chapter 2, the predictive value of a diagnostic test depends on the prevalence of the condition in the group of people to whom the test is applied. If a diagnostic test is used indiscriminately, its predictive value will be low.

The majority of biochemical investigations made for clinical purposes involve analysis of plasma or serum. However, changes in the concentration of analytes in these fluids do not necessarily parallel changes in intracellular or whole body content, and yet it may be these quantities that are more relevant to the underlying pathology. Furthermore, single measurements may not provide reliable information in non-steady-state situations, for example, the plasma concentration of thyroid stimulating hormone (TSH), which is typically very low in patients with thyrotoxicosis, may remain low for some weeks after treatment has rendered patients clinically euthyroid.

For whatever purpose biochemical data are used, it is essential that they are reliable and are available in time to be of use. Under some circumstances, it may be permissible to sacrifice some quality in order to obtain a result rapidly, but in general, every attempt should be made to minimize the influence of both analytical and preanalytical factors on the accuracy and precision of data. This topic is considered further in Chapter 2.

Management

Assessment of disease severity

Most biochemical investigations are quantitative, and the more abnormal a result is, the more likely it is that a pathological disturbance is causing it. Often, the extent

to which a result is abnormal correlates well with the severity of a condition but this is not always the case. The diagnostic test may not reflect that aspect of the condition of greatest importance in terms of severity; thus two patients with hepatitis may have equally raised plasma aminotransferase activities (reflecting tissue damage), but the condition will be judged more severe if, in one patient, the prothrombin time is prolonged (reflecting impaired hepatic functional capacity). Furthermore, overall disease severity (in relation to its effect on the patient) is likely to depend on many other factors, including the nature of the condition itself, the patient's age, previous state of health, the existence of other illness etc. For example, hepatitis due to infection with hepatitis A virus tends to have a good prognosis compared with that caused by hepatitis B or C.

Prognosis

In general, the results of biochemical tests are poor indicators of prognosis, but there are exceptions to this. For example, the plasma bilirubin concentration at the time of diagnosis in patients with primary biliary cirrhosis correlates well with outcome; a high plasma concentration of α -fetoprotein in a patient with testicular teratoma is of prognostic significance, but the concentration of paraprotein in a patient with myeloma is not. Other examples are discussed in the ensuing chapters.

One aspect of prognosis is the assessment of the benefits and risks of treatment. It has long been appreciated that different patients do not necessarily respond identically to the same drug. Many factors impinge on patients' responses to drugs including, for example, nutrition or the concomitant use of other drugs. Genetic factors are also important, and often many different genes are involved. Pharmacogenetics (see Chapter 43) is the name given to the science relating the effects of genes on our response to drugs, and is a rapidly expanding field within molecular genetics that is likely to become established within the repertoire of diagnostic clinical biochemistry laboratories in the future.

Monitoring the progression of disease

Although biochemical data alone may be of limited use in diagnosis, serial measurements can be of considerable value in monitoring the course of a disease or its response to treatment. The more closely the variable being measured relates to the underlying pathological process or functional abnormality, the better it will be for this purpose.

However, the reason for a change in a biochemical variable is not always the most obvious (or hoped for), so that even if an observed change is as expected or desired, the result should be interpreted with care. For example, a decrease in urine protein excretion in a patient with glomerular disease may indicate resolution of the underlying condition, but it could also be a result of deterioration leading to a decrease in the glomerular filtration rate. Biochemical data must always be interpreted in the light of clinical assessment and the results of other relevant investigations, not in isolation. Nevertheless, intervention may sometimes be appropriate on the basis of a

biochemical change alone, if this has been shown reliably to predict a significant clinical change, for example in hyperkalaemia in a patient with renal failure.

When serial biochemical measurements are used to follow the response to treatment, the failure of an expected change to occur may suggest that the treatment is inadequate or inappropriate, or even that the diagnosis is incorrect. In therapeutic drug monitoring (TDM, see Chapter 39), biochemical measurements may actually indicate a possible cause for non-response to treatment.

Biochemical investigations can also be used to detect the development of complications of diseases or their treatment before these become obvious clinically, and thus allow appropriate action to be taken before there is any clinical deterioration. They may even be used to prevent complications: for certain drugs, TDM allows presymptomatic detection of potentially toxic concentrations of the drug.

Screening

Screening for disease implies attempting to detect disease before it becomes manifest through the development of a clinical disturbance. Inherent in the concept of screening is that appropriate management of subclinical disease is of potential benefit to the patient. Screening can involve clinical assessment and laboratory and other investigations. For some conditions (particularly inherited metabolic diseases), screening may involve a single biochemical test. But the term is also used in relation to the performance of a range of biochemical tests (often combined with other types of investigation) in healthy people, in an attempt to detect any of a number of conditions, in the belief that a set of 'normal' results – that is, results within the appropriate reference limits – excludes these conditions. As will be seen in Chapter 2, considerable care is required both in the devising of screening tests and in their interpretation. While a set of 'normal' results may appear reassuring and may, indeed, exclude the presence of certain diseases, it may also convey a false impression and even delay the diagnosis of early disease. Because of the way in which reference ranges are defined, the more tests that are performed, the more likely it is that an 'abnormal' result (i.e. outside the reference limits) will be generated that is not related to the presence of disease.

A positive result in a screening test on its own should not usually be regarded as being diagnostic. When the prevalence of a condition in the population being screened is low, the predictive value of a positive result is often lower than is generally supposed. A positive result in a screening test must always be confirmed by further investigation. The use of direct methods (e.g. oligonucleotide probes, see Chapter 43) to detect mutations in DNA is an exception to this. Properly conducted, they are definitive with regard to the detection of mutations, although not necessarily for the development of disease.

Screening may be applied to a population, to groups sharing a common characteristic within a population or to individuals. According to the nature of the condition in question, screening may be carried out antenatally, shortly after birth, during childhood or during adult life. The strategy adopted will depend on the risk of the condition, the probability of its presence, the availability

of suitable screening tests and, inevitably, the cost. The latter includes particularly the economic cost of the programme but also the personal cost to individuals, for example those who test 'false positive' (individuals identified by the programme but on further investigation found not to have the condition in question) and, with inherited diseases, the relatives of individuals detected by the programme.

Population screening

Economic and logistic considerations preclude the screening of whole populations for disease, although it has been advocated, for example, that all adults (some suggest only males, others males and females) should be screened for hypercholesterolaemia. Although this would undoubtedly lead to the identification of a significant number of individuals at greatly increased risk of coronary heart disease because of severe but asymptomatic hypercholesterolaemia, such a programme, however desirable, would be very costly, and it has been argued that resources would be better devoted to measures to improve the general health of the population, by encouraging a healthy diet and lifestyle.

Selective screening

Selective biochemical screening for disease is already practised extensively in developed countries. The neonatal screening programmes for phenylketonuria, congenital hypothyroidism, sickle cell disease and cystic fibrosis are the best known examples. With the advent of tandem mass spectrometry, it is possible to screen for many more conditions such as medium chain fatty acid oxidation disorders, some organic acidaemias and the commonest form of congenital adrenal hyperplasia, using a tiny quantity of blood and at reasonable cost. These complement the thorough clinical screening of the newborn for conditions such as congenital cataract, imperforate anus etc.

Where a condition is particularly common in a defined group, screening may be appropriate, even though it would not be for the population at large. Antenatal screening for Tay–Sachs disease in Ashkenazi Jews is one example.

For hypercholesterolaemia, selective screening is a more practicable procedure than population screening. It can be applied to people in whom there is a high probability of hypercholesterolaemia being present, for example members of families in which there is a history of familial hypercholesterolaemia or premature heart disease. Such screening can also be directed towards people already at increased risk of coronary heart disease because, for example, they are smokers or have hypertension or type 2 diabetes, whose risk would be increased further by hypercholesterolaemia. Other examples of selective screening are discussed in the relevant chapters of this book.

Individual screening

Examples of individual screening include antenatal screening of a fetus for an inherited disease when a previous child of the parents has been found to have the condition

or when there is a strong family history of the condition. This has been practised for some time for certain inherited diseases, but the number for which it can be done is growing rapidly now that the mutations responsible for inherited diseases are becoming known. Although, undoubtedly, it will become possible to treat some of these conditions in utero, at present, antenatal screening is mainly aimed at detecting conditions with consequences so severe that it is considered appropriate to terminate the pregnancy if the genetic abnormality is present. Given this possible outcome, it is clearly essential that if the diagnosis is to rest only on the result of the screening test, this should provide accurate and unequivocal results.

Other uses of biochemical investigations

All the uses of biochemical investigations that have been discussed thus far are potentially of direct benefit to the patient. Other important uses include the provision of information for teaching, research and public health. Usually, this will relate to one of the categories discussed. Although such data may not be of immediate benefit to the patient, these areas are of immense potential benefit to the population, providing information fundamental to the advancement of knowledge. This use has ethical implications and is increasingly subject to scrutiny by bodies such as the network of research ethics committees in the UK. The use of biochemical investigations to assess organ function in potential transplant donors is an example of the use of investigations primarily for the benefit of other people. Data collection in specific disorders, such as for the UK Renal Registry for patients on dialysis, can help to improve the standard of care given to selected patient groups by comparing results achieved by different centres against pre-defined targets.

Extensive biochemical investigations are usually carried out during trials of drugs: these may be required as part of the assessment of a drug's efficacy but are also essential for the detection of possible toxicity.

Investigations may also be performed for the benefit of the doctor rather than the patient. Few doctors have not been guilty at some time, of requesting biochemical tests for reassurance. The supposition is that if the results of a range of test results are within reference limits, then the conditions in which abnormalities are known to occur cannot be present. As has been emphasized above, this supposition is erroneous and any reassurance may be unfounded. Biochemical investigations should be requested for one of the reasons discussed in the relevant chapter

of this book and not 'routinely'. Neither should junior medical staff be put under pressure to request unnecessary tests to placate their seniors.

It is regrettable that there is an increasingly perceived need for doctors to carry out a comprehensive range of investigations in case of subsequent litigation. While this is understandable, it should not be necessary if investigations are requested and performed in response to the individual clinical circumstances. There will always be other investigations that could have been done, but no blame should be attached to a doctor who failed to carry one out if it was not indicated clinically, either on the basis of the known natural history of the disease or the predicted response to, and known complications of, treatment.

CONCLUSION

Biochemical data are used extensively in medicine, both in the management of patients and in research. But before an investigation is requested, the rationale for testing should always be considered. Automated analysers can perform many tests at a very low cost in relation to the total expenditure on healthcare, but the cost is not negligible. There may also be a cost to the patient. Repeated venepunctures to obtain blood for 'routine' tests are at best a nuisance, and at worst can, particularly in small children, cause a significant fall in the haematocrit. The laboratory handbook at one hospital of the authors' acquaintances used to contain the following advice to junior medical staff: 'If you need advice or time to think, ask for it; do not ask for a full blood count and measurement of "urea and electrolytes".' In common with other investigations, biochemical investigations should be requested to answer specific questions; if there is no question, the result cannot provide an answer.

CONCLUSION 20

INTRODUCTION

It was emphasized in Chapter 1 that all investigations in medicine should be performed to answer specific questions. Biochemical data obtained must be considered in relation to the reason for the request, and against the background of an understanding of the relevant normal physiological and biochemical mechanisms and the way in which these respond to disease. One of the objectives of any laboratory is to ensure these data are available in a timely manner, and generated efficiently. The achievement of this goal requires careful attention to every step in the process, from the ordering of the investigation, the collection of the specimen(s) required, their transport to the laboratory and analysis, to the delivery of a report to the clinician, appropriate action being taken and the effects of this action being assessed. Amongst these many steps, the interpretation of data by clinical biochemists adds considerably to the value of the data. The workload of most laboratories is so great that it would be impossible (as well as being unnecessary) to add such comments to all reports (e.g. where the results are clearly normal). Interpretative comments (which may be individual or rule-based) are more likely to be required for more unusual tests, and for requestors who have only limited experience of the investigation in question. Typical reports requiring more detailed

interpretation include those with borderline data, results that are not consistent with the clinical findings, apparently contradictory data and changes in biochemical variables during dynamic function tests.

THE TEST REQUEST

The first step in performing a biochemical investigation is for a request form to be completed, often electronically, which prompts the collection of the appropriate specimen(s) and instructs the laboratory on the investigations(s) to be performed. Depending upon the reason for the request, the expertise of the clinician and the practice of the laboratory, the request may simply be for one or more specified analyses on a body fluid; for a set (often referred to as a 'profile') of standard investigations (e.g. 'thyroid function tests'); for a more involved procedure such as a dynamic function test involving the collection of serial samples following a specific stimulus, or an open request to perform whatever assays are deemed appropriate by the laboratory staff to answer the question posed in the request. The majority of biochemical test requests fall into the first two categories.

The information that is required when a test is requested is summarized in [Table 2.1](#).

TABLE 2.1 Information required when requesting a biochemical investigation

Information	Reason
Patient's name, identifying (e.g. hospital) number ^a , date of birth and sex	Identification and (age, sex) interpretation of results
Home address for primary care patients	Address may be useful if grossly abnormal results are found
Return address (e.g. ward, clinic, surgery; telephone/pager number if urgent)	Delivery of report
Name of clinician (and telephone/pager number)	Liaison Audit Billing
Clinical details (including drug treatment)	Justification of request Audit Interpretation Selection of appropriate assays Choice of analytical method (to avoid drug interference)
Test(s) requested	Instruction to analyst
Sample(s) required	Instruction to phlebotomist
Date (and time ^b if appropriate)	Identification Interpretation (with timed/sequential requests)

^aIn the UK, it is mandatory to supply the National Health Service Number.

^bIt is good practice also to record the time at which the specimen and request is received in the laboratory.

FACTORS AFFECTING TEST RESULTS

The generation of biochemical data is potentially subject to error at every stage in the process. It is essential that the sources of error are identified and understood, so that their effects can be minimized.

The sources of errors in biochemical tests are conventionally described in three categories:

- preanalytical: that is, either outside or within the laboratory, but before the analysis is performed
- analytical: these may be random (e.g. due to the presence of an interfering substance in the specimen) or systematic (e.g. because of a bias in the method)
- postanalytical: that is, occurring during data processing or transmission, or in relation to the interpretation of the data.

Preanalytical factors

Preanalytical factors may appear to be beyond the remit of clinical biochemists, but accreditation bodies are increasingly expecting laboratories to take responsibility for all aspects of testing. Laboratories should ensure that clinicians requesting investigations and the staff responsible for collecting the specimens understand the problems that can arise, so that specimens are collected and transported appropriately.

Preanalytical factors fall into two categories: those that relate to the specimen obtained for analysis (technical factors) and those that relate directly to the patient (biological factors).

Technical factors

These include:

- correct identification of the patient
- appropriate preparation of the patient where necessary
- collection of the specimen into an appropriate container with the correct anticoagulant or preservative
- accurate labelling of the specimen container after the sample has been collected (not before, as this carries a higher risk of a specimen being put into a container bearing another patient's name). Primary labelling of the sample with a barcode at source reduces the risk of mislabelling in the laboratory
- rapid and secure transport to the laboratory. Some specimens need to be transported under special conditions, for example arterial blood for 'blood gases' in a sealed syringe in an ice-water mixture; requests for blood, urine or faecal porphyrins must be protected from light.

Care must be taken during specimen collection to avoid contamination (e.g. with fluid from a drip), haemolysis of blood or haemoconcentration (due to prolonged application of a tourniquet). Appropriate precautions are also required during the collection and transport of urine, faeces, spinal fluid or tissue. Specimens known to be infective (e.g. from patients carrying the hepatitis B or HIV viruses) are occasionally handled specially, but it is good practice to handle all specimens as if they were potentially hazardous.

On receipt in the laboratory, the patient's name and other identifiers on the specimen must be checked against these details on the request form, whether paper or electronic. The specimen and form should then be labelled with the same unique number. As electronic requesting becomes more common, the majority of specimens are now being labelled with a unique barcode at source. Secondary containers (e.g. aliquots from the primary tube) should also be identified with patient details and the same unique number as the primary container. Automated preanalytical robotics and track systems can minimize the number of manual interventions required during sample handling, thereby minimizing risk of errors. All these processes are facilitated if computer systems in hospitals or surgeries have electronic links to the laboratory information system.

Laboratories should have written protocols (standard operating procedures) for the receipt and handling of all specimens to ensure the positive identification of specimens throughout the analytical process.

Biological factors

Numerous factors directly related to the patient can influence biochemical variables, in addition to pathological processes. They can conveniently be divided into endogenous factors, intrinsic to the patient, and exogenous factors, which are imposed by the patient's circumstances. They are summarized in [Table 2.2](#).

In addition, all biochemical variables show some intrinsic variation, tending to vary randomly around the typical value for the individual.

TABLE 2.2 Some biological factors affecting biochemical variables

Factor	Example
Endogenous	
Age	Cholesterol Alkaline phosphatase Urate
Sex	Gonadotrophins Gonadal steroids
Body mass	Triglycerides
Exogenous	
Time	Cortisol (daily) Gonadotrophins (in women, catamenial) 25-Hydroxyvitamin D (seasonal)
Stress	Cortisol Prolactin Catecholamines
Posture	Renin Aldosterone Proteins
Food intake	Glucose Triglycerides
Drugs	see Table 2.3 and text

Endogenous factors

Age. The reference values (mentioned in more detail later in the chapter) for many biochemical variables do not vary significantly with age during adult life. Some, however, are different during childhood, particularly in the neonatal period. A well-known example is plasma alkaline phosphatase activity, which is higher in children, particularly during the pubertal growth spurt, than in adults. Plasma cholesterol concentrations tend to increase with age, but may fall slightly over the age of 70; plasma urate concentrations tend to rise with age. Given that renal function tends to decline with age, it might be anticipated that mean plasma creatinine concentrations would rise with age, but the tendency for loss of muscle bulk in the elderly has a balancing effect. Other age-related changes are discussed elsewhere in this book.

Sex. Apart from the obvious differences in plasma gonadal hormone concentrations between adult men and women, other analytes demonstrate sex-related differences in concentration, often because their metabolism is influenced by gonadal hormones. Thus, total cholesterol concentrations tend to be higher in healthy men than in women until the menopause, after which concentrations in women tend to rise. In general, sex-related differences in biochemical variables are less between boys and girls prepubertally, while the differences between adult males and females decrease after the menopause.

When age and sex are important determinants of the level of a biochemical variable, measurements in patients should be considered in relation to age- and sex-related reference values, if valid conclusions are to be drawn.

Changes in many biochemical variables occur during pregnancy and, where necessary, measurements must be compared with reference values appropriate to the stage of gestation. The clinical biochemistry of pregnancy is considered in detail in Chapter 22.

Ethnic origin. Plasma creatine kinase activity tends to be higher in people of sub-Saharan African descent

TABLE 2.3 Some examples of in vivo effects of drugs on biochemical variables

Drugs	Effect	Mechanism
Glucocorticoids	Decreased plasma cortisol	Suppression of ACTH secretion
Thiazide diuretics	Decreased plasma potassium	Increased renal potassium excretion
Oestrogens	Increased plasma total thyroxine	Increased synthesis of binding proteins
Phenytoin, phenobarbitone, alcohol	Increased plasma γ -glutamyltransferase	Increased enzyme synthesis (enzyme induction)

than Caucasians (typically up to three times the upper reference limit; people of southern Asian origin may have intermediate values), but otherwise, there are no significant differences in the typical values for most biochemical variables between individuals of different ethnic origin living in the same region.

Body mass. Obese individuals tend to have higher plasma insulin and triglyceride concentrations than lean individuals, with an increased risk of developing type 2 diabetes and cardiovascular disease. Creatinine production is related to muscle bulk and plasma concentration may be above the usual reference range in a muscular individual, despite having a normal glomerular filtration rate. Twenty-four hour urinary excretion of many substances is greater in people of higher body mass. On the whole, however, body mass has little effect on the *concentrations* of substances in body fluids, although, of course, it is an important determinant of the total *quantities* of many substances in the body.

Exogenous factors. Many exogenous factors can have profound influences on the concentrations of biochemical variables even in healthy individuals. They include the time of day, stress, posture, fasting status, drugs, exercise and concurrent illness (see Tables 2.2 and 2.3).

Time-dependent changes. Rhythmic changes occur in many physiological functions and are reflected in changes in the levels of biochemical variables with time. The time base may be diurnal (related to the time of day, but usually nycthemeral, i.e. related to the sleep-wake cycle), catamenial (relating to the menstrual cycle) or seasonal. In addition, some hormones are secreted in sporadic bursts (e.g. growth hormone); when this occurs, it may be helpful to collect several blood samples over a short period of time and to base clinical decisions on the mean value.

The best known analyte having a diurnal variation in concentration is cortisol. Its concentration is at a nadir at about midnight, rises rapidly to reach a peak at 08.00–09.00h and then declines throughout the day. Observed values must be compared with reference values for specific times, with sampling at expected peak or trough times being the most informative. Other analytes

showing a diurnal rhythm (but to lesser extents) include thyroid stimulating hormone, testosterone and prolactin.

Some analytes show regular variations with a different time base. In women, during the reproductive years, the menstrual cycle is associated with regular changes in the concentrations of gonadotrophins, oestrogens and progesterone. Measurements made for diagnostic purposes must be made at the appropriate time in the cycle: for example, an increase in plasma progesterone concentration seven days before the onset of the next menstrual period is due is taken as an indication that ovulation has occurred.

Plasma 25-Hydroxycholecalciferol concentration varies with the season, being higher in summer than in winter.

Stress. Concern for the patient dictates that stress should be minimized at all times, but this is particularly important in relation to blood sampling for those analytes with concentrations that are responsive to (usually by increasing) stress. Pituitary and adrenal hormones are particularly affected. Thus plasma adrenocorticotrophic hormone (ACTH), cortisol, prolactin, growth hormone and catecholamine concentrations all rise in response to stress. Indeed, this effect is utilized in investigations of pituitary function. However, avoidance of stress is vital when collecting specimens for the measurement of these hormones under other circumstances.

Posture. Posture has a significant effect on a wide range of analytes. The best known of these are plasma renin activity and aldosterone concentration. Both are higher in the standing than the recumbent (or even sitting) position, particularly shortly after the change in posture, as a result of a decrease in renal blood flow.

The effect of posture on certain other analytes is less well appreciated. When people are upright, there is a greater tendency for fluid to move from the vascular to the interstitial compartment than when they are recumbent. Small molecules and ions in solution move with water, but macromolecules and smaller moieties bound to them do not. As a result, the concentrations of proteins, including lipoproteins, and of protein-bound substances, for example thyroid and other hormones, calcium and iron, tend to be approximately 10% higher when an individual is in the upright position than when recumbent. Intermediate values occur when sitting. This effect may be relevant when values obtained from individuals when they are outpatients are compared with values obtained when they are inpatients.

Food intake. The concentrations of many analytes vary in relation to food intake. Frequently encountered examples include glucose, triglycerides and insulin, the plasma concentrations of which all increase following a meal, so that they should usually be measured in the fasting state, unless the effect of recent intake (as in the glucose tolerance test) is being examined. Some specific dietary constituents can affect biochemical variables; consumption of red meat in the hours before venepuncture may increase plasma creatinine concentrations by as much as 30% from fasting values. A protein-rich meal results in increased urea synthesis and increases plasma urea concentration. Long-term dietary habits can also significantly affect biochemical variables (e.g. cholesterol).

The urinary excretion of many substances is highly dependent on their intake and, although some laboratories publish reference ranges for them, they are very wide. In assessing the significance of the excretion of substances in the urine, it is important to consider their intake and thus their expected excretion if renal function is normal. Thus, for example, a low urinary sodium excretion is a normal response to sodium depletion.

Drugs. Drugs, whether taken for therapeutic, social or other purposes, can have profound effects on the results of biochemical tests. These can be due to interactions occurring both in vivo and in vitro.

In vivo interactions occur more frequently. They can be due to direct or indirect actions on physiological processes or to pathological actions. There are numerous examples in each category. Some of the better known physiological interactions are indicated in Table 2.3. Others are discussed elsewhere in this book.

Pathological consequences of drug action in vivo can be idiosyncratic (unpredictable) or dose related. A measurable biochemical change may be the first indication of a harmful effect of a drug, and biochemical tests are widely used to provide an early indication of possible harmful effects of drugs, both for those in established use (e.g. measurement of serum creatine kinase activity in patients being treated with statins) and in drug trials.

Drugs can also interfere with analyses in vitro (this is strictly an analytical factor, but is mentioned here for completeness), for example by inhibiting the generation of a signal or by cross-reacting with the analyte in question and giving a spuriously high signal. This field is well documented, but the introduction of new drugs means that new examples of this source of error are continually being described.

Other factors. Exercise can cause a transient increase in plasma potassium concentration and creatine kinase activity; the latter used to be a potential confounding factor in the diagnosis of myocardial infarction in a patient who had developed chest pain during exercise before cardiac-specific troponin measurement was introduced. Even uncomplicated surgery may cause an increase in creatine kinase as a result of muscle damage, and tissue damage during surgery can also cause transient hyperkalaemia. Major surgery and severe illness can elicit the 'metabolic response to trauma' (see Chapter 20), which can lead to changes in many biochemical variables.

Intrinsic biological variation. The contributions to biological variation discussed thus far are predictable, and either preventable or can be allowed for in interpreting test results. However, levels of analytes also show random variation around their homeostatic set points. This variation contributes to the overall imprecision of measurements and must also be taken into account in the interpretation of test results. It is also relevant to the setting of goals for analytical precision (see below).

Intrinsic biological variation can be measured by collecting a series of specimens from a small group of comparable individuals over a period of time (typically several weeks) under conditions such that analytical imprecision is minimized. The specimens should be handled identically and analysed in duplicate, using an identical technique (e.g. the same instrument, operator, calibrators and

reagents). This may either be done at the time the specimens are collected or in a single batch. If the latter approach is adopted, the specimens must be stored in such a way that degradation of the analyte is prevented (e.g. by freezing at a sufficiently low temperature). Using a single batch procedure is preferable as it eliminates between-run analytical variation.

If the specimens are analysed in a single batch, the analytical imprecision (see below) can be calculated from the differences in the duplicate analyses and is given by:

$$SD_A = \sqrt{\frac{\sum (\text{differences})^2}{2n}}$$

where SD is the standard deviation and n is the number of pairs of data. If, however, specimens are analysed at the time they are taken, the analytical imprecision must be calculated from replicate analyses of quality control samples.

The standard deviation of a single set of data from each individual is then calculated after excluding any outliers ('fliers') using an appropriate statistical test. This standard deviation will encompass both analytical variation and the intraindividual variation (SD_I), such that:

$$SD = \sqrt{SD_A^2 + SD_I^2}$$

Since SD_A is known, the intraindividual variation can then be calculated. It is also possible to calculate the interindividual variation (SD_G , due to the difference in the individual homeostatic set points for the analyte between each member of the group) by calculating the SD for all single sets of data for all subjects in the group, since this SD is given by:

$$SD = \sqrt{SD_A^2 + SD_I^2 + SD_G^2}$$

The calculations required can be performed using a nested analysis of variance technique as provided in many statistical software packages. An alternative approach is to calculate coefficients of variation (CV) (given by $(SD \times 100)/\text{mean}$). Values for CV can be substituted for SD in these formulae because the means are similar.

Some typical values of biological variation for frequently measured analytes are given in Table 2.4. (A reference to a more extensive list is provided in the Further reading section at the end of the chapter.) It should be noted that, while in most instances the interindividual variation is greater than the intraindividual variation, this is not always the case. When it is not, it means that the extent of natural variation around individuals' homeostatic set points is more than the range of variation between these set points. The relative sizes of intra- and interindividual variation have important consequences for the interpretation of analytical data in relation to reference ranges, as will be discussed later in the chapter.

Analytical factors

It is clearly essential that every effort is made to reduce the possibility of errors arising during analysis. A rigorous

quality assurance programme (discussed in Chapter 3), is required to ensure the quality of results. The production of reports and their transmission to the requesting clinician are discussed below (see Postanalytical factors).

Test methods and procedures must be selected to allow adequate performance. Some of the important factors that impinge on performance will now be considered. The question of what is adequate performance will also be discussed. It should be appreciated that deciding on the standards for performance of individual assays requires an appreciation of all the factors involved: efforts to reduce specimen volume (an important consideration in paediatric, and particularly neonatal, practice) may affect accuracy and precision; these may also be influenced by a requirement to achieve a very rapid turnaround time. Cost, instrumentation and staff skill mix are other important factors.

Analytical range. The test selected must be capable of measuring the analyte in question over the whole range of concentrations that may be expected to occur. Measuring large quantities of an analyte is usually easier than measuring small quantities (though dilution of the sample may be necessary to bring the concentration within the range of acceptable performance, i.e. to avoid nonlinearity of signal to concentration). Note, however, that if dilutions are to be employed, their validity must be established by appropriate studies to demonstrate that dilution, per se, does not affect the relationship between analyte concentration and the signal generated. It is not always possible to design an assay that has a low enough detection limit (i.e. the lowest level of the analyte that can be reliably distinguished from zero, usually taken as the mean signal generated by zero standards plus two standard deviations); this has been a particular problem with the analysis of certain hormones, the plasma concentrations of which are in the nano- or even picomolar range, but is becoming less so with the introduction of more sensitive assay techniques.

For some analytes, the need to be able to measure concentrations over very wide ranges can pose technical problems, for example the 'high dose hook effect' with immunoassays for prolactin and human chorionic gonadotrophin. This term refers to the decrease in signal that occurs at high concentrations as a result of binding sites on the capture and labelled antibodies being occupied by separate molecules of the analyte rather than these causing crosslinking between them (the usual situation when the antibodies are in excess). For C-reactive protein (CRP) in serum, the requirement to be able to measure concentrations accurately in two different ranges ('high sensitivity' CRP as a cardiovascular risk marker or marker of neonatal sepsis and CRP as an inflammatory marker) has led to the introduction of separate assays for each of the two ranges of concentration.

Accuracy and bias. Accuracy reflects the ability of an assay to produce a result that reflects the true value. Inaccuracy is the numerical difference between the mean of a set of replicate measurements and the true value. The term 'bias' is often preferred to 'inaccuracy' in laboratory medicine as it implies a persistent characteristic rather than an

TABLE 2.4 Biological and analytical variation and consequent desirable analytical performance parameters for some frequently measured constituents of plasma expressed as coefficients of variation (CV=(SD×100)/mean)

Analyte	Intra-individual variation (%)	Inter-individual variation (%)	Typical analytical imprecision (%)	Desirable analytical precision (%)	Desirable analytical bias (%)
Sodium	0.7	1.0	1.1	0.4	0.3

Data from various sources, including UKNEQAS (UK National External Quality Assurance Scheme) website and Ricos et al. on Westgard QC website (see Further reading).

occasional effect. It is due to systematic error (*cf.* precision, below) and can be positive (the result is higher than the true result) or negative (lower than the true result), and constant (being the same absolute value throughout the analytical range) or proportional (having the same *relative* value to the true result).

Ideally, analyses should be without bias, but, provided that its extent and characteristics are known, the predictability of bias makes it less of a problem in the interpretation of laboratory data than imprecision.

Precision. Precision is a reflection of reproducibility. Imprecision is defined as the standard deviation for a series of replicate analyses (i.e. made on the same sample, by the same method, under identical conditions). For many analytes it is very low, giving coefficients of variation (CV, defined as (SD×100)/mean value) of 1% or less. For others it is higher, giving CVs as high as 5%. The median imprecisions for some serum analytes, as achieved by a group of laboratories in the UK, are given in Table 2.4.

Imprecision in analysis can never be entirely eliminated. Such analytical variation is an important factor to be borne in mind when interpreting the results of laboratory tests, as discussed later.

Analytical variation or imprecision can be measured by performing repeated analyses on a single sample and calculating the standard deviation of the results, or by doing duplicate measurements on a series of samples as described in the section on biological variation, above. Imprecision tends to be highest when the signal generated by an assay (e.g. a colour change or electric potential) is low. To be of value in interpreting results, imprecision should be determined over a range of concentrations and particularly in the region of critical values (decision levels), where a

small change in a result can lead to a significant change in management of the patient.

Specificity and interference. Specificity is the ability of an assay to measure only the analyte it purports to measure. Most assays are highly specific, but exceptions do occur, both owing to endogenous substances and to drugs that can give a signal in the assay and cause the concentration/activity to appear higher or lower than it is. A detailed discussion of this topic is beyond the scope of this chapter. Some important examples are mentioned elsewhere in this book and further information is available from the bibliography. Interference is a related, but separate problem, in that a substance alters the signal given by the analyte in question, but does not generate a signal itself.

Practicalities: what is desirable performance? In their enthusiasm to perfect analytical methods, clinical biochemists must be careful not to lose sight of the application of their work. A result is of no value if its bias or imprecision render it dangerously unreliable; neither is it of value if the method is practically too complicated or too expensive to be useful, or if it takes so long to perform that the need for the result has passed by the time it becomes available.

What is required of a test is that it should be capable of providing a result that will answer the question that is posed. To give a simple example, if the requirement is to confirm that a patient with the typical clinical features of diabetic ketoacidosis does indeed have this condition, what is needed is a rapid test that will confirm the presence of hyperglycaemia. In this context, it is of little relevance whether the blood glucose concentration is 30 or 35 mmol/L. But if a glucose tolerance test is required to establish (or refute) a diagnosis of diabetes because the

clinical features are equivocal, time is of little concern, but the precision and accuracy are of paramount importance. Imprecision or bias may lead to the diagnosis being missed or a patient being classified as having diabetes and managed as if he had the condition when he does not.

In practice, it is rarely necessary to sacrifice accuracy and precision for the sake of a result being available rapidly. Providing that they are used competently, and in accordance with standard operating procedures, many rapid methods, including point-of-care (near-patient) testing instruments, using 'dry chemistry' techniques, are intrinsically as reliable as traditional laboratory-based procedures. But, although clinical biochemists rightly strive to increase the accuracy and precision of assays, there must come a point where further efforts may not result in significant improvements in the reliability of data or their value when applied to patient care. The question: 'What is desirable performance?' needs examination in some detail.

Analytical goals. Numerous strategies have been applied to the setting of desirable standards for the performance characteristics of laboratory tests or 'analytical goals'. These have been based, for example, on the opinions of clinical users, of laboratory-based experts, on imprecision data, on arbitrary fractions of the reference range etc. The most widely accepted strategy for defining analytical goals is based on data on analytical imprecision in the assay and biological variation for the analyte. The *desirable* goal is that analytical imprecision should be less than or equal to half the intraindividual biological variation.

Expressing imprecision as coefficients of variation (CV), the goal is thus: $CV_A \leq 0.5 \times CV_I$, where CV_A is the CV for analytical imprecision and CV_I is the CV for intraindividual variation. Since the overall imprecision is equal to the square root of the sum of the squares of individual imprecisions, i.e.:

$$CV_{TOTAL} = \sqrt{CV_A^2 + CV_I^2}$$

it follows that if the goal is achieved, $CV_{TOTAL} \sim 1.12 \times CV_I$. This means that if the goal is achieved, analytical imprecision will contribute only about 12% to the overall imprecision of the result.

This concept has been extended to encompass goals for *optimum* performance ($CV_A \leq 0.25 \times CV_I$) and *minimum* performance ($CV_A \leq 0.75 \times CV_I$). Clearly, the less the analytical precision, the less the overall precision, but at any level of biological imprecision, equal increments in analytical precision (that is, lower imprecision) will produce relatively smaller increments in the overall quality of the result. Striving for analytical perfection may, therefore, be an inappropriate use of resources, which does not provide additional clinical value in decision-making. Some examples of analytical goals are given in Table 2.4. The relevance of both analytical and biological variation to the interpretation of results must not be understated. High precision and accuracy must be obtained over the whole range of concentrations that are likely to be encountered, but particularly over the range(s) critical to decision-making.

This brief discussion of analytical goals has centred on imprecision. Bias may appear less important, since most results on most patients will be compared with their own previous values or with reference ranges obtained using the same method. But patients may move from one healthcare setting to another and analyses may be performed by different methods in a variety of settings, so that accuracy (or lack of bias) to ensure comparability of results is also important. This is particularly the case when diagnoses and management decisions may be based on consensus opinions, for example the World Health Organization criteria for the diagnosis of diabetes, targets for glycated haemoglobin in the management of diabetes or the recommendations of various expert bodies for the management of hyperlipidaemias. An alternative approach to minimizing differences between methods is to develop nationally agreed guidelines or standards. In the UK, the introduction of the modified Modification of Diet in Renal Disease (MDRD) formula for calculating estimated glomerular filtration rate (eGFR) that is traceable back to the reference method for measuring creatinine (see Chapter 7), is an example of such standardization.

Desirable standards for bias have also been set and can be combined with those for precision to produce standards for total allowable error. For analytical bias (B_A), the desirable goal is given by:

$$B_A = < 0.25 \sqrt{(CV_I^2 + CV_G^2)}$$

This can be combined with the analytical goal for imprecision to produce the 'total allowable error' (TE_a) given by:

$$TE_a = < 0.25 \sqrt{(CV_I^2 + CV_G^2)} + 1.65(0.5 \times CV_I)$$

The interested reader is referred to the detailed discussion of this topic by Fraser (see Further reading, below). In practice, these concepts are less widely applied to assay performance than perhaps they should be, but ideally, their value should be assessed for individual analytes on the basis of their influence on clinical outcome.

Postanalytical factors

Errors can still arise even after an analysis has been performed, for example if calculations are required or if results have to be transferred manually, either directly from an analyser to a report or entered into a computer database. Even computers are not immune to error.

An error in the transmission of the report to the responsible clinician can also lead to an incorrect result being used for the management of the patient. Transcription errors can arise if results are telephoned, although it may be essential to do this if results are required urgently. Strict procedures should be followed when telephoning reports, both in the laboratory and by the person receiving the report. Although time-consuming, it is advisable for the person receiving the report to read it back to the person telephoning, to ensure that it has been recorded correctly.

Increasingly, data transfer is direct from the laboratory to the electronic patient record (EPR) and paper reports may not be printed routinely. Where paper reports are still used they must be transferred to the patient's notes. Even at this stage (especially if there are patients with the same or similar names in the same area), care must be taken; misfiled reports are at best wasted and at worst, if acted on as if they referred to another patient, positively dangerous.

The final stage in the process is for the requesting clinician to take action on the basis of the report. The report must be interpreted correctly in relation to the clinical situation and the question that prompted the request. This interpretation may be provided by a member of the laboratory staff, by the requesting clinician or may be a matter for discussion between them. However, errors can arise even at this stage, leading to an inappropriate clinical decision. The interpretation of data is discussed in the next section. Requesting laboratory investigations can appear to be a simple process, but it should by now be apparent that there are many potential sources of error. All laboratories should engage in a programme of audit, whereby action is taken to maintain and improve performance on a continuing basis, which will be discussed in Chapter 3.

INTERPRETATION OF RESULTS

Normal and abnormal

In interpreting the results of a biochemical investigation, one of two questions is likely to be posed: 'Is the result normal?' or, if it has been performed before, 'Has the result changed significantly?'. Arguably, a more relevant question to ask is, 'What does this result add to my knowledge that will allow me to manage this clinical situation better?'. The importance of considering this broader question should become apparent from a consideration of the problems associated with answering the first two, narrower, questions.

When an investigation is performed on an individual for the first time, the result must be assessed against a reference point. Usually, it is assessed specifically against what is expected in a healthy individual, although it might be more relevant in a symptomatic individual to assess it against what is expected in a comparable patient with similar clinical features. The range of values expected in healthy individuals has often been termed the 'normal range', but for various reasons, the term 'reference range' (strictly, 'reference interval') is now preferred.

The meaning of normal

Normal ranges have traditionally been defined on the basis of measurements of the analyte in question in a sufficiently large sample of individuals from an appropriate (in terms of, e.g. age, sex or ethnicity) healthy population. For data having a Gaussian distribution, the normal range is defined as the range of values lying between the limits specified by two standard deviations below the mean and two standard deviations above (Fig. 2.1). This

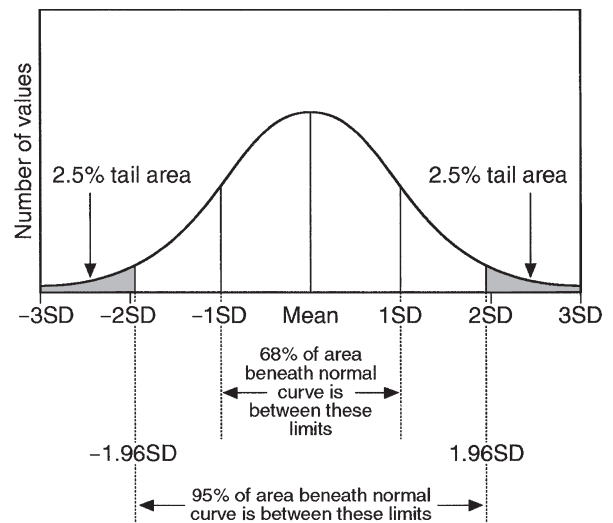

FIGURE 2.1 ■ The normal (Gaussian) distribution. The normal range encompasses values falling between two standard deviations above and below the mean and includes approximately 95% of all the values.

range encompasses 95% of the values found in the sample. The implication is that the great majority of healthy people will have a value for the analyte within this range.

'Normal' is a term used in statistics to describe a Gaussian distribution. Although the term 'normal range' is statistically valid only when the distribution is Gaussian, many analytes frequently measured in the laboratory have a skewed distribution – most frequently with a skew (tail) towards higher values. Examples include plasma alkaline phosphatase activity and the concentrations of triglycerides and bilirubin. A further drawback to the use of the term 'normal range' is that the word 'normal' has several different meanings in addition to its use in statistics. Given that the normal range, as defined above, encompasses only 95% of values characteristic of the chosen sample, 5% of individuals are bound to have values outside that range and might thus be considered 'abnormal'. This is clearly absurd in relation to the more colloquial meanings of the word, for example 'usual', 'acceptable', 'typical' or 'healthy'.

Often there is not a definite cut-off associated with an analyte, but a continuum of increasing risk with increasing concentration. An excellent example of this is the risk of coronary heart disease associated with increasing plasma cholesterol concentration, which extends below even the value of 5.0 mmol/L, often regarded as being an appropriate target for healthy (low risk) individuals. Indeed, although the curve of risk against cholesterol concentration becomes very shallow at low concentrations, it does not entirely flatten out (Fig. 2.2): that is, there is a continuum of increasing coronary risk associated with higher plasma cholesterol concentrations even in the lower part of the range of values typically found in adults in the UK. In this context, then, the term 'normal range' is potentially misleading: it is more relevant to define target values, which will depend on the overall level of coronary risk.

Furthermore, even in patients with established disease, results may fall within the 'normal range'. For most analytes, there is an overlap between the values usually

FIGURE 22 ■ The distribution of serum cholesterol concentration in healthy subjects and risk of coronary heart disease. More than one-third of the values exceed the recommended highest acceptable concentration (5.0 mmol/L) and are associated with significantly increased risk. Note that the distribution is non-Gaussian, being skewed to the right.

encountered in health and those encountered in disease (particularly if the disturbance is mild). Thus, it should not be assumed that all patients with values within the normal range for a particular analyte are free of the relevant disease, just as it has been indicated that (by definition) not all patients with values falling outside the range are necessarily abnormal in any other way.

Reference values

Such considerations led to the development, in the late 1960s, of the concept of reference values. The word 'reference' is free of the ambiguities associated with 'normal'. A reference value is defined as the value for an analyte obtained by measurement in an individual (reference individual) precisely selected using defined criteria, for example sex, age, state of health or other relevant characteristics.

The qualities required of a reference individual are only those specified: the term should not be taken as implying the possession of any quality (e.g. 'healthiness') that has not been specified. If measurements are made on a representative sample (reference sample) from a population of reference individuals (reference population) a distribution of values (a reference distribution) is obtained.

Reference limits can then be set and the range between these is defined as a reference interval. Typically, reference limits are set so that the interval encompasses values found in 95% of the reference samples, and this interval may then numerically be the same as the statistically defined normal range. Reference intervals are often colloquially termed 'reference ranges', but, strictly speaking, this is incorrect usage, since the true reference range encompasses the whole range of values derived from the reference population. The term 'reference range' is used in this book in accordance with common practice as a more familiar synonym for the term 'reference interval'.

Reference values can be obtained by carrying out measurements on a carefully selected and precisely defined

reference sample. If the distribution of values is Gaussian, the reference limits are the mean minus two standard deviations and the mean plus two standard deviations. When the distribution is non-Gaussian, the range can be calculated by ranking the values and deleting the lowest and highest 2.5%. Such a procedure has the considerable advantages that it requires no assumptions to be made about the characteristics of the distribution and does not require any transformation of the data to be made.

When the reference interval is derived from a sample of healthy individuals not known to be at increased risk of disease, the term effectively means 'values characteristically found in a group of healthy individuals and thus likely to encompass values found in other, comparable (with regard to age, sex etc.) healthy individuals'. It is sometimes called a 'health-associated reference interval'. Note, however, that health is not essential to the definition. Reference values could as well be established for analytes in disease as in health, although in practice this has not often been done (and, as indicated above, their ranges would almost always overlap with the corresponding health-related reference ranges).

Many strategies have been suggested for expressing observed values for biochemical variables in relation to the reference range: for example, the observed value can be expressed as a percentage of the mean of the reference interval or of the upper reference limit to give a 'centi-normalized unit'. Most such suggestions have not been adopted in clinical practice. For enzyme measurements, however, where the values obtained can be highly method-dependent and can, in disease, be orders of magnitude higher than reference values, it is sometimes helpful to express results as multiples of the upper reference limit. Measurements used in antenatal screening, e.g. α -fetoprotein and human chorionic gonadotrophin, are often reported as 'multiples of the median'.

An alternative suggestion has been to quote a 'reference change value', which looks at a patient's usual intra-individual variation and expresses the observed value as a percentage of the mean individual reference interval. The development of sophisticated laboratory information systems has enabled alternatives to the reference range to become a realistic possibility.

Problems with reference intervals

Even reference intervals have disadvantages. However derived, they encompass the values from only 95% of the reference population. Thus, 5% of reference individuals will have values outside the reference limits. If two analytes that vary independently are measured, the probability of one of them being outside its reference limits is $(1-0.95^2)$, that is 0.10. Of the reference individuals, 10% would be expected to have one of the measured values outside the reference limits. For 'n' analytes that vary independently, the probability is $(1-0.95^n)$, so that if 20 analytes were to be measured in an individual, there would be a 64% chance of one result being outside the reference limits. In practice, many tests are dependent on one another to some extent (e.g. total protein and albumin), so that this probability is reduced, but the calculation serves to emphasize that, even where values characteristic of

health and disease have a completely bimodal distribution (i.e. non-overlapping ranges, something that happens very rarely in practice), by no means all observed results outside the health-related reference limits would be associated with disease. On the other hand, common sense dictates that the further away from the reference limit an observed result is, the more likely it is to be pathological in origin.

Comparison of observed results with reference limits

The importance of comparing observed results with appropriate (e.g. age- and sex-specific) reference intervals has already been emphasized.

As has been discussed, the appreciation of analytical and intrinsic biological variation for each analyte is also important. The implications for the interpretation of observed data on patients are considerable. As an example, we can consider the measurement of creatinine in plasma, widely used as a test of renal function. Its (health-related) reference interval is of the order of 60–110 µmol/L, but this does not mean that this range of values will be observed over time for a single healthy individual. The intraindividual biological variation of creatinine concentration is around 4.6 µmol/L so that the reference interval for individuals is approximately 18 µmol/L. Thus, two healthy individuals from the reference population might have typical creatinine concentrations that ranged between, for example 60–78 µmol/L and 85–103 µmol/L, respectively. But, as will be discussed in the next section, a *change* in plasma creatinine concentration in an individual from 70 to 98 µmol/L would almost certainly signify a decrease in renal function, even though both results are well within the population-based reference interval.

When (as is usual) there is overlap, or even a continuum, of values of an analyte in health and disease, it may be necessary to define a cut-off value to determine if further action should be taken (e.g. initiating further investigations). This is particularly true of screening tests, when there may be no other information to take into account in deciding the significance of a result. The considerations on which the selection of such a cut-off value depends are discussed later in this chapter.

In summary, it is important to appreciate that the information that can be provided by a single biochemical measurement is limited. In general, the results of complementary or serial measurements are often of much greater value.

Comparison of results with previous values

The problem posed in the interpretation of a test result when the test has been performed previously, is a different one. The relevant questions are, ‘Has there been a change and, if so, is it clinically significant?’

In order to assess the relevance of any change to a pathological process, it is necessary to have a quantitative indication of the possible contribution of analytical and intrinsic biological variation to the observed change. The probability that a difference between two results (whether an increase or a decrease) is significant at the

95% level (i.e. that such a difference would only be expected to occur by chance alone on fewer than one in 20 occasions), requires that the difference is 2.8 times the variation (SD) of the test (for the basis of this calculation, see Fraser 2001, in Further reading, below). Because of the contribution of both analytical and biological variation, the standard deviation of the test is given by:

$$SD = \sqrt{SD_A^2 + SD_B^2}$$

where SD_A is the analytical variation and SD_B is the biological variation. One set of estimates of the value of $2.8 \times SD$, also known as the critical difference (more formally called the ‘reference change value’), for some frequently measured analytes, is given in Table 2.5. These values appear to differ little in health and disease and are valuable guides to clinical decision-making. Two caveats are important. First, the values quoted are mean values: individuals may show greater or lesser intrinsic biological variation. Second, analytical performance (and hence analytical variation) varies considerably between laboratories: ideally, laboratories should calculate their own values for critical differences, although in practice, this is seldom done.

It should be emphasized that, just because a change in the level of a biochemical variable exceeds the critical difference calculated from the known biological and analytical variation, it does not necessarily follow that it is clinically significant: that will depend on the precise clinical circumstances and needs to be assessed in relation to whatever clinical and other data are available. For example, restriction of dietary protein intake may cause a considerable reduction of plasma urea concentration

TABLE 2.5 Critical differences: changes required in the plasma level of some frequently measured analytes to be of significance in an individual

Analyte	Concentration	Change absolute	Change (%)
Sodium	140 mmol/L	5.1	4
Potassium	4.2 mmol/L	0.6	14
Calcium (total)	2.4 mmol/L	0.2	9
Magnesium	1.0 mmol/L	0.2	16
Phosphate	1.2 mmol/L	0.3	25
Bicarbonate	26 mmol/L	6.4	25
Urea	5.0 mmol/L	1.8	37
Creatinine	60 µmol/L	16.7	28
Urate	260 µmol/L	69.8	27
Glucose	4.6 mmol/L	0.7	14
Bilirubin (total)	10 µmol/L	6.9	69
Cholesterol	5.8 mmol/L	1.0	17
Triglycerides	1.2 mmol/L	0.7	60
Total protein	75 g/L	9.6	13
Albumin	40 g/L	5.2	13
Alkaline phosphatase	60 U/L	13.3	22
Alanine aminotransferase	20 U/L	10.4	52
γ-Glutamyltransferase	40 U/L	16.2	40
Creatine kinase	150 U/L	97.4	65

Data from various sources, including UKNEQAS (UK National External Quality Assurance Scheme) website and Ricos et al. on Westgard QC website (see Further reading).

in a patient with chronic renal disease, but this does not signify an improvement in renal function. The reverse is also true: the lack of a change does not necessarily imply that there is no cause for concern. For example, the haemoglobin concentration of blood may initially remain within health-related reference limits for a short period, even after severe acute bleeding, because erythrocytes and plasma have been lost together.

Another important point in relation to critical difference values, is a possible difference between laboratory staff and clinical staff in ascribing significance to an apparent change. The choice of a probability of 0.95 that two results are significantly different is arbitrary, although hallowed by practice. A probability of 0.99 is clearly more significant, but if two results differ with a probability of only 0.9, there is still a 9 in 10 chance that they *are* truly different. Decisions in medicine are still frequently made on much lower probabilities. It would be feasible to construct lists of critical differences at different levels of probabilities, but to publish such lists in laboratory handbooks would make them cumbersome and potentially confusing. However, laboratories should be able to provide guidance in this area to recently qualified clinicians and for newly introduced investigations.

In practice, critical values for difference used by clinicians are often empirical and not based on any formal assessment. This does not invalidate their use; indeed, they have often been validated informally by long experience and observation of outcomes. However, they fall short of the requirements of 'evidence-based clinical biochemistry' (discussed in Chapter 3).

Most instrument-based or laboratory-based management systems incorporate automatic procedures for identifying large (and potentially significant) changes in biochemical variables ('delta checks'). Despite every effort to reduce analytical variation, such changes may arise because of unusual analytical imprecision or random error. Gross analytical errors ('fliers') will often be obvious because they are greater than typically occurs clinically. Smaller errors may not be obvious. Deciding whether a change in a variable is likely to represent a real change in the patient requires checks on the identity of the specimen, internal quality control performance and the clinical details, if these are available on the request form or can be deduced from other information (the patient being located in the intensive therapy unit, for example), all of which the clinical biochemist will use in deciding what action to take. If the identity of the specimen is confirmed, the assay run was in control and the change is consistent with what is known about the patient, the result can be reported; if not, the original specimen may need to be re-analysed or a further specimen obtained from the patient.

As well as 'delta checks', laboratories should be able to identify action limits, such that unexpectedly high or low results that may require an immediate change of management (e.g. low or very high serum potassium concentrations) are checked and communicated rapidly to the requesting clinician. Specific values may be set to trigger further investigations on the basis of protocols agreed with the appropriate clinicians, for example magnesium if the corrected calcium concentration is low, or serum protein electrophoresis if the total globulin concentration is

increased. All these procedures are of potential value to the patient and add to the clinical usefulness of the results in question.

THE PREDICTIVE VALUE OF TESTS

Introduction

It will have become clear that the interpretation of biochemical data is bedevilled by the inevitable presence of analytical and intrinsic biological variation. It is still frequently assumed that a result within reference limits indicates freedom from disease or risk thereof, while a result outside reference limits at least requires that the patient be further investigated. What is lacking is any numerical indication of the *probability* that a particular result indicates the presence or absence of disease.

The predictive value concept, introduced into clinical biochemistry in the mid-1970s by Galen and Gambino, represents an attempt to address these shortcomings. Essential to the concept of predictive values is that disease or freedom from disease can be defined absolutely, that is, that there is a test which can be regarded as the 'gold standard'. For some conditions, this will be histological examination of tissue obtained at surgery or post-mortem, but it may be the eventual clinical outcome or some other more or less well-defined endpoint. It is against the gold standard that biochemical tests may be judged.

Definitions

If all the members of a population consisting of people with and without a particular disease are subjected to a particular test, the result for each of them will fall into one of four categories:

- true positives (TP) – individuals with disease, who test positive
- false positives (FP) – individuals free of disease, who test positive
- true negatives (TN) – individuals free of disease, who test negative
- false negatives (FN) – individuals with disease, who test negative.

Clearly, the number of individuals with disease equals (TP+FN) and the number without equals (TN+FP). The total number of positive tests is (TP+FP) and of negative (TN+FN).

These data can conveniently be arranged in a matrix (Table 2.6). It is then easy to derive the other important

TABLE 2.6 A matrix for classifying test results

		Test result		Totals
		Positive	Negative	
Disease status	Positive	TP	FN	TP+FN
	Negative	FP	TN	FP+TN
Totals		TP+FP	TN+FN	ALL

TP = true positive; TN = true negative; FP = false positive; FN = false negative.

TABLE 2.7 Important parameters relating to test performance

Parameter	Definition	Formula (expressed as %)
Prevalence	Number of individuals with the disease expressed as a fraction of the population	$\frac{TP+FN}{(TP+FN+TN+FP)}$
Sensitivity	Number of true positives in all individuals with disease	$\frac{TP}{(TP+FN)}$
Specificity	Number of true negatives in all individuals free of the disease	$\frac{TN}{(TN+FP)}$
Positive predictive value	Number of individuals correctly defined as having disease	$\frac{TP}{(TP+FP)}$
Negative predictive value	Number of individuals correctly defined as free from disease	$\frac{TN}{(TN+FN)}$
Efficiency of test	Fraction of individuals correctly assigned as either having, or being free from disease	$\frac{(TN+TF)}{(TP+TF+FP+FN)}$

TP = true positive; TN = true negative; FP = false positive; FN = false negative.

TABLE 2.8 Results matrix using the upper reference limit as cut-off

		Test result		Totals
		Positive	Negative	
Disease status	Positive	TP = 62	FN = 18	TP + FN = 80
	Negative	FP = 11	TN = 109	FP + TN = 120
Totals		TP + FP = 73	TN + FN = 127	ALL = 200

TABLE 2.9 Results matrix using a higher upper reference limit as cut-off

		Test result		Totals
		Positive	Negative	
Disease status	Positive	TP = 50	FN = 30	TP + FN = 80
	Negative	FP = 2	TN = 118	FP + TN = 120
Totals		TP + FP = 52	TN + FN = 148	ALL = 200

parameters relating to test performance, that is, prevalence, sensitivity, specificity, predictive value and efficiency (Table 2.7).

The predictive value model examines the performance of a test in defined circumstances. Clearly, it depends upon being able to determine the numbers of true and false positive and negative results, which depends upon there being an independent, definitive diagnostic test. The importance of the independence of the test under investigation from the definitive test may appear self-evident but, in practice, it is frequently overlooked.

Example

These concepts, and some of the pitfalls inherent in their use, can be illustrated with reference to a hypothetical example. Suppose that it is desired to assess the value of measurements of serum γ -glutamyltransferase activity to assist in the diagnosis of alcohol abuse in patients attending a drug-dependency clinic. It is decided that the test will be regarded as positive if the γ -glutamyltransferase activity exceeds the upper reference limit. Disease status is determined by a validated questionnaire.

Over the course of a year, 200 patients are tested. Enzyme activity is found to exceed the chosen limit in 73, but only 62 are judged to be abusing alcohol on the basis of the rigorous questionnaire. In 18 individuals judged to be abusing alcohol, enzyme activity is not elevated.

The results matrix can thus be completed as in Table 2.8. Calculation then shows that:

$$\text{Prevalence} = (62 + 18) / 200 = 0.400 = 40\%$$

$$\text{Sensitivity} = 62 / (62 + 18) = 0.775 = 78\%$$

$$\text{Specificity} = 109 / (109 + 11) = 0.908 = 91\%$$

$$\text{PV}(+) = 62 / (62 + 11) = 0.849 = 85\%$$

$$\text{PV}(-) = 109 / (109 + 18) = 0.858 = 86\%$$

$$\text{Efficiency} = (62 + 109) / 200 = 0.855 = 86\%$$

Thus, the test correctly identifies 78% of alcohol abusers; further, if a patient has an elevated enzyme activity, there is an 85% probability that he is abusing alcohol. However, it might be considered that a significant number of patients are being misclassified and that better performance might be achieved if the cut-off value for a positive test were to be set at a higher enzyme activity, say twice the upper reference limit.

The results matrix might then appear as in Table 2.9, from which:

$$\text{Prevalence} = (50 + 30) / 200 = 0.400 = 40\%$$

$$\text{Sensitivity} = 50 / (50 + 30) = 0.625 = 63\%$$

$$\text{Specificity} = 118 / (118 + 2) = 0.983 = 98\%$$

$$\text{PV}(+) = 50 / (50 + 2) = 0.961 = 96\%$$

$$\text{PV}(-) = 118 / (118 + 30) = 0.797 = 80\%$$

$$\text{Efficiency} = (50 + 118) / 200 = 0.840 = 84\%$$

The effect has been to decrease the sensitivity of the test, which now only correctly identifies 63% of alcohol abusers. On the other hand, if a patient tests positive, the

probability that he is an alcohol abuser is now 96%. The overall efficiency of the test is little changed.

This example illustrates two important points about the predictive value model. The first is that sensitivity and specificity tend to vary inversely; second, appropriate selection of the criterion for positivity or negativity (here the level of enzyme activity) allows either one to be maximized. If the cut-off is set very high, positive results will only occur in individuals with disease; there will be no false positives and specificity will be 100%, although sensitivity will be low. On the other hand, if the cut-off is set low, no cases will be missed, but the false positive rate will be high; sensitivity will be 100%, but specificity will be low. This is illustrated in Figure 2.3.

Whether it is desirable to maximize sensitivity, specificity or efficiency depends on the nature of the condition being investigated, as discussed below.

Prevalence and predictive value

While sensitivity and specificity are dependent on the characteristics of the test and the nature of the condition being investigated, predictive values are dependent on the prevalence of the condition in the population under examination. Consider the application of the measurement of γ -glutamyltransferase activity to identify alcohol abuse during pregnancy. If 500 women were screened and the cut-off taken as the upper limit of the reference range, then the results matrix might show as in Table 2.10, from which:

$$\begin{aligned} \text{Prevalence} &= (24+7)/500 = 0.062 = 6\% \\ \text{Sensitivity} &= 24/(24+7) = 0.774 = 77\% \\ \text{Specificity} &= 426/(426+43) = 0.908 = 91\% \\ \text{PV}(+) &= 24/(24+43) = 0.358 = 36\% \\ \text{PV}(-) &= 426/(426+7) = 0.983 = 98\% \\ \text{Efficiency} &= (426+24)/500 = 0.900 = 90\% \end{aligned}$$

The sensitivity and specificity are unchanged compared with the previous example, but, because of the much lower prevalence of alcohol abuse in this group, the predictive value of a positive test is low: only 36% of those with a positive test are alcohol abusers. At the same time, the predictive value of a negative test is higher than in the patients attending the drug dependency clinic: this is again a consequence of the lower prevalence in pregnant women. It is instructive to note that the efficiency of the test appears greater in this context (90% in comparison to 84% in the drug abuse patients). Overall, the proportion of tests that correctly assign patients to the alcohol abuse or non-abuse categories is higher, although its performance in diagnosing abuse alone is poorer.

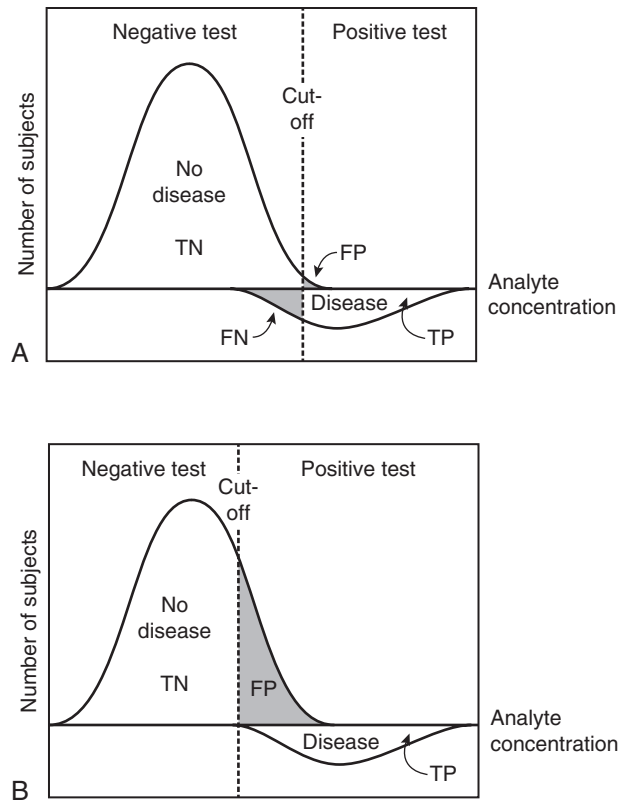

FIGURE 2.3 ■ The effect of moving the cut-off point that determines positivity/negativity of a test result. Hypothetical distributions for the concentrations of an analyte with and without disease are shown. Because these overlap, if the cut-off is selected to decrease the number of false positive (FP) results (and hence increase specificity), (A) there are a significant number of false negative (FN) results (decreasing the sensitivity). If the cut-off is set lower (B), false negatives are eliminated (maximizing sensitivity), but at the expense of increasing the number of false positives (and decreasing specificity). The distribution for individuals with disease has been shown below the axis for clarity. TP, true positive; TN, true negative.

The effect of disease prevalence on predictive values is an important one. It means that the performance of a test in one group of patients cannot be translated to a different group. Although the predictive value of a new test may appear high in the typical experimental setting where equal numbers with and without disease are tested (the prevalence is 50%), it is likely to be much lower 'in the field'. Thus, the performance of a new test must be analysed in groups of individuals comparable with those in whom it is to be used in practice. In the past, many exaggerated claims for tests have been made on the basis of their performance in a highly selected group.

TABLE 2.10 Results matrix in a population with a lower disease prevalence

		Test result		Totals
		Positive	Negative	
Disease status	Positive	TP=24	FN=7	TP+FN=31
	Negative	FP=43	TN=426	FP+TN=469
Totals		TP+FP=67	TN+FN=433	ALL=500

Practical applications of the predictive value model

High sensitivity in a diagnostic test is required when a test is being used to diagnose a serious and treatable condition. The false negative rate (missed diagnoses) must be as low as possible, even though this inevitably means that false positives will occur. Individuals testing positive will be subjected to further, definitive tests and, provided that these cause no harm to those who test positive and turn out not to have the condition, this may be an acceptable price to pay for making the diagnosis in all those who have the condition. The programmes for neonatal screening for phenylketonuria and other harmful conditions in the newborn exemplify tests requiring maximum sensitivity. In this context, it is instructive to note that although the sensitivity of the screening test for phenylketonuria is 100%, and its specificity approaches this value, because the condition has such a low prevalence (approximately 1 in 10 000), the predictive value of a positive test is only of the order of 10%.

High specificity (no false positives) is desirable in a test to diagnose a condition that is severe, but either it is untreatable or the benefits of treatment are unpredictable, when knowledge of its absence is potentially beneficial. Multiple sclerosis is frequently cited as the classic example of such a condition. High specificity is also required when it is desired to select patients with a condition for a trial of some new form of treatment. If individuals without the condition were to be included in the treatment group, the results of the trial (assuming that the treatment is in some measure effective and does no harm to those without the disease) would give a false view of its efficacy.

Diagnoses are rarely made on the basis of single tests. Ideally, a single test or combination of a small number of tests should be used to identify individuals in whom the probability of a condition is significantly higher than in the general population (the prevalence is higher), who can then be further investigated. The initial tests can be simple, cheap and unlikely to do harm, but the further tests may be more elaborate, expensive and possibly associated with some risk. In essence, if the performance of individual tests is known and the objectives of testing can be precisely defined, the predictive value model can be used to determine the appropriate sequence or combination of tests to achieve the desired objective.

Receiver operating characteristic curves

Another use of the predictive value model is to compare the performance of two tests. This can be done by determining sensitivity and specificity for each test using a range of cut-off limits to define positivity and plotting one rate against the other. The resulting curves are known as receiver operating characteristic (ROC) curves. The reader is warned that four variants of ROC curves may be encountered, according to the way the data are projected on the axes, but this does not affect their interpretation. Figure 2.4 shows hypothetical ROCs for two tests, A and B, each applied to the same group of individuals to make the same diagnosis.

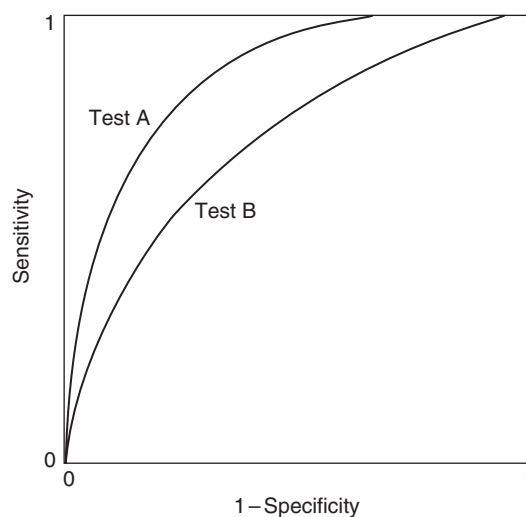

FIGURE 2.4 ■ Receiver operating characteristic curves for two tests being assessed for the diagnosis of the same condition in the same patients. Test A gives better specificity at any level of sensitivity.

It is clear that test A gives the better discrimination, since for any level of sensitivity its specificity is superior. This may be useful information, but these are by no means the only factors that may need to be taken into account in choosing a test. The economics and practicalities of the tests will also be of relevance to which one is chosen.

The interpretation of the ROC curves in Figure 2.4 is straightforward. In practice, the curves for two tests may cross; the relative performance must then include assessment of the areas under the curves. The greater the area, the greater the efficiency.

Likelihood ratios

Although the predictive value model can be used to determine the most appropriate cut-off for a test result for clinical purposes, it can only classify results as positive or negative, and does not give any indication of the degree of abnormality, which may be of prognostic significance.

In contrast, likelihood ratios can be applied to individual test results. The likelihood ratio states how much more likely a particular test result (or combination of results) is to occur in an individual with a disease than without it (positive likelihood ratio, LR(+)), or not to occur, again in individuals with a disease than without it (negative likelihood ratio LR(-)). The ratios are calculated thus:

$$\text{LR}(+) = \text{sensitivity} / (1 - \text{specificity})$$

$$\text{LR}(-) = (1 - \text{sensitivity}) / \text{specificity}$$

To give an example, an LR(+) of 10 implies that the given result will be obtained ten times more frequently in a population with the condition in question than in one without. A LR(-) of 0.01 implies that the given result will be obtained 100 times more often in individuals without the condition than in those who have it. Calculation of the LR(+) and LR(-) allows the post-test probabilities for

either a positive or negative result to be calculated. The post-test probability can be calculated as follows:

$$\text{Post-test probability} = \frac{(\text{pre-test probability} \times \text{LR})}{(1 + \text{pre-test probability} \times (\text{LR} - 1))}$$

The pre-test probability is equal to the prevalence of the condition in comparable individuals (e.g. a population being screened).

Positive and negative likelihood ratios can be combined to give the diagnostic odds ratio (DOR) for a particular test result:

$$\text{DOR} = \text{LR}(+) / \text{LR}(-) = (\text{TP} \times \text{TN}) / (\text{FP} \times \text{FN})$$

The DOR expresses the odds of a result being positive in a patient with the condition being investigated compared with one who does not have the condition, and is a measure of the overall accuracy of a test.

CONCLUSION

It is a simple matter to fill out a request form for a biochemical test, but before doing so, it is essential to consider why the test is being done and for what the results will be used. Many factors can affect the results of laboratory tests, apart from the pathological process that is being investigated. Some of these are obvious, others less so. All need to be minimized by careful patient preparation, sample collection and handling, analytical procedures and data processing, if the results are to be reliable and fit for whatever purpose they are to be used.

The interpretation of biochemical data requires adequate knowledge of all the factors that can affect the test result. These include the physiological, biochemical and pathological principles on which the test is based, as well as the reliability of the analysis. It is also necessary to understand the statistical principles that relate to the distribution of data in healthy individuals and those with disease, and how the test performs in the specific circumstances in which it is used. Such knowledge is

also essential for the appropriate selection of laboratory investigations.

ACKNOWLEDGEMENT

We would like to thank William Marshall, who wrote this chapter for previous editions of the book.

CONCLUSION 26

INTRODUCTION

It was emphasized in Chapter 2 that every step in the process, from the ordering of the investigation, through collection of the specimen(s) required, their transport to the laboratory and analysis, to the delivery of a report to the clinician, is vital in ensuring that results of investigations are used appropriately. Interwoven throughout each step is the requirement to ensure the quality of the whole process. Chapter 2 has already discussed the need to minimize analytical variation through the use of processes to reduce imprecision and bias. The use of standard operating procedures has also been alluded to, but this chapter will expand on the use of laboratory standards to maintain quality.

WHAT IS QUALITY?

Quality is difficult to define, and may be considered to be 'doing the right test, for the right patient, at the right time for the right reason', but may equally be defined as 'adhering to stringent processes in order to complete the task'. Ultimately, perhaps the question to ask is how to assess the quality of a laboratory service.

QUALITY STANDARDS

Quality assurance

Clinical biochemistry laboratories operate extensive quality assurance procedures to ensure that the results

that they produce can be relied upon to support clinical decision-making. They include internal quality control (IQC) schemes, for example involving replicate analysis of clinical samples and the repeated analysis of reference samples of identical composition, and external quality assurance (EQA) schemes involving the analysis of identical samples by a large number of laboratories.

The measurement of IQC samples allows a prospective estimate of the precision of the analyses that are being performed. The frequency of measurement of such controls may depend upon each laboratory's workload and the type of analysis undertaken. For example, it is not unusual to run quality control material at the start and the end of a sample batch measured by enzyme-linked immunosorbent assay (ELISA).

The measurement of EQA samples provides laboratories with a retrospective view of the accuracy of their measurements and the consistency of any bias that may be present. The data can be invaluable when troubleshooting possible assay problems, by allowing the laboratory to compare their result with both the reference value (if available) and the method-specific mean. The review and interpretation of EQA reports is an important skill for laboratory personnel to develop because of the variety of ways in which different EQA schemes choose to present their data. (Examples may be accessed via the website addresses of the various EQA providers included in Further reading, below.)

Not only the analysis itself, but also the interpretation of the result should be subjected to quality assurance: there exists a peer-reviewed EQA scheme for interpretative comments.

Reviewing quality assurance procedures is an essential part of the audit of laboratory performance (the assessment of overall performance with regard to the appropriateness of the use of tests, the interpretation of their results, adherence to standard procedures, cost-effectiveness etc.). Laboratory data should also be included in the medical audit, in which the effectiveness of all aspects of clinical care is examined. The ultimate test of the performance of laboratory data is provided by the clinical outcome when this has been determined, in whole or in part, by those data.

Regulation of laboratories

External regulation of laboratories has evolved over some time to include every aspect of the laboratory service. Independent regulatory bodies are empowered to award accredited status to laboratories meeting stringent standards and to fail to award or remove accreditation from laboratories which are found to have serious failings at inspection. Throughout the world, there are several organizations that fulfil this role: International Standards Organization (ISO), United Kingdom Accreditation Service (UKAS) and the Division of Laboratory Services and Standards in the USA, to name but a few. Their main aim is to ensure a laboratory's quality and competence to perform specified tasks. It is important to note that all parts of the laboratory are inspected, including the environment in which the laboratory is based. Very dilapidated buildings (in which pathology departments are sometimes located) will be a cause of concern for the inspectors, as it may reflect the low priority given to laboratories within a wider healthcare setting, such as in a hospital.

Within the UK, for example, the current list of standards against which laboratories are judged comprises almost 60 pages. The broad areas covered are listed in [Box 3.1](#). It is worth noting that the analytical process itself is just one out of eight categories examined by such an inspection.

Quality management systems

A system of 'Quality Management' is an all-encompassing term used to describe the steps a laboratory may take to maintain current procedures and to establish continual service improvement via quality objectives.

The majority of laboratories in the UK will have a designated Quality Manager, either exclusively within

their own discipline or as part of a multidisciplinary team. The development of web-based document management systems (e.g. QPulse, i-Passport) has enabled laboratories to greatly improve document control and to track review dates, changes and the number of printed copies in circulation. Complete written procedures should be in place for all tasks performed in a laboratory. Manufacturers are obliged to publish 'Instructions for Use' with each reagent supplied that contains the majority of worthwhile data. These procedures, however, form only part of the process, as the essence of a quality management system is that it documents what should take place within the laboratory in its entirety. All members of laboratory staff should be familiar with the quality management system, understand the requirement for such a system and the need to maintain the documents within it. Indeed, it is the effective implementation of the system, and adherence to it, that is likely to lead to quality improvement. Monitoring the effectiveness of the system is achieved by audit (see below) and by reviewing processes in a regular basis.

Many laboratories try to minimize the amount of printed material generated, owing to ever greater space and storage constraints. Improved reliability of information technology and the need to minimize waste are also important driving factors towards operating a paperless Quality Management system.

Personnel

When contemplating quality, staffing issues may not immediately spring to mind. Staff are, however, the most valuable assets of any laboratory. Staff morale and continuing professional development play a vital role in a 'good' quality laboratory. Education and training of all levels of staff within the laboratory ensures that their knowledge and understanding of laboratory science is current and up-to-date. The competence of staff undertaking laboratory tasks should be documented and regularly reviewed. Formal individual review meetings are recommended to assess training needs and to promote further development.

Premises and environment

The control of access to laboratories and the efficient use of heating, lighting and space are important considerations when evaluating a suitable working environment. Health and safety aspects of the premises and environment need to be reviewed, both in terms of staff safety (e.g. lone working, risk of slips and trips, adequate fire plan) and general laboratory safety such as electrical issues (e.g. overloaded sockets, regular testing of electrical appliances, use of extension cables) and chemical safety (e.g. appropriate use of material safety data sheets and adequate storage facilities for acids, controlled drugs and toxins). The latter category may also include awareness of laboratory waste disposal, which will encompass both biological and chemical waste. In the UK, for example, NHS Trusts have financial incentives related to recycling and alternative methods of disposal other than incineration.

BOX 3.1

The areas examined by the UK Accreditation Service

- Quality management system
- Personnel
- Premises and environment
- Equipment, IT and materials
- Pre-examination processes
- Examination processes
- Post-examination phase
- Evaluation and quality assurance

Information systems

The development of sophisticated information systems has had a huge impact on numerous aspects of laboratory medicine. Pre-analytical improvements include the ability to display relevant test information and sample requirements via electronic requesting. Real-time availability of results and the possibility of report acknowledgement are also areas revolutionized by information systems.

Information systems affect the way in which laboratories communicate with their users. Many laboratories now maintain an electronic laboratory handbook, as well as a paper copy. The advantages of an electronic version are that it reduces the cost of production (and paper waste) and it is easier to maintain and keep up-to-date. Patient information leaflets and testing protocols such as dynamic function tests can easily be accessed via hyperlinks, if available.

The increasing use of e-mail has allowed laboratories to communicate electronically with end-users, although security must be assured before sending patient identifiable data. Future developments will increasingly allow patients to use this or other electronic means to access their own results directly. In the UK, some patient groups, such as those with kidney disorders, already have electronic access to selected results via a nationally organized database.

The integration of laboratory information systems with electronic patient records in both primary and secondary care has revolutionized the delivery of pathology results over the past decades. The ability to view test results remotely and securely has improved the safe delivery of healthcare, especially in non-traditional settings, and has expedited the move of care from hospitals to within the community.

Evaluation and audit

The use of audit tools in laboratory medicine is widespread. During formal assessment of the laboratory's service, a combination of vertical, horizontal and examination audits are used to assess compliance with the quality standards set. Vertical audits generally look at the sample journey throughout the entire testing process, from test requesting and phlebotomy (if possible), to report generation and receipt by the requestor. Actual events are compared with written procedures to check adherence. A failure to follow any stated procedure may trigger a horizontal audit of that particular part of the testing process. A rather extreme example would be that during the course of a vertical audit, it is discovered that no quality control material was run during analysis of a particular analyte such as glycated haemoglobin; examiners may act upon this information and perform a horizontal audit of all recent analytical batches of glycated haemoglobin to see if this was an isolated occurrence or if there was a systematic failure to follow the stated procedure.

Ensuring that the audit cycle is complete is critical for continued quality improvement. Re-auditing previous processes, in which highlighted deficiencies have forced a change in practice, is vital to ensure that the changes in practice have resulted in the anticipated improvements. [Figure 3.1](#) shows the key steps to completing an audit cycle.

Clinical audit is another key aspect of evaluating laboratory effectiveness. Clinical audit plays an important role

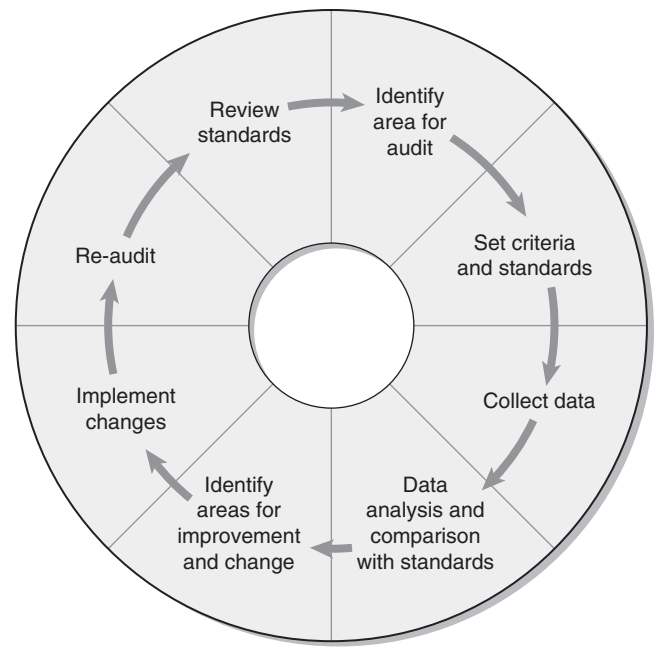

FIGURE 3.1 ■ The complete audit cycle. The process can be started at almost any point of the cycle, but often the first task is to identify an area of interest and then determine standards against which to conduct an audit.

in trying to assess the impact of laboratory testing on patient pathways and outcomes. Ultimately, the role of the laboratory is to improve the healthcare of patients and, although difficult to measure, the contribution of laboratory testing should be documented. Collaboration with other clinical disciplines allows the laboratory to forge vital relationships with clinicians and other staff within the healthcare environment.

The third type of evaluation that the laboratory should undertake is an assessment of user satisfaction. It is important to engage all users of the laboratory service, as each different group may have different needs and requirements. Clinicians, nurses, other healthcare professionals and other laboratories should be asked to contribute. All aspects of the service can be covered from the users' opinions on the judicious use of interpretative comments to turnaround times and phlebotomy services. User satisfaction surveys may eventually be circulated to patients (who may be the true end-users of the service), especially those with long-term chronic disease states (e.g. diabetes mellitus, chronic kidney disease), as they take greater ownership of their health and treatment targets. [Box 3.2](#) gives a list of the other areas covered by questions commonly seen in user surveys.

BOX 3.2

Examples of topics covered within user satisfaction surveys

- Availability of clinical advice
- Ease of requesting
- Availability of test information
- Frequency of phlebotomy collections (primary care)
- Online access to results (availability of)
- Out of hours service provision

CLINICAL QUALITY INDICATORS

Laboratories are generally adept at maintaining quality standards within their own environment; however, the need to determine and measure objectively their clinical effectiveness is growing, owing to increasing pressure on limited resources. Clinical quality indicators have recently been developed to aid in this process. The key to the use of these indicators is that they must be easily measurable and that the results can be collected in a timely manner (a yearly review would be of limited use in highlighting errors and improving performance promptly). Several quality indicators can be brought to mind, but if the mechanism for capturing the necessary data is too demanding or difficult to achieve, then the whole process becomes meaningless.

Quality indicators can fall into two broad categories: those that are designed to highlight improvement and those that are used to capture a possible deterioration in standards. An example of each may include the use of external quality assurance to show improving assay precision and the monitoring of turnaround times from emergency departments to detect peaks and troughs in service provision. Turnaround times in particular, can be an area where the laboratory and requesting clinicians can have differing views, with clinicians considering turnaround time to be 'vein-to-brain' time rather than from receipt of sample in the laboratory to a clinically validated result. [Table 3.1](#) lists other potential quality indicators that laboratories may be able to use to monitor their own performance.

Clinical effectiveness

In the context of laboratory medicine, this may be perceived as the laboratory's ability to introduce new tests and to dissuade clinicians from using tests deemed to be obsolete. Clinical biochemists may be involved in the development of specific testing protocols in Emergency Departments, for example, or in the interpretation of data in complex cases. Another way in which laboratories contribute to effective clinical care, is the identification of artefactual causes of altered biochemical analytes, such as the effect of thrombocytosis on potassium concentration. The implementation of national guidelines and the adoption of agreed testing strategies or more precise analytical methods (such as the measurement of creatinine by enzymatic methods), are all examples of ways in which the clinical effectiveness of laboratories has been improved.

Key performance indicators

In an attempt to objectively assess the quality and effectiveness of predominantly pre- and postanalytical processes within the laboratory, the Royal College of Pathologists in the UK has established Key Performance Indicators. These suggested standards cover a wide range of areas, from the percentage of staff in training to the speed at which a laboratory can respond to a request for clinical advice (what defines clinical advice may be a contentious issue). [Table 3.2](#) lists some of the other additional performance standards suggested by the Royal College of Pathologists. These are still in their infancy and some

TABLE 3.1 Examples of potential quality indicators

Category	Example quality indicator
Preanalytical	Investigation strategies and protocols
Analytical	Introduction and maintenance of reference (critical) change values
Postanalytical	Matching analytical performance to clinical requirements
	Data interpretation
	Addition of appropriate further tests
Direct clinical services	Patient/ward interventions, e.g. review of patients with metabolic disease, electrolyte or fluid balance problems
	Participation in multidisciplinary team meetings
Education	Undergraduate and postgraduate teaching; participation at hospital-wide events such as Grand Round meetings; newsletters

TABLE 3.2 Some key performance indicators recommended by the UK Royal College of Pathologists

Category	Performance standard and method of measurement
Training	15–30% of the biomedical scientist, clinical scientist and medical staff should be in training posts
User surveys	The laboratory should include patients in the annual user satisfaction survey
Turnaround times	The percentage of investigations from A&E to be completed within 1 h. Target: 90% from April 2014
Results communication	The percentage of critical results phoned to the requesting clinician within 2 h of availability. Target: 97% by April 2014

will require further clarification. However, they do provide an excellent basis on which a laboratory can assess its current performance. In order for these key performance indicators to have an impact on commissioning patterns and thereby possibly reward the best-performing laboratories, each participating laboratory should be expected to publish some of their results on a regular basis, thus allowing comparison with their peers.

Demand management

In the past, clinicians were often allowed unrestricted access to all available assays within the laboratory, but as costs increase, test repertoires expand and undergraduate training in laboratory medicine decreases, laboratories now find themselves attempting to manage the increasing demand placed on them. Considerable work has been done to ascertain sensible repeat testing intervals for analytes which are too frequently requested in secondary care. Some examples include bone and liver profiles, vitamin D and thyroid function testing. Electronic order requesting enables the laboratory to communicate warning messages to the clinician prior to further repeat requesting and also to educate the users about the most efficient use of laboratory services. Another form of demand management may involve the manual vetting of requests from within the laboratory. This may be for specialist tests that are referred to other laboratories or for analytes that have a specific clinical role, such as tumour markers. Vetting performs a dual purpose; first, it enables the lab to control costs and second, it allows the lab to open a dialogue with the requestor regarding the need and suitability of the test.

EVIDENCE-BASED CLINICAL BIOCHEMISTRY

The later years of the 20th century saw the establishment and development of the concept of evidence-based medicine, in essence the use of the best available data from robust clinical studies to inform the management of patients, including diagnosis, prognosis and treatment. This has led to the promulgation of the concept of evidence-based clinical biochemistry (and evidence-based laboratory medicine in general) in which, for example, the relationship between investigations and clinical outcomes is rigorously analysed, using tools such as likelihood ratios (see p. 19), to determine which investigations are the most appropriate (in terms of being valid and informative) in individual clinical situations and evaluating their subsequent use.

In evidence-based medicine, the gold standard for providing evidence is the systematic review of evidence adduced from clinical trials, preferably randomized and double blinded. Such reviews should be designed to minimize bias, random errors and confounding. Systematic reviews may include meta-analysis – a statistical analysis of the results from a series of independent studies designed to produce a single statement about outcome, whether it be the efficacy of a particular treatment or the value of a particular diagnostic investigation.

Although the number of systematic reviews of diagnostic investigations published annually is increasing,

there are none for many well-established biochemical tests, and there is no requirement to conduct studies of the efficacy and validity of new tests before they are introduced to the market, as there is with therapeutic agents. For example, numerous new tumour markers have been developed in recent years, but for many, there is only limited evidence (and only in specific contexts) of their clinical value. The context in which an investigation is used is an essential consideration. For example, there is no doubt that the measurement of prostate-specific antigen (PSA) is of value in monitoring the response of patients with prostatic cancer to treatment, but basal values have little prognostic significance and there remains no definite evidence that screening older men for prostatic cancer by measuring PSA has any effect on outcome.

Evidence-based clinical biochemistry is gathering momentum. It starts with the technical evaluation of a test and encompasses the assessment of diagnostic performance and clinical utility, as discussed in Chapter 2. One of its important products is the development of guidelines for the investigation of patients with specific conditions. But just as there is continued clinical surveillance of drugs after they have been introduced to the market (resulting, in some cases, in their later being withdrawn or having their licences altered), so the impact of guidelines and other products of evidence-based laboratory medicine must be reviewed to ensure that they are appropriate and effective, and remain so with the passage of time. The process of clinical audit – defining standards; examining processes against these standards; identifying deficiencies; modifying the processes to correct them, and repeating the cycle to check for improved performance – is fundamental to this.

POINT-OF-CARE TESTING

There is a current trend to deliver a more patient-centric service with some laboratory testing taking place within the community, at point-of-care. This desirability, under some circumstances, to provide biochemical services at the bedside or in the clinic or doctor's surgery, has led to the development of techniques and analytical instruments that can be used reliably by individuals who do not necessarily have rigorous laboratory training. Examples include hydrogen ion and blood gas analysis in intensive therapy units, principally as an aid to the management of patients on ventilators; dipstick analysis of urine samples; blood glucose measurements on hospital wards and in patients' homes, and bilirubin analysis in neonatal intensive therapy units. The advantages of such testing include the rapid availability of results at the location where management decisions are made and an ability to perform the test frequently; both these facilitate rapid responses to changes in the patient's condition. Certain sources of error may be eliminated (although care must be taken not to introduce others) and there may be financial savings, for example in relation to the transport of specimens or of patients; however, the cost per test is frequently much higher for point-of-care tests (PoCTs) than for the central laboratory.

This is not a new concept. In Victorian times, physicians would perform simple pathological tests at the bedside and it was the increasing complexity of the tests that led to the setting up of centralized laboratory facilities. Point-of-care testing offers considerable advantages over laboratory-based testing under some circumstances, as is apparent from the examples cited above. However, it is important that the tests and instruments are reliable; that only staff who have been trained to use them are allowed to do so; that the results are subject to appraisal through a quality assurance scheme (preferably supervised by a clinical biochemist) and that there is adequate skilled technical and analytical back-up, should problems arise. Laboratories are expected to be at the forefront of these developments and work with the PoCT user to establish a set of quality standard analogous to those used in the main laboratory. The international standard, ISO 22870, sets out the specific standards that should be met when such testing takes place within a hospital environment.

There are however, ongoing clinical governance issues regarding the use of PoCT. Two key areas of concern are the assimilation of the PoCT result into the patient record and the need to ensure adherence to rigorous testing processes (a complete audit trail). As an example, the latest blood glucose meters available on the market have the capability of connecting to both laboratory and hospital information management systems. These meters control access by requiring unique identification of individual users. Additionally, connected meters can be controlled remotely from the laboratory to ensure that the meter has had quality control checks prior to measurement of patient samples. Remote access to these meters can also ensure that use by untrained individuals is prevented.

These developments are excellent examples of the progress that has been made by manufacturers in this area. The need to establish good working relationships with the manufacturer and colleagues that use the system is vital to ensure success.

As the use of PoCT devices becomes more prevalent, regulation will become stricter and it is envisaged that the laboratory will take a greater role in their provision and

management, possibly through service level agreements with community practitioners.

CONCLUSION

Laboratories are obliged to provide a good-quality service, which should be independently assessed and regulated. As quality standards have evolved, so has the need to include inspection of procedures to cover the entire sample journey, from phlebotomy to receipt of the final report. Laboratories should review the needs of their end-user, be it clinician, nurse or patient and try to adapt their service accordingly.

The need to monitor the clinical effectiveness of laboratories to demonstrate continuous quality improvement and better patient outcomes has resulted in the development of clinical quality indicators. These indicators should be used to provide laboratories with sufficient data to identify areas of good practice and areas where further improvement is necessary and to promote a culture where continuous quality improvement is integrated into routine activity.

APPENDICES 62

PHYSIOLOGY

Introduction

Water is the most abundant molecule in the human body and is the major solvent (the only other of consequence is fat). The physiological control of the composition and distribution of the fluid spaces is a highly sensitive and complex homeostatic process necessary to maintain a constant milieu interieur. Two main fluid spaces exist: the intracellular fluid (ICF) and the extracellular fluid (ECF). The latter is further separated into the intravascular space (plasma), the interstitial space (which includes lymph) and transcellular fluid (pleural, pericardial, peritoneal, cerebrospinal and gastrointestinal fluids), formed by the transport activity of cells. [Table 4.1](#) summarizes the water content of the body and the distribution of fluid between the main body spaces; the proportion of body water to total body weight is affected by age, gender and body fat content.

The electrolyte compositions of the ECF and the ICF are different – in essence, the extracellular space is a predominantly sodium-containing solution and the intracellular space a potassium-containing solution ([Table 4.2](#)). This fundamental difference in electrolyte composition is maintained by cell membrane transport pumps (energy-consuming ATPases). Electrolyte and protein concentrations of blood are now most commonly measured in serum. In this chapter, unless specified, the term *plasma* is used for describing in vivo concentrations and the term *serum* for measured in vitro concentrations.

Body water moves between the main body spaces through water channels (aquaporins), predominantly under the influence of the osmotic pressures resulting from

dissolved particles in the ECF and ICF on either side of the cell membrane. Under steady-state physiological conditions, the osmotic pressure of the ICF equates exactly with the plasma osmotic pressure. Osmolality represents the molal concentration of solute in a litre of solvent (water) and is expressed as mmol/kg, as opposed to a molar (or calculated osmolar) solution, which is the concentration in the space of a litre of solution (which includes solute space) and is expressed as mmol/L. This apparent nicety in definition does have its uses in differentiating certain real from apparent electrolyte disorders (see [p. 46](#)).

The measured osmolality in ECF cannot, however, always be equated with transcellular osmotic pressure. The cell membrane is selectively permeable to a variety of solutes, but certain natural solutes such as urea, or exogenous solutes such as alcohol, are freely permeable. Thus, an increase in plasma osmolality due to sodium implies an increase in osmotic pressure across the cell membrane, tending to withdraw water from the cell to equalize osmolalities. However, an increase in plasma osmolality due to urea does not have this effect because of the free permeability of urea between the ICF and ECF. This leads to the concept of *effective osmolality or tonicity*, which, under physiological conditions, is primarily dependent on plasma sodium concentration, but under pathological or iatrogenic conditions, may be dependent on other solutes, for example, the effect of glucose in untreated diabetes mellitus or mannitol following its intravenous infusion (used therapeutically precisely for this effect).

The distribution of water between different body spaces is thus dependent on the permeability of the relevant membrane barriers to water, and the quantity of

TABLE 4.1 Body fluid distribution in relation to age and gender

Chloride	109	10
Bicarbonate	29	10
Phosphate	1.5	50

solute within each space. Because water is freely permeable across all cell membranes (except some highly specialized membranes in the nephrons and sweat glands), the water content of body spaces is dependent on the solute content of the space. The Gibbs–Donnan effect is an important force that influences the distribution of solutes. If the barrier separating two compartments is permeable to water and small ions, but impermeable to large ionized molecules, and the larger molecules are confined to one compartment, the concentration of small ions will differ between compartments at equilibrium, and the compartment containing the protein will exert an osmotic force.

Oncotic pressure (colloid osmotic pressure) is the osmotic pressure resulting from the difference within the ECF between the protein contents of plasma and interstitial fluid. The major contribution to oncotic pressure under physiological conditions is plasma albumin concentration. The hydrostatic pressure of the plasma across the afferent capillary membrane creates a counter force to the oncotic pressure: the combination of the changing hydrostatic and oncotic pressure gradients across the capillary bed is known as the Starling forces.

Because the total solute content of cells under physiological conditions is essentially fixed and water is freely permeable across most cell membranes, the volume of the ICF is determined by the body water content. Intracellular fluid tonicity will in turn determine ECF tonicity, but ECF volume is essentially dependent on its sodium content.

Extracellular fluid and sodium

The sodium content of a normal adult is 55–65 mmol/kg body weight. The concentration of sodium in plasma is ~140 mmol/L (~152 mmol/kg). Under physiological conditions, the control of the ECF volume is through the control of functioning or *effective* plasma volume (that part of the plasma volume actively perfusing tissues). There are a variety of afferent mechanisms to monitor effective plasma volume (and thus ECF volume), which include intrathoracic volume receptors such as atrial stretch receptors, hepatic volume receptors, arterial baroreceptors, intrarenal baroreceptors and, possibly, tissue receptors monitoring tissue perfusion. Whatever the actual or relative function of all these sensory systems, their resultant influence is fine control over the renal conservation of sodium and the appetite for oral sodium intake.

Sodium intake varies considerably between different human cultural and ethnic groups. Variations in intake between 5 and 500 mmol/24h have been recorded and physiological mechanisms balance this with the renal excretion of sodium. Sodium delivery to the renal tubules is a function of plasma sodium concentration and the glomerular filtration rate (GFR). Every 24h, the kidneys of an average healthy adult male will filter in excess of 24 000 mmol of sodium, most of which is reabsorbed in the tubules so that, in health, sodium balance is achieved. In a healthy individual, renal sodium conservation can be extremely efficient, with urine sodium concentration falling to <1 mmol/L urine. Conversely, when sodium intake is excessive, the capacity to excrete sodium can result in urine sodium concentrations up to 300 mmol/L urine.

Renal control of sodium output

Intrinsic renal control of tubular reabsorption of sodium. Under normal physiological conditions, approximately 80% of the sodium in the glomerular filtrate is reabsorbed in the proximal tubules. The protein concentration of the blood within the post-glomerular peritubular capillary beds is believed to exert a strong oncotic pressure on fluid in the proximal tubules, and this in turn helps to regulate the volume of fluid reabsorbed. This process contributes to the autoregulation of filtration and reabsorption known as *glomerulo–tubular balance*. There has been considerable physiological interest in the control of proximal tubular sodium reabsorption and other intrinsic renal control mechanisms, such as redistribution of filtering activity from superficial nephrons (relatively salt-losing) to juxtamedullary nephrons (relatively salt-retaining). However, to date, the major humoral influences on sodium reabsorption appear to reside in the distal tubules and collecting ducts.

Renin–angiotensin–aldosterone axis. Aldosterone is a steroid hormone released from the zona glomerulosa of the adrenal cortex. The major control of aldosterone secretion is through angiotensin II, an octapeptide produced in the circulation as a final product of the action of renin. Renin is a proteolytic enzyme secreted by a group of

cells (the juxtaglomerular apparatus) situated between the afferent and efferent glomerular arterioles, and specialist chemoreceptor cells found within the distal convoluted tubular epithelium of the kidneys – the macula densa. Renin release is stimulated by decreased sodium delivery to the distal tubules (sodium depletion, ECF volume contraction), renal artery hypotension (due to systemic hypotension or renal artery stenosis) and by sympathetic nerve activity via β_1 -adrenergic receptors. The substrate for renin is angiotensinogen, an α_2 -globulin produced by the liver. Renin releases an amino-terminal decapeptide from angiotensinogen known as angiotensin I, which in turn is acted upon by angiotensin-converting enzyme (ACE), predominantly within the pulmonary capillaries. The action of ACE is to cleave the carboxy-terminal dipeptide of angiotensin I to produce angiotensin II. The renin–angiotensin–aldosterone axis is summarized in Figure 4.1. The major physiological influences on aldosterone are body sodium content and renal perfusion pressure, although hyperkalaemia can stimulate aldosterone release directly.

Aldosterone acts through the specific nuclear mineralocorticoid receptor, which is protected from cortisol (for which it has equal affinity) through the intracellular production of 11β -hydroxysteroid dehydrogenase (11β -HSD). This enzyme converts cortisol to cortisone, for which the receptor has weak affinity. The response within the *principal cells* lining the distal tubules and collecting ducts is the apical influx of sodium via epithelial Na^+ channel (ENaC) stimulation and its efflux via basolateral

Na^+, K^+ -ATPase. The net effect is active sodium reabsorption in exchange for potassium. In addition, angiotensin II has direct vasoconstrictive actions, thus having an immediate influence on *effective* plasma volume.

Natriuretic peptides. Glomerular filtration and the action of aldosterone do not constitute the complete control over renal sodium excretion within mammalian systems. The existence of a third factor (or factors) had been proposed for 20 years prior to the identification of a specific natriuretic factor in 1981. This factor was originally identified in rat cardiac atria and was termed atrial natriuretic factor (now known as atrial natriuretic peptide, ANP). Since then, a further two natriuretic peptides have been identified in humans. Circulating ANP is a 28 amino acid (AA) peptide with a 17 AA ring structure formed by a disulphide bridge between cysteines at positions 7 and 23: the gene for the ANP precursor molecule is located on the short arm of chromosome 1. Three exons code for a 151 AA peptide (preproANP) which, following removal of the signal peptide, results in a 126 AA peptide (proANP) – the main storage form. On secretion into the circulation, proANP is cleaved into the N-terminal 1–98 peptide (NT-proANP), and the biologically active 99–126 peptide (ANP). The major stimulus to the secretion of ANP is atrial stretch and the major sites of synthesis are the atria.

In 1988, a second natriuretic peptide was identified, in porcine brain, and termed brain natriuretic peptide (BNP). It was later shown to be produced predominantly in the ventricles of the heart. Circulating BNP is a 32

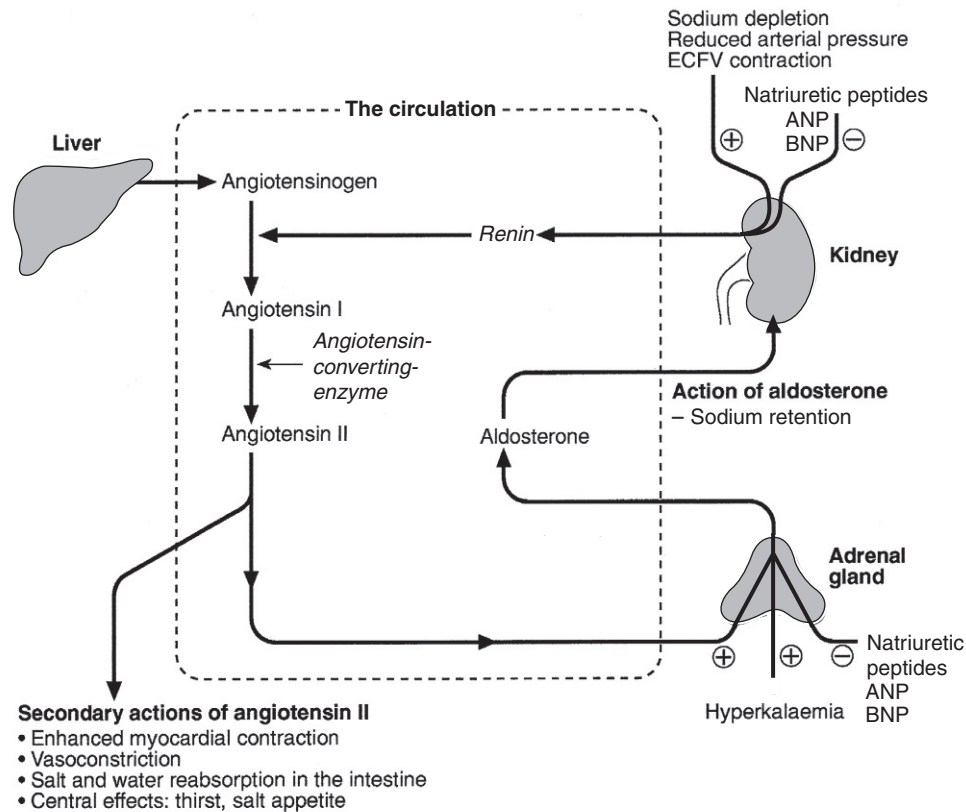

FIGURE 4.1 ■ The renin–angiotensin–aldosterone system. +, stimulatory signal; –, inhibitory signal; ANP, atrial natriuretic peptide; BNP, brain natriuretic peptide.

AA peptide, also with a 17 AA ring structure formed by a disulphide bridge between cysteines at positions 10 and 26. The ring structure has a high level of homology with the ring of ANP. Also like that of ANP, the gene for BNP is located on the short arm of chromosome 1. Three exons code for a 134 AA peptide (pre-proBNP) which, following removal of the signal peptide, results in a 108 AA peptide (proBNP). Further cleavage on release into the circulation results in the N-terminal 1–76 peptide (NT-proBNP) and the biologically active 77–108 peptide (BNP). Both ANP and BNP share a common receptor that mediates a natriuretic response in the kidneys by causing an increase in glomerular filtration rate and blocking sodium reabsorption in the inner medullary collecting ducts. They also influence sodium reabsorption through antagonism of the renin–angiotensin–aldosterone axis. Both ANP and BNP reduce sympathetic tone in the peripheral vasculature. The basic physiology of ANP and BNP is summarized in [Figure 4.2](#).

In 1990, a further ‘natriuretic peptide’ was described in porcine brain and termed C-type natriuretic peptide (CNP). The gene for CNP is coded on chromosome 4. Although CNP has been identified in human plasma, this peptide is mediated through a different receptor and does not have direct natriuretic function, but acts primarily as an antiproliferative regulator in the vascular cell system and as a neuropeptide.

There is no doubt that ANP, and to a lesser extent BNP, has important physiological functions in relation to sodium balance. Simple experiments can readily demonstrate changes in ANP and BNP concentrations in relation to dietary sodium intake, and the interaction of ANP and BNP with the renin–angiotensin–aldosterone axis results in a dual ‘fine-tuning’ system of sodium control, using afferent information obtained from the heart and kidneys simultaneously. However, unlike the situation with the renin–angiotensin–aldosterone axis, no primary disorders of natriuretic hormone excess or deficiency have yet been identified with certainty. Because the major stimulus to the release of ANP and BNP is cardiac wall

FIGURE 4.2 ■ The physiology of ANP and BNP. N-terminal propeptides are co-secreted with the active natriuretic peptides. Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) share a common receptor to increase glomerular filtration rate (GFR) and urine sodium excretion (UNaV), and to reduce renin and aldosterone secretion.

stretch, the major current clinical utility of measuring these peptides, particularly BNP and NT-proBNP, is in the diagnosis and monitoring of cardiac failure.

Sodium appetite

The renal conservation of sodium is remarkably efficient, but when sustained, non-renal losses occur under physiological conditions, such as through sweating due to prolonged vigorous physical activity or as a result of prolonged exposure to high ambient temperature, then a mechanism for increasing sodium intake comes into play – the salt appetite. That such a mechanism exists in humans can be observed in pathological states of impaired sodium conservation such as Addison disease. However, accurately defining the sodium appetite in humans under physiological conditions is a subjective and difficult task. Salt intakes are largely conditioned by traditions of food intake and cultural habits of seasoning food with salt. The impulse to add salt to prepared food appears to be automatic in many people, who do so even before tasting. Animal experiments have implicated an entirely separate, brain-based, renin–angiotensin–aldosterone system as a controlling influence on active salt-seeking behaviour.

Intracellular fluid and water

Water crosses cell membranes by simple diffusion through the lipid bilayer and through specific water channels known as aquaporins. The existence of specific water channels had been suspected for many years, not least to explain the dramatic changes that can occur in water permeability in the epithelial cells of the renal collecting ducts during hydration or dehydration. However, it was not until 1992 that the first aquaporin was characterized in human red cells – aquaporin 1 (AQP 1). To date, 13 different mammalian aquaporins have been identified (AQP 0–12). Specific human disease has been associated with mutations in the genes coding for AQP 0 (congenital cataracts) and AQP 2 (autosomal recessive nephrogenic diabetes insipidus – see [p. 41](#)). Although mutations in the gene for AQP 1 have been described, affected individuals remain asymptomatic. In addition, the condition neuromyelitis optica (NMO), a rare demyelinating and inflammatory disease of the central nervous system (CNS), is caused by autoantibodies directed against the main water channel of the CNS – AQP 4. The regulation of the gene expression of aquaporins may have important pathophysiological consequences in disease states associated with water retention or cerebral oedema.

Under physiological conditions, the solute content of cells is constant and, therefore, cell volume is dependent on solvent, not solute, content. The majority of cells behave as ‘effective’ osmotic meters – swelling when body water increases and contracting when body water decreases. Normally, the ECF and hence ICF osmolality are maintained at about 285 mmol/kg.

Control of renal water output

Osmoregulation. There is a minimum obligatory loss of water by the kidneys each day that is dependent upon

the maximum achievable urine concentration and the osmotic load for excretion. The maximum renal loss of water occurs when, for a given osmotic load, the minimum urine concentration is achieved.

The control of water output by the body is through secretion of antidiuretic hormone (arginine vasopressin, AVP) and its renal action. Arginine vasopressin is a nonapeptide synthesized in magnicellular neurons within two paired nuclei in the hypothalamus – the supraoptic and paraventricular nuclei. The gene for AVP in humans is located on the short arm of chromosome 20. Three exons code for a pre-pro-vasopressin that, following removal of the signal peptide, results in pro-vasopressin, which is subsequently packaged into neurosecretory granules. The granules are then transported by axonal flow to nerve terminals in the posterior pituitary. During transport, pro-vasopressin is further cleaved to AVP, neurophysin II and a glycoprotein. The neurophysin II forms tetramers, with one AVP molecule bound to each neurophysin moiety and the whole possessing a further AVP binding site. The stimulus to release AVP into the circulation results in the simultaneous release of AVP, neurophysin II and the glycoprotein. Closely associated cells within the hypothalamus (the osmoreceptor cells), by virtue of their swelling or shrinking in response to changes in ECF osmolality, control the release of AVP from the posterior pituitary. The effect of changing plasma sodium concentration (and hence osmolality) on plasma AVP concentration is shown in Figure 4.3. Other solutes confined to the ECF, for example exogenously administered mannitol, have a similar effect. By contrast, urea produces no significant stimulation of AVP because it freely permeates cell membranes. The osmoreceptor response is often characterized by its set point (variously defined by the plasma osmolality at which a measurable AVP response commences or by the basal state osmolality) and by its responsiveness (gain or sensitivity as judged by the slope of the response).

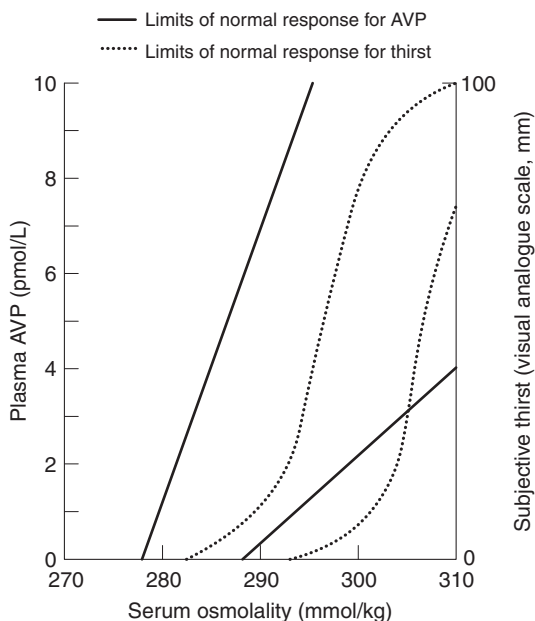

FIGURE 4.3 ■ Osmoregulation of arginine vasopressin (AVP) and thirst.

Thus, in situations of water depletion, ECF osmolality will increase, osmoreceptor cells will contract and plasma AVP secretion will increase. Hydration will reverse these events and suppress AVP. This system constitutes the osmoregulatory control of AVP release.

Non-osmotic control of arginine vasopressin. In addition to osmoregulation, certain non-osmotic controls over the secretion of AVP exist, including ECF hypovolaemia, hypotension, nausea and an oropharyngeal response. The AVP response to hypovolaemia and hypotension is relatively insensitive when changes are proportionally small (5–10% reductions), but increases exponentially as further reductions occur. Thus, a reduction in ECF volume or blood pressure of 20% or more will result in a plasma AVP concentration far in excess of that observed during normal osmoregulation. The influence of baroreceptor or volume receptor afferent input appears to modulate the osmotic response but does not abolish it: modulation occurs by decreasing the threshold for AVP release and increasing the gain of the systems.

Nausea is the single most powerful stimulus to AVP secretion. It overrides osmoregulatory control, and plasma AVP concentrations may increase 100-fold or more. A short-lived oropharyngeal suppression of AVP can occur following oral ingestion of fluid and prior to any reduction in serum osmolality, thus direct studies of osmoregulation of AVP need to avoid any such stimulus.

Renal responsiveness to arginine vasopressin. The apical (luminal) surface of the specialized cells lining the collecting ducts is essentially impermeable to water, except when AVP occupies its specific receptors on the basolateral (contraluminal) surface – the V_2 receptor (AVPR2). Stimulation of AVPR2 results in AQP 2 channels, located in vesicles beneath the apical membrane, fusing with that membrane and rapidly delivering water channels to the cell surface. A schematic representation of this model is shown in Figure 4.4. Under these conditions, water is absorbed into the collecting duct cells as a result of medullary hyperosmolality and is then absorbed into the bloodstream: concentrated urine is formed. During states of overhydration, when AVP secretion is suppressed, the luminal surfaces of the collecting duct cells remain impermeable to water. Luminal fluid rendered hypotonic in the diluting segments of the nephrons is not exposed to the medullary hypertonicity and, hence, no water is absorbed into the bloodstream; dilute urine is formed. The renal response to AVP is thus dependent on an intact receptor–effector mechanism within the collecting duct cells, resulting in an alteration in luminal membrane permeability, and upon the presence of a renal medullary osmotic gradient. Human urine osmolality varies between approximately 50 and 1400 mmol/kg.

Control of water intake

Osmoregulation. The physiological stimulus to water intake is thirst. However, the act of drinking in human societies in temperate regions is predominantly a social

FIGURE 4.4 ■ Renal action of arginine vasopressin (AVP). Interaction of AVP with its V_2 receptor located on the basolateral membrane results in the generation of cAMP, which subsequently causes the fusion of AQP 2 laden vesicles with the otherwise impermeable apical membrane. Under the influence of the medullary osmotic gradient, water is drawn across the cell and is taken up within the blood via AVP-independent AQP 3 water channels.

or habitual act not dependent on thirst. The control of water balance under non-pathological conditions is thus, in many individuals and for much of the time, achieved by control of output.

The osmoregulation of water output by the kidneys can only modulate and restrict an established deficit, but to reverse such a deficit, a specific water input mechanism – thirst – is required. The osmoregulation of thirst is similar in principle to that of AVP and appears to be primarily governed by alteration in osmoreceptor cell size. The osmoreceptor cells controlling thirst are considered to be closely linked to, but distinct from, those controlling AVP secretion. A common method of study in human subjects is the measurement of subjective thirst during continuous osmotic stimulation with hypertonic saline infusion, and a typical range of normal responses is shown in Figure 4.3. Controversy exists as to the exact relationship between the onset of effective renal water conservation and the onset of effective thirst – that is, a sensation of thirst sufficient to cause active seeking and intake of water. However, physiologically, the onset of AVP secretion (and hence water conservation) differs from the onset of thirst and normally precedes it. The magnitude of this difference in water output and input effector controls will determine whether an individual controls physiological water balance primarily by thirst and water intake or by renal conservation of water.

Non-osmotic control of thirst. Non-osmotic thirst occurs when extracellular fluid is lost without corresponding cellular dehydration, the osmotic pressure of the extracellular fluid remaining unchanged. In this respect, the overall control of thirst parallels the control of AVP, with both osmotic and hypovolaemic stimuli. There is good evidence from animal experiments of both neural

and hormonal mediators controlling non-osmotic thirst. Angiotensin II is the most potent human thirst stimulant and may act directly upon the brain, but even when the effects of angiotensin II are blocked, significant hypovolaemia will still stimulate thirst.

Thirst following haemorrhage is a commonly reported clinical observation but, like the AVP responses to extracellular hypovolaemia, often a considerable degree of haemorrhage (15–20% of total blood volume) is necessary before the sensation becomes strong. Thus for day-to-day water balance, the primary physiological control of thirst is osmotic.

Extracellular fluid, intracellular fluid and potassium

In health, plasma potassium concentrations range between 3.1 and 4.6 mmol/L, with values in serum approximately 0.3–0.4 mmol/L greater, owing to release of potassium during clot formation (mean serum concentration 4.0 mmol/L). The intracellular concentration of potassium is ~160 mmol/kg, and 98% of the total body potassium is present in the intracellular fluid. There are two aspects to the physiological control of potassium, namely, the total body content and its distribution between intra- and extracellular spaces.

Extracellular and intracellular fluid distribution of potassium

The potassium content of cells is determined by the balance of activity between uptake of potassium due to membrane-bound Na^+, K^+ -ATPase and the passive loss or leakage of potassium out of the cell. Many factors can influence the distribution of potassium, for example acid–base status, hormones (insulin, catecholamines), osmolality and the cellular content of potassium. The influence of acid–base status is widely recognized as an important contributor to potassium distribution, with an association between hypokalaemia and alkalosis and between hyperkalaemia and acidosis, particularly when the acidosis is induced by mineral rather than organic acids.

Insulin promotes active uptake of potassium by cells, probably by direct stimulation of Na^+, K^+ -ATPase, and this activity appears to be independent of the effect of insulin on glucose uptake. The importance of the effects of insulin in controlling plasma potassium under physiological conditions is not understood, but its action has an important therapeutic role in the treatment of hyperkalaemia.

Catecholamines have an effect on potassium distribution, with β -adrenergic actions essentially promoting cellular uptake and α -adrenergic actions resulting in increases in plasma potassium concentration, but again the significance of these effects under physiological conditions is not understood. The net effect of catecholamines on cellular uptake of potassium probably explains the transient hypokalaemia frequently observed in acutely ill patients.

An acute increase in extracellular tonicity, such as occurs following hyperosmotic infusions of saline or mannitol, results in an increase in plasma potassium

concentration. This results from leakage of potassium from cells, a phenomenon that is not related to extracellular acidosis, but may be linked to cellular dehydration, altered cell membrane function or altered cell metabolism. An increase in extracellular tonicity is also observed in patients with hyperglycaemia in the absence of insulin and has important therapeutic relevance in the provision of potassium replacement during the treatment of hyperglycaemia. The effects of tonicity under physiological conditions are probably of no significance.

Potassium depletion results in a greater loss of potassium from the ECF than the ICF, and potassium excess results in a greater proportional rise of ECF than of ICF potassium concentration. The controlling influences over these changes are not defined, but the result is a significant alteration in membrane potential: this is increased with potassium depletion and decreased with excess. The effects on neuromuscular function of either condition constitute the most important clinical complications of disorders of potassium metabolism.

Renal control of potassium output

Intrinsic tubular control. The traditional understanding of potassium handling by the kidneys is that potassium is freely filtered by the glomeruli, but that up to 95% has been reabsorbed before the tubular fluid reaches the distal convoluted tubules. The predominant control of potassium excretion appears to reside in the control of distal tubular reabsorption and secretion.

Plasma potassium itself has a major effect on potassium secretion in the distal tubules, tending to correct any imbalance. Acute changes in sodium delivery to the distal tubules may also influence potassium excretion – restricted sodium delivery impairs potassium excretion, but a tendency to natriuresis is accompanied by a kaliuresis. However, chronic effects on potassium excretion as a result of changes in sodium intake are not seen because of the influence of the renin–angiotensin–aldosterone axis.

Aldosterone. Potassium directly influences aldosterone secretion from the adrenal cortex. A high plasma potassium concentration stimulates aldosterone secretion and a low concentration suppresses secretion. In addition to its effects on sodium reabsorption by the principal cells, aldosterone stimulates hydrogen ion secretion by the α -intercalated cells of the distal tubules and collecting ducts. Acidosis is associated with reduced potassium secretion and alkalosis with enhanced secretion. The net effect of aldosterone is to stimulate exchange of potassium and hydrogen ions for sodium ions. Therefore, the relative proportions of potassium and hydrogen ions within the cells of the distal tubules, together with the ability to secrete hydrogen ions, will determine the effect of systemic acidosis or alkalosis on potassium excretion. Acting alone, an acidosis will promote potassium retention and an alkalosis will promote a kaliuresis.

Urine potassium concentration can vary between about 5 mmol/L and 150 mmol/L. Adaptation of urinary excretion to a variation in input tends to be slow, taking a

few days to achieve a new balance. In this respect, urinary control of potassium is less sensitive than the control of sodium.

DISORDERS OF SODIUM METABOLISM

As sodium is predominantly an extracellular cation, the control of sodium balance will control the volume of the ECF. The tonicity of body fluids is under osmoregulatory control, therefore sodium deficit or sodium excess presents clinically with primary changes in ECF volume rather than changes in sodium concentration within the ECF. Hyponatraemic and hypernatraemic states are discussed in the section on water metabolism.

Sodium deficiency

Clinical presentation

Sodium is always lost from the body in association with water. As the sodium concentration of all body fluids is equal to or less than plasma (except on occasions of high sodium intake, when urine sodium concentration may exceed plasma concentration), loss of any body fluid except plasma will generally result in an excess loss of water over sodium. Any loss of sodium, however, will result in a reduction of ECF volume, including a reduction in circulating plasma volume. Clinical presentation will depend on the severity of the decrease. When the changes are mild, patients are often described clinically as being dehydrated, a description that should be confined to pure water deficiency but, unfortunately, in general usage is not. Except in rare instances, truly dehydrated (water depleted) patients are extremely thirsty; patients with all but the most severe salt and water deficiency are not.

Reduced intravascular volume, when mild, will result in postural hypotension and a compensatory increase in pulse rate; central venous pressure is reduced and this can be assessed clinically by observation of neck vein filling or directly measured following insertion of a cannula into a central vein. When the volume reduction is more severe, hypotension and eventually shock will result in oliguria; the central venous pressure is further reduced. Reduction in interstitial fluid volume results in reduced skin turgor and transcellular fluid reductions result in dry mouth and reduced intraocular pressure.

Causes of sodium deficiency

The causes of sodium deficiency can be classified broadly into extrarenal, primary renal (resulting from renal disease) and secondary renal (resulting from disturbed hormonal control of renal sodium retention or from inappropriate use or abuse of diuretics). In addition, and somewhat difficult to classify, is the sodium deficiency that can occur when isolated jejunal segments are incorporated into urinary diversion operations (jejunal conduit, jejunal continent diversion, see p. 55). These procedures are now rarely performed, as alternative sources of donor intestine are preferred. When jejunum is used in such procedures, there is a risk of postrenal loss of sodium.

Extrarenal sodium loss. Extrarenal fluids have sodium concentrations that may approach the concentration in plasma (Table 4.3). The major causes of extrarenal sodium deficiency are summarized in Box 4.1. The commonest clinical presentations result from gastrointestinal disease. The clinical history may considerably underplay the degree of deficit, especially in chronic conditions or conditions resulting in sequestration of fluid.

Primary renal sodium loss. The major causes of primary renal sodium loss are summarized in Box 4.2. The recovery phase of acute kidney injury is often associated with a polyuria, kaliuresis and natriuresis. Usually this stage is short lived, lasting only a few days, but it may occasionally be prolonged. A natriuresis may occur following successful renal transplantation and this may be in part due to transient tubular dysfunction; the recovery phase usually lasts only a few days, but occasional patients show prolonged natriuresis.

Relief of urinary tract obstruction, most commonly seen in patients with prostatic enlargement, is often followed by a short period of diuresis and natriuresis. The exact mechanism of this is not fully understood, but is probably related to a urea-induced osmotic diuresis, together with elimination of excess sodium retained during the obstruction phase. The natriuresis in these cases is corrective and is not strictly a primary renal condition: it is unlikely to lead to sodium depletion. Normally, this phase of post-obstructive natriuresis and diuresis lasts between one and seven days, but occasionally a more prolonged natriuresis occurs, leading to sodium deficiency. This rare event is secondary to tubular damage occurring during obstruction. Salt wasting has been described in association with meticcillin-induced acute interstitial nephritis. Full resolution of the condition may be delayed for several months, during which time minimum obligatory losses of sodium may exceed 100 mmol/24 h.

Chronic kidney disease is generally associated with a reduced capacity to excrete sodium. Considerable adaptation occurs to increase the natriuretic capacity of the remaining functioning nephrons, which paradoxically impairs the overall sodium conserving function. On a Western type diet, sodium intake normally exceeds minimum obligatory urine sodium loss, but if dietary salt is restricted or non-renal losses of sodium are increased, the obligatory loss may induce sodium deficiency. Minimum obligatory losses may be as little as 40 mmol/24 h and even lower if enough time is given for adaptation, but occasionally patients have minimum

obligatory losses exceeding 150 mmol/24 h (3 mmol/kg body weight in children). The term *salt-losing nephropathy* is appropriate for this group of patients.

Salt-losing nephropathy is a clinical state, rather than a specific disease. It is normally associated with chronic kidney disease due to tubulointerstitial disease or to glomerulonephritis with significant interstitial abnormalities. A common example of a toxic nephropathy inducing a salt-losing state is analgesic abuse, in which there is typically also reduced concentrating ability and renal tubular acidosis.

BOX 4.1 Causes of extrarenal sodium loss

Gastrointestinal

- Gastric, e.g. vomiting, aspiration, fistula, blood loss
- Midgut, e.g. ileostomy, pancreatic and biliary fistulae
- Hindgut, e.g. diarrhoea, bleeding, excess mucus production

Skin

- Sweating, e.g. thermal or increased sodium content (cystic fibrosis)
- Burns
- Exudative skin disease

Sequestration

- Gastrointestinal, e.g. ileus, small bowel obstruction
- Other transcellular spaces, e.g. peritonitis, pleural effusion

BOX 4.2 Causes of primary renal sodium loss

Acute

- Diuretic phase of acute kidney disease
- Postrenal transplantation
- Following relief of urinary tract obstruction
- Acute interstitial nephritis

Chronic

- Chronic kidney disease with salt restriction
- Salt-losing nephropathy
 - Chronic pyelonephritis
 - Medullary cystic disease
 - Toxic nephropathies, e.g. chronic analgesic abuse, cisplatin

TABLE 4.3 Examples of fluid composition of extrarenal fluids

	Sodium (mmol/L)	Potassium (mmol/L)	Chloride (mmol/L)	Bicarbonate (mmol/L)
Gastric juice (with parietal cell secretion)	20–70	5–15	80–160	0
Pancreatic juice	140	6–9	110–130	25–45
Bile	130–165	3–12	90–120	30
Ileal fluid	105–144	6–29	42–60	50–70
Stool water	32–40	75–90	12–18	30–40
Sweat	5–80	5–15	5–70	–

Secondary renal sodium loss. The disruption of extrinsic controls over renal sodium handling can give rise to a secondary renal sodium loss. Patients present with a variety of symptoms, some specifically related to a contracted ECF volume, such as postural hypotension and an increased sodium appetite. Causes of secondary renal sodium loss, presented in [Box 4.3](#), are essentially hormone or diuretic induced. In Addison disease, the synthesis and secretion of aldosterone are reduced because of adrenal gland destruction, leading to distal renal tubular sodium wasting. Congenital adrenal hyperplasia (CAH) with associated sodium wasting is a result of impaired mineralocorticoid synthesis, most commonly as a consequence of 21-hydroxylase deficiency, but also, less commonly, 3 β -hydroxysteroid dehydrogenase deficiency. In either condition, the degree of sodium wasting is variable: it is present in about two-thirds of patients with 21-hydroxylase deficiency (see Chapter 18). Very rare forms also exist, including cholesterol desmolase deficiency (lipoid adrenal hyperplasia) and corticosterone methyl oxidase deficiency – a deficiency in the mixed-function oxidase catalysing the final steps of aldosterone synthesis. Corticosterone methyl oxidase deficiency is not strictly a type of CAH, as the synthesis of cortisol is unaffected and, consequently, the adrenals are not hyperplastic. In all these conditions, the associated hypovolaemia stimulates renin production, and all may be associated with hyperkalaemia. Treatment is primarily by glucocorticoid and mineralocorticoid replacement.

It might be predicted that deficient production of renin would also lead to renal sodium loss because of a secondary deficiency of aldosterone. The condition hyporeninaemic hypoaldosteronism is invariably associated with renal insufficiency, but the characteristic feature is hyperkalaemia rather than hypovolaemia. As in the majority of patients with renal insufficiency, inappropriate renal sodium loss will induce hypovolaemia if the patient is placed on a low sodium intake, but it is unclear if this is more severe in hyporeninaemic hypoaldosteronism. Although this condition is a cause of secondary renal sodium loss, its main importance is in the differential diagnosis of hyperkalaemia and it is discussed in more detail later in this chapter (see [Syndromes of hypoaldosteronism, p. 60](#)).

Pseudohypoaldosteronism (type 1) is a rare congenital disease existing in two forms, caused by an end organ failure of response to aldosterone within the principal cells

BOX 4.3 Causes of secondary renal salt loss

- Hyper-reninaemic hypoaldosteronism
 - Addison disease
 - Congenital adrenal hyperplasia
 - Corticosterone methyl oxidase deficiency types I and II
- Hyporeninaemic hypoaldosteronism
- Pseudohypoaldosteronism (type 1)
- Diuretics
- Bartter syndrome
- Gitelman syndrome

lining the renal collecting ducts. It is caused by either a loss of function mutation in the mineralocorticoid receptor (MR) gene (autosomal dominant form) or a mutation resulting in loss of function in the epithelial Na⁺ channel (ENaC – autosomal recessive form). Infants present with dehydration, hyponatraemia, hyperkalaemia, metabolic acidosis, failure to thrive and weight loss. Renal sodium wasting is unresponsive to exogenous mineralocorticoids. Pseudohypoaldosteronism is also discussed in more detail later in this chapter (see [Syndromes of hypoaldosteronism, p. 60](#)).

Diuretic abuse, especially when surreptitious, may present a difficult diagnostic problem. The major potent diuretics, such as furosemide or bumetanide, may induce significant renal sodium loss and the differential diagnosis includes Bartter syndrome. Chronic abuse with thiazide diuretics may produce a clinical picture similar to Gitelman syndrome. In all cases, however, the major and persistent finding is significant hypokalaemia (see [p. 55](#)).

Laboratory investigation of sodium deficiency

No single laboratory finding is diagnostic of sodium deficiency, which, therefore, remains primarily a clinical diagnosis. There may be uraemia, particularly of a prerenal pattern (with urea concentration disproportionately elevated in relation to that of creatinine). Serum sodium concentration may be normal, decreased (usually in association with uraemia) or even increased when the sodium deficit is proportionately less than the water deficit. Serum sodium and urea concentrations cannot indicate accurately the degree of sodium depletion or reduction in ECF volume.

Measurement of the haematocrit may help to establish the degree of reduction in ECF volume, especially if the individual's normal haematocrit is known (see [Appendix 4.1a](#)). Similarly, serum protein measurements may suggest ECF volume contraction. In a steady state, hyponatraemia in association with clinical evidence of sodium deficit can also be used to estimate the extent of sodium deficit (see [Appendix 4.1b](#)). Either method provides only a rough guide to subsequent replacement.

Urine electrolytes will help to establish whether the loss has been renal or extrarenal. If there has been gastrointestinal loss of sodium or another extrarenal loss, renal sodium retention should be maximized. Random urine sodium concentrations will show conservation of sodium with a concentration <10 mmol/L. The mature, fully functioning renal system can reduce urine sodium concentration to <1 mmol/L, but this capacity is less in the very young and old. Twenty-four hour urine sodium output will show significant sodium retention, with 24h urine sodium excretion as low as 1 mmol and invariably <15 mmol, even in the elderly. Serum osmolality measurements are of no value in the differential diagnosis of sodium depletion, adding nothing to the information obtained from serum electrolytes, urea and creatinine measurements. Urine osmolality will generally show an overall significant increase towards maximum, reflecting the oliguric state, especially when sodium depletion is sufficient to cause a non-osmotic increase in arginine vasopressin (AVP).

Only when a renal loss of sodium is present without evidence of renal impairment should secondary hormonal or diuretic-related sodium depletion be considered. For the majority of hypoaldosterone-related disorders, there will be associated hyperkalaemia (for specific investigation of hypoaldosteronism, see Chapter 18). Diuretic abuse can provide an intriguing puzzle as, along with Bartter syndrome and Gitelman syndrome, it provides the major differential diagnosis of renal sodium loss in association with hypokalaemia.

Management of sodium deficiency

The essential steps in treating sodium deficiency and ECF volume depletion are to attempt to treat the causes of sodium and water loss and to adequately replace the fluid already lost. The amount of fluid replacement must be balanced against measured or estimated losses, both intra- and extracorporeal. The measurement of body weight is a useful adjunct to monitoring; an increase in weight may indicate accumulation of interstitial or transcellular fluid. Accurate fluid balance charts (see Table 4.4) should indicate a positive or negative balance, but even the most assiduously prepared charts (many are not) provide only an approximate estimate of balance, especially when confounding problems such as pyrexia (increasing insensible losses) or hypermetabolic states (increasing metabolic water) intervene. Vital signs: pulse, blood pressure and central venous pressure (if measured), all provide additional useful information to improve the practice of the art.

The type of replacement will be dependent on cause and severity. Mild forms of sodium deficit, such

as caused by overtreatment with diuretics or chronic salt-losing nephropathy, may be adequately treated with oral sodium and water supplementation. For more severe forms of sodium deficit, intravenous infusion is required; the types of fluids available are shown in Table 4.5. All of them are iso- or hypoosmolal to normal plasma. Hyperosmolal fluids, such as 1.8% or 5% sodium chloride or 2.74% or 8.4% sodium bicarbonate, are not appropriate treatments for sodium depletion with clinical evidence of reduced ECF volume, even in the presence of hyponatraemia, as infusions of such fluids will increase ECF volume in part by shifting fluid from the ICF volume.

Hypoosmolal fluids may be used when sodium deficit is associated with a greater degree of water deficit, that is, sodium deficit in association with hypernatraemia.

Sodium excess

Clinical presentation

Sodium excess is almost invariably associated with water excess (and is usually an iso-osmolal sodium excess). The clinical presentation will depend on the severity of the expansion of ECF volume and its relative distribution within the ECF volume compartments. In practice, the clinical presentation is with oedema (peripheral or pulmonary) or effusions (pleural, ascites) or with hypertension.

Peripheral oedema, due to sodium retention, is characteristically 'pitting' when digital pressure is applied to the affected part (lymphoedema, due to lymphatic obstruction, is characteristically non-pitting, while in myxoedema, the swelling is brawny in nature). Measurement or clinical observation of the central venous pressure may suggest an associated increase in intravascular volume, as may the demonstration of hepatic congestion or the presence of pulmonary crepitations.

Hypertension is a common clinical finding, but hypertension specifically due to chronic iso-osmolal sodium excess is rare. Causes of this form of hypertension are discussed later, but all are associated with an increased mineralocorticoid effect in the initial stages, promoting renal sodium conservation and renal loss of potassium. The association of muscle weakness (caused by hypokalaemia) with hypertension is an important clinical pointer to such a cause of sodium retention.

TABLE 4.4 Ideal components of a fluid balance chart

Input	Output	Extravasation
Oral fluid	Urine output	Body weight
Intravenous fluid	Gastrointestinal losses	
Water generated in metabolism (~500 mL/24 h)	Surgical drains etc.	
	Insensible losses (~900 mL/24 h)	

TABLE 4.5 Iso- and hypoosmolal fluids for treatment of sodium and water deficiency

	Na ⁺ (mmol/L)	K ⁺ (mmol/L)	Cl ⁻ (mmol/L)	HCO ₃ ⁻ (mmol/L)	Glucose (mmol/L)	Ca ²⁺ (mmol/L)	Osmolality (mmol/kg)
0.9% saline	154	–	154	–	–	–	290
0.45% saline	77	–	77	–	–	–	145
0.18% saline	31	–	31	–	–	–	58
Dextrose saline (2.5/0.45%)	77	–	77	–	140	–	290
(4.0/0.18%)	31	–	31	–	222	–	290
Ringer's solution	147	4.2	156	–	–	2.2	290
Hartmann's solution	131	5.4	112	29	–	1.8	290
Sodium lactate	167	–	–	(≅167)	–	–	290

Causes of sodium excess

Sodium excess with oedema. The causes of sodium excess in association with oedema formation are shown in Box 4.4. Congestive cardiac failure (CCF) is a common clinical example of sodium excess, presenting with dependent oedema, congested liver, increased jugular venous pressure and pulmonary crepitations due to oedema. The 'backward failure' hypothesis suggests that increased transcapillary pressure resulting from increased central venous pressure causes oedema and hence reduces intravascular volume. Reduced intravascular volume will in turn stimulate sodium retention. Although readily understandable, this theory is inadequate because patients generally have increased intravascular volumes. The 'forward failure' hypothesis suggests inadequate perfusion of the kidneys because of reduced cardiac output, which in turn promotes sodium retention. However, high cardiac output failure demonstrates that sodium retention can be independent of cardiac output. The reduced 'effective circulating volume hypothesis' lacks precise definition, but suggests that only a proportion of the volume is 'effective', that is, circulating volume appears to be reduced in that the renin-angiotensin-aldosterone mechanism is activated, as is the release of AVP. The onset of CCF causes ANP and, particularly, BNP, release, leading to markedly elevated plasma concentrations. However, the natriuretic effect of the hormones is severely blunted and corrective natriuresis does not occur without therapeutic intervention, with diuretics or with exogenous natriuretic peptide administration in pharmacological doses.

The nephrotic syndrome is characterized by severe glomerular proteinuria, hypoalbuminaemia and oedema.

BOX 4.4 Causes of sodium excess

Sodium excess with oedema

- Congestive cardiac failure
- Nephrotic syndrome
- Liver disease
- Pregnancy
- Menstrual cycle
- Idiopathic oedema

Sodium excess without oedema

- Acute sodium loading (excess i.v. or oral saline)
- Renal sodium retention
 - Primary hyperaldosteronism: adenoma, idiopathic hyperplasia, carcinoma, glucocorticoid suppressible
 - Secondary hyperaldosteronism with hypertension: renin secreting tumour, renovascular hypertension, accelerated hypertension
 - Glucocorticoid excess (mineralocorticoid function): Cushing disease, ectopic adrenocorticotrophic hormone (ACTH) secretion, exogenous glucocorticoids
 - Exogenous mineralocorticoids: prescribed mineralocorticoids, glycyrrhizic acid (liquorice), glycyrrhetic acid (carbenoxolone)
 - Congenital adrenal hyperplasia: 11 β -hydroxylase deficiency, 17 α -hydroxylase deficiency
 - Pseudohyperaldosteronism: Liddle syndrome, apparent mineralocorticoid excess (cortisol 11 β -hydroxysteroid dehydrogenase deficiency)

The classic hypothesis explained the oedema and secondary sodium retention, on the basis of reduced oncotic pressure owing to hypoalbuminaemia. However, the rare condition congenital analbuminaemia is not associated with significant oedema, and nephrotic patients infused with albumin do not consistently respond with a natriuresis and reduction of oedema. Sudden remission of minimal-change glomerulonephritis may result in clinical resolution prior to an increase in plasma albumin, and the presumed reduced circulating volume in nephrotic syndrome is less commonly found when sought than normal or increased circulating volume. These observations imply an intrarenal mechanism of sodium retention in the nephrotic syndrome. Sodium retention does not appear to be primarily driven by the renin-angiotensin-aldosterone system; moreover, ANP concentrations are moderately increased, not decreased, and the natriuretic effect of the hormone is maintained.

Chronic liver disease frequently results in a state of sodium retention leading to oedema and ascites. Again, the physiology of sodium retention is multifactorial, resulting from decreases in glomerular filtration, enhanced proximal tubular reabsorption and increased renin-angiotensin-aldosterone production, presumably from decreased 'effective' intravascular volume. As in CCF, the plasma ANP concentration is significantly increased, but again the natriuretic response is blunted. The concentration of AVP may also be significantly increased.

Pregnancy. Pregnancy demands a retention of between 700 and 1000 mmol of sodium in order to expand the maternal plasma volume and interstitial space and to provide the fetus with sodium. Sodium retention occurs progressively during pregnancy, even though the glomerular filtration rate is greatly increased, so that the reabsorption of filtered sodium must be substantially increased above the non-pregnant level. The renin-angiotensin-aldosterone system is stimulated during pregnancy, a finding that supports the theory of renal sodium retention as a response to reduced 'effective' vascular volume (due to redistribution of ECF volume to the growing fetus and its maternal circulatory support). However, many studies have shown increased plasma ANP concentrations during pregnancy, a finding somewhat at odds with the presumed reduced 'effective' vascular volume. Thus, the kidneys may retain sodium in response to some other stimulus (such as the effect of oestrogens), and the increase in ANP may represent the response to the resultant increased atrial pressure from expanded vascular volume. However, these two apparently conflicting theories are not mutually exclusive and it seems likely that the resultant increase both in the activity of the renin-angiotensin-aldosterone system and the secretion of ANP forms the basis for an enhanced control over sodium balance. Enormous differences in daily sodium intake (from <10 mmol to >300 mmol) can be adequately accommodated during pregnancy.

Dependent leg oedema is extremely common during pregnancy, especially during the third trimester, and much of this is attributable to the mechanical pressure of the uterus upon the venous return from the lower limbs. However, there is a general tendency to an increased

interstitial fluid content because of reduced oncotic pressure (as a result of reduced plasma protein concentration) and because of the effects of oestrogens, which enhance the hydration of the mucopolysaccharide ground substance of connective tissue. This general tendency to increased interstitial fluid content may also produce a more generalized oedema.

Excessive sodium retention occurs in pre-eclampsia. Total body sodium is increased, but plasma volume is usually decreased, with shifts of fluid to the interstitium. The reduced plasma volume is the result of intense vasoconstriction, which also results in hypertension. In pre-eclampsia, renin activity and aldosterone concentrations in plasma in the third trimester are less than those observed during normal pregnancy. Furthermore, ANP concentrations are significantly increased above those found in normal pregnancy, or indeed those found in pregnancy associated with essential hypertension. Atrial natriuretic peptide appears to be released into the maternal circulation in response to vasoconstriction and an increased volume load to the cardiac atria. Thus in pre-eclampsia, as compared with normal pregnancy, renin, aldosterone and ANP all act as if to promote natriuresis, but, for reasons which are not understood, natriuresis is impaired.

Menstrual cycle. Despite intensive study over 50 years or so, the question of whether the normal menstrual cycle is associated with sodium retention remains unresolved. There is widespread belief that the majority of women retain sodium premenstrually, giving rise to premenstrual oedema in some. Plasma aldosterone and renin concentrations are elevated during the luteal phase of the ovulatory cycle, but this elevation is coupled with an increase in progesterone, which is thought to antagonize the renal actions of aldosterone. Studies have shown that plasma ANP concentrations remain the same during the follicular and luteal phases. It has also been demonstrated that, in healthy females, the ANP response to volume expansion is no different in the follicular and luteal phases of the menstrual cycle, and the proportional suppression of renin and aldosterone is also identical between the two phases of the cycle. When these findings are coupled with the observations that body weight, creatinine clearance and basal sodium excretion do not alter during the phases of the cycle, it is apparent that there is little evidence of renal sodium retention. This remains an area for further research, particularly as inappropriate treatment of perceived symptoms may lead to further complications of sodium balance (see below).

Idiopathic oedema. Idiopathic oedema, sometimes known as cyclical oedema, is a condition that occurs in females postpuberty. Oedema of the face, hands and legs can develop rapidly, and weight gains up to 4 kg in 24 h have been described. The aetiology of this condition is unknown, but one suggestion is that diuretics may be used to produce rapid weight loss and that cessation of this self-medication leads to rebound sodium retention. The diuretic is subsequently recommenced for cosmetic reasons to reduce oedema formation and weight gain. Thus, a vicious cycle of sodium depletion

followed by sodium retention and oedema is set in place. However, in some patients prior diuretic use cannot be demonstrated.

Many patients with idiopathic oedema show exaggerated sodium retention on assuming an upright posture with a marked reduction in renal blood flow and GFR. Oestrogens do not appear to play an important role, as the condition has been demonstrated in a patient who had previously undergone bilateral oophorectomy. The role of renin–angiotensin–aldosterone is not fully understood, with a proportion of patients having increased plasma renin and aldosterone concentrations, particularly when in an upright posture, but with suppression of concentrations by a high salt diet. Limited studies of ANP have been performed, but no abnormalities have been demonstrated: normal basal values are found and are stimulated by volume expansion.

Sodium excess without oedema. The causes of sodium excess without oedema are shown in [Box 4.4](#). Acute sodium loading is a rare event, invariably caused by inappropriate sodium administration to highly dependent individuals, for example those in intensive therapy units, especially the very young, the old and the highly incapacitated. Acute hypernatraemia is a powerful stimulus for thirst and thus, to maintain the condition, the intake of fluid must be prevented by an inability, for whatever reason, to express or act upon the desire to drink. Examples of acute sodium loading include administration of high sodium concentration oral feeds to infants (either accidentally or as a form of abuse), the use of oral hypertonic sodium chloride solutions as emetics, excessive administration of intravenous hypertonic sodium bicarbonate and the voluntary consumption of excessive quantities of table salt. In the past, the accidental introduction of hypertonic sodium into the circulation during therapeutic abortion has been a cause of acute sodium excess. Acute sodium loading associated with hypernatraemia is a life-threatening condition and should be treated promptly with free water administration.

Mineralocorticoid excess has a variety of causes (see [Box 4.4](#)). Although this is a condition of excess sodium retention, the usual clinical presentation is hypertension with hypokalaemia. The severity of hypokalaemia is in turn dependent on sodium intake, being reduced in severity if sodium intake is reduced. All of these conditions are discussed elsewhere in this book, either as part of the pathology of the adrenal glands (see Chapter 18) or in relation to hypokalaemia (see [p. 55](#)). The fascination of these conditions with respect to sodium is why sodium retention does not usually progress to increase the volume of all the ECF spaces sufficiently to cause oedema.

As the ECF volume expands, the filtered load of sodium increases and the fraction reabsorbed by the renal tubules decreases. This mechanism constitutes the ‘escape’ for sodium (but not potassium) from mineralocorticoid effects. The underlying mechanism of escape has been the subject of investigation since it was first described over 50 years ago. The mechanism appears multifactorial with a haemodynamic response to increased intravascular volume resulting in reduced proximal reabsorption of sodium. There is good evidence

that natriuretic peptides may account for a part of the escape mechanism – ANP concentrations are elevated in primary hyperaldosteronism and return to normal when the effects of hyperaldosteronism are reversed or antagonized. Evidence also exists of a decrease in the thiazide-sensitive $\text{Na}^+\text{-Cl}^-$ co-transporter (NCCT) within the distal convoluted tubules. In addition intrarenal substances such as prostaglandins, kinins and nitric oxide may also promote natriuresis.

Laboratory investigation of sodium excess

The investigation of sodium excess is confined almost exclusively to the investigation of oedema and of hypertension; hypernatraemia is not a feature of sodium excess except in rare instances of acute sodium loading, when the cause is usually clear from the clinical history.

In practice, the purpose of the investigation of oedema is primarily to differentiate reduced oncotic pressure from other causes, usually by the measurement of serum protein concentration and the confirmation of any route of protein loss, for example the measurement of urine protein excretion. The diagnosis of oedema secondary to CCF and liver disease is primarily clinical; detailed sodium balance studies are not normally justified or, indeed, practicable. Idiopathic oedema is also a condition that is initially diagnosed from the clinical history, although periods of continuous sodium loading with simultaneous sodium balance studies may reveal a propensity for sodium retention.

The laboratory investigation of sodium excess as a contributor to hypertension involves the demonstration of increased mineralocorticoid action, the simplest pointer being the association of hypokalaemia and hypertension. Investigation of primary hyperaldosteronism, conditions of increased glucocorticoid secretion and conditions of sodium retention due to congenital adrenal hyperplasia are covered in Chapter 18. Other causes of hypokalaemia and hypertension are discussed in the section on potassium metabolism (see p. 55).

Management of sodium excess

For those conditions associated with oedema, the management will be aimed primarily at ameliorating the primary cause. This primary treatment, when applicable, needs to be coupled with attempts to control sodium and water retention by the restriction of dietary sodium and, when appropriate, the use of diuretics. The laboratory's role in management is to monitor the potential complications of diuretic treatment, notably hypokalaemia (especially with the use of loop diuretics), hyperkalaemia (with the use of potassium-sparing diuretics such as spironolactone) and hyponatraemia (when over-diuresis results in non-osmotic stimulation of AVP with secondary water retention). In addition, the laboratory's function is to monitor the effects of natriuresis on renal function by monitoring serum urea or creatinine concentrations.

For conditions of sodium excess without oedema, the initial management is to increase renal sodium excretion,

either by attention to iatrogenic causes (such as exogenous mineralocorticoid treatment) or by treatment with diuretics such as spironolactone. This treatment is combined, when appropriate, with antihypertensive therapy. The laboratory's role in management is to monitor for possible complications, particularly with respect to potassium homeostasis. For those patients with surgically correctable conditions, such as primary hyperaldosteronism due to an adrenal adenoma, the definitive treatment is surgery.

DISORDERS OF WATER METABOLISM

As water is distributed throughout all body spaces, the effects of pathological excess or deficiency will be reflected in the relative functional sensitivities of each space. For example, a 10% excess or reduction in total body water (TBW) is unlikely to result in clinical features of alterations in ECF volume. However, ICF volume changes may considerably impair cellular function; in particular, rapid changes may significantly impair brain cell function.

Disorders of water metabolism include three categories of conditions. First are conditions in which polyuria is the major feature. Polyuria is defined as a urine output in adults in excess of 50 mL/kg body weight/24h. In polyuria, one aspect of water homeostasis is defective but may be compensated by another: either a reduced ability to concentrate the urine is compensated by a secondary increase in thirst, or an excessive water intake is compensated with a secondary increase in urine output. In either case, patients are usually normonatremic unless the compensatory mechanism is compromised.

Second are those of water deficiency in which homeostasis is defective and normal body water content cannot be maintained: patients present with hypernatraemia (serum sodium above 145 mmol/L).

Third are conditions of primary water excess in which homeostasis is defective: patients present with hyponatraemia (usually defined as a serum sodium <130 mmol/L) or clinical features of water intoxication.

Polyuria

Primary polyuria with secondary polydipsia

Polyuria is an early feature of diabetes mellitus as a result of the osmotic effects of an increased filtered load of glucose. Polyuria can also be a feature of renal failure due to the loss of medullary hypertonicity and the reduction in the production of AQP 2. Thus polyuria due to diabetes mellitus or renal failure should be differentiated at the outset. A primary inability to concentrate urine with secondary polydipsia is known as diabetes insipidus (DI), and may be due to either impaired release of AVP from the posterior pituitary (cranial diabetes insipidus, CDI) or to impaired renal response to AVP (nephrogenic diabetes insipidus, NDI).

The major causes of CDI and NDI are shown in Box 4.5. There are four causes of inherited CDI, all extremely rare. Autosomal dominant CDI is caused by mutations involving the pre-pro-vasopressin gene excluding the region coding for AVP itself. The disorder is due to

BOX 4.5 Causes of diabetes insipidus**Cranial diabetes insipidus***Hereditary*

- Autosomal dominant
- Autosomal recessive
- Wolfram (DIDMOAD) syndrome
- Congenital septo-optic dysplasia.

Acquired

- Traumatic
- Post-hypophysectomy
- Tumour (primary or secondary)
- Granuloma (e.g. sarcoid, tuberculosis, histiocytosis)
- Infection
- Vascular impairment
- Autoimmune
- Idiopathic

Nephrogenic diabetes insipidus*Hereditary*

- X-linked (loss of function mutation AVPR2)
- Autosomal (loss of function mutation AQP 2)

Acquired

- Hypokalaemia
- Hypercalcaemia
- Drug induced (e.g. lithium, demeclocycline, methoxyflurane, amphotericin)
- Renal disease (e.g. medullary cystic disease, obstructive uropathy)

Vasopressinase-related diabetes insipidus

- Pregnancy

a progressive degeneration of magnicellular neurons, probably due to the accumulation of abnormal AVP-neurophysin II complexes. Presentation may be in the neonatal period or delayed until later in childhood. An even rarer autosomal recessive form exists in which the coding for AVP is mutated; presentation is in the early neonatal period. The two other causes of inherited CDI

are Wolfram syndrome and congenital septo-optic dysplasia, with about one-third of patients with each condition exhibiting overt symptoms of CDI. Wolfram syndrome may present with a combination of diabetes insipidus, diabetes mellitus, optic atrophy and deafness – hence the alternative name of DIDMOAD syndrome. Patients with either CDI or NDI may retain a partial ability to concentrate the urine, which can lead to diagnostic confusion. The osmoregulatory set point for AVP release and thirst is maintained in both conditions. Thus, in developing CDI, as the number of active cells releasing AVP from the posterior pituitary diminishes, the slope of the osmoregulatory response will decrease (see Fig. 4.5). With a plasma osmolality for thirst normally set slightly above that for AVP release, the urine concentration that can be achieved at the onset of thirst will diminish. When CDI is severe, thirst will be stimulated even though the urine is close to maximum dilution. Intermediate stages can, therefore, provide confusion, as an increase in plasma osmolality due to water deprivation despite thirst can be associated with a normally concentrated urine. Diagnostic confusion may be further compounded by two additional features not shown in Figure 4.5:

- an upregulation of renal responsiveness to AVP in CDI in which the kidney becomes more responsive to circulating vasopressin
- a secondary loss of urine-concentrating ability once the sustained polyuria has resulted in medullary washout, with a reduction of the concentration gradient within the medulla of the kidneys.

The former phenomenon may mask a developing CDI. The latter feature may result in a very blunted response to endogenous and exogenously administered AVP (or analogue), thus suggesting a primarily nephrogenic basis to the polyuria, whereas in fact the loss of renal concentrating ability is secondary to the severe polyuria.

Congenital NDI is a rare condition. About 90% of cases are X-linked and due to a loss of function mutation within the gene coding for the V_2 AVP receptor (AVPR2). Affected males present within the first six months of life with failure to thrive, irritability, severe thirst and excessive wetting. Often the diagnosis is made during the

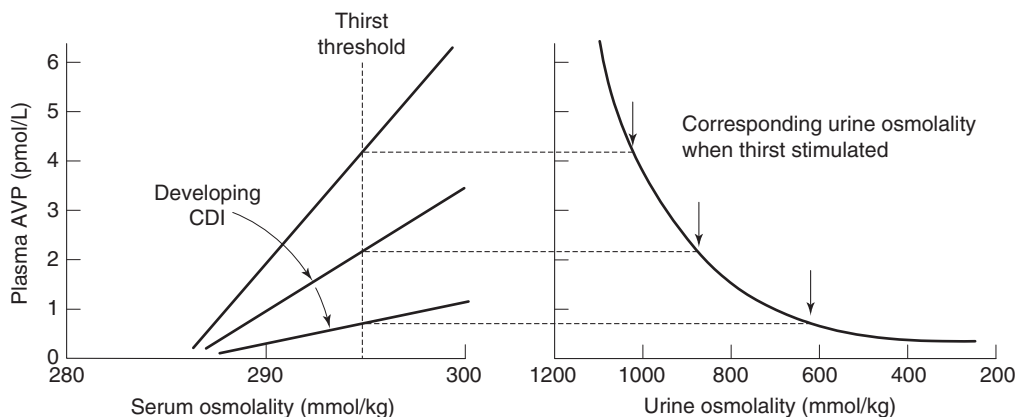

FIGURE 4.5 ■ The relationship between the osmoregulatory control over arginine vasopressin (AVP) secretion and the renal response to its action. For illustrative purposes, thirst is shown as a single point threshold. Normally, thirst does not become active until urine concentration approaches maximum. In developing cranial diabetes insipidus (CDI), as the number of cells releasing AVP diminishes, so thirst becomes active at correspondingly reduced urine osmolality. Polyuria leads to polydipsia.

first acute hospital admission because of impaired consciousness or convulsions, due to severe water depletion leading to significant hypernatraemia. The kidneys are completely unresponsive to AVP or AVP analogues. The female carriers of the condition are of interest, as many show evidence of polyuria, especially during pregnancy. Originally, this polyuria was considered to be due to the mimicking of affected males within the family, but this explanation is now disproven, with many females having demonstrably impaired renal responses to AVP – a partial form of congenital NDI – but some being almost as severely affected as males with congenital NDI. Of the remaining 10% of congenital NDI, inherited as autosomal recessive conditions, about 7% are due to mutations in the AQP 2 gene and the remaining 3% currently have no identified cause.

Both lithium and demeclocycline may produce clinically severe NDI with marked degrees of polyuria. Patients receiving lithium should be monitored strictly, to ensure effective but safe plasma concentrations of lithium to reduce the incidence of unwanted effects, including polyuria. Demeclocycline, once used to treat acne vulgaris, is no longer used as an antibiotic in man, but has, in the recent past, occasionally been used to control water-retaining states (see p. 51). The NDI of hypokalaemia and hypercalcaemia is generally less severe, with polyuria rarely greater than 4L/24h in adults. Recent work has suggested that NDI secondary to lithium, hypokalaemia and obstructive uropathy may all be related to alterations in AQP 2 expression.

Pregnancy and polyuria

There are several subtle alterations to normal osmoregulation in pregnancy, with the osmotic thresholds for both thirst and AVP secretion falling ~10 mmol/kg around the 6th week of gestation and remaining at these lower levels throughout pregnancy, so that a new steady state is achieved. The postpartum rise of these thresholds to normal occurs within approximately three weeks.

The major potential complication of osmoregulation in pregnancy is polyuria with secondary polydipsia. Pregnancy is discussed separately from other causes of polyuria because, although partial forms of CDI and NDI may be unmasked, one underlying cause is unique to pregnancy. This is due to the massive increase in the clearance of AVP, in both the placenta and the circulation, as a result of the release from the placenta of vasopressinase (cystine aminopeptidase, oxytocinase). In addition, there is evidence of increased clearance of AVP by the liver and kidneys related to increased blood flow to both organs. The increased clearance of AVP produces a form of diabetes insipidus that is unresponsive to exogenous pharmacological doses of AVP, but is responsive to the now commonly prescribed vasopressin analogue desamino-8-D-arginine vasopressin (dDAVP, desmopressin), which is resistant to enzymic degradation by vasopressinase. The response to a standard water deprivation test is thus identical to that found in CDI. Diabetes insipidus related to excessive vasopressinase activity resolves quickly following birth, with normal osmoregulation resuming within two weeks.

Polyuria secondary to primary polydipsia

Primary polydipsia is found in association with a variety of psychiatric and other CNS disorders. The commonest form is the ‘compulsive water drinking’ found in up to 7% of psychiatric inpatients. One possibility is that these patients have a reduced osmoreceptor setting for thirst, which is at or below the setting for AVP release. However, a subgroup of compulsive water drinkers use excessive water intake as a form of purging or self-therapy, and thus formal assessment of thirst thresholds using subjective visual analogue scales may be difficult, if not impossible, to interpret. This latter group has sometimes been classified as having psychogenic polydipsia, although the terms ‘compulsive water drinking’ and ‘psychogenic polydipsia’ are often used synonymously. The mechanisms are further complicated by the fact that many of the drugs used in psychiatry have powerful anticholinergic effects and may cause dryness of the mouth with a subsequent desire for oral fluids.

Primary polydipsia due to a hypothalamic disorder is rare, but can be dramatic. Even immediately following ingestion of large volumes of water, patients may possess such cravings for further water intake that they will go to extreme lengths to obtain it, such as consuming bath water or even lavatory water. Hypothalamic disorders can occasionally give rise to a water-retaining state and, if excessive thirst is also present, severe acute hyponatraemia may result (see p. 46).

Excessive thirst is a rare feature of conditions in which the renin–angiotensin system is stimulated, possibly because the concentration of angiotensin II, a powerful central thirst stimulant, is increased. Thus, pathological thirst has been described in renal artery stenosis, Wilms tumour, end-stage renal disease and even congestive cardiac failure. There is some evidence that when thirst occurs in these conditions, it can be controlled by angiotensin-converting enzyme (ACE) inhibitors. The mechanisms, however, are not well understood, as paradoxically, some animals develop increased thirst in response to ACE inhibitors; this is presumed to be because of increased angiotensin I delivery to thirst-stimulating areas of the brain that are inaccessible to ACE inhibitors, and at which conversion to angiotensin II subsequently occurs.

Laboratory investigation and treatment of polyuria

The first step is to confirm polyuria. Patients (and doctors) may confuse frequency of micturition with polyuria. True polyuria is invariably associated with polydipsia, and nocturnal polydipsia is an important pathological symptom. Fasting plasma glucose, serum potassium, calcium and urea measurements in the basal state may reveal diabetes mellitus, hypokalaemia, hypercalcaemia or renal impairment. Serum sodium may provide a pointer to the final diagnosis, tending towards the upper reference limit in secondary polydipsia and DI, but towards the lower reference limit in primary polydipsia. However, overlap of serum sodium concentrations between the diagnostic groups means that a water deprivation test is often necessary.

Water deprivation test. A standard protocol that can be performed on outpatients or day cases in the majority of patients is provided in [Appendix 4.2a](#). The test is conceptually simple to understand but is often incorrectly performed. Weighing the patient prior to and during water deprivation is a most important component of the test. Weighing allows the detection of surreptitious water intake – weight loss during the test should approximate to urine output (1 L = 1 kg). Weighing is also necessary to prevent gross dehydration in patients with severe DI; a weight loss of 3% body weight is normally the maximum that should be allowed, and if this is achieved, the test is concluded with dDAVP administration. However, care should be applied with respect to the weight loss limit as certain patients, often but not invariably with primary polydipsia, may prepare for the test by considerable water loading. Alternatively, patients with severe DI may start the test grossly dehydrated. Basal serum and urine osmolality should be measured before the test is started, as a low serum sodium and/or osmolality ($[Na]_s < 135$ mmol/L, $[Osm]_s < 275$ mmol/kg) may imply prior water loading and therefore the limit on weight loss can be extended, whereas an elevated serum sodium and/or osmolality ($[Na]_s > 145$ mmol/L, $[Osm]_s > 295$ mmol/kg) with dilute urine at the start of the test should preclude initiation of water deprivation.

If the water deprivation part of the test is concluded without adequate urine concentration being achieved (urine osmolality < 600 mmol/kg or urine:serum osmolality ratio $< 2:1$), dDAVP should be administered intravenously or intramuscularly. A sample of urine is collected after 2 h and, if necessary, at intervals during the next 16 h to determine maximum achievable urine concentration. Patients are allowed to drink during this time, but intake should be limited: a total input over 16 h of not more than 1000 mL is recommended. This is particularly important in patients who have primary polydipsia, as otherwise water intoxication could ensue. For patients with severe NDI, however, this limit may be inadequate and some extension may be required, matching output to input. Problematic patients should, therefore, be admitted to hospital and kept under strict observation.

Some care is required in interpretation of the final results of urine concentration achieved following dDAVP. Any patient with a history of prolonged polyuria of whatever cause will have some impairment of urine concentrating ability because of renal medullary washout. Attempts have been made to establish diagnostic criteria based upon the percentage increase of urine concentration following exogenous AVP preparations and that achieved by water deprivation alone. Such fixed criteria do not take into account serum osmolality measurements during or after water deprivation and may lead to misclassification. The majority of patients under investigation will be patients who have CDI or primary polydipsia. These patients may only achieve urine concentrations of 400 mmol/kg following dDAVP but, in the case of CDI, serum osmolality at the end of water deprivation would be at or above the physiological range. If diagnostic confusion exists, then further information may be achieved by plasma AVP measurements

during a repeat water deprivation test. Alternatively, a hypertonic saline infusion with serial plasma AVP measurements may be necessary.

Hypertonic saline infusion. A protocol for hypertonic saline infusion is given in [Appendix 4.2b](#). This test involves producing an acute elevation in serum sodium (~ 10 mmol/L) with frequent monitoring of plasma AVP concentration. Although acute extracellular osmotic changes should generally be avoided, the degree of change induced by the procedure is sufficient to induce significant and easily detectable increases in plasma AVP without complications; the morbidity of the test is extremely low. The major function of this test is to differentiate partial forms of CDI from primary polydipsia and from partial NDI. In CDI, the slope of the relationship between the plasma osmolality and the plasma AVP is reduced, but thresholds for thirst and AVP release are normal (see [Fig. 4.5](#)). The slope of this relationship remains normal in primary polydipsia and NDI.

Management of polyuria

The treatment of CDI has been revolutionized following the introduction of dDAVP. This analogue of AVP has a prolonged action and virtually no pressor activity. It is simple to administer either orally or nasally (by metered dose nasal spray). Patients tolerate the treatment extremely well and soon become practised in altering doses to meet their social requirements. Dilutional hyponatraemia is a potentially serious side-effect, but, in practice, is rarely encountered.

Because of the efficacy and patient acceptance of dDAVP, other forms of treatment have virtually disappeared. Lysine vasopressin (porcine antidiuretic hormone, available in oil as Pitressin) suffers the major disadvantage of native AVP in that, to achieve reasonable duration of action, a dose high enough to produce pressor effects may be required. Other drugs, which act by either enhancing renal responsiveness to AVP, for example chlorpropamide, or inhibiting renal diluting capacity, for example thiazide diuretics, are no longer used for CDI.

Primary polydipsia is a difficult condition to treat, but, in many instances, requires no primary treatment other than reasonable restriction of access to water. The major problem in this condition is the avoidance of antidiuresis and thus the potential for acute water intoxication.

The treatment of NDI is dependent on the cause. Acquired forms, such as those resulting from hypokalaemia or hypercalcaemia, require correction of the primary metabolic disturbance. Lithium treatment is probably the commonest cause of NDI, although the prevalence has fallen considerably since the recommended therapeutic range for serum lithium in the treatment of bipolar affective disorder has been reduced. Some reduction of polyuria can often be attained by reduction of lithium dose or by dividing doses of lithium to avoid very high peak serum concentrations. The renal resistance to AVP is related to serum lithium concentration. For intractable cases of lithium-induced polyuria, alternatives to lithium therapy should be sought.

Congenital NDI poses considerable problems of management. The severe polyuria may lead to enlarged bladder, hydronephrosis and hydronephrosis, and eventually to renal impairment, which ironically will reduce the symptoms. In addition, any failure to respond to the secondary polydipsia, such as may occur during illness or any degree of incapacity, will lead rapidly to hypernatraemia. The main treatment available until now has been thiazide diuretics, which inhibit the function of the diluting segment of the distal tubule, coupled with sodium restriction (<1.5 mmol/kg per 24h). This treatment can be used in combination with amiloride in older children, but is less well tolerated in the infant. Alternative combinations include a thiazide with a non-steroidal anti-inflammatory drug such as indometacin or a combination of thiazide with a cyclooxygenase-2 inhibitor. Treatments such as these can reduce urine flow rates to about one-third of pretreatment levels. New treatments are now under active investigation. Many of the loss of function mutations of AVPR2 lead to intracellular retention of the receptor (impaired trafficking to the basolateral membrane) rather than actual reduced affinity for AVP. Molecular chaperones, also known as 'pharmacochaperones', show promise as future therapies for such mutations. In addition, AVP-independent targeting of AQP 2 insertion into the apical membrane by selective E-prostanoid receptor agonists, may also prove to be a useful therapy.

Nocturnal polyuria

The study of renal diurnal rhythms of water and electrolyte excretion consistently demonstrates that, in health, both urine flow and electrolyte excretion are attenuated during sleep. Thus, it is expected that, unless significant water and/or electrolyte loading occurs immediately prior to retiring to bed, physiologically there will be no interruption to sleep due to the need to urinate. The terms nocturia and nocturnal polyuria are poorly defined. Nocturia as a descriptive symptom simply means the voluntary voiding of an indeterminate volume of urine at night (as opposed to enuresis, which is involuntary voiding). As a symptom, it can be extremely debilitating, as the frequent and persistent interruption of sleep can lead to severe fatigue. Nocturia is a common complaint of increasing prevalence with age in both men and women. One reason for the lack of consistency in the definition or investigation of nocturia, and in particular nocturnal polyuria, is that patients can present to a variety of medical and surgical specialties dependent on age, gender and on associated conditions, symptoms and subjective assessment.

Any disease process that reduces the functional capacity of the bladder or reduces the ability of the kidney to concentrate urine may give rise to daytime frequency and/or polyuria and nocturia. For some patients, however, nocturia is not associated with either daytime frequency or polyuria, but is associated with relative polyuria only at night. **Box 4.6** lists the common causes of nocturnal polyuria.

BOX 4.6 Causes of nocturnal polyuria

Sequestered fluid excreted at night

- Congestive heart failure
- Nephrotic syndrome
- Autonomic failure
- Severe varicose veins

Failure to conserve fluid at night

- Poor control of diabetes mellitus at night
- Suboptimal treatment of diabetes insipidus at night
- Non-dipping hypertension (sustained hypertension at night)
- Obstructive sleep apnoea
- Chronic renal failure

Laboratory investigation and treatment of nocturnal polyuria

To diagnose nocturnal polyuria, it is first necessary to exclude daytime polyuria and urodynamic causes of frequency. The investigation of the osmoregulation of a patient with suspected nocturnal polyuria is difficult, not least because there are no universally accepted investigation protocols. Moreover, it is likely now that investigations would be expected to take place in an outpatient setting, rather than on a fully staffed and equipped clinical investigation unit. The simplest demonstration of the existence and severity of nocturnal polyuria is to perform a 12 h-split 24 h urine collection, with one 12 h session incorporating the whole period of sleep, for example collection one 09.00–21.00 h, collection two 21.00–09.00 h. A 12 h urine collection overnight normally contains approximately one-half of the total 24 h creatinine excretion, but much less than half the volume of overall solute excretion. More detailed study is possible but requires a high degree of patient cooperation in the outpatient setting. Patients can be instructed to collect a complete 24 h urine collection, while maintaining an accurate diary of voiding times, collecting individual aliquots of each voiding and, if possible, an accurate volumetric measurement of each voiding. Alternatively, estimates of the volume of each voiding can be made from the relative creatinine concentration of each timed voiding, particularly if the patient is willing to reduce diurnal variations in creatinine excretion by avoiding meat consumption over the period of study. Providing the patient is willing and capable of following such a protocol, detailed diurnal patterns of excretion of volume, sodium and osmoles (or, indeed, any measurable urine constituent) can be constructed. **Figure 4.6** demonstrates the diurnal pattern of sodium excretion in a man presenting with severe nocturnal polyuria and a 12 h split urine volume of 0.57 L (daytime) to 1.75 L (night-time). This man was subsequently shown to suffer from severe obstructive sleep apnoea. Following treatment with continuous positive airways pressure (CPAP), the nocturnal polyuria resolved completely as the nocturnal natriuresis was reversed. Other causes of nocturnal polyuria, for which treatment of the primary cause is not possible or is insufficient to ameliorate symptoms, have been managed either with a loop diuretic taken 6 h prior to retiring to

FIGURE 4.6 ■ Diurnal pattern of urine sodium excretion in a man presenting with severe nocturnal polyuria due to obstructive sleep apnoea. The shaded area shows the mean and 95% confidence limits of normal cumulative 24 h sodium excretion (...△..., pre-treatment; ...□..., post-treatment with continuous positive airways pressure).

bed (to induce a relative sodium depletion at night) or in combination with night-time dDAVP.

Hypernatraemia

Mild hypernatraemia (serum sodium >145 mmol/L) is not uncommon in hospital patients, especially in the elderly, but severe hypernatraemia (>154 mmol/L) has an incidence of less than 0.2% of hospital admissions per annum. The causes of hypernatraemia are shown in [Box 4.7](#).

Spurious hypernatraemia may occur due to sampling error, for example sampling from the same limb receiving a hypertonic sodium infusion such as 8.4% sodium bicarbonate. Spurious hypernatraemia may also occur because of post-collection contamination of the sample with sodium salts or because of evaporative losses after collection.

Acute sodium poisoning may also result in severe hypernatraemia (see [p. 38](#)), which is not initially due to water depletion, but will induce water depletion through

BOX 4.7 Causes of hypernatraemia

Spurious

- Sampling error
- Contamination
- Evaporation

Acute sodium poisoning

- Without polyuria (confusion, coma, immobility)

Water deficiency without conscious thirst

- Hypodipsic hypernatraemic syndromes

natriuresis and diuresis, and will require correction with free water administration.

The major clinical causes of hypernatraemia are due to water deficit, either physiologically, when the desire to drink cannot be expressed, e.g. in neonates, the old or incapacitated or unconscious patients, or pathologically, e.g. with a history of polydipsia and thirst that is, for whatever reason, not satisfied.

Water deficiency with thirst

Adult patients with water deficiency, whose ability to ingest water is impaired by incapacity, will be oliguric (<400 mL/24h). The urine will be concentrated (osmolality >1000 mmol/kg), although the capacity for urinary concentration is restricted in the neonate to ~ 500 mmol/kg and, in the adult, urine concentrating capacity declines in the elderly and may fall to <700 mmol/kg over the age of 70.

In patients whose water deficiency is due to complete DI (cranial or nephrogenic), the urine is not concentrated. However, if the water deficiency is sufficient to reduce ECF volume and thus renal function significantly, the urine may not be maximally dilute, but will approximate to the osmolality of serum. In addition, in partial forms of DI, severe water deficiency may result in near maximally concentrated urine. In order to avoid diagnostic confusion, it is, therefore, advisable to correct any water deficiency prior to establishing the diagnosis with a water deprivation test.

Water deficiency without thirst

Patients rarely may present with severe hypernatraemia but no thirst or polyuria. The cause is a group of conditions known collectively as adipsic hypernatraemia and hypodipsic or essential hypernatraemia. The hypothalamic disorder causing hypodipsic hypernatraemia may be due to trauma, a primary or secondary tumour, a granuloma (e.g. sarcoid or histiocytosis) or vascular impairment, or the condition may be idiopathic. The aetiological similarity to those conditions causing CDI underlines the close proximity of osmoreceptors for AVP and thirst control within the hypothalamus. Four subtypes of hypodipsic hypernatraemia have been recognized ([Fig. 4.7](#)).

In type 1 ([Fig. 4.7, line A](#)), normal osmotic control over AVP release is retained but thirst appreciation is absent – primary adipsia. This disorder is rare, but demonstrates the separate osmoregulation of thirst and AVP. An example of this defect in a male patient with a history of chronic hypernatraemia is shown in [Figure 4.8](#). During hypertonic saline infusion, he retained normal osmotic control over plasma AVP release, but subjective thirst assessment remained absent throughout. He had undergone hypothalamic surgery for severe behavioural disturbance and his serum sodium was found to be consistently >150 mmol/L without any experience of thirst. Adipsic hypernatraemia has been described in up to 20% of patients surgically treated for craniopharyngioma.

In type 2 hypodipsic hypernatraemia ([Fig. 4.7, line B](#)), the plasma AVP response is similar to that seen in patients with severe CDI, with a substantial loss of incremental gain of plasma AVP as serum osmolality rises.

FIGURE 4.7 ■ Relationship between plasma arginine vasopressin (AVP) and serum osmolality in patients with hypodipsic hypernatraemia: (A) normal regulation of AVP release; (B) partial defect in AVP release; (C) total defect; (D) reset osmostat. The dashed line represents the limit of detection of current AVP assays. Adapted from Robertson et al. 1982.

Unlike the situation in CDI, however, the osmotic thirst response is severely blunted. This group of patients is of interest, as the renal responsiveness to AVP is often considerably enhanced and patients are thus not polyuric. Urine concentration may approach the maximum when hypernatraemia is severe and patients retain the ability to dilute urine.

In type 3 (Fig. 4.7, line C), plasma AVP concentration is unresponsive to changes in serum osmolality, but is fixed at a low level. Osmotic thirst is entirely absent. Patients are, therefore, at risk of developing either

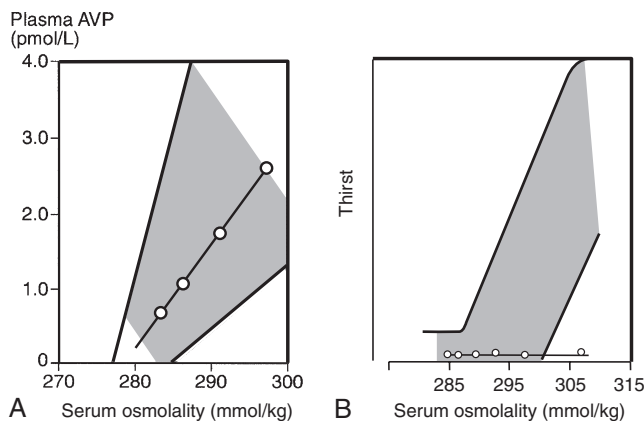

FIGURE 4.8 ■ Osmoregulation in a patient with type 1 hypodipsic hypernatraemia syndrome. (A) Normal osmotic control of arginine vasopressin (AVP) release. (B) Complete absence of thirst stimulation despite significant osmotic stimulus. Shaded areas represent 95% confidence limits of normal response.

hypernatraemia or hyponatraemia, depending on the prevailing fluid intake.

Type 4 hypodipsic hypernatraemia (Fig. 4.7, line D) represents true resetting of the osmostat for both plasma AVP response and thirst: the incremental gain for both remains normal and patients can concentrate and dilute urine normally, but around a higher setting of plasma sodium and hence serum osmolality. Severe hypernatraemia is generally not a feature, as dehydration does result in thirst. Thus, hypodipsia in these patients is only relative to the degree of thirst seen in normal subjects with corresponding degrees of hypernatraemia; the full range of thirst appreciation is maintained.

Management of hypernatraemia

Hypernatraemia in the incapacitated patient is invariably due to water depletion and should be corrected. Care should be exercised in the rate of correcting severe hypernatraemia in which the duration is greater than 48 h, and the rules on the rate of correction are directly comparable with those applicable to the correction of chronic dilutional hyponatraemia (see p. 51). The response of brain cells to persistent severe dehydration is to generate intracellular solutes, sometimes termed idiogenic osmoles or osmolytes. These are organic solutes that can be synthesized without apparent detrimental effect on cell structure or function. Recent nuclear magnetic resonance spectra of hypernatraemic human brains in vivo have identified myoinositol, scylloinositol, N-acetylaspartate and choline as osmolytes. Oral hydration with plain water is the simplest regimen (for estimate of deficiency, see Appendix 4.1c), but if oral or enteral fluids cannot be given, then hypotonic sodium or isotonic glucose solutions should be infused. It is strongly recommended that serum sodium is corrected at a rate of no greater than 12 mmol/L per 24 h; once corrected, any underlying polyuria should then be investigated as outlined in the previous section. A conscious patient with hypernatraemia, but without expressed thirst, is by definition suffering from one or other form of hypodipsic hypernatraemic syndrome. Although it is possible to differentiate pure adipsia (type 1) from other types of the syndrome by the use of tests of water deprivation and water loading (see Appendix 4.2), in practice the diagnosis can only be confirmed by the study of plasma AVP secretion and thirst in response to hypertonic saline infusion.

Management of hypodipsic hypernatraemia syndromes. The treatment of hypodipsic hypernatraemic syndromes varies considerably with type. Type 1, in which AVP release is normal but thirst is absent, and type 2, with a reduced pituitary release of AVP, enhanced renal response to AVP and blunted thirst response, both require a fluid intake regimen of more than 2 L/24 h for an adult to avoid hypernatraemia. Concentration of the urine should be avoided and at least one dilute urine should be passed each day. Type 3 poses the greatest problem of management, as fluid output and urine concentration cannot be used by the patient to gauge fluid balance. A standard regimented fluid intake is required and body weight needs to be accurately monitored each day to

monitor fluid status. Frequent plasma monitoring is required to avoid the progressive development of hyper- or hyponatraemia. Type 4 requires no specific treatment, as alterations in fluid regimens will simply be handled in a physiologically normal way except at a higher osmotic setting than in normal individuals.

Hyponatraemia

Hyponatraemia (serum sodium concentration <130 mmol/L) is common in hospital inpatients, with a prevalence of 2–3%. The lower reference limit for serum sodium is reduced by ~ 5 mmol/L in hospitalized patients as opposed to healthy controls. The majority of cases of hyponatraemia are mild, self-limiting and require neither treatment nor extensive investigation.

By definition, hyponatraemia implies an excess of water in comparison with sodium, although primary water excess is not always responsible for hyponatraemia. For example hyperglycaemia or the infusion of mannitol may induce significant fluid shifts from the ICF to the ECF. An estimate of the expected fall in serum sodium in relation to hyperglycaemia is given in [Appendix 4.1d](#). However, this section is primarily concerned with states of water excess and with acute and chronic dilutional hyponatraemia: dilutional hyponatraemia is also defined as hyponatraemia with clinically normal ECF volume or normovolaemic hyponatraemia. The full classification of hyponatraemia is shown in [Box 4.8](#).

Spurious hyponatraemia is due to *in vivo* or *in vitro* contamination of the specimen with water or fluid containing sodium at a concentration that is less than that of plasma. The commonest example seen in hospital practice is venesection from a limb concurrently receiving a dextrose infusion.

Pseudohyponatraemia (molar concentration) is due to the replacement of a portion of the plasma water space with either lipid or protein. This can occur in patients with severe endogenous or exogenous hypertriglyceridaemia and in patients with high plasma protein concentrations (usually due to paraproteinaemia). The concentration of sodium in plasma water (molal concentration) is normal, but each litre of plasma now contains less water. Serum osmolality (molal concentration) is normal.

Patients with hypovolaemic or hypervolaemic hyponatraemia present with signs of ECF volume depletion

or excess. These conditions are discussed under disorders of sodium metabolism; they are usually differentiated clinically from dilutional hyponatraemias and also by the presence of biochemical evidence of the underlying cause, for example renal or hepatic dysfunction.

Although acute and chronic hyponatraemia may share certain common causes and the definition is somewhat arbitrary (acute hyponatraemia is of <48 h duration), these conditions present and are managed in quite separate ways. This is because of the adaptation of cells, in particular brain cells, to chronic hypotonicity. The nature of this adaptation is summarized in [Figure 4.9](#) and can, in part, be attributed to the reduction of cerebral osmolytes (see [p. 45](#)).

Acute dilutional hyponatraemia

The main causes of acute dilutional hyponatraemia are shown in [Box 4.9](#). Self-inflicted acute hyponatraemia has been described, but is extremely difficult to induce due to the enormous human capacity for renal water excretion – urine flow rates of 27.5 mL/min (equivalent to 39.6 L of urine in 24 h) have been described, although low osmotic loads for excretion or renal impairment can severely reduce water clearing capacity.

Psychogenic polydipsia (and the much rarer hypothalamic polydipsia) may result in acute hyponatraemia. However, the commonest cause of acute dilutional hyponatraemia seen in hospitalized patients is inappropriate postoperative fluid regimens involving the intravenous infusion of excessive volumes of low-sodium fluid (e.g. ‘dextrose saline’). The acute hyponatraemia following transurethral prostatectomy (TURP), known as the transurethral resection syndrome (TURS), is also worthy of specific mention, as it is the most serious acute hyponatraemia likely to present at the current time. In the development of TURS, irrigant fluid (1.5% glycine) is absorbed into the circulation via the open venous sinuses of the prostatic bed; glycine is used as it provides a non-electrolytic medium that will not dissipate the energy of cautery used in the resection, and the slightly hypotonic concentration provides an ideal optical interface. Risk factors for the development of the syndrome include a prolonged operative procedure, high irrigant hydrostatic pressure and significant blood loss. Strict control over these risks has resulted in a marked reduction in the incidence of this complication in recent years. If, however, sufficient irrigant is absorbed, this fluid will reduce plasma sodium concentration by simple dilution, but osmolality will not initially be reduced by an equivalent extent. An osmolal gap (see [Appendix 4.1e,f](#)) will initially develop as a result of high plasma glycine concentrations (up to 15 mmol/L), but unless the resultant free water is subsequently excreted, the osmolal gap will disappear as the glycine is metabolized. High plasma concentrations of both glycine and ammonia (which may result from the rapid metabolism of glycine) have been proposed to contribute to the severe deterioration in mental state that occurs in full-blown TURS. However, patients with hypoosmolal hyponatraemia respond rapidly to measures designed to treat acute water intoxication alone.

BOX 4.8 Classification of hyponatraemia

- Spurious (sampling error)
- Pseudohyponatraemia
- Hypovolaemic hyponatraemia
 - Renal sodium loss (diuretic excess, adrenal failure, sodium losing nephropathy)
 - Non-renal sodium loss (gastrointestinal, haemorrhage, burns)
- Hypervolaemic hyponatraemia
 - With oedema (cirrhosis, CCF, nephrotic syndrome)
 - Without oedema (acute or chronic renal failure)
- Normovolaemic hyponatraemia
 - Acute dilutional hyponatraemia (see [Box 4.9](#))
 - Chronic dilutional hyponatraemia (see [Box 4.10](#))

FIGURE 4.9 ■ The major differences in brain cell volume in acute hyponatraemia and chronic hyponatraemia. In chronic hyponatraemia, cell osmotic content has been reduced.

BOX 4.9 Causes of acute dilutional hyponatraemia

- Self-induced
- Psychogenic
- Freshwater drowning
- Iatrogenic
 - Inappropriate i.v. fluid regimen
 - Absorption of irrigant (transurethral prostatectomy, transcervical endometriectomy, transcutaneous ureterolithotomy, vesical ultrasonic lithotripsy)
- Syntocinon induction of labour with isotonic dextrose infusion

Acute hyponatraemia of sufficient severity to present clinically, with symptoms of headache, confusion and drowsiness, is a medical emergency, as the condition may lead to coma and death. Progressive clinical symptoms may be associated with signs of raised intracranial pressure, decerebrate posturing, fixed dilated pupils, bradycardia, hypertension and convulsions. All cells swell in size when placed in hypotonic medium: the change in size is particularly important with respect to brain cells confined within the fixed volume of the cranium (see Fig. 4.9). In acute hyponatraemia, adaptation of brain cell size cannot occur quickly enough to prevent the effects of cellular swelling and subsequent tentorial herniation with dramatic clinical sequelae. Females of reproductive age appear to be particularly prone to the effects of acute hyponatraemia.

Chronic dilutional hyponatraemia

Chronic dilutional hyponatraemia is common and has many possible causes (Box 4.10). The majority (excluding chronic hyponatraemia associated with beer potomania; see p. 49) can be related to a failure of water excretion,

presumed to be due to a failure to suppress AVP secretion. There is good evidence that certain tumours (e.g. small cell (oat cell) carcinoma of the bronchus) possess the capacity to synthesize and secrete AVP, but in the majority of cases, the origin of the AVP is presumed to be the hypothalamic-posterior pituitary axis.

Patterns of plasma AVP response to increasing plasma sodium concentration induced by hypertonic saline infusion have been studied in chronic hyponatraemia. Four patterns of response have been described, as shown in Figure 4.10.

1. In type A, there is no relationship between plasma AVP concentration and plasma sodium (osmolality); AVP is released either at fixed concentration or shows random variation. This pattern is often seen in association with ectopic production of AVP by tumours.
2. In type B, there is a normal response of AVP release to osmotic stimulation but it occurs at a much lower setting – a resetting of the osmostat. Theoretically, this condition could result from the adaptive response to chronic hyponatraemia as the osmotic content of brain cells falls. This condition has been described in association with tumours and various neurological disorders.
3. In type C, there is a constant low-level release of AVP, even when osmolality is suppressed below the normal threshold, but a qualitatively and quantitatively normal response above the threshold. This pattern may be seen transiently following pituitary/hypothalamic trauma.
4. In type D, there is suitable suppression of AVP concentration when the patient is hyposmolal, suggesting either that immunologically distinct antidiuretic material is being secreted or that the renal tubules are somehow rendered more sensitive to extremely low concentrations of circulating AVP. This pattern of response is seen in patients with gain of function mutations of the AVPR2 gene.

BOX 4.10 Conditions associated with chronic dilutional hyponatraemia**Tumours***Thoracic*

- Bronchogenic
- Carcinoma
- Bronchial carcinoid
- Mesothelioma
- Thymoma

Non-thoracic

- Pancreatic carcinoma
- Duodenal carcinoma
- Ureteral, bladder and prostatic carcinoma
- Lymphoma
- Myeloproliferative diseases
- Olfactory neuroblastoma

Pulmonary disease*Infections*

- Tuberculosis
- Empyema
- Lung abscess
- Pneumonias (bacterial, viral and mycoplasmal)
- Aspergillosis

Ventilatory

- Asthma
- Bronchiolitis
- Pneumothorax
- Emphysema
- Cystic fibrosis
- Positive-pressure ventilation

CNS disorders*Space-occupying lesions*

- Tumour (any type)
- Abscess
- Subdural haematoma

Degenerative

- Guillain–Barré
- Multiple sclerosis
- Cerebral atrophy

Infections

- Meningitis
- Encephalitis

Inflammatory conditions

- Systemic lupus erythematosus

Miscellaneous

- Head trauma
- Hydrocephalus
- Subarachnoid haemorrhage
- Cavernous sinus thrombosis

Drugs*AVP analogues*

- dDAVP
- Oxytocin/syntocinon

AVP potentiation

- Prostaglandin synthetase inhibitors, e.g. aspirin, indometacin
- Chlorpropamide

Stimulation of AVP release

- Nicotine
- Phenothiazines
- Vincristine
- Tricyclic antidepressants

Mixed or unknown action

- Colchicine
- Carbamazepine
- Clofibrate
- Cyclophosphamide
- Clozapine

Miscellaneous

- Idiopathic
- Gain of function mutation AVPR2
- Acute porphyrias
- Hypothyroidism
- Low osmotic load

Although this classification of AVP responses in chronic dilutional hyponatraemia assists pathophysiological understanding, no reliable relationship has been found between the aetiology of the condition and any one pattern of response, save for the gain of function mutations in the AVPR2 gene. The measurement of AVP in chronic dilutional hyponatraemia, therefore, for the vast majority of patients has no current diagnostic or prognostic function.

The syndrome of inappropriate antidiuretic hormone secretion. The term ‘syndrome of inappropriate antidiuretic hormone secretion’ (SIADH) was first coined by Bartter and Schwartz in 1957, to describe patients with severe hyponatraemia who were without evidence of renal failure, adrenal failure or saline depletion, but who had indirect evidence of persistent AVP secretion. The criteria for diagnosing the syndrome are shown

in **Box 4.11**. Before this description, such patients were often misclassified as suffering from renal salt wasting because of the associated hyponatraemia and natriuresis. The original description thus provided a useful explanation of the biochemical findings and led to more rational therapeutic regimens.

Unfortunately, the term SIADH tends to be used universally to describe any acute or chronic dilutional hyponatraemia. Apart from certain causes of acute water intoxication and rare forms of chronic hyponatraemia, plasma AVP is detectable in the vast majority of patients with hyponatraemia of whatever cause. In addition, the criteria for diagnosis may produce anomalies, for example chronic dilutional hyponatraemia with reset osmostat (**Fig. 4.10B**) could fit the criteria when plasma osmolality is above the new threshold for AVP release, but fail to comply when plasma osmolality falls below this threshold, when maximally dilute urine is excreted. The term

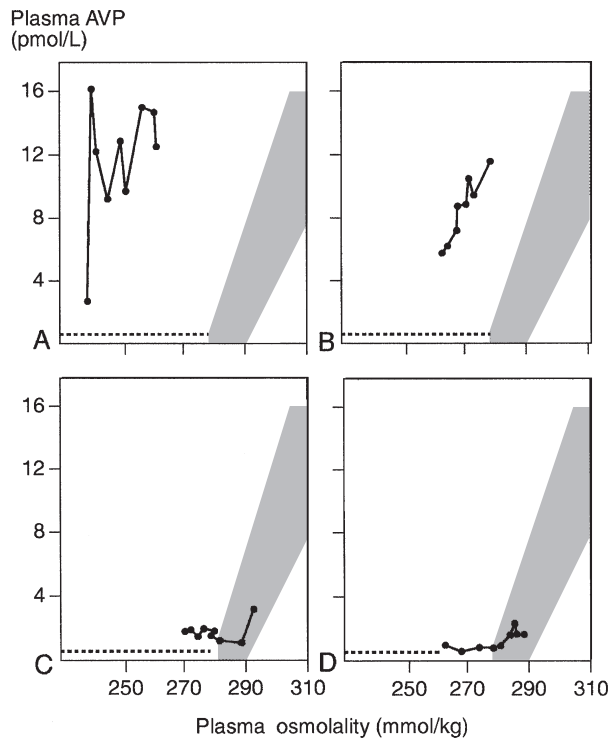

FIGURE 4.10 ■ The four patterns of plasma arginine vasopressin (AVP) responses to changes in plasma osmolality induced by hypertonic saline infusion in patients with chronic dilutional hyponatraemia. (A) Random variation. (B) Resetting of osmostat. (C) Constant low-level release. (D) Hypovasopressinaemic antidiuresis. Shaded areas represent the inter-subject variation limits of normal response. The dotted line represents the limit of detection of current AVP assays. Data from Zerbe R L, Stropes L, Robertson G L. Vasopressin function in the syndrome of inappropriate antidiuresis. *Annual Review of Medicine* 1980; 31:315–327.

BOX 4.11 Criteria for diagnosing the syndrome of inappropriate antidiuretic hormone secretion (SIADH)

1. Hyponatraemia with corresponding hypoosmolality of the serum and ECF
2. Continued renal excretion of sodium
3. Absence of clinical evidence of fluid volume depletion or overload, that is, normal skin turgor and blood pressure, or absence of oedema
4. Osmolality of the urine greater than that appropriate for the concomitant tonicity (effective osmolality) of the plasma, that is, urine not maximally dilute
5. Normal renal function
6. Normal adrenal function
7. Normal thyroid function

SIADH implies physiological understanding when often very little exists, and is a diagnosis that does not indicate immediate management or prognosis. Syndrome of inappropriate antidiuretic hormone secretion is a term that should now be replaced with more descriptive terminology, for example chronic dilutional hyponatraemia secondary to small cell carcinoma of the lung.

Sick cell syndrome. The association of sick cells and hyponatraemia was first explored by Flear and Singh in 1973, and it was an attempt to explore critically the assumption of common pathophysiology of the vast number of conditions grouped under SIADH, as well as to explain the hyponatraemia of seriously ill patients with conditions such as congestive cardiac failure (CCF), cirrhosis or serious pulmonary or CNS infections. One hypothesis was that sick cells leak normally non-diffusible solutes, but gain sodium, leading to extracellular hyponatraemia, but maintenance of serum osmolality. This combination of events may be observed in extremely ill patients after major surgery or burns, but has not been detected in the vast majority of patients with chronic hyponatraemia. However, a type of sick cell syndrome that is relevant to the development of chronic hyponatraemia is that resulting from a primary overall reduction in cellular osmotic content, through either increased loss or reduced production. Osmoreceptor cells so affected would result in control of AVP around a lower osmotic setting – a reset osmostat (SIADH type B). In practice, however, it is difficult to distinguish between a primary loss of cellular osmotic content (sick cells) or a secondary adaptive loss in response to a primary chronic dilutional hyponatraemia. Like SIADH, the term ‘sick cell syndrome’ should now be replaced by descriptive terminology, for example ‘chronic dilutional hyponatraemia secondary to chest infection’.

Low osmotic load hyponatraemia

One unusual cause of hyponatraemia requiring special mention is that associated with a low osmotic load for renal excretion. Beer potomania is an example of such a condition. It is caused by the consumption of a large volume of beer containing only very low quantities of electrolytes, coupled with a diet poor in protein and other minerals. Unlike starvation, in which osmoles such as ketones and urea are generated and excreted in the urine, the daily osmolal load for excretion in individuals at risk for beer potomania can be extremely low (<250 mmol/24h). Thus, if the minimum achievable urine osmolality is normal at about 50 mmol/kg, then, allowing for insensible fluid loss, a consumption of more than 6L of such beer over the 24h period will result in water retention independent of AVP secretion or responsiveness. Binges can result in acute hyponatraemia, although the more usual presentation is of a severe chronic hyponatraemia, occasionally complicated by plasma electrolyte changes secondary to alcoholic liver disease. The condition is unusual in the UK, probably because of the higher mineral content of traditional beers compared with continental beers, together with the tradition of serving bar snacks rich in sodium chloride. An association with excess cider consumption (cider potomania) has also been described, although this condition can only occur in an individual with normal urine diluting capacity if factory-type cider is consumed, rather than traditional craft cider. The former may have only the equivalent of 25% apple juice content, whereas the latter has 100% with a corresponding mineral content providing non-metabolizable osmoles in excess of 70 mmol/kg.

The concept of beer potomania as a cause of dilutional hyponatraemia is that of a mismatch between fluid intake and the capacity for excretion, independently of AVP secretion or responsiveness. This concept may have other parallels, for example in elderly patients treated with thiazide diuretics and with diets of low mineral content, adequate calories and relatively high fluid loads – the so-called ‘tea and toast’ diet. Thiazide diuretics act by blocking the reabsorption of sodium and chloride in the cortical diluting segment of the nephron. Thus, the capacity to generate maximally dilute urine is impaired and a concomitant ‘tea and toast’ diet can result in the development of severe dilutional hyponatraemia.

Cerebral salt wasting

The association of cerebral pathology, hyponatraemia and failure to retain urine sodium is termed cerebral salt wasting (CSW). This term was coined before the description and understanding of SIADH, in which there is also hyponatraemia and, during access to free water or following infusion of saline, a continued renal loss of sodium. Recent reports have attempted to re-implicate a primary renal sodium loss in some patients with cerebral pathology. Natriuretic peptide excess has been suggested as a mechanism. Caution is required, however, as many of such case reports invariably describe a euvolaemic, as opposed to hypovolaemic, hyponatraemia indistinguishable from hyponatraemia associated with SIADH. Differentiation of CSW from SIADH will become increasingly important as selective AVPR2 antagonists (vaptans) become more widely available and affordable (see p. 51). Vaptans are contraindicated in hypovolaemic hyponatraemia.

Laboratory investigation of hyponatraemia

Hyponatraemia is, by definition, a laboratory diagnosis, but the differentiation of hypovolaemic and hypervolaemic hyponatraemia is largely clinical, as is the differentiation between acute and chronic dilutional hyponatraemia.

Acute dilutional hyponatraemia may constitute a medical emergency, yet its laboratory investigation is often cursory and incomplete. The diagnosis is by clinical history of acute water loading without evidence of corresponding diuresis, and rapid deterioration in mental state, possibly coupled with signs of cerebral oedema. It is most important to confirm the serum sodium measurement, preferably with a fresh sample, ensuring that contamination of the specimen is avoided. The most important additional laboratory investigation is the measurement of serum osmolality, which will validate the serum sodium measurement or indicate the extent of any osmolal gap. Measurement of urine osmolality is superfluous, even if a sample is available.

The laboratory investigation of chronic dilutional hyponatraemia is predominantly to confirm the water-retaining state that has produced the condition and to exclude correctable metabolic causes. The serum electrolyte pattern in chronic dilutional hyponatraemia will usually show normokalaemia, but a hypochloraemia of corresponding degree to the hyponatraemia. The serum

urea concentration is often low and is reduced not only by dilution, but also because of reduced tubular reabsorption. Serum urate concentration may also be low because of changes in tubular function, but this is not invariable and renal handling of urate may be directly affected by the cause of the hyponatraemia, for example a thiazide diuretic.

Urine measurements may be of confirmatory help in chronic dilutional hyponatraemia, but can be misleading. The urine is inappropriately concentrated, that is, it is anything other than maximally dilute. There is widespread belief that urine osmolality must exceed serum osmolality for the diagnosis of a water retaining state, but this is not the case. The concentration of urine is dependent on both water and osmolal content. An anorexic patient may have a total osmolal load of only 400 mmol/24h to excrete, but if fluid intake is sufficient to produce 2 L of urine, then the overall urine concentration at balance is 200 mmol/kg. A urine concentration of 220 mmol/kg would produce a positive water balance, even though the urine is hypoosmolal to plasma.

One of the remarkable features of chronic dilutional hyponatraemia, especially when it is clearly demonstrated that plasma AVP concentrations are grossly elevated, is that patients do not form maximally concentrated urine. Patients with chronic dilutional hyponatraemia reach new steady states and then remain in sodium and water balance. Thirst thresholds appear to be downregulated to match the reduced plasma osmolality. Sudden increases or decreases in fluid intake may upset the steady state until a new one is reached. The mechanism of renal adaptation is probably related to downregulation of the expression of AQP 2 in the renal collecting ducts coupled to a reduction in the concentration gradient within the renal medulla.

The urine sodium concentration may also be of diagnostic value to differentiate hypovolaemic hyponatraemia if clinical signs are absent or misleading, but only if the sodium deficit is not renal in origin. Again, some care is needed, as chronic dilutional hyponatraemia is classically associated with a natriuresis, which can be defined essentially as anything other than maximal sodium retention. Often, when the patient is on free fluids, the natriuresis is very marked, with a urine sodium concentration >100 mmol/L. But as a new steady state is approached, urine sodium excretion falls, and when fluid and sodium intake are restricted, urine sodium may fall to very low concentrations (<10 mmol/L); this then indicates the total body sodium deficit that has developed secondarily to the natriuresis induced by initial positive water balance.

Other laboratory investigations recommended when the cause of the water-retaining state is not clear include thyroid function tests and a short tetracosactide stimulation test. There is a recognized, but variable, association of chronic hyponatraemia with hypothyroidism, and occasionally patients with primary or secondary adrenal failure present with nothing more specific than chronic dilutional hyponatraemia.

As previously stated, measurements of plasma AVP concentration are not normally of any assistance in the diagnosis of chronic dilutional hyponatraemia, but may

be of value to determine if normal osmoregulation has been restored following a period of treatment. An indirect assessment of water handling using a water load test can also occasionally be used for this purpose (see [Appendix 4.2c](#)).

Management of hyponatraemia

The management of hypovolaemic hyponatraemia is primarily to restore blood volume and ECF volume to normal and to correct the underlying disorder. The management of hypervolaemic hyponatraemia is primarily to treat the underlying disorder and to use diuretic therapy when appropriate. Management of both these conditions is covered within the sections on sodium deficiency and excess.

The management of euvolaemic or dilutional hyponatraemia has created considerable controversy in recent years. This has its origins in the morbidity and mortality of uncorrected severe dilutional hyponatraemia (serum sodium ≤ 115 mmol/L), whether it is acute or chronic in nature. In the USA, a regimen of partial correction of hyponatraemia was adopted in the past, which resulted in patients' serum sodium concentrations being increased rapidly to ~ 125 mmol/L. The rate of increase in sodium was usually in excess of 0.5 mmol/L per hour and often several-fold greater. Unfortunately, this regimen has become increasingly associated with the development of the neurological disorder known variously as central pontine myelinolysis (CPM), pontine and extrapontine myelinolysis or osmotic demyelination syndrome. The usual course of events in such cases is that the patient presents clinically with hyponatraemic symptoms, which can be either mild, such as weakness and confusion or severe, such as convulsions or coma. During the rapid correction of the plasma sodium concentration, these symptoms improve, but in the following few days the patient's neurological condition deteriorates and further symptoms develop, including behavioural disturbances and convulsions and these, in turn, may lead on to the full-blown condition of CPM, including pseudobulbar palsy and quadriparesis. Further confusion as to the origin of the condition has been a continued, but unsubstantiated, association in the literature of CPM with uncorrected hyponatraemia.

Recommended management of symptomatic acute dilutional hyponatraemia. The biggest danger in this condition is failure to treat promptly. Water restriction has a supportive role, but must not be used alone. Cerebral oedema is the major complication, and acute elevation of plasma sodium using 5% sodium chloride infusion to produce a *maximum* increase of 12 mmol/L per 24h or a serum sodium concentration of approximately 125 mmol/L (whichever is the lesser), is recommended. If an osmolal gap exists, then the infusion should increase serum osmolality to no greater than 255 mmol/kg. A formula to calculate the amount of sodium required is given in [Appendix 4.1g](#). Short-term rates of infusion resulting in an increase of serum sodium up to 5 mmol/L per hour, have, in acutely symptomatic patients, been used successfully

with dramatic clinical improvement and with no long-term sequelae. A simple general rule for patients falling within the definition of acute hyponatraemia and who are symptomatic is to match the rate of correction with the presumed rate of onset. Diuretics such as furosemide and mannitol may be of benefit, but lack the precision of control afforded by hypertonic saline infusion, and when used in combination with hypertonic saline infusion may make controlling the rate of correction more difficult.

Recommended management of chronic dilutional hyponatraemia. The cornerstones of management in chronic dilutional hyponatraemia are to prevent further falls in plasma sodium concentration, to treat any underlying condition, to alleviate any symptoms attributable to hyponatraemia and to avoid any therapeutic complications. Many patients who are in a steady state with mild hyponatraemia require no specific treatment. For those at risk of further falls in plasma sodium, water should be restricted to a degree sufficient to induce negative water balance (usually 500–800 mL of water per 24h). Water restriction will increase plasma sodium concentration in anyone, but the rate of increase may be very slow, and if any degree of sodium depletion exists, an increase in plasma sodium will only be achieved at the expense of a contraction in ECF volume and a potential deterioration in renal function. Certain patients cannot tolerate fluid restriction, and for these, until recently, treatment with the tetracycline antibiotic demeclocycline (DMC) may have been considered. Arginine vasopressin receptor antagonists (collectively termed 'vaptans') are now commercially available. Tolvaptan is a selective vasopressin V_2 -receptor antagonist with an affinity for the V_2 -receptor greater than that of native arginine vasopressin. Treatment of chronic dilutional hyponatraemia commences with a single 15 mg oral dose and can be titrated up to a single daily dose of 60 mg, depending on response. Regular monitoring of serum electrolytes and renal function is strongly recommended. Tolvaptan should not be used in the treatment of acute dilutional hyponatraemia, which requires hypertonic saline infusion. The introduction of selective AVPR2 antagonists has rendered previous treatment options of DMC or lithium, obsolete.

In the very rare instances in which severe chronic hyponatraemia produces neurological symptoms, it may be considered prudent to raise the plasma sodium concentration acutely with hypertonic saline. If this is considered, the rate of infusion should be most carefully controlled with frequent monitoring of serum sodium. As in the management of acute hyponatraemia, it is recommended that serum sodium is raised to a concentration no greater than 125 mmol/L by this method. In this instance, however, the rate of infusion should produce a change in serum sodium of no greater than 0.5 mmol/L per hour to minimize the risk of the development of CPM: this is in contrast to the treatment of acute symptomatic hyponatraemia, in which the recommended 24h rate and maximum concentration are the same, but the maximum rate for short periods may be much more rapid – up to 5 mmol/L per hour.

DISORDERS OF POTASSIUM METABOLISM

Potassium is predominantly an intracellular cation, but disorders of potassium metabolism are generally identified by measurements of extracellular potassium. Dramatic changes in plasma potassium concentration may occur as a result of transcellular shifts without necessarily any alteration of total body potassium. Clinical disorders are therefore classified on the basis of serum potassium concentration, rather than of potassium depletion or excess.

Hypokalaemia

The definition of hypokalaemia is not strict, but persistent serum potassium concentrations <3.4 mmol/L (plasma 3.1 mmol/L) require investigation. The immediate clinical effects of hypokalaemia are on neuronal and muscular function: they result from an increase in the ratio of the intracellular to extracellular potassium concentrations. In addition, hypokalaemia, when associated with severe potassium depletion, affects the function of a wide variety of organ systems. [Box 4.12](#) lists the possible clinical effects of hypokalaemia.

BOX 4.12 The clinical effects of hypokalaemia

Cardiovascular

- Electrocardiographic changes – depressed ST segment, inverted T waves, prominent U waves
- Arrhythmias
- Potentiation of digitalis intoxication
- Hypotension
- Myocardial necrosis

Neuromuscular

- Weakness, flaccid paralysis
- Pain, tenderness, cramps
- Tetany
- Rhabdomyolysis

Neuropsychiatric

- Lethargy, apathy, depression
- Acute memory loss, disorientation, confusion

Renal

- Polyuria
- Sodium retention
- Increased renal ammoniogenesis
- Metabolic alkalosis

Gastrointestinal

- Decreased motility (constipation, paralytic ileus)
- Decreased gastric acid secretion

Endocrine

- Increased renin secretion
- Decreased aldosterone secretion
- Decreased insulin secretion

BOX 4.13 Causes of redistribution hypokalaemia

In vitro redistribution

- Uptake by white blood cells (e.g. in leukaemia)
- Uptake by erythrocytes following in vivo insulin administration

In vivo redistribution

- Alkalosis
- Increased plasma bicarbonate
- Insulin administration
- β -adrenergic agonists
- Toxic chemicals (toluene, soluble barium salts)
- Hypokalaemic periodic paralysis

Causes of hypokalaemia

Hypokalaemia can be caused by redistribution of potassium (in vitro or in vivo), inadequate intake or excessive loss (renal or extrarenal).

Redistribution hypokalaemia in vitro. This form of hypokalaemia, sometimes known as spurious hypokalaemia, has been described in association with two clinical situations ([Box 4.13](#)). First, it may occur in patients with leukaemia and very high white blood cell (WBC) counts; if the blood is taken and allowed to stand at room temperature without separation, the WBCs take up extracellular potassium. The second situation in which this phenomenon may occur is if blood is taken from a diabetic patient who received intravenous insulin a few minutes prior to venesection; erythrocytes take up extracellular potassium, and if blood is subsequently left to stand at room temperature unseparated for 2 h or so prior to analysis, serum potassium concentration will decrease.

Redistribution hypokalaemia in vivo. The major causes of transcellular shift of potassium occurring in vivo are also shown in [Box 4.13](#). Both alkalosis and increased plasma bicarbonate concentration without alkalosis will induce increased cellular uptake of potassium, as does endogenous or exogenous insulin. Catecholamines and β -adrenergic agonists such as adrenaline (epinephrine), salbutamol and fenoterol can all promote cellular uptake of potassium, and many patients admitted as acute medical emergencies may have significant, but transient, hypokalaemia, probably secondary to endogenous catecholamine release. Toxic chemicals such as toluene (involved in some forms of glue sniffing) and the ingestion of soluble barium salts (such as barium carbonate, which is used in certain pottery glazes, but has occasionally been mistaken for flour in cooking) have been implicated in redistribution hypokalaemia. It should be noted that barium salts used as contrast material for radiological investigations are not water soluble and do not pose a risk of toxicity.

Hypokalaemic periodic paralysis. This type of periodic paralysis occurs in two forms.

Familial hypokalaemic periodic paralysis (FHPP) is a rare autosomal dominant condition found most commonly in male Caucasians (male to female ratio 3:1 because of reduced penetrance and expression in females). The condition is characterized by attacks of flaccid paralysis affecting the limbs and trunk but rarely the facial and respiratory muscles; attacks commonly commence at night and patients present with weakness or paralysis on awakening. Attacks can last for up to 24 h and other acute manifestations of hypokalaemia such as cardiac arrhythmias may also be present. Spontaneous remission occurs with the re-establishment of normokalaemia. The attacks can begin in childhood, but often the onset may be delayed until the second decade of life. Periodicity of attacks is extremely variable between patients, with daily to yearly intervals (median four to six weeks). The attacks may be provoked by exercise followed by rest, a high carbohydrate intake, a glucose and insulin infusion, high sodium intake, adrenaline, glucagon administration and hypothermia. The total body potassium is unchanged during the attack, but potassium moves rapidly from the extracellular space into muscle. Mutations in three separate genes have now been implicated. The commonest mutations found are in the gene encoding the skeletal muscle voltage-gated calcium channel α -subunit (CACNA1S), which accounts for the majority of cases. Also described are mutations in the gene coding for the skeletal muscle voltage-gated sodium channel α -subunit (SCN4A) and the skeletal muscle voltage-gated potassium channel (KCNE3).

The management of FHPP is similar to that of any other hypokalaemia (see later), with either oral potassium supplements (up to 120 mmol/day) or, if necessary, intravenous administration, though particular care must be taken to avoid infusion of solutions containing glucose. Monitoring of serum potassium is important following the attack to ensure rebound hyperkalaemia does not occur. Prophylaxis against attacks includes a low carbohydrate diet, together with oral potassium supplements and the daily administration of spironolactone (100–200 mg), but probably most effective is the daily administration of acetazolamide (250–750 mg), although in patients with SCN4A mutations, acetazolamide may be contraindicated.

Hypokalaemic periodic paralysis with thyrotoxicosis (THPP) is a condition which primarily occurs in individuals of Chinese or Japanese extraction, but has been described in other races, including Caucasians and black people. The male preponderance is even more marked than in familial hypokalaemic periodic paralysis (FHPP) (20:1), and the age of onset is later (generally in the third decade). Links with mutations in the KCNE3 gene are described, but not in Chinese populations for whom links with mutations in CACNA1S have been made.

The clinical presentation of THPP is indistinguishable from the familial form, but the condition completely remits when the patient becomes euthyroid.

Extrarenal causes of potassium depletion. Box 4.14 lists the causes of extrarenal potassium depletion.

BOX 4.14 Causes of hypokalaemia due to extrarenal potassium depletion

Inadequate intake

- Fasting
 - Anorexia
 - During rapid cell synthesis

Increased loss

- Excessive sweating
- Gastrointestinal
 - Fistula
 - Diarrhoea
 - Cation exchange
 - Geophagia

A low dietary intake of potassium as the sole cause of hypokalaemia is rare. Renal conservation can reduce urine potassium in normal subjects to <5 mmol/L, so that without severe polyuria, a considerable lead-in period is necessary before clinically apparent hypokalaemia develops. Anorexia nervosa may, because of associated vomiting, speed the onset of clinically significant deficiency (see p. 55). One interesting cause of hypokalaemia is seen occasionally when patients with severe anaemia are treated with haematinics, resulting in a considerable and rapid increase in reticulocyte count; it has been speculated that, in certain patients, the degree of hypokalaemia that develops may induce cardiovascular death.

Excessive sweating is a potential cause of hypokalaemia. Sweat has relatively low potassium concentration (normally <10 mmol/L), but subjects who undergo severe physical exertion in hot climates, or who exercise vigorously in saunas, can lose considerable volumes of sweat (up to 12 L in a day). Subjects undergoing such ordeals may be aware of the potential for severe sodium depletion without necessarily compensating for the associated potassium depletion.

The commonest causes of extrarenal potassium depletion are those involving loss of gastrointestinal fluid rich in potassium, in particular diarrhoea. Stool water is rich in potassium with concentrations of up to 90 mmol/L, although the normal daily volume of water lost by this route results in stool potassium losses of <10 mmol/24 h. Diarrhoea of whatever cause results in an increase in stool weight and fluid content, so that severe diarrhoea may lead to stool volumes up to 2 L/24 h. Although potassium concentration in stool water tends to decrease as the volume increases, there is a limited colonic capacity for sodium/potassium exchange, and the daily losses of potassium in severe diarrhoea may exceed 100 mmol. As the stool water contains significant concentrations of bicarbonate, diarrhoea is often accompanied by a metabolic acidosis with hyperchloraemia. Thus, common causes of diarrhoea, such as bacterial causes, inflammatory bowel disease and diarrhoea associated with malabsorption syndromes, as well as less common causes, such as the watery diarrhoea-hypokalaemia achlorhydria (WDHA) syndrome – due to a pancreatic adenoma secreting vasoactive intestinal peptide (VIPoma) – are typically associated with a metabolic acidosis. Certain causes of diarrhoea, however, such as

chloride-losing diarrhoea, Zollinger–Ellison syndrome (gastrinoma) and laxative abuse, are associated with a metabolic alkalosis. Typically, these conditions are associated with hypokalaemia because of associated renal, rather than gastrointestinal, potassium loss. Villous adenoma of the rectum results in the loss of large volumes of mucus, often rich in sodium, potassium and chloride. The acid–base association can, therefore, be variable depending on predominant losses and replacement.

Potassium may be lost from the gastrointestinal tract as a result of the use of cation exchange resins such as sodium polystyrene sulphonate (Resonium A). This material is used primarily to treat clinically important hyperkalaemia. Geophagia (soil-eating) can, under certain circumstances, result in the development of hypokalaemia, as clay in the soil may bind potassium in the gut, which then passes into the stool and is lost from the body.

Renal causes of potassium depletion. The classification of renal potassium depletion adopted here is based on the associated acid–base disorder.

Renal hypokalaemic acidosis. The causes of renal hypokalaemic acidosis with normotension are summarized in Box 4.15. Acidosis, with renal potassium loss, hypokalaemia and hyperchloraemia, is found in both distal (type 1) and proximal (type 2) renal tubular acidosis (RTA), as well as in RTA induced by the carbonic anhydrase inhibitor acetazolamide.

The need for urinary diversion from the bladder, as may occur following severely impaired capacity due to fibrosis or following cystectomy for carcinoma, presents the urological surgeon with four options.

1. Bringing the ureters to the skin surface (cutaneous ureterostomy) is rarely performed, except temporarily in children: the operation will usually result in two stomata – if both kidneys are functioning – which are incontinent and require an external reservoir for collection. In addition, obstruction due to stricture is a frequent complication.
2. Transplantation of the ureters into the intact sigmoid colon (ureterosigmoidostomy) was the original diversion operation involving the gastrointestinal tract, and is occasionally still performed when medical or religious objections preclude the fashioning of an alternative exit: the urine is passed with faeces via the rectum and anus. Potentially, ureterosigmoidostomy is associated with significant metabolic complications (see below).
3. The commonest diversions now performed are those utilizing an isolated segment of bowel to form a conduit leading to the skin surface, which require a stoma bag or a constructed bladder fashioned to contain a valve to maintain continence.
4. Finally, if enough of the bladder is salvageable, then the wall may be augmented with opened segments of bowel (augmentation cystoplasty).

To understand the potential metabolic complications of potassium and other electrolytes that might arise from such procedures, it is necessary to know in some detail

BOX 4.15

Causes of renal hypokalaemia, classified by associated acid–base disorder

Renal hypokalaemic acidosis

- Renal tubular acidosis
 - Distal (type 1)
 - Proximal (type 2)
 - Carbonic anhydrase inhibitor
- Urinary tract diversion
 - Ureterosigmoidostomy
 - Colonic conduit
 - Colonic continent diversion
- Diabetic ketoacidosis

Renal hypokalaemic alkalosis with normotension

- Gastric fluid loss (chloride depleting)
- Diuretics (chloride depleting)
- Congenital chloride-losing diarrhoea
- Cystic fibrosis
- Bartter syndrome
- Gitelman syndrome

Renal hypokalaemic alkalosis with hypertension

- Primary hyperaldosteronism
- Secondary hyperaldosteronism
- Familial hyperaldosteronism types FH-1, FH-2, FH-3
- Glucocorticoid excess
- Exogenous mineralocorticoid activity
 - Congenital adrenal hyperplasia
 - 11 β -hydroxylase deficiency
 - 17 α -hydroxylase deficiency
 - Pseudohyperaldosteronism
 - Liddle syndrome
 - Apparent mineralocorticoid excess

Renal hypokalaemia without specific acid–base disorder

- Drug-related
 - Penicillin
 - Cisplatin
 - Aminoglycosides
- Leukaemia
 - Myelomonocytic leukaemia with lysozymuria
- Post relief of urinary tract obstruction
- Diuretic phase of acute kidney injury
- Magnesium depletion

how the bowel normally handles the absorption of fluid and electrolytes. The jejunum normally rapidly absorbs fluid and electrolytes, but the electrolyte components, including potassium, will be absorbed only if there is a favourable concentration gradient; if the gradient is reversed then secretion of electrolytes into the lumen can occur. In the normal ileum, active sodium absorption occurs by sodium and chloride co-transport, which is coupled to bicarbonate excretion; potassium transport is passive. In the normal colon, there is a mixture of electrogenic sodium absorption with passive chloride absorption, together with sodium and chloride co-transport coupled to bicarbonate excretion, as occurs in

the ileum. However, potassium is actively secreted into the lumen until the concentration rises to approximately 20–30 mmol/L.

As may be predicted, if bowel wall is exposed to urine, the prevalence of metabolic complications due to electrolyte redistribution will be based on the exposed surface area of bowel, the duration of contact and the type of bowel wall exposed. The diet and fluid intake will alter the urinary constituents and their concentrations, which can influence passive transport and concentration-limited active secretion. Any associated renal disease may have a direct metabolic effect. Thus, predictions in individual patients may be difficult but, in general, ureterosigmoidostomies give the greatest complication rate overall with lower rates for the other techniques. Diversions involving the sigmoid colon result in loss of bicarbonate and may result in loss of potassium, depending on the urine concentration of potassium entering the colon. Thus there is the potential for the development of significant hyperchloraemic acidosis with hypokalaemia.

Diversions involving ileal segments usually have low complication rates and, although hyperchloraemic acidosis may occur, hypokalaemia is rare. Diversions using jejunal segments are mentioned here for completeness, but the potential effect on potassium is quite different. Complications include sodium, chloride and bicarbonate depletion, with hyperkalaemia. For that reason, jejunal segments are rarely used for urinary diversion.

Diabetic ketoacidosis is associated with severe potassium depletion, but patients are usually hyperkalaemic or normokalaemic at presentation; if hypokalaemia is present, this is associated with extreme potassium depletion.

Renal hypokalaemic alkalosis. Potassium depletion with hypokalaemia and metabolic alkalosis can be further classified into normotensive and hypertensive conditions.

The causes of renal hypokalaemic alkalosis with normotension are summarized in [Box 4.15](#). Loss of gastric fluid through prolonged vomiting, or drainage of fluid via nasogastric aspiration, results in hypochloraemic alkalosis with renal excretion of bicarbonate and potassium. The associated chloride depletion results in enhanced potassium secretion by the distal tubule (see *Non-respiratory alkalosis*, Chapter 5, p. 82).

Diuretics that act primarily on the thick ascending limb of the loops of Henle (furosemide, ethacrynic acid) or on the distal collecting ducts (thiazides, chlorthalidone) can result in chloride depletion, which can further enhance the direct diuretic induced urinary potassium loss. Laxative abuse is often associated with metabolic alkalosis and renal chloride wasting; it may also be associated with simultaneous, but unrecognized, diuretic abuse or with self-induced vomiting.

Congenital chloride-losing diarrhoea is a rare condition in which ileal chloride absorption is defective. Patients present within the first decade of life with watery diarrhoea and metabolic alkalosis. The diagnosis is made from the association of hypochloraemia (serum chloride usually <90 mmol/L), alkalosis, low urine chloride concentration (<20 mmol/L), but a high stool water chloride

concentration (130–147 mmol/L). A similar clinical picture is seen in some patients with Zollinger–Ellison syndrome and in the rare condition of systemic mastocytosis secondary to basophil leukaemia; in the latter condition there is hypersecretion of gastric fluid due to histamine release, with diarrhoea, intestinal loss of chloride and secondary renal loss of potassium.

Rarely, cystic fibrosis (CF) may result in hypokalaemia in association with hypochloraemic alkalosis because of the high sweat chloride concentration in CF.

Barter syndrome, a recessive autosomal condition, presents with hypokalaemic alkalosis in association with hyperreninaemic hyperaldosteronism. There is renal wasting of potassium and chloride, but patients are resistant to the pressor effects of angiotensin II and, thus, are normotensive or mildly hypotensive. Patients present in childhood with failure to thrive, unexplained hypokalaemia and, occasionally, renal impairment. Renal biopsy typically reveals hyperplasia of the juxtaglomerular apparatus. Occasionally, presentation is delayed until adulthood, at which time the major differential diagnosis is of diuretic abuse.

Barter syndrome is caused by a loss of function mutation in one of the genes coding for three transport proteins located in the epithelial cells of the thick ascending limb of the loops of Henle – respectively the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ co-transporter (NKCC2), the potassium-secreting channel (ROMK1), which are both located on the apical membrane and the basolateral chloride channel (CLC-K6). Variations in phenotypic expression of Barter syndrome have been explained by association with specific transport protein mutations, for example early presentation, associated hypercalciuria and impaired urine-concentrating ability are typically associated with apical transport proteins, whereas later presentation and normal urine calcium excretion are associated with CLC-K6 mutations.

Gitelman syndrome is an autosomal recessive condition presenting with hypokalaemic alkalosis, but, unlike Barter syndrome, is associated with hypomagnesaemia and hypocalciuria. Gitelman syndrome is caused by loss of function mutations in the gene coding for the thiazide-sensitive $\text{Na}^+\text{-Cl}^-$ co-transporter (NCCT), situated in the distal convoluted tubules. This disorder may be asymptomatic in childhood and then present in adult life with weakness, fatigue, paraesthesia and, rarely, tetany.

A detailed classification of conditions causing renal hypokalaemic alkalosis with hypertension is given earlier in this chapter (see [Box 4.4](#), p. 37), but these are summarized in [Box 4.15](#).

The association of hypokalaemic alkalosis with hypertension is due to functional mineralocorticoid excess, resulting in sodium retention and distal tubular potassium wasting with net acid excretion. Excess production of aldosterone may be primary (hyporeninaemic) due to adenoma, hyperplasia or, rarely, carcinoma of the zona glomerulosa of the adrenal cortex (see Chapter 18). Three forms of familial hyperaldosteronism are currently described. Familial hyperaldosteronism type I (FH-I), a rare autosomal dominant condition, is also known as glucocorticoid suppressible hyperaldosteronism. It is due

to genetic recombination, resulting in the adrenocorticotrophic hormone (ACTH)-responsive region of 11-hydroxylase being incorporated into aldosterone synthase (hybrid CYP11B1/CYP11B2 gene mutation). FH-II is not glucocorticoid suppressible, appears to be up to five times more prevalent than FH-I and is clinically indistinguishable from apparent sporadic primary hyperaldosteronism. Family studies reveal linkage at chromosome 7p22. Candidate genes involved in cell cycle control are implicated as adrenal hyperplasia and adrenal adenomas are reported as common in FH-II patients. FH-III, also not glucocorticoid suppressible, has been described in a single affected family in which all three members had hypertension, hyperaldosteronism and high plasma concentrations of the hybrid steroids 18-hydroxycortisol and 18-oxocortisol. Only bilateral adrenalectomy could normalize blood pressure.

Secondary (hyper-reninaemic) hyperaldosteronism with hypertension is seen in patients with accelerated (malignant) hypertension and renal artery stenosis. Renin-producing tumours, such as benign haemangiopericytoma of the juxtaglomerular apparatus, are rare causes of hyper-reninaemic hyperaldosteronism.

Cortisol possesses only weak mineralocorticoid activity, but when plasma concentrations are sufficiently elevated, a mineralocorticoid effect results. Cushing syndrome, ectopic ACTH syndrome or the administration of exogenous glucocorticoid with mineralocorticoid activity can result in significant hypokalaemic alkalosis and hypertension.

Two forms of congenital adrenal hyperplasia result in excess production of deoxycorticosterone (DOC), which has mineralocorticoid action. These are 11 β -hydroxylase deficiency and 17 α -hydroxylase deficiency.

Pseudohyperaldosteronism can present in two forms. Liddle syndrome is a rare autosomal dominant condition that clinically resembles primary hyperaldosteronism, but in which aldosterone and renin are suppressed. The onset of hypertension and hypokalaemia occurs typically in childhood, but, even within a single family, penetrance can be extremely variable. The condition is caused by mutation within the gene coding for the collecting duct amiloride-sensitive epithelial sodium channel (ENaC), resulting in an 'open' channel, unregulated by the mineralocorticoid receptor (compared with loss of function mutations causing pseudohypoaldosteronism type 1, see p. 35).

Apparent mineralocorticoid excess has been described in children and, as in Liddle syndrome, there is hyporeninaemic hypoaldosteronism, but unlike Liddle syndrome, patients are responsive to spironolactone. This rare autosomal recessive condition is caused by impaired activity of the enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) due to mutations within the HSD11B2 gene. This enzyme normally inactivates cortisol in the kidney by conversion to cortisone (see p. 29). The mineralocorticoid receptor has equal affinity for cortisol, and selectivity for aldosterone is normally maintained by 11 β -HSD activity. An acquired form of this syndrome can be produced by excess ingestion of glycyrrhizic acid found in natural liquorice root, as well as glycyrrhetic acid, the active component of the peptic ulcer drug carbenoxolone.

Renal hypokalaemia without specific acid-base disorder. There remains a miscellaneous group of conditions that result in renal loss of potassium, but without a specific acid-base disorder: these conditions are summarized in [Box 4.15](#).

Several drugs can result in renal potassium loss. Penicillins, especially those administered in large molar quantities, e.g. carbenicillin, are excreted in anionic form in the urine and are associated with kaliuresis. Both cisplatin and the aminoglycoside group of antibiotics have been associated with hypokalaemia, probably because of associated magnesium depletion (see below).

Acute myelomonocytic leukaemia is associated with renal loss of potassium, especially in association with renal excretion of lysozyme released from the leukaemic cells.

Both the diuretic phase of acute kidney injury and that following the relief of urinary tract obstruction can result in a negative potassium balance with associated hypokalaemia.

Finally, there is increasing evidence that magnesium depletion, of whatever aetiology, is associated with an increase in renal potassium loss. Intracellular magnesium deficiency affects potassium excretion by reducing Na⁺,K⁺-ATPase activity proximally within the nephron, thus increasing distal sodium delivery and hence potassium secretion. In addition, magnesium deficiency reduces magnesium dependent inhibition of ROMK channels within the collecting duct principal cells, which also increases potassium secretion. In patients who are both potassium and magnesium depleted, supplementation with potassium will not result in correction of hypokalaemia unless magnesium is also supplemented.

Laboratory investigation of hypokalaemia

In the majority of patients presenting with hypokalaemia, the cause is clear from the clinical history. The role of the laboratory is then to provide a monitoring service for serum potassium and no further specific investigation is required. However, on occasion, patients presenting with inexplicable, consistent, severe hypokalaemia provide a considerable diagnostic challenge.

The first stage in differentiating the cause of hypokalaemia is to ensure that the serum potassium is a true reflection of in vivo concentration and not due to in vitro redistribution (see [Box 4.13](#)). A fresh sample of blood should be obtained for immediate separation and measurement of sodium and potassium concentration, and at the same time, renal function should be assessed by the measurement of serum urea or creatinine concentrations (or both), and magnesium should be measured to exclude concomitant magnesium depletion. If possible, blood should also be obtained for assessment of acid-base status. The clinical history, including a detailed past and present drug history, is essential. The next step in laboratory investigation is to differentiate renal from extrarenal causes of hypokalaemia by measuring urine potassium. The definition of renal potassium conservation is not absolute, but, in the presence of hypokalaemia,

a 24h potassium excretion of <15 mmol and a random urine potassium/creatinine ratio of <1.5 mmol/mmol provide strong evidence of extrarenal loss. The trans-tubular potassium gradient (TTKG) can also be used. TTKG is calculated by dividing the urine/serum potassium concentration by the urine/serum osmolality ratio (see [Appendix 4.1h](#)). The TTKG in renal conservation of potassium is expected to be <2.

When potassium is not conserved by the kidneys, the presence of a metabolic acidosis would suggest one of the causes listed in [Box 4.15](#) under renal hypokalaemic acidosis, although the majority of such conditions, excepting certain RTAs, should be apparent from the clinical history.

Hypokalaemia with metabolic alkalosis can be further differentiated by measurement of urine chloride. Again, no absolute criteria are available, but a random urine chloride <20 mmol/L (or, with polyuria, 2 mmol/mmol creatinine) indicates renal chloride retention and implies chloride depletion. Those conditions listed in [Box 4.15](#) as chloride-depleting include certain conditions that frequently provide a diagnostic challenge, such as diuretic abuse and surreptitious vomiting. If the urine chloride concentration exceeds 20 mmol/L, then Bartter syndrome, Gitelman syndrome and diuretic abuse (with recent diuretic ingestion) should be considered; in the presence of hypertension, those conditions associated with glucocorticoid or mineralocorticoid excess should be considered, although it should be remembered that hypertension is common, but mineralocorticoid-induced hypertension is not. (For full investigation of states of glucocorticoid or mineralocorticoid excess, see Chapters 18 and 38). Particular care should be exercised when interpreting urine electrolyte concentrations in hypokalaemic states. As mentioned previously, the concentration of potassium or chloride may be reduced if polyuria secondary to hypokalaemia is present. Therefore, it may be necessary to express concentrations in terms of creatinine or some other measure of urine concentration. The excretion or retention of electrolytes may be time-dependent; for example, diuretics may induce a kaliuresis and chloururesis following ingestion, which reverts between doses to a kaliuresis with chloride retention. If stopping the diuretic, with subsequent chloride, but not potassium replacement, induces urine potassium conservation, the implication is that there is extrarenal loss of potassium. In addition, two or more conditions may coexist, for example anorexia and vomiting, laxative abuse and diuretic abuse. Finally, severe potassium depletion may of itself induce renal chloride wasting, thus potentially, a severe extrarenal loss of potassium may result in renal potassium wasting.

Management of hypokalaemia

The decision to treat hypokalaemia will depend on the severity of the condition, the presence of symptoms, particularly muscle weakness, electrocardiographic evidence of cardiovascular effects and concomitant therapies, for example with cardiac glycosides, which increase cardiac sensitivity to hypokalaemia.

TABLE 4.6 Potassium content of oral preparations

Preparation	Potassium content
Salt	(mmol/g)
Potassium chloride	13.4
Potassium bicarbonate	9.9
Potassium citrate	9.2
Fruit juice	(mmol/100 mL)
Tomato juice	8.2
Orange juice	3.0
Grapefruit juice	3.0
Apple juice (and craft cider)	3.2

The magnitude of any potassium deficit can only be estimated. For hypokalaemia associated with a deficit rather than redistribution, a rough guide is that a serum potassium of 3.0 mmol/L equates with a total body deficit of 300 mmol and a serum potassium of 2.0 mmol/L, with a total deficit of 700–800 mmol.

Unless hypokalaemia is severe and potentially life-threatening (serum potassium <2.5 mmol/L), then in general, oral replacement is preferred. Although certain fruit juices contain relatively high concentrations of potassium, the volumes required to provide sufficient potassium for replacement may be impracticable (see [Table 4.6](#)). Potassium salts are available in various formulations, including syrups, effervescent preparations and sustained-release tablets. Potassium chloride is usually the preferred salt, and potassium bicarbonate should only be used in hyperchloraemic states. Potassium citrate is usually prescribed to alkalinize the urine and reduce the discomfort of urinary tract infections, but can be substituted for potassium bicarbonate in the treatment of hypokalaemia. Currently, the preferred sustained-release formulation is a microencapsulated form, which spreads the release of the potassium salt within the gastrointestinal tract and minimizes the risk of ulceration and stricture formation. Oral replacement is usually prescribed in doses that equate with a normal adult dietary intake of between 40 and 120 mmol/day, although up to 200 mmol/day may be required and tolerated.

In states of severe hypokalaemia, or when oral replacement is not possible, potassium can be given intravenously into peripheral veins. The maximum rate of infusion should not usually exceed 20 mmol/h, although this limit can, with cardiac monitoring, be increased to 40 mmol/h. The maximum concentration of potassium in the infusion should not usually exceed 40 mmol/L. If it is necessary to minimize fluid intake, or if hypokalaemia proves resistant to such replacement, concentrations up to 80 mmol/L may be infused into a central vein.

Hyperkalaemia

There is no strict definition of hyperkalaemia, but persistent serum potassium concentrations >5.3 mmol/L (plasma >5.0 mmol/L) warrant further investigation. The most significant clinical effect of hyperkalaemia is on cardiac function, most importantly to cause cardiac

arrest. This risk does not become appreciable until serum potassium is $>6\text{mmol/L}$, but is considerable at concentrations $>8\text{mmol/L}$, particularly if the increase is rapid. Electrocardiographic changes become apparent at lower concentrations of potassium and are more prominent if the hyperkalaemia is associated with hypocalcaemia, hyponatraemia, hypermagnesaemia or acidosis. Occasionally, patients present with a form of ascending muscular weakness resembling the Guillain-Barré syndrome. [Box 4.16](#) shows the major clinical effects of hyperkalaemia.

Causes of hyperkalaemia

Hyperkalaemia may reflect an inappropriate retention of potassium within the body or an alteration in the distribution of potassium intra- and extracellularly. This alteration in distribution may occur *in vivo*, or *in vitro*, when there has been redistribution of potassium from blood cells to serum during the time between venesection and separation of serum.

Redistribution hyperkalaemia *in vitro*. This form of hyperkalaemia is sometimes known as spurious or pseudohyperkalaemia ([Box 4.17](#)). The most common form is due simply to *in vitro* loss of potassium from erythrocytes, and may or may not be associated with visible haemolysis. This type of spurious increase in serum potassium is also seen in certain patients with leukaemia with extremely high WBC counts ($>100\times 10^9/\text{L}$), and in patients with thrombocythaemia when platelet counts exceed $1000\times 10^9/\text{L}$; in both situations the cells are fragile and lyse during blood clotting. To exclude these causes in patients with leukaemia or thrombocythaemia,

BOX 4.16 The clinical effects of hyperkalaemia

Cardiovascular

- Electrocardiographic changes
 - Tall T waves
 - Prolonged PR interval
 - Flat P waves
 - Widening QRS complex
 - 'M' complex sine wave
 - Ventricular fibrillation or asystole

Neuromuscular

- Paraesthesia
- Weakness, flaccid paralysis

Renal

- Natriuresis
- Decreased renal ammoniogenesis
- Decreased reabsorption of bicarbonate in the proximal tubule

Endocrine

- Decreased renin secretion
- Increased aldosterone secretion
- Increased insulin secretion

BOX 4.17 Causes of redistribution hyperkalaemia

In vitro redistribution

- Haemolysis of erythrocytes
- Release from white blood cells (high leukaemic counts)
- Release from platelets (thrombocythaemia)
- Storage of whole blood at low temperature
- Familial pseudohyperkalaemia

In vivo redistribution

- Acidosis
- Insulin deficiency with hyperglycaemia
- Drugs
 - Succinylcholine
 - β -Adrenergic blockers
- Acute tissue damage
- Hyperkalaemic periodic paralysis

blood should be collected into a heparinized container and the plasma separated quickly from the cells at room temperature.

Whole blood samples stored at 4°C will eventually release potassium from red cells into the plasma, without necessarily any evidence of haemolysis. In certain families, this tendency is greatly accentuated, giving rise to the condition familial pseudohyperkalaemia, which is due to disordered cation transport in the erythrocyte membrane.

Redistribution hyperkalaemia *in vivo*. The major causes of transcellular shift of potassium occurring *in vivo* are also shown in [Box 4.17](#). As previously discussed, acidosis, particularly that induced by mineral acid, will result in increased extracellular potassium concentration. Acidosis and hypertonicity due to hyperglycaemia and insulin deficiency lead to the hyperkalaemia frequently seen in potassium-depleted diabetic patients with ketoacidosis.

Various drugs may promote or accentuate hyperkalaemia. Succinylcholine, a depolarizing muscle relaxant, results in some increase in plasma potassium in all subjects, but this is particularly evident in patients with increased total body potassium. Thus succinylcholine should be avoided in all patients who are hyperkalaemic. β -Adrenergic blocking agents have been associated with minor increases in plasma potassium concentration, but this may be greatly accentuated during vigorous exercise.

The release of potassium from cells during strenuous exercise is well described, and a similar phenomenon may occur locally in an ischaemic limb, such as may happen during prolonged venous stasis prior to venesection. Hyperkalaemia has been described in patients undergoing chemotherapy for malignancy, which causes massive lysis of neoplastic cells. This phenomenon has been described in the treatment of chronic lymphocytic leukaemia, acute lymphoblastic leukaemia and lymphosarcoma. Its occurrence emphasizes the need for maintenance of hydration and for careful electrolyte monitoring during aggressive chemotherapy. Acute

haemolytic disorders can give rise to hyperkalaemia by a similar mechanism.

Hyperkalaemic periodic paralysis. Hyperkalaemic periodic paralysis (HYPP) is a rare autosomal dominant condition that presents with attacks of muscular weakness, paralysis (usually sparing the respiratory muscles) and an associated acute rise in plasma potassium (up to 8.0 mmol/L). The periodicity of attacks is variable, ranging from daily to only a few attacks a year. This type of periodic paralysis is provoked by a high potassium intake, glucocorticoids, hypothermia and during the recovery phase after vigorous exercise. During attacks, electrocardiographic monitoring shows tall T waves but cardiac arrhythmias are rare. The disorder is due to gain of function mutations in the skeletal muscle voltage-gated sodium channel X subunit (SCN4A) gene. The management of HYPP is administration of the β_2 -agonist salbutamol, which can easily be taken by inhalation. Salbutamol has also been used prophylactically.

Potassium retention. The major causes of potassium retention are listed in Box 4.18. An increased potassium intake alone, without associated renal impairment, in practice only occurs as an iatrogenic complication of inappropriate intravenous loading. Excessively high oral loads of potassium are counteracted by a combination of reduced gastrointestinal absorption, vomiting and diarrhoea.

A reduction in glomerular filtration rate (GFR), of whatever cause, increases the risk of development of hyperkalaemia. However, on a normal diet containing approximately 100 mmol of potassium per day, GFR may fall to less than 10 mL/min before a significant risk of hyperkalaemia arises, and increased colonic secretion of potassium may further protect the patient when GFR is reduced further. It is important, however, that patients with significantly reduced GFR avoid high intakes of potassium or any condition that results in endogenous shifts of potassium.

Decreased tubular secretion of potassium may occur in response to treatment with the potassium-sparing diuretics: spironolactone, triamterene or amiloride. Hyperkalaemia is a particular risk when such a drug is used in a patient with impaired renal function or in a patient with a high potassium intake. Urinary diversions that involve jejunal segments (see p. 55) result in a significant incidence of hyperkalaemia due to reabsorption

BOX 4.18 Causes of hyperkalaemia due to potassium retention

Increased intake

- Increased post-tubular reabsorption following surgical urinary diversion involving jejunal segments

Decreased output

- Decreased glomerular filtration rate
- Decreased tubular secretion
 - Potassium-sparing diuretics
 - Syndromes of hypoaldosteronism

of potassium from the urine while contained within the segment.

Syndromes of hypoaldosteronism. This broad group of conditions is summarized in Table 4.7. Primary hyperreninaemic hypoaldosteronism is found in Addison disease (see Chapter 18) and the rare condition corticosterone methyl oxidase deficiency, in which aldosterone synthesis is impaired. Heparin given in continuous high doses can also inhibit aldosterone synthesis through inhibition of 18-hydroxylase and possibly by inducing atrophy in the zona glomerulosa.

Two forms of congenital adrenal hyperplasia (CAH) result in impaired mineralocorticoid synthesis. 21-Hydroxylase deficiency is the most common form of CAH. Virilization is characteristic, but not all patients exhibit features of hypoaldosteronism; up to two-thirds develop renal sodium wasting with hyperkalaemia. 3 β -Hydroxydehydrogenase deficiency is a rarer condition, in which the majority of patients have renal sodium wasting and hyperkalaemia.

Hypoaldosteronism may occur in patients receiving angiotensin-converting enzyme (ACE) inhibitors such as captopril. Patients at particular risk of developing hyperkalaemia include those with associated renal impairment or with high renin concentrations, for example resulting from congestive heart failure or renal artery stenosis.

Hyporeninaemic hypoaldosteronism is an increasingly recognized syndrome in which patients present with hyperkalaemia out of proportion to a reduction in GFR. The majority of such patients develop a hyperchloraemic metabolic acidosis and fall, therefore, into the classification of type 4 renal tubular acidosis (see Chapter 5). The syndrome is particularly prevalent in elderly patients with type 2 diabetes, but is also found in many other diseases in association with interstitial nephritis, including systemic lupus erythematosus, multiple myeloma, chronic obstructive uropathy, gout, sickle cell disease, lead nephropathy, following renal transplantation and in association with treatment with prostaglandin

TABLE 4.7 Syndromes of hypoaldosteronism with relative plasma renin activities and aldosterone concentrations (\uparrow , increased; \downarrow , decreased; N, normal)

Syndrome	Renin	Aldosterone
Primary hypoaldosteronism		
Addison disease	\uparrow	\downarrow
Isolated aldosterone deficiency	\uparrow	\downarrow
Heparin treatment	\uparrow	\downarrow
Congenital adrenal hyperplasia	N to \uparrow	N to \downarrow
Angiotensin-converting-enzyme inhibition	N to \uparrow	N to \downarrow
Hyporeninaemic hypoaldosteronism	\downarrow	\downarrow
Secondary tubular disorders	N	N
Pseudohypoaldosteronism		
type I	\uparrow	\uparrow
type II	\downarrow	N to \downarrow

synthetase inhibitors and treatment with ciclosporin. Plasma renin activity is reduced, as is aldosterone concentration. Renin response to upright posture or to salt depletion is also reduced. The pathogenesis is not fully understood, but includes structural damage to the kidney, including the juxtaglomerular apparatus, and there is evidence in diabetes of impaired conversion of renin precursor to active renin. One intriguing aspect of hyporeninaemic hypoaldosteronism is why hyperkalaemia occurs, as aldosterone secretion is known to be stimulated by hyperkalaemia. However, it is likely that this direct stimulation of aldosterone can only occur in the presence of angiotensin II. An important aspect of this syndrome is that, because it occurs more frequently in the elderly, drugs that suppress both renin and aldosterone, such as β -blockers and calcium channel blockers as well as prostaglandin synthetase inhibitors, should generally be avoided in this age group.

Interstitial nephritis may give rise to hyperkalaemia in which aldosterone secretion is not suppressed. The pathogenesis in these conditions is presumed to be a direct impairment of tubular secretion of potassium. Many of the diseases associated with tubular dysfunction are those that are also associated with the development of hyporeninaemic hypoaldosteronism and include obstructive uropathy, sickle cell disease and systemic lupus erythematosus. The main clinical difference between direct tubular dysfunction and hyporeninaemic hypoaldosteronism is the failure of the former condition to respond adequately to mineralocorticoid replacement, and alternative treatments such as thiazide diuretics must be used.

Pseudohypoaldosteronism (PHA) is a term applied to a heterogeneous group of rare disorders linked by association with hyperkalaemia, metabolic acidosis, normal glomerular function and apparent renal tubular unresponsiveness or resistance to mineralocorticoids. The conditions are broadly segregated into PHA types I and II.

Pseudohypoaldosteronism type I can be inherited either as an autosomal dominant or autosomal recessive trait. Pseudohypoaldosteronism type II, alternatively known as Gordon syndrome, is inherited as an autosomal dominant condition. The major characteristics of these syndromes are summarized in Table 4.8.

Laboratory investigation of hyperkalaemia

The first stage in any laboratory investigation of hyperkalaemia is to ensure that the serum potassium is a true reflection of in vivo concentration. The storage of whole blood specimens in a refrigerator at 4°C is widely practised by clinicians in the belief that this will aid the preservation of a specimen, but this practice can greatly increase serum potassium without any evidence of haemolysis. This effect is particularly noticeable in familial pseudohyperkalaemia, but can affect any blood sample if storage is prolonged for 8–12 h. As previously mentioned, hyperkalaemia in patients with high WBC counts or platelet counts should be confirmed in freshly separated plasma, rather than serum.

Having confirmed true hyperkalaemia, the clinical history is required with particular emphasis on drug and dietary regimens, with information being sought regarding possible causes of in vivo redistribution.

Assessment of blood acid–base status and glucose concentration may be valuable. Serum potassium is usually measured with other electrolytes and markers of renal function, including urea and creatinine. When GFR is reduced to <10 mL/min, hyperkalaemia is likely to develop unless dietary potassium is restricted. The measurement of urine potassium output is of marginal value except possibly in steady-state conditions when a 24 h urine potassium will provide evidence of excessive ingestion.

If GFR is not reduced sufficiently to explain the hyperkalaemia, a syndrome of hypoaldosteronism should be considered. The measurement of TTKG may provide

TABLE 4.8 Characteristics of pseudohypoaldosteronism (PHA) types I and II

	PHA type I		PHA type II
	Autosomal dominant PHA	Autosomal recessive PHA	Autosomal dominant Gordon syndrome
Age at presentation	Newborn/early infancy	Newborn/early infancy	Late childhood/adulthood
Mechanism	Loss of function mineralocorticoid receptor mutation <i>NR3C2</i> gene	Loss of function epithelial sodium channel (ENaC) <i>SCNN1A</i> , <i>SCNN1B</i> , <i>SCNN1G</i> subunit genes	Enhanced distal tubular chloride reabsorption in preference to potassium excretion <i>WNK1</i> , <i>WNK4</i> genes
Organ affected	Kidneys	Kidneys, sweat glands, salivary glands, colon	Kidneys
Blood pressure	Hypotension	Hypotension	Usually hypertension
Renal sodium loss	Present	Present	Absent
Treatment	Sodium supplements Restricted potassium intake K ⁺ -binding resins	Sodium supplements Restricted potassium intake K ⁺ -binding resins High-dose fludrocortisone or carbenoxolone	Dietary sodium restriction Thiazide diuretics
Prognosis	Improvement with advancing age	Lifelong therapy required	Lifelong therapy required

useful information (see [Appendix 4.1h](#)). The expected physiological response in hyperkalaemia would result in a TTKG of >10. A value for TTKG of <7 is compatible with hypoaldosteronism. Normally, the clinical presentation of Addison disease is sufficiently characteristic to require only studies of cortisol response to exogenous ACTH preparations, but other forms of hypoaldosteronism require measurement of renin and aldosterone. Unfortunately, the various combinations of findings do not fit snugly with clinical classification of disorders. Hyper-reninaemic hypoaldosteronism is found in primary hypoaldosteronism, the exceedingly rare condition of corticosterone methyl oxidase deficiency, some forms of CAH, and with ACE inhibitor treatment. Hyporeninaemic hypoaldosteronism is found in the conditions grouped under the syndrome of the same name and is also found in the rare PHA type II (Gordon syndrome). In contrast, high renin and high aldosterone are found in PHA type I. However, normal renin concentrations and aldosterone activity may be found in those conditions causing interstitial nephritis with direct tubular inhibition of potassium excretion. Renin and aldosterone values are not always easy to interpret, as high plasma potassium directly stimulates aldosterone and suppresses renin activity. In addition, aldosterone concentration increases as the GFR falls without a corresponding change in renin activity. In situations in which diagnostic difficulty may exist, for example in hyporeninaemic hypoaldosteronism, it may be necessary to reassess aldosterone concentrations when plasma potassium has been reduced to within the reference range; alternatively a trial of mineralocorticoid replacement will differentiate hyporeninaemic hypoaldosteronism from direct tubular dysfunction.

Management of hyperkalaemia

Hyperkalaemia, particularly when severe (>6.0 mmol/L), is a serious condition requiring immediate treatment because of the risk of sudden death. Emergency management is intravenous 10% calcium gluconate – 10 mL injected over 60–120 s and repeated every 15 min or so until the electrocardiographic changes improve (maximum dose 50 mL). This does not correct the hyperkalaemia, but is directly cardioprotective. In patients receiving digoxin, calcium gluconate should be infused more slowly – 10 mL over 30 min – to avoid digoxin toxicity induced by hypercalcaemia.

Two therapeutic regimens are available to lower plasma potassium rapidly. Glucose (50 mL of 50% glucose) can be infused over 15 min together with ten units of soluble insulin. This regimen may be repeated at hourly intervals and should be accompanied by serum potassium and plasma glucose monitoring. Alternatively, plasma potassium may be reduced by the infusion of 50–100 mL of 4.2% sodium bicarbonate (500 mmol/L) over a 15–30 min period (provided that the patient is not sodium overloaded).

For haemodialysis patients with hyperkalaemia, a regimen that has been shown to be of equal benefit to glucose and insulin in reducing plasma potassium is

treatment with the β_2 -adrenergic agonist salbutamol. Inhalation of nebulized salbutamol (10–20 mg) will reduce plasma potassium by approximately 1 mmol/L within 30 min.

If hyperkalaemia is the result of increased body stores of potassium, then this excess must be removed. The relationship of plasma potassium to excess body potassium is highly variable and is not reliably predictable. As an approximation, elevation of plasma potassium by 1 mmol/L above normal without evidence of redistribution will roughly equate with a 200 mmol total excess. Polystyrene sulphonate resins (sodium or calcium salts) may be given by mouth (15 g, 3–4 times daily in water) or as an enema (30 g in methylcellulose, retained for 9 h). As an approximation, each gram of resin removes 1 mmol of potassium, so that up to 60 mmol may be removed in each 24 h period. For more dramatic reductions in body potassium, renal replacement treatment is required. Peritoneal dialysis is capable of removing 10–15 mmol of potassium each hour, whereas the efficiency of haemodialysis will allow up to 30 mmol to be removed each hour.

If a reversible cause of hyperkalaemia cannot be identified, then therapy for chronic hyperkalaemia should be designed to minimize the recurrence of severe hyperkalaemia. This should include a reduction in dietary potassium intake (<50 mmol/day) and avoidance of volume contraction and drugs that cause redistribution hyperkalaemia. Sodium bicarbonate and thiazide diuretics may be useful and, in some cases, treatment with mineralocorticoids.

CONCLUSION

The physiological control over sodium, water and potassium within the human body is a complex interrelated series of systems of extreme precision and sensitivity. These systems regulate the extracellular fluid volume, the extra- and intracellular solute content, the intracellular volume and neuromuscular function, and, therefore, indirectly influence myriad functional and metabolic processes essential for life. The pathological causes and consequences of recognized abnormalities in the control of sodium, water and potassium have been explored in this chapter, together with the details of diagnosis and treatment.

APPENDIX 4.1 FORMULAE

Formulae (a)–(e) provide approximations only and are supplied as illustrative guidelines. Any corrective procedure based upon any of these formulae should be accompanied by detailed clinical and laboratory monitoring.

[Concentrations]: serum (s), plasma (p) or urine (u) in mmol/L or mmol/kg (osmolality).

(a) Estimate of reduction in ECF volume from rise in haematocrit (HCT) when no blood loss has occurred

$$\text{ECF volume reduction (litres)} = 0.2 \times \text{body weight (kg)} \times \left[1 - \left[\frac{\text{normal hct}}{\text{measured hct}} \right] \right]$$

(b) Estimate of sodium deficit in patients with hypovolaemic hyponatraemia

$$\text{sodium deficit (mmol)} = 0.6 \times \text{body weight (kg)} \times (140 - [\text{Na}^+]_s)$$

(c) Estimate of water deficit in hypernatraemia

$$\text{water deficit (litres)} = 0.6 \times \text{body weight (kg)} \times \left[1 - \frac{140}{[\text{Na}^+]_s} \right]$$

(d) Estimate of the expected sodium depression in hyperglycaemia-induced hyponatraemia

$$\text{expected sodium depression (mmol/L)} = 0.288 \left([\text{glucose}]_p - 5.5 \right)$$

Reference

Adapted from Katz MA. Hyperglycemia-induced hyponatremia – calculation of expected serum sodium depression. *N Engl J Med* 1973;289:843–4.

(e) Calculation of serum osmolality

$$\begin{aligned} \text{calculated osmolality} &= 1.89 [\text{Na}^+]_s + 1.38 [\text{K}^+]_s \\ &+ 1.03 [\text{urea}]_s + 1.08 [\text{glucose}]_p \\ &+ 7.45 \end{aligned}$$

Reference

Adapted from Behagat CI, Garcia-Webb P, Fletcher E, Beilby JP. Calculated vs measured osmolalities revisited. *Clin Chem* 1984;30:1703–5.

(f) Calculation of osmolal gap

$$\text{osmolal gap} = \text{measured osmolality} - \text{calculated osmolality}$$

(g) Estimate of sodium required in acute water intoxication

(To increase serum sodium to 125 mmol/L):

$$\text{sodium required (mmol)} = (125 - [\text{Na}^+]_s) \times 0.6 \times \text{body weight (kg)}$$

(Hypertonic saline (5%) = 855 mmol/L)

(h) Calculation of the transtubular potassium gradient (TTKG)

$$\text{TTKG} = \frac{[\text{K}^+]_u \times [\text{Osm}]_s}{[\text{K}^+]_s \times [\text{Osm}]_u}$$

Reference

APPENDIX 4.2 DYNAMIC FUNCTION TESTS

(a) Water deprivation test

This test is used to differentiate between cranial diabetes insipidus, nephrogenic diabetes insipidus or primary polydipsia as causes of polyuria.

The patient is denied fluid and sloppy food from 08.30 h onwards. All patients should be observed closely to prevent covert access to fluid. The following protocol should be followed. Urine should, if possible, be collected hourly, the volume recorded and an aliquot tested for osmolality. Blood should be obtained for serum sodium and osmolality measurements. Accurate weight recordings are required to monitor loss and, in certain cases, detect surreptitious fluid consumption.

Time of urine collection (h)	Time of blood collection (h)	Time of weighing (h)
09.00–10.00	09.00	09.00
10.00–11.00	–	–
11.00–12.00	–	–
12.00–13.00	12.00	12.00
13.00–14.00	–	–
14.00–15.00	–	14.00
15.00–16.00	–	–
16.00–17.00	17.00	17.00

Notes

- If the patient develops symptoms of water loss, or loses more than 3% of initial body weight, samples for serum and urine osmolality should be collected immediately.
- If serum osmolality exceeds 295 mmol/kg and/or serum sodium exceeds 145 mmol/L, the test should be discontinued and the vasopressin test performed.
- If the test runs to completion and the urine osmolality remains below 600 mmol/kg, the supplementary vasopressin test should be performed.

Vasopressin test

Give 2 µg of dDAVP i.v. The patient is allowed to drink, but total fluid intake should be restricted to 1000 mL until 09.00 h the next morning, unless the patient's weight loss continues above 3%, when free fluids should be allowed. Further urine collections are made the same day at 19.00 and 22.00 h, and on the following day at 07.00 and 09.00 h.

Interpretation

A normal subject will concentrate urine to >600 mmol/kg during the period of water deprivation, and the serum

osmolality will remain within the physiological range (or, more strictly, the urine:serum osmolality ratio will be greater than 2:1). If urine osmolality fails to increase to >600 mmol/kg, but increases following dDAVP by >20%, then cranial diabetes insipidus (CDI) is likely. The weight loss recorded should always equate with total urine volume passed.

Reference

This protocol is modified from the original description of the 'short' water deprivation test by Dashe AM, Cramm RE, Crist AC, Habener JF, Solomon DH. A water deprivation test for the differential diagnosis of polyuria. *J Am Med Assoc* 1963;185:699–703.

(b) Hypertonic saline infusion

This test is used to directly assess the osmoregulatory control of the release of plasma AVP and/or to assess the control of subjective thirst.

The patient is food-fasted overnight (12 h), but is allowed free access to water. Smoking is not allowed during this 12 h period or during any part of the test. No fluid of any kind should be consumed during the test, including sips, mouthwashes or ice cubes: all of these oropharyngeal stimuli can suppress the release of arginine vasopressin (AVP) from the posterior pituitary.

Pre-infusion preparation

09.00 h	Weigh Supine position Indwelling cannulae with both antecubital veins kept patent with heparinized saline	One for eventual infusion of hypertonic saline, one for blood sampling
09.00–10.00 h	Rest hour	

Infusion protocol

Time of blood collection (h)	Tests
10.00	AVP, osmolality, urea and electrolytes
10.30	"
11.00	"
11.30	"
12.00	"

Commence 5% saline (0.06 mL/kg/min) infusion into one cannula at 10.00 h, following the first blood sample.

For interpretation of results, see [Figure 4.3](#) and text.

Notes

- If information is required on subjective thirst rating, then the patient should be shown, at each time blood is sampled, a unitless 100 mm scale with a maximum limit labelled 'Extreme thirst' and a minimum limit 'No thirst'. The patient is asked to indicate thirst levels on the scale. Two separate scales should be

completed on each occasion to obtain a measure of precision.

- Information concerning the handling of blood samples for AVP should be obtained from the laboratory. In general, samples should be collected into pre-chilled heparin tubes, transported on ice to the laboratory immediately, centrifuged rapidly at 4°C and the plasma stored at a maximum temperature of -20°C (preferably -70°C). The time from collection to storage should not usually exceed 20 min.
- Patients with a history of congestive cardiac failure should be closely monitored and, if necessary, the test curtailed and furosemide (40 mg i.v.) administered.

Reference

Adapted from Robertson GL, Athar S. The interaction of blood osmolality and blood volume in regulating plasma vasopressin in man. *J Clin Endocrinol Metab* 1976;42:613–20.

(c) Water load test

This test is used to assess osmoregulation indirectly by determining the renal response to water loading.

The patient is allowed free access to fluid 12 h prior to the test to ensure adequate patient-determined hydration at commencement. No smoking is allowed during the test period or for the 12 h prior to this. Adequate glucocorticoid replacement is required for patients with hypoadrenalism.

At 09.00 h, the bladder is emptied and an aliquot of urine (10–15 mL) saved for osmolality measurement. Blood (for urea and electrolytes, and osmolality) is collected and the patient weighed. An oral water load (20 mL/kg) is then consumed within 20 min. Further samples and weighings are obtained according to the following schedule. Urine volume output is measured accurately each hour.

Sample	Time of urine collection (h)	Time of blood collection (h)	Time of weighing (h)
1	09.00	09.00	09.00
2	09.00–10.00	–	–
3	10.00–11.00	–	–
4	11.00–12.00	–	–
5	12.00–13.00	13.00	13.00

Interpretation

In a normally hydrated subject, over 80% of a standard water load is excreted within 4 h of ingestion. Urine osmolality will typically fall to <100 mmol/kg. Weight changes should confirm the observed difference between the water volume ingested and the urine volume loss. Difficulties in micturition may make the test difficult or impossible to interpret.

INTRODUCTION

Disorders of both hydrogen ion homoeostasis and tissue oxygenation will be discussed in this chapter. Abnormalities of hydrogen ion homoeostasis occur frequently in respiratory disorders, as a result of changes in the rate of excretion of carbon dioxide. Such disorders can also affect oxygenation, and impaired tissue oxygenation is an important potential cause of acidosis. Furthermore, hydrogen ion concentration, carbon dioxide and oxygen are measured using related technologies, usually with the same instrument.

The first part of this chapter deals with hydrogen ion homoeostasis and its disorders (colloquially often referred to as ‘acid–base balance’ and ‘acid–base disorders’, respectively), while the second part deals with the mechanism whereby oxygen is made available to the tissues, disorders in which tissue oxygenation is impaired and how tissue oxygenation is measured.

THE PHYSIOLOGICAL ROLE OF HYDROGEN IONS

Hydrogen ions are ubiquitous in the body and maintenance of appropriate concentrations is critical to normal function. The gradient of hydrogen ion concentration

between the inner and outer mitochondrial membrane drives oxidative phosphorylation; changes in hydrogen ion concentration can affect the surface charge and physical conformation of proteins and thus their function, and hydrogen ion concentration determines the degree of ionization of weak acids and bases and can thus affect the disposition of such substances, among which are many with important physiological and pharmacological functions.

The hydrogen ion concentration of the blood is normally controlled within narrow limits, in health rarely exceeding 46 nmol/L or falling below 35 nmol/L. This regulation is achieved in spite of the continuous production of hydrogen ions as a result of the normal processes of metabolism. Intracellular hydrogen ion concentration is, in general, higher; in the cytosol being slightly so while in lysosomes it is several orders of magnitude higher. However, the interior of mitochondria is slightly alkaline.

Definitions

An increase in the hydrogen ion concentration of the blood is termed acidaemia and a decrease, alkalaemia. The term ‘acidosis’ strictly describes a pathological disturbance that can result in acidaemia, but may not necessarily do so

because of the simultaneous existence of another disturbance (possibly the result of a physiological compensatory process) that has an opposing effect. Similarly, alkalaemia is not always present in alkalosis. These distinctions, although made much of by some authors, often only introduce confusion and will not be pursued in this chapter.

Strictly speaking, it is the *activity* of hydrogen ions and not their *concentration* that is relevant, and devices for measuring hydrogen ions respond to their activity. Activity and concentration are only the same in ideal solutions, which biological fluids are not, but the distinction can be ignored for practical purposes.

Hydrogen ion concentration can also be expressed in terms of pH. The pH of a solution is the logarithm (base 10) of the reciprocal of hydrogen ion concentration (or minus the logarithm of hydrogen ion concentration). Thus, a solution with hydrogen ion concentration of 100 nmol/L (100×10^{-9} mol/L) has a pH of 7.00 ($\log_{10} 1/100 \times 10^{-9}$). pH does not have units; it varies in a reciprocal and nonlinear fashion with hydrogen ion concentration. The reference range for the pH of blood, corresponding to the range for hydrogen ion concentration given above, is 7.36–7.42. It is necessary, in discussing hydrogen ion homeostasis and its disorders, to consider the production and disposal of hydrogen ions; it is therefore logical to discuss the effects of changes in these processes on hydrogen ion concentration rather than on a derived unit. Furthermore, as will be seen, the analysis of disorders of hydrogen ion homeostasis is facilitated considerably if direct measurements are used.

In health, the rates of formation of hydrogen ions and of their consumption and excretion are in balance, but disturbances of hydrogen ion homeostasis occur frequently and in a wide variety of disease states. They are classified traditionally as respiratory or non-respiratory in origin, according to whether the primary abnormality is the result of an excess or deficiency of carbon dioxide (respiratory) or of bicarbonate (non-respiratory). Non-respiratory disturbances are often referred to as metabolic. As will be seen, however, a respiratory disorder that causes hypoxia may produce an acid–base abnormality whose characteristics are non-respiratory, or even combine respiratory and non-respiratory features. Nevertheless, the distinction is a useful one and is of considerable value in analysing disorders of hydrogen ion homeostasis.

HYDROGEN ION HOMOEOSTASIS

Buffering

What follows is a brief, simplified account of the essential features of buffering, sufficient for an appreciation of the physiology of hydrogen ion homeostasis.

In essence, buffer systems limit the extent to which the hydrogen ion concentration actually changes in the face of any tendency to change. A buffer system (or buffer pair) consists of a weak (that is, only partly dissociated) acid and its conjugate base (that is, the anion that combines with a hydrogen ion to form the acid). If the acid is HB and the conjugate base is B^- , the relevant reactions are:

and

Bicarbonate

An example of central importance to physiology is the carbonic acid–bicarbonate system. Carbonic acid is a weak acid, which partly dissociates to bicarbonate and hydrogen ion:

If an amount of hydrogen ions were to be added to a solution containing this buffer pair, some would combine with bicarbonate to form carbonic acid, thus limiting the increase in hydrogen ion concentration that otherwise would be expected to occur, but at the expense of consuming bicarbonate. Removal of hydrogen ions (or addition of hydroxyl, which, by combining with hydrogen ions to form water, has an identical effect) would cause dissociation of carbonic acid, producing hydrogen ions (and bicarbonate) and thus limiting the fall in hydrogen ion concentration that otherwise would be expected to occur.

It will be apparent that if a buffer is to function effectively in the face of equal tendencies for hydrogen ion concentration to increase and decrease, the concentrations of the acid and conjugate base should be equal, for example for the acid HB, $[HB] = [B^-]$. Since at equilibrium:

$$[H^+] = K_a [HB] / [B^-] \quad (4)$$

(where K_a is the equilibrium constant), it follows that a buffer will be most effective when the hydrogen ion concentration to be defended is numerically similar to the equilibrium constant. It should also be appreciated that hydrogen ion concentration, $[H^+]$, depends not on the absolute values for the concentrations of acid and conjugate base, but on the *ratio* of their concentrations. On the other hand, the buffer capacity, that is, the extent to which the buffer can absorb hydrogen ions, clearly will depend upon the absolute values of these concentrations.

For bicarbonate, it follows from the general equation (Eqn. 4) that:

$$[H^+] = K_a [H_2CO_3] / [HCO_3^-] \quad (5)$$

The concentration of carbonic acid cannot readily be determined, but it is directly proportional to the concentration of carbon dioxide $[CO_2]$, since carbonic acid is formed by the hydration of carbon dioxide:

Thus, Equation 5 can be rewritten in the form:

$$[H^+] = K_a' [CO_2] / [HCO_3^-] \quad (7)$$

where K_a' is a constant numerically incorporating the equilibrium constants for the reactions represented by Equations 3 and 5. The value of K_a' is approximately 800 nmol/L and, at physiological extracellular hydrogen ion concentration (40 nmol/L), the numerical value of

the molar ratio $[\text{CO}_2]/[\text{HCO}_3^-]$ is approximately 0.05, suggesting that this system should be a poor buffer, particularly against a tendency for hydrogen ion concentration to fall. However, the body is a net producer of acid, that is, the tendency is for hydrogen ion concentration to rise. More importantly, carbon dioxide, generated by the buffering of hydrogen ion by bicarbonate and the subsequent dissociation of carbonic acid, can be removed by the lungs, keeping the carbon dioxide concentration constant. As a result, the effective buffering capacity of the carbonic acid–bicarbonate system is greatly increased, and it is a vitally important physiological buffer, particularly in the extracellular fluid.

In practice, carbon dioxide *concentration* cannot be readily determined, but it is related to the partial pressure, PCO_2 , such that $[\text{CO}_2] = 0.225 \times PCO_2$ when PCO_2 is measured in kilopascals (kPa).

Phosphate

The monohydrogen and dihydrogen phosphate ions (HPO_4^{2-} and H_2PO_4^-) form a buffer pair with K_a being approximately 160 nmol/L. Although the K_a appears relatively favourable for buffering at physiological hydrogen ion concentrations, the concentration of phosphate in the extracellular fluid is too low for it to be of significance in this respect. Phosphate is, however, an important buffer in the urine, where its concentration is much greater.

Haemoglobin

All proteins can buffer hydrogen ions to some extent by virtue of their content of polar amino acid residues. Haemoglobin (Hb) is an important buffer. The reaction can be represented as:

although each haemoglobin molecule is capable of buffering a number of hydrogen ions. It is relevant to note that haemoglobin is a more effective buffer for hydrogen ions when it is in the deoxygenated rather than the oxygenated form, and that oxygen release is facilitated by the buffering (the Bohr effect).

The efficacy of haemoglobin as a buffer is enhanced by the presence in erythrocytes of the enzyme carbonate dehydratase, which catalyses the hydration of carbon dioxide (Eqn. 6). Despite the fact that they are responsible for the majority of oxygen transport in the blood, erythrocytes obtain their energy anaerobically, by glycolysis, and thus do not generate carbon dioxide. In the capillary beds of tissues, carbon dioxide produced by aerobic metabolism readily diffuses down the concentration gradient into erythrocytes, where it is hydrated to form carbonic acid, which dissociates to form bicarbonate and hydrogen ions (Fig. 5.1). The latter are buffered by haemoglobin while bicarbonate diffuses out of the cells in exchange for chloride, so that the products of the dissociation of carbonic acid are removed, allowing further dissociation to occur and thus, by a mass action effect, stimulating its formation. In the lungs, alveolar PCO_2 is lower than venous PCO_2 and

FIGURE 5.1 ■ Transport and buffering of carbon dioxide in erythrocytes. Carbon dioxide is converted into carbonic acid in erythrocytes; this dissociates to form bicarbonate, which diffuses into the plasma in exchange for chloride and hydrogen ions, which are buffered by haemoglobin. In the alveoli, the reverse process liberates carbon dioxide.

the process reverses, carbon dioxide being generated and excreted, while the release of hydrogen ions from haemoglobin favours oxygen uptake.

Thus, in addition to transporting carbon dioxide, the conversion of carbon dioxide to bicarbonate serves to minimize the potential change in the value of the ratio $[\text{CO}_2]/[\text{HCO}_3^-]$ (and hence in hydrogen ion concentration) between arterial and venous blood. However, although erythrocytes are a potential source of bicarbonate, they can only generate bicarbonate if the hydrogen ion produced simultaneously can be buffered. There is clearly a limit to the extent to which this can occur, imposed by the buffering capacity of haemoglobin, so that this mechanism can have only a limited role in the correction of an acidosis. The way in which such correction is achieved is considered in a later section.

Other proteins

Although plasma proteins buffer hydrogen ions, their molar concentrations are lower than that of haemoglobin and their buffering capacity is less. In contrast, intracellular and tissue proteins make an important contribution to buffering. In chronic acidosis, they may contribute up to one-third of total buffer capacity. Buffering by bone is particularly important.

Ammonia

It is often stated that ammonia is an important buffer in the urine because it can combine with hydrogen ions to form ammonium ions. This cannot be true. Ammonium is a very weak acid, with an equilibrium constant approximately 100 times lower than physiological hydrogen ion concentration, so that when ammonia is produced in the body, it is immediately and almost completely converted to ammonium ions. The urinary excretion of ammonium is of relevance to hydrogen ion homeostasis because it represents a route for the disposal of ammonium which, unlike urea synthesis, does not result in the generation of hydrogen ions (see p. 70).

Hydrogen ion turnover

The fact that, on a normal diet, the daily excretion of hydrogen ions by the kidneys (the only physiologically important route of excretion) is 40–80 mmol tends to distract from the fact that there is a massive endogenous turnover of hydrogen ions. In the resting adult, intermediary metabolism accounts for a hydrogen ion turnover of 2500–3000 mmol/24 h (Table 5.1).

Normally, the rates of hydrogen ion formation and utilization during intermediary metabolism are in overall balance, although any discrepancy can have a major effect on hydrogen ion concentration. But even this turnover of hydrogen ions appears insignificant in comparison with that which is associated with the turnover of adenine nucleotides – the movement of hydrogen ions that takes place across the mitochondrial membrane during oxidative phosphorylation and the synthesis and hydrolysis of ATP. This has been estimated at 500 mol/24 h. The potential for a disturbance in these processes to cause an acidosis is clearly colossal, although, in health, the rates of adenine nucleotide reduction and oxidation and of ATP formation and utilization are equal, so that these processes have no net effect on hydrogen ion homeostasis. This may not, however, be true in disease.

As a result of oxidative metabolism, carbon dioxide is produced and excreted by the lungs. The rates of formation and excretion are normally equal, but carbon dioxide can combine with water to form carbonic acid, and the daily production of carbon dioxide in a resting adult is a potential source of approximately 15–20 mol of hydrogen ions. As has been alluded to, disorders affecting the excretion of carbon dioxide are an important cause of abnormalities of hydrogen ion homeostasis.

Tendencies for hydrogen ion concentration to change can be limited to some extent by buffering, but this process can only offer a temporary solution to an imbalance between the rates of hydrogen ion production and disposal, because the body's buffers have a limited capacity. Physiological processes often bring about a partial reversal of a change in hydrogen ion concentration (see Compensation, below), but ultimate correction of any disturbance requires equalization of the rates of production and disposal of hydrogen ion.

Hydrogen ion production

The processes involved in hydrogen ion production and utilization are summarized in Table 5.1. They comprise: processes involving carbon dioxide formation, reactions of intermediary metabolism and processes involving 'fixed' acids. In addition, and responsible for the bulk of hydrogen ion turnover, are the reactions involved in the complete oxidation of energy substrates. These processes are interlinked, but it is instructive to consider them separately.

Carbon dioxide

The role of carbon dioxide in relation to the formation of hydrogen ions has been mentioned above. Carbon dioxide, produced by oxidative metabolism, can become hydrated to carbonic acid, a weak acid that partly dissociates to hydrogen ion and bicarbonate:

The equilibrium for this reaction strongly favours carbon dioxide and water, but in tissues containing carbonate dehydratase (e.g. tubular cells in the kidneys), the rate of formation of carbonic acid is increased and it can become an important source of bicarbonate and hydrogen ions.

Incomplete metabolism of glucose: glycolysis and lactate metabolism

The most familiar process of intermediary metabolism that results in the formation of hydrogen ions is anaerobic glycolysis, the metabolism of glucose to lactate. The overall equation for this reaction is:

This process, which takes place particularly in skeletal muscle and erythrocytes, results in the formation of ~1.3 mol of hydrogen ions per 24 h in a 70 kg man at rest. The major route of disposal of lactate is glucose synthesis by gluconeogenesis in the liver and kidneys. The overall equation for this process is the reverse of that for glycolysis (most enzymes involved being common to both

TABLE 5.1 Approximate daily production and elimination of acid in a resting adult

Type of acid	Production	mmol/24 h	Disposal	mmol/24 h
Carbon dioxide	Tissue respiration	~17 500	Excretion by lungs	~17 500
Lactate	Glycolysis	~1300	Gluconeogenesis, oxidation	~1300
Free fatty acids	Lipolysis	~650	Re-esterification, oxidation	~650
Ketoacids	Ketogenesis	~500	Oxidation	~500
H ⁺ generated during urea synthesis	Ureagenesis	~1100	Oxidation of amino acids	~1100
Sulphuric and phosphoric acids	Metabolism of sulphur- and phosphate-containing amino acids	~40	Renal excretion ('fixed' or buffered acid)	~40

Note that all figures are approximate, being dependent on diet, body mass index, physical activity etc.

pathways, although some are unique). Gluconeogenesis thus consumes hydrogen ions. In health, lactate production and disposal are equal and so, too, are the production and disposal of hydrogen ions by these pathways. At rest, most of the lactate produced is converted back to glucose; during exercise, when lactate production is increased, 50% or more is completely oxidized instead. This process also consumes the hydrogen ions that are generated in its production and results in the formation of carbon dioxide and water:

Thus, when lactate production and utilization are in balance, there is no net production of hydrogen ions. However, in disease states, an imbalance between these processes can be responsible for the development of acidosis.

The hydrogen ions generated in lactate production will be buffered principally by bicarbonate, so that Equation 10 could be written:

Clearly, the reverse reaction, gluconeogenesis, will regenerate the bicarbonate, and Equation 11 can be rewritten to show that this also occurs with complete oxidation of lactate:

It is pertinent to point out that hyperlactataemia does not automatically indicate an acidosis. If it is a result of increased lactate production or decreased excretion, acidosis will only be present if the hydrogen ions produced simultaneously are not removed by excretion or metabolism. Intravenous fluids containing sodium lactate (e.g. Hartmann's solution) are actually a source of alkali, because the lactate ions are metabolized to bicarbonate (Eqn. 13).

Incomplete metabolism of triglycerides: ketogenesis

The liberation of free fatty acids from triglyceride (triacylglycerol) in adipose tissue results in the generation of hydrogen ions. The process is exemplified by the equation:

In the liver and adipose tissue, free fatty acids can be re-esterified to triacylglycerol, a process that consumes three hydrogen ions for each molecule of triacylglycerol synthesized. The further metabolism of free fatty acids to ketones in the liver (ketogenesis) also results in hydrogen ion production. An example of the reaction, starting from palmitate, is:

In health, this process may account for up to 0.4 mol hydrogen ion per 24 h, although in pathological states, its contribution may be much greater. However, ketoacids (strictly, oxoacids) are utilized as energy sources by skeletal muscle and other tissues. Their oxidation consumes hydrogen ions so that, in health, the overall rates of hydrogen ion production and disposal are equal:

In disease, notably in diabetic ketoacidosis, excessive ketogenesis is an important cause of acidosis. Ketonuria may exacerbate the acidosis: ketoacid anions are a potential source of bicarbonate so that their loss in urine (in maximally acidic urine, about half the ketoacids are present in this form) effectively reduces the potential for bicarbonate generation.

Complete oxidation of glucose and triglycerides

Glucose can also be completely oxidized to carbon dioxide and water; indeed, this is the major route of glucose metabolism in the body.

This is a complex process: oxidation is indirect, involving the transfer of hydrogen ions to adenine nucleotides, which are mainly oxidized by the mitochondrial electron transport system. Electrons are transferred to oxygen and combination with hydrogen ions produces water, while the energy released is transferred to ATP. But as Equation 18 indicates, the complete oxidation of glucose to carbon dioxide does not give rise to net formation of hydrogen ions: the products of its oxidation are carbon dioxide and water.

The same is true for the complete oxidation of triacylglycerols:

As with glucose oxidation, the process is far more complicated than appears from Equation 19, again involving the reduction of nucleotides, transfer of electrons to molecular oxygen, formation of water and trapping of energy in ATP, but the net production of hydrogen ions is zero.

Amino acid metabolism

Amino acid metabolism both produces and consumes hydrogen ions, according to the type of amino acid concerned. The metabolism of neutral amino acids

FIGURE 5.2 ■ Reabsorption of filtered bicarbonate. Bicarbonate ions cannot be directly reabsorbed. Instead, hydrogen ions and bicarbonate are generated from carbon dioxide in tubular cells; the hydrogen ions are secreted into the tubular lumen in exchange for sodium and titrate the filtered bicarbonate. Some of the carbon dioxide thus formed diffuses into renal tubular cells. The bicarbonate formed in the cells accompanies sodium as it is pumped into the interstitial fluid and thence reaches the plasma.

of approximately 4.5, equivalent to a hydrogen ion concentration of $38\ \mu\text{mol/L}$. This represents a 1000-fold concentration gradient with respect to the extracellular fluid, but clearly, excretion of free hydrogen ions alone would be insufficient to remove the daily burden of acid produced by metabolic processes, which is measured in millimoles. Significant acid excretion is achieved by hydrogen ions being buffered by phosphate, titrating monohydrogen phosphate (HPO_4^{2-}) (the principal form in the plasma and thus the glomerular filtrate) to dihydrogen phosphate (H_2PO_4^-) ions. It should be noted that, since the formation of hydrogen ions in renal tubular cells is accompanied by stoichiometric generation of bicarbonate ions, the excretion of hydrogen ions additionally results in the regeneration of bicarbonate ions and thus restores buffering capacity. This process is summarized in [Figure 5.3](#).

The role of urinary ammonium excretion. Although the urine contains ammonium and, indeed, the amount excreted increases considerably in states of chronic acidosis, this cannot, for the reasons indicated above, in itself, constitute net hydrogen ion excretion. Ammonium is produced in renal tubular cells by the action of the enzyme glutaminase on glutamine, the amide of glutamic acid ([Eqn. 27](#)), and the oxidative deamination of glutamate by glutamate dehydrogenase ([Eqn. 28](#)).

Glutamate is formed by transamination of 2-oxoglutarate with other amino acids, a process that does not involve either the production or utilization of hydrogen ions, and the equation for glutamine synthesis is the reverse of [Equation 27](#). Thus, glutamine synthesis is a mechanism for the disposal of ammonium ions that does not (unlike urea synthesis) produce hydrogen ions. Although subsequent urinary ammonium excretion appears to be a means whereby hydrogen ions can be excreted in a buffered form, it does not represent direct excretion of hydrogen ions: rather, it is a process through which nitrogen can be excreted without the concomitant generation of hydrogen ions. As indicated in [Equations 27 and 28](#), the production of ammonium from glutamine also yields 2-oxoglutarate: this is a substrate for gluconeogenesis, a process that consumes hydrogen ions.

In acidosis, hepatic glutamine synthesis is increased: in the kidneys, the formation of ammonium from glutamine, urinary ammonium excretion and gluconeogenesis are all increased. The net result is a decrease in hydrogen ion formation and an increase in bicarbonate generation, both of which tend to correct the acidosis. Renal ammonium excretion is illustrated in [Figure 5.4](#).

The luminal membranes of renal tubular cells are actually impermeable to ammonium ions, but are permeable to ammonia. Continued diffusion of small amounts

FIGURE 5.3 ■ Renal hydrogen ion excretion. Carbonic acid is generated from carbon dioxide and water and dissociates into hydrogen ions and bicarbonate. The hydrogen ions are secreted into the tubular lumen in exchange for sodium, where they titrate monohydrogen phosphate to dihydrogen phosphate. Bicarbonate and sodium ions are pumped from the cells into the interstitial fluid and thence reach the plasma.

FIGURE 5.4 ■ Renal ammonium excretion. Ammonium is formed directly from glutamine and glutamate and is excreted in the urine. There is no net excretion of hydrogen ion. This process is accompanied by the formation of oxoglutarate, which can undergo gluconeogenesis, and results in the consumption of hydrogen ions that are produced with bicarbonate from carbonic acid.

of ammonia in equilibrium with ammonium within renal tubular cells into the tubular fluid, results in continued formation of ammonia from ammonium. In the lumens of nephrons, this ammonia is immediately converted back to ammonium ions. This process does not entail *net* excretion of hydrogen ions; indeed, the *net* result is the same as if ammonium ions *were* transported directly.

The role of the liver in hydrogen ion homeostasis. Traditionally, the kidneys have been considered (together with the lungs) as the major organs responsible for hydrogen ion homeostasis, but the liver also plays a role, although its extent remains controversial. While the kidneys are the only organs capable of excreting hydrogen ions from the body, the liver both generates and consumes hydrogen ions. As indicated above, it has a central role in the production (e.g. ketogenesis, ureagenesis) and utilization of hydrogen ions (e.g. gluconeogenesis), yet an abnormal hydrogen ion concentration is an uncommon finding in patients with liver failure unless this is severe or there is accompanying renal disease. But this should not be surprising, since it is well known that the liver has substantial reserve capacity, and functional impairment may only occur with massive liver damage. There is certainly evidence that acid-base status has an influence on hepatic urea synthesis and glutamine synthesis, and affects lactate and ketone metabolism. For example, acidosis tends to stimulate hepatic glutamine synthesis and lactate disposal, but inhibits ketogenesis.

Summary

Three organs are involved in hydrogen ion homeostasis: the lungs, the kidneys and the liver. Extracellular hydrogen ion concentration depends on the ratio $PCO_2 / [HCO_3^-]$. The respiratory centre is exquisitely sensitive to arterial PCO_2 and, given normal respiratory function, PCO_2 is maintained within narrow limits by changes in the rate and depth of respiration. It has been calculated that cessation of carbon dioxide excretion would lead to potentially fatal acidosis within 30 min (although this is purely hypothetical, since the accompanying failure in oxygen supply would be fatal before this time).

Nearly all the carbon dioxide produced each day is excreted through the lungs in the expired gas, although the liver is capable of disposing of a very small amount through the anaplerotic carboxylation of pyruvate to oxaloacetate. Although the liver can both generate and utilize hydrogen ions in metabolism, only the kidneys can excrete hydrogen ions from the body. In terms of the total turnover of hydrogen ions, the amount excreted this way is small. Nevertheless, it is vitally important, and a failure of renal hydrogen ion excretion frequently leads to acidosis, although even in acute kidney injury, if there are no additional causes of acidosis, it can take several days before the acidosis itself becomes severe.

Whilst any one of abnormal respiratory, hepatic or renal function may lead to the development of acidosis or alkalosis, changes in the others may ameliorate the effect on arterial hydrogen ion concentration. The compensatory hyperventilation seen in patients with non-respiratory acidosis is an example of this. Such compensatory processes are of vital importance in disturbances of hydrogen ion homeostasis, and are discussed in relation to the specific conditions in which they occur. However, it is important to appreciate that, although they may restore an abnormal hydrogen ion concentration to, or at least towards, normal, they do not correct the underlying disturbance.

THE ASSESSMENT OF ACID–BASE STATUS

Clinical assessment

None of the clinical features of acidosis and alkalosis is specific to these disturbances and they may only be present when the disturbances are severe. The conditions that give rise to acidosis and alkalosis may have specific features, but, while clinical assessment is important in patients with disturbances of hydrogen ion homeostasis, laboratory investigations are vital for their diagnosis, the assessment of their severity and for monitoring their progress.

Laboratory assessment

Hydrogen ion concentration and PCO_2

Measurements of arterial blood hydrogen ion concentration (strictly, activity) and $PaCO_2$ (the 'a' indicates arterial, and 'A' alveolar; in this chapter, for the sake of simplicity, the 'a' is omitted except where doing so could lead to ambiguity) are fundamental to the assessment of acid–base

status. Analysers may express hydrogen ion concentration as pH, but the SI unit is concentration and the use of concentration greatly facilitates data interpretation.

Since the hydrogen ion concentration is determined by the ratio of PCO_2 to bicarbonate concentration, bicarbonate concentration is not an independent variable and knowledge of it is not necessary for the characterization of acid–base disorders. Analysers calculate bicarbonate from PCO_2 , $[H^+]$ and K_a' , using the formula given in Equation 7. However, although K_a' is supposedly a constant, there is evidence that it can vary unpredictably, particularly in severely ill patients.

True bicarbonate concentration is not readily measurable. Most laboratory measurements of 'bicarbonate' are in fact measurements of total carbon dioxide (TCO_2), to which bicarbonate makes by far the greatest contribution, but which also measures dissolved carbon dioxide, carbonic acid and carbamino compounds (histidine residues in proteins that have combined with carbon dioxide). Together, all these other species contribute only about 10% to the TCO_2 . It should be noted that the TCO_2 concentration of plasma and serum decreases in vitro, as carbon dioxide is lost to the atmosphere. Caution should thus be exercised in interpreting its value if there has been any significant delay between the times of the blood sample being taken and the plasma or serum being analysed. Arterial blood for analysis must be suitably anticoagulated; any gas bubbles must be expelled and the specimen protected from the atmosphere and either analysed immediately using a point of care instrument, or transported rapidly to the laboratory, chilled by placing the syringe in which it is collected in iced water.

Derived variables

Analysers that measure hydrogen ion concentration and PCO_2 are generically termed 'blood gas analysers'; they also measure PO_2 and may provide other information of value in determining arterial oxygen content. They also frequently generate various derived terms, including 'standard bicarbonate', 'base excess' and 'standard base excess'. These are calculated terms and add nothing to the characterization of disorders of hydrogen ion homeostasis beyond what can be determined from consideration of $[H^+]$ and PCO_2 .

As will be seen, bicarbonate can be affected by both respiratory and non-respiratory disturbances. The standard bicarbonate is the bicarbonate concentration that would be expected in that blood sample were the PCO_2 to be normal. It supposedly eliminates any contribution by a respiratory disturbance, so that an abnormal standard bicarbonate concentration is taken as indicating the presence of a non-respiratory disturbance of hydrogen ion homeostasis. The base excess is the calculated amount of acid in millimoles that would have to be added to 1 L of the patient's blood in vitro to restore the hydrogen ion concentration to normal in an alkalosis (the base deficit is the corresponding figure for alkali in an acidosis). The standard base excess extends the base excess to include the whole extracellular compartment. The calculation of these derived variables makes unwarranted assumptions, and the data themselves can confuse, rather

than facilitate, the analysis of clinical disorders. The only *measurement* required to derive these variables in addition to PCO_2 and $[H^+]$ is the haemoglobin concentration. Since, therefore, derived units do not incorporate any other independent measurements of acid–base status, it follows that they cannot provide any information that cannot be derived from the measured variables alone. Furthermore, although it is correct that abnormal values for standard bicarbonate and base excess indicate the presence of a non-respiratory component in an acid–base disorder, *they do not distinguish between this being a primary disorder or a compensatory response to a primary respiratory disorder.*

Base deficit is sometimes used to calculate the amount of bicarbonate that is required to correct an acidosis, but, in practice, if an acidosis is so severe that bicarbonate treatment is warranted, this should be given in small amounts and the effect assessed by frequent measurements of $[H^+]$ and PCO_2 .

Anion gap

The anion gap is the sum of the concentrations (in mmol/L) of the two major cations in plasma minus those of the two major anions (i.e. $([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])$). The total concentration of anionic charge in plasma must equal the concentration of cationic charge: the anion gap reflects mainly the anionic nature of most proteins in plasma at physiological hydrogen ion concentration, although phosphate and other anions make a small contribution. Its normal value is related to the concentrations of the species that determine it, and is ~15 mmol/L.

Determination of the anion gap can be of help in determining the cause of a non-respiratory acidosis. When acidosis is due to loss of bicarbonate (e.g. renal tubular acidoses, loss of bicarbonate from the gut), there is increased renal chloride retention; the lost bicarbonate is replaced by chloride and the anion gap is unaffected. On the other hand, when acidosis is due to ingestion or excess generation of acids, the associated anions (e.g. lactate) replace bicarbonate as this is consumed by buffering, and the anion gap is increased. In practice, determination of the anion gap is only likely to be helpful if the cause of the acidosis is not already obvious. It certainly does not substitute for careful clinical assessment. For its calculation, plasma chloride concentration must be known, and in the UK, this often must be requested individually, rather than being available as part of a profile of tests. Also, the imprecision of the value of the anion gap, summing as it does the individual imprecisions of the measurements of the analytes that are required to calculate it, needs to be taken into account.

Other investigations

Other biochemical measurements may be of value in the assessment of disorders of hydrogen ion homeostasis under certain conditions, for example in patients with diabetes, in neonates and in poisoned patients. These measurements are discussed in the sections that follow.

DISORDERS OF HYDROGEN ION HOMOEOSTASIS

Introduction

Although they differ in their pathogenesis, an understanding of the disorders of hydrogen ion homeostasis is facilitated by considering them in a similar way. The processes involved are the generation of the disorder, buffering, physiological compensation and ultimate correction. In practice, there is often overlap between these.

Disorders of hydrogen ion homeostasis may be simple, that is, involving only one type of disturbance, or mixed (two or more disturbances arising together). Unless rapidly corrected, simple disturbances typically generate secondary changes, which, in terms of bicarbonate concentrations and PCO_2 , can take on the characteristics of mixed disturbances.

Non-respiratory acidosis

This disorder can develop as a consequence of any, or a combination of, an increase in the rate of generation of hydrogen ions, a decrease in the rate of their utilization or excretion or a decrease in buffering capacity.

A list of some of the causes of non-respiratory acidosis is given in [Box 5.1](#). Frequently, more than one cause may contribute to an acidosis in an individual patient. For example, patients with diabetic ketoacidosis are usually hypovolaemic and their renal function is impaired. Many of these conditions are discussed in detail in other chapters of this book; the reasons why they can cause acidosis should be evident from the first section of this chapter. Some conditions of particular interest are discussed later. Although many of the conditions causing acidosis have distinct clinical features, some of the features of acidosis, and of the body's response to it, are common to them all. Non-respiratory acidosis can develop rapidly, particularly when it is due to increased production of hydrogen ions or loss of bicarbonate.

Compensatory responses in non-respiratory acidosis

Buffering. A tendency for hydrogen ion concentration to increase will be resisted by buffering; bicarbonate will be consumed and its concentration in the plasma will tend to fall. In the early stages of a condition that can cause acidosis, buffering, together with increased renal hydrogen ion excretion and bicarbonate regeneration, may prevent the development of a significant rise in hydrogen ion concentration. In chronic acidosis, buffering of hydrogen ions by tissue proteins also plays an important part in limiting the rise in hydrogen ion concentration.

Hyperventilation. Provided that respiratory function and its control are normal, acidosis stimulates ventilation through effects on aortic and carotid body chemoreceptors, and directly on the respiratory centre. Kussmaul breathing – deep, sighing respiration – is characteristic of non-respiratory acidosis. This not only allows excretion of carbon dioxide derived from the carbonic acid produced

BOX 5.1 Some causes of non-respiratory acidosis

Predominant increased acid formation

- Ketoacidosis^a
 - Diabetic
 - Alcoholic
 - Starvation
- Lactic acidosis^a
 - Hypoxic (type A)
 - Other causes (type B, see Box 5.2)
- Poisoning^a
 - Salicylate
 - Alcohols
- Inherited organic acidoses^a

Predominant decreased acid excretion

- Uraemic acidosis^a
- Renal tubular acidoses types 1 and 4 (see Table 5.3)

Predominant gain of acid or substances causing acidosis

- Ingestion of strong acid
- Ingestion/infusion of ammonium chloride
- Intravenous feeding with excess cationic amino acids
- Dilutional acidosis

Predominant loss of base

- Gastrointestinal loss
 - Diarrhoea
 - Pancreatic fistula
- Renal loss
 - Renal tubular acidosis type 2
 - Acetazolamide treatment
 - Ureteroenterostomy

^aAcidoses associated with a high anion gap. Note: In many instances, more than one mechanism may contribute to the acidosis.

by buffering, but actually reduces the PCO_2 , which in turn tends to lower the hydrogen ion concentration towards normal. The muscular effort of hyperventilation itself generates carbon dioxide, and there is a lower limit to the PCO_2 that can be obtained as a result of hyperventilation (approximately 1.4–1.6 kPa). Many causes of non-respiratory acidosis are progressive conditions, and the acidosis may be so severe that respiratory compensation cannot normalize the hydrogen ion concentration. However, when the acidosis is only mild, a new steady state may be achieved in which hyperventilation maintains a hydrogen ion concentration that is only slightly higher than normal.

The increased ventilation, and thus respiratory compensation for non-respiratory acidosis, develops rapidly, so that the predicted changes of a 'pure', that is uncompensated, non-respiratory acidosis (elevated blood hydrogen ion concentration, decreased bicarbonate and normal PCO_2) do not occur. However, compensation may take several hours to become maximal. This is because carbon dioxide equilibrates more rapidly across the blood–brain barrier than bicarbonate. Initial hyperventilation lowers cerebrospinal fluid (CSF) PCO_2 , and thus hydrogen ion concentration, and tends to counter the stimulation of respiration by peripheral chemoreceptors. Only as CSF bicarbonate concentration falls will its hydrogen

ion concentration rise and augment the respiratory drive. The reverse phenomenon may be seen if rapid correction of an acidosis is attempted.

In patients with respiratory impairment, the efficacy of the compensatory process may be greatly reduced.

Renal hydrogen ion excretion. Provided that renal dysfunction is not the cause of acidosis and renal function is not compromised, the urine hydrogen ion concentration rises to its maximum possible value. However, the capacity of the kidneys to excrete acid is limited: the fixed buffering capacity of the urine is approximately 2–3 times the normal acid load. In this process, filtered mono-hydrogen phosphate is titrated virtually completely to dihydrogen phosphate. In mild or transient acidosis, this may be sufficient to prevent a significant increase in blood hydrogen ion concentration occurring. If acidosis persists, however, there is an adaptive increase in the excretion of ammonium ions. Ammonium excretion may increase five-fold or more. As has been discussed above, although it has been widely considered that this represents the excretion of buffered hydrogen ions, it is more accurate to consider renal ammonium excretion as representing an alternative pathway for ammonium disposal that, unlike urea synthesis, does not involve the *generation* of hydrogen ions. Acidosis induces increased synthesis of glutaminase, the enzyme responsible for the formation of ammonium from glutamine. It is noteworthy in this respect that renal gluconeogenesis, which provides a pathway for the utilization of the 2-oxoglutarate derived from the carbon skeleton of glutamine, is also increased in acidosis.

Biochemical characteristics of non-respiratory acidosis

The cardinal features of a non-respiratory acidosis are an elevated blood hydrogen ion concentration and a decrease in bicarbonate. Hyperventilation results in a decrease in PCO_2 . The extent of the change in PCO_2 predicted for a given decrease in bicarbonate is discussed later. Comparison of the observed change with the predicted change can indicate whether there is an additional component to the acid–base disturbance.

In addition to these changes, other consequences of acidosis, especially hyperkalaemia, may be present, together with any specific features of the cause of the acidosis.

Systemic effects of acidosis

Many of the systemic effects of acidosis are common to acidosis of whatever cause. The effects on the cardiovascular system, oxygen delivery to tissues, the nervous system, potassium homeostasis and bone are of particular significance. Acidosis also has important effects on intermediary metabolism.

The cardiovascular system. Acidosis has a negative inotropic effect, although this is probably only of significance in severe acidosis. Acidosis causes arteriolar vasodilatation and constriction of peripheral veins, but in many forms of acidosis these responses are obscured by other influences on vasomotor tone.

Oxygen delivery to tissues. Acidosis causes a right shift in the oxyhaemoglobin dissociation curve (the Bohr effect, see p. 90) and this facilitates oxygen delivery to tissues. An increase in hydrogen ion concentration decreases erythrocyte 2,3-diphosphoglycerate (2,3-DPG) concentrations through effects on both synthesis and breakdown; this causes a left shift in the curve, but, whereas the Bohr effect is immediate, the fall in 2,3-DPG takes place over a matter of hours. The reverse is also true; so, if hydrogen ion concentration is restored to normal rapidly, oxygen delivery will be compromised until 2,3-DPG concentrations are restored to normal. This is a potential hazard if an attempt is made to correct an acidosis rapidly by the intravenous infusion of bicarbonate.

The nervous system. Patients with acidosis can demonstrate impaired consciousness of varying degrees of severity, but there is little correlation between this and the severity of the acidosis. In many patients with acidosis, other factors are operating that may affect CNS function, and changes in blood flow and oxygen delivery secondary to the acidosis may also be relevant.

Potassium homeostasis. There is a well-known association between acidosis and hyperkalaemia. This is multifactorial: movement of potassium ions from the intracellular to the extracellular compartment used to be thought to be related to intracellular buffering of hydrogen ions, but is probably to a greater extent the result of a loss of intracellular potassium to the plasma for other reasons, including a decrease in ATPase activity. It is of practical importance to note that total body potassium stores are frequently depleted, despite the high plasma concentration, and treatment of the acidosis may cause hypokalaemia if potassium is not replaced.

Bone. In chronic non-respiratory acidosis, there is significant buffering of hydrogen ions by bone, accompanied by decalcification, leading to a negative calcium balance. This is one factor contributing to renal osteodystrophy, the bone disease of chronic kidney disease. In addition, acidosis tends to increase ionized calcium concentration and so the filtered load presented to the renal tubules; renal calcium reabsorption may be decreased and calcitriol synthesis decreased.

Other effects. Acute acidosis can cause a leukocytosis; chronic acidosis can have a detrimental effect on nitrogen balance and insulin resistance can be a feature of both acute and chronic acidosis.

Management of non-respiratory acidosis

The logical management of a non-respiratory acidosis is to treat the underlying cause(s) of the disturbance appropriately. However, this may not always be possible and then, if the acidosis itself is having a significantly adverse effect on the patient, it may be necessary to attempt to lower the blood hydrogen ion concentration by giving alkali. The potential advantages are the reversal of the effects discussed above, including the hyperventilation, which may be particularly distressing for a conscious patient. There are, however, significant disadvantages. As

indicated above, rapid correction of an acidosis may have an adverse effect on oxygen delivery to tissues. When acidosis is associated with the presence of organic anions (e.g. lactate, acetoacetate), continued metabolism of these after correction of the acidosis (rather than *pari passu* with the correction, as would happen if the underlying cause were reversed) may, by consuming hydrogen ions, cause the blood hydrogen ion concentration to fall. This is a rebound phenomenon and not just a direct consequence of excessive alkali administration.

The alkali used most frequently when it is considered necessary to correct an acidosis is sodium bicarbonate. Buffering of hydrogen ions will result in the formation of carbon dioxide and blood PCO_2 may rise. Since carbon dioxide equilibrates across the blood-brain barrier more quickly than bicarbonate, the resulting increase in CSF carbon dioxide may cause a paradoxical rise in CSF hydrogen ion concentration. This may perpetuate the hyperventilation, even though the peripheral stimulus has been reduced by restoration of blood hydrogen ion concentration to normal.

There is general agreement that, in otherwise uncomplicated cases of non-respiratory acidosis that have a reversible cause (e.g. ketoacidosis and some forms of lactic acidosis), bicarbonate administration should not be considered unless the arterial hydrogen ion concentration is unusually severe (e.g. >100 nmol/L). In acute kidney injury, however, bicarbonate administration may have a rapid and beneficial effect on dangerous hyperkalaemia, while renal replacement treatment is being put in place. If intravenous bicarbonate is to be given, it should be given as a series of small quantities (e.g. 50 mmol) in isotonic solution (unless there is a danger of fluid overload, when a hypertonic solution may be used); after each infusion, the patient should be reassessed clinically and arterial $[H^+]$ and PCO_2 measured.

The use of bicarbonate in the treatment of renal tubular acidosis (RTA) is discussed on p. 79.

Specific causes of non-respiratory acidosis

Ketoacidosis. Diabetic ketoacidosis is discussed in detail in Chapter 16. The primary abnormality is increased lipolysis and ketogenesis (production of acetoacetic and 2-hydroxybutyric (β -hydroxybutyric) acids), coupled with decreased utilization of these acids. In addition, dehydration may decrease the glomerular filtration rate (GFR) and impair renal hydrogen ion excretion. Some patients also have a lactic acidosis (see below). It is noteworthy that resolution of the acidosis and clinical improvement of conscious level can lag behind the correction of the hyperglycaemia and ketosis in this condition. As normovolaemia is restored by the administration of 0.9% saline, renal excretion of sodium together with ketoacid anions results in loss of a source of bicarbonate and there is a tendency to hyperchloraemic acidosis, which may not be so rapidly reversed.

Ketoacidosis can also occur in association with alcohol ingestion (see Chapter 40), typically in alcoholics one or more days after a drinking bout, so that ethanol may not be detectable in the blood at the time that acidosis becomes apparent. Ketoacidosis develops as a result of a combination of factors, which are summarized in Table 5.2. The term ketoacidosis is a relative misnomer

TABLE 5.2 Factors involved in the pathogenesis of alcoholic ketoacidosis

Factor	Mechanism(s)
Fasting	Decreased insulin and increased counter-regulatory hormones, ^a leading to: increased lipolysis increased ketogenesis decreased ketone utilization
Hypoglycaemia	Effects of fasting exacerbated
Dehydration	Increased counter-regulatory hormones Impaired renal ketone excretion Impaired insulin secretion ^b
Ethanol	Metabolism inhibits lipolysis but lipolysis is stimulated as ethanol is cleared from the blood

^aCounter-regulatory hormones include glucagon, adrenaline (epinephrine) and cortisol.

^bVia stimulation of α -adrenergic receptors by adrenaline (epinephrine).

when applied to this condition; the oxidation of ethanol to acetaldehyde and acetate increases the [NADH]/[NAD⁺] ratio and hence the ratio [2-hydroxybutyrate]/[acetoacetate], so that dipstick tests for urinary ketones (which do not detect 2-hydroxybutyrate) may be negative or only weakly positive.

In both types of ketoacidosis, significant excretion of the organic acids can occur in urine; at the lowest attainable urinary hydrogen ion concentration, some 50% of 2-hydroxybutyrate, but only 10% of acetoacetate, is in the form of the undissociated acid. Although this is advantageous in that it represents a route of buffered hydrogen ion excretion, the fact that the bulk of acetoacetate and 50% of 2-hydroxybutyrate are excreted as organic cations has adverse consequences. It entails obligatory excretion of sodium and potassium as the accompanying anions, thus contributing to their deficits, and also removes substrate for the later regeneration of bicarbonate by oxidation of these anions. It is of interest that, in patients with ketoacidosis with poor renal function (in whom less excretion of organic anions will occur), the extent of the fall in plasma bicarbonate concentration at the time of admission tends to match the increase in the anion gap and in the plasma concentrations of organic acid anions; in contrast, in patients with good renal function, the anion gap is less and plasma chloride concentration is increased. A third, but rare, cause of ketoacidosis is severe starvation.

The non-enzymatic decarboxylation of acetoacetate to acetone consumes hydrogen ions, but adds to the burden of carbon dioxide to be excreted.

Other acid–base disturbances associated with alcohol. A range of other acid–base disturbances can occur in association with alcohol ingestion. In normal subjects, the severe hypoglycaemia that can occur when ethanol is taken after a period without food, can be accompanied by a mild lactic acidosis. In chronic alcoholics, severe

vomiting may cause a non-respiratory alkalosis, and continued ethanol ingestion can cause a lactic acidosis.

In patients with cirrhosis, alcohol can precipitate hepatic encephalopathy, which is often associated with respiratory alkalosis, as a result of stimulation of the respiratory centre by ammonia and other nitrogenous toxins.

Lactic acidosis. Lactate is formed from pyruvate as the end-product of glycolysis. Normal venous plasma lactate concentration is 0.6–1.2 mmol/L, tending to the lower end of this range during fasting and to the higher end after meals. Concentrations of up to 10 mmol/L can occur during severe physical exercise, but they fall rapidly once exercise ceases. Lactate is generated by glycolysis, principally in skeletal muscle, brain, erythrocytes, the skin and the gut, and is disposed of by gluconeogenesis in the liver and kidneys, thereby providing an important source of glucose, and by complete oxidation.

Lactic acid is a strong acid and is virtually completely dissociated at normal physiological hydrogen ion concentrations. Thus, the generation of lactate is always accompanied by equimolar generation of hydrogen ions. Buffering or other compensatory processes may prevent a significant rise in hydrogen ion concentration so that hyperlactataemia is not always associated with acidosis, but if the lactate concentration is greater than about 5 mmol/L, the hydrogen ion concentration is usually elevated.

Lactic acidosis can occur as a result of either excessive lactate formation or decreased lactate disposal or a combination of both. It is conventionally divided into type A (hypoxic) lactic acidosis, and type B, in which hypoxia is not the primary event. Causes of type B lactic acidosis include exposure to drugs, toxins and other chemicals, severe liver disease and certain inherited metabolic diseases. Some of the more important causes of lactic acidosis are indicated in **Box 5.2**. This list is not meant to be exhaustive; many rare conditions that have been reported to cause lactic acidosis and some conditions that only occasionally cause it, have not been included.

BOX 5.2 Some causes of lactic acidosis

Type A

- Shock (haemorrhagic, cardiogenic etc.)
- Severe hypoxia
- Severe exercise

Type B

- Associated with the ingestion of drugs etc.
 - Biguanides (especially phenformin)
 - Ethanol
 - Fructose administration (also sorbitol)
- Associated with inherited metabolic diseases
 - Fructose 1,6-diphosphatase deficiency
 - Pyruvate carboxylase deficiency
 - Pyruvate dehydrogenase deficiency
 - Glucose 6-phosphatase deficiency (glycogen storage disease type I)
- Other causes
 - Liver failure
 - Thiamin deficiency
 - Metabolic myopathies etc.

Type A lactic acidosis is the commoner variety. It is due primarily to an increase in lactate formation, as a consequence of tissue hypoxia, resulting, for example, from cardiogenic or haemorrhagic shock. Approximately half the lactate is produced by the gut. Decreased disposal of lactate is also important. Hepatic uptake and metabolism of lactate may be decreased in acidosis and when perfusion is decreased. The effects of acidosis on the cardiovascular system (negative inotropism and vasoconstriction) may further impair tissue perfusion (so that in the gut, a vicious spiral may develop, whereby splanchnic vasoconstriction induced by acidosis itself contributes to the acidosis). Although an acidosis-induced right shift in the oxyhaemoglobin dissociation curve may promote oxygen delivery to tissues, type A lactic acidosis can become self-perpetuating unless vigorous measures are undertaken to reverse the disturbance and treat the underlying cause. The prognosis is poor and appears to be related directly to the blood lactate concentration, mortality exceeding 80% with a concentration >9 mmol/L. The specific treatment of the acidosis, for example by the judicious administration of bicarbonate, has been described above. Measures to correct the underlying cause are more important.

The mechanisms of lactate accumulation in type B lactic acidosis vary. The classic descriptions of this condition relate to phenformin-induced lactic acidosis; phenformin is a biguanide formerly used for treating type 2 diabetes mellitus. It causes lactic acidosis primarily as a result of decreased utilization of lactate for gluconeogenesis, but increased production may also contribute. Lactic acidosis frequently leads to shock, and increased production may then become the predominant mechanism. Metformin, also a biguanide, has low risk of causing lactic acidosis except in patients with renal impairment, in whom it should not be used.

The inherited metabolic diseases shown in Box 5.2 are a useful paradigm to illustrate the mechanisms that can lead to the accumulation of lactate (Fig. 5.5). Two reactions in the glycolytic pathway are not simply reversible for gluconeogenesis. Deficiency of both fructose 1,6-diphosphatase and pyruvate carboxylase, the enzymes that catalyse these steps in gluconeogenesis, are associated with lactate accumulation, particularly when production is increased as, for example, during exercise. In glucose 6-phosphatase deficiency, glucose 6-phosphate released from glycogen cannot be converted to glucose and so is metabolized through the glycolytic pathway to lactate, particularly when glycogenolysis is stimulated, for example during fasting. Pyruvate dehydrogenase is responsible for converting pyruvate to acetyl coenzyme A, which subsequently enters the tricarboxylic acid cycle: its deficiency decreases pyruvate, and hence lactate, oxidation.

The association between alcohol and lactic acid, mentioned above, is not confined to ethanol. Methanol and ethylene glycol are metabolized by alcohol dehydrogenase and the reactions consume NAD^+ , which is then not available for the lactate dehydrogenase reaction. Particularly with ethylene glycol poisoning, other acids (e.g. glycolic and glyoxylic acids) also contribute to the acidosis (it should, however, be noted that glycolate may cause an apparent elevation of lactate concentration in lactate assays employing lactate oxidase).

FIGURE 5.5 ■ Key reactions in glycolysis/gluconeogenesis. Inherited metabolic diseases affecting the enzymes indicated can cause lactic acidosis, by blocking gluconeogenesis (fructose 1,6-diphosphatase and pyruvate decarboxylase deficiencies), pyruvate oxidation (pyruvate dehydrogenase deficiency) or by increasing glycolysis (glucose 6-phosphatase deficiency). Intermediate reactions have been omitted for clarity.

Hyperlactataemia is common in patients with severe acute hepatic failure, but in many such patients the predominant acid–base disturbance is not acidosis, but alkalosis, either respiratory (as a result of direct stimulation of the respiratory centre by toxins) or non-respiratory, thought to be caused by a decrease in ureagenesis such that the consumption of hydrogen ions during the oxidation of the carbon skeletons of amino acids is not balanced by hydrogen ion formation.

The naturally occurring isomer of lactic acid in man is the L-isomer. Lactic acidosis due to accumulation of the D-isomer has been reported in patients with blind intestinal loops and short bowel syndrome, resulting from overproduction by the altered gut flora. The diagnosis may be missed, since D-lactate is not measured by the usual assays based on lactate dehydrogenase.

Dilutional (expansion) acidosis. Excessive infusion of isotonic saline solution can cause a mild acidosis. Expansion of the extracellular fluid (ECF) volume leads to a dilutional decrease in bicarbonate concentration, but, more importantly, volume expansion decreases renal bicarbonate reabsorption. This form of acidosis is self-correcting when ECF volume is allowed to return to normal.

Acidosis in renal disease. Acidosis is common in patients with renal disease. In acute kidney injury, acidosis is frequently multifactorial. Patients are often shocked and may have increased acid production, while the failure

of urine production prevents renal acid excretion. In chronic kidney disease, the urine can usually be maximally acidified – that is, the hydrogen ion concentration can be raised (the pH lowered) to the same extent as can occur in normal individuals (exceptions include renal disease particularly affecting the medulla, for example chronic pyelonephritis, in which acidification may be impaired). In the early stages, the development of hyperphosphataemia results in an increase in the amount of phosphate filtered in each nephron, and phosphate reabsorption is decreased secondarily to increased secretion of parathyroid hormone. This may allow the excretion of a normal load of hydrogen ion buffered by phosphate. However, although individual nephrons may secrete a normal or even increased amount of ammonium, overall ammonium excretion decreases early in chronic renal disease and, as a consequence, systemic acidosis develops. Nevertheless, severe acidosis is unusual in chronic kidney disease, with plasma bicarbonate concentration rarely falling below 10–12 mmol/L. This is a result of extensive buffering of hydrogen ions by bone, a factor of importance in the pathogenesis of renal osteodystrophy. Uraemic acidosis is an example of a type of acidosis in which alkali treatment is beneficial, though usually with oral

calcium carbonate rather than sodium bicarbonate in order to reduce the risk of sodium overload and also bind phosphate.

Impairment of renal tubular function is an important cause of acidosis. Three distinct syndromes of renal tubular acidosis (RTA) have been described: type 1 or distal RTA (sometimes referred to as ‘classic’ RTA); type 2 or proximal RTA, and type 4 or hyperkalaemic RTA. Both type 1 and type 4 owe their pathogenesis to defective mechanisms in the distal tubules: they are sometimes called hypokalaemic and hyperkalaemic distal RTA, respectively. Their principal characteristics are summarized in Table 5.3.

Normal urinary acidification requires the generation of nearly a 1000-fold gradient in hydrogen ion concentration between the blood and the lumen of the nephron, and type 1 RTA can be due to a failure to maintain this gradient because secreted hydrogen ions diffuse back into the tubular cells or due to defective hydrogen ion secretion. It can be inherited as an isolated defect (autosomal dominant) or be acquired. Unusually, for a systemic acidosis, there is associated potassium wasting, leading to hypokalaemia, partly because more potassium is excreted to maintain electrochemical neutrality and partly because the impairment of hydrogen ion excretion impairs

TABLE 5.3 Some causes and features of renal tubular acidosis

Type	Pathogenesis	Causes	Features
1 (distal)	Impaired ability to generate [H ⁺] gradient between blood and tubular lumen	Inherited idiopathic Autoimmune disease: Systemic lupus erythematosus: Primary biliary cirrhosis Sjögren syndrome Multiple myeloma Drugs: Amphotericin Lithium Non-steroidal anti-inflammatory drugs (NSAIDs) Renal disease: Analgesic nephropathy Sickle cell nephropathy Nephrocalcinosis	Minimum urine pH >5.5 Hypokalaemia Hypocitraturia Hypercalciuria Nephrocalcinosis Renal calculi Rickets Osteomalacia
2 (proximal)	Impaired reabsorption of filtered bicarbonate	Inherited idiopathic Metabolic disease: Tyrosinosis Cystinosis Hereditary fructose intolerance Wilson disease Drugs and toxins: Lead, mercury, acetazolamide Miscellaneous: Multiple myeloma Amyloidosis Sjögren syndrome	Minimum urine pH 4.5 if plasma [HCO ₃ ⁻] low Hypokalaemia Glycosuria Uricosuria Amino aciduria Hyperphosphaturia Hypophosphataemia Rickets Osteomalacia Polyuria Thirst
4 (hyperkalaemic)	Hypoaldosteronism	Adrenal failure Renal disease: Diabetic nephropathy Interstitial nephropathy Drugs: Indometacin Spironolactone	Minimum urine pH >5.5 ^a Hyperkalaemia Low plasma [renin] Low plasma [aldosterone]

^a Lower urinary pH may be achieved in ‘rate’ defects, see text for details.

sodium reabsorption and may lead to secondary aldosteronism. Buffering of acid in bone contributes to hypercalciuria and there is a risk of nephrocalcinosis. Type 1 RTA is typically treated with modest amounts of oral sodium bicarbonate (typically 2–3 mmol/kg body weight/day; cf. type 2 RTA, below); potassium supplements, citrate and thiazide diuretics (which increase proximal tubular sodium – and thus bicarbonate – reabsorption by inducing volume contraction) may also be helpful. The principal aim of treatment is to allow normal growth in children and to correct the bone disease and reduce the risk of renal damage in adults.

Type 2 RTA is less common than type 1. It is due to a failure of proximal tubular bicarbonate reabsorption, which leads to bicarbonaturia. The fall in plasma bicarbonate concentration causes a systemic acidosis, but as the amount of filtered bicarbonate falls, the amount presented to the proximal tubules for reabsorption falls, and bicarbonate may be completely reabsorbed. Since the distal acidification mechanism is normal, excretion of an acidic urine is possible, albeit only at the expense of a systemic acidosis. Plasma bicarbonate concentration is typically 15–20 mmol/L. Type 2 RTA is usually associated with other abnormalities of proximal tubular function, for example glycosuria, amino aciduria, hypercitraturia and phosphaturia; it can be a feature of inherited diseases (classically, the Fanconi syndrome caused by cystinosis) or be acquired. Plasma potassium concentration is usually normal or only slightly decreased. Hypercalciuria is not a feature of type 2 RTA. However, metabolic bone disease (rickets in children, osteopenia in adults) occurs frequently. It is, in part, a direct consequence of the acidosis; defective synthesis of calcitriol and hypophosphataemia may also be contributory factors. Correction of the acidosis in type 2 RTA requires the ingestion of much larger quantities (typically 5–15 mmol/kg body weight/day) of bicarbonate than are required in RTA type 1. Appropriate treatment is particularly important in children, to optimize growth (the condition is in any case rare in adults). Bicarbonate replacement leads to bicarbonaturia and potassium wasting; potassium replacement is also required.

Renal tubular acidosis type 4 can be subdivided into two types. So-called ‘rate defects’ (which occur more frequently) are associated with decreased secretion of aldosterone, resulting from either primary adrenal disease or renal disease in which renin secretion is impaired (e.g. diabetic nephropathy, tubulointerstitial nephropathy). They can also be seen in syndromes of aldosterone resistance, in patients being treated with spironolactone and in patients treated with non-steroidal anti-inflammatory drugs (in whom it is probably as a result of a decrease in renin secretion secondary to decreased renal prostaglandin synthesis). The acidosis is due, in part, to reduced hydrogen ion secretion secondary to decreased sodium reabsorption, and usually responds to treatment with small doses of a synthetic mineralocorticoid together with bicarbonate, diuretics or ion exchange resins to correct the hyperkalaemia. However, there is also decreased ammonium excretion, and the fact that this, and the acidosis, may be corrected if the plasma potassium concentration is lowered without giving aldosterone suggests that the hyperkalaemia itself contributes to the

acidosis. The other subtype comprises ‘voltage defects’, in which the secretion of hydrogen and potassium ions in the cortical collecting ducts is reduced as a result of a decrease in the usual negative intratubular electrical potential. This can occur with structural damage to the nephrons (e.g. sickle cell nephropathy), drugs (lithium, triamterene and amiloride, among others) and a decrease in the supply of sodium to the distal nephron as a result of avid proximal absorption (e.g. in hepatic cirrhosis). The urine pH can be reduced below 5.5 in rate defects, but not in voltage defects. In contrast to type 2 RTA, where acidosis is often severe, the acidosis in both subtypes of 4 RTA is often mild (plasma bicarbonate concentration typically 18–21 mmol/L), and the hyperkalaemia is often more remarkable.

If a diagnosis of renal tubular acidosis is not clear from the clinical findings and the simple laboratory measurements outlined above, tests of urinary acidification (for distal RTA) or bicarbonate reabsorption (for proximal RTA) may be required (see Chapter 9). Investigations that may be of value in the diagnosis of type 4 RTA include assessment of adrenal function and demonstration of a failure of plasma renin and aldosterone concentrations to respond to oral furosemide.

Respiratory acidosis

This is a consequence of carbon dioxide retention. In health, the rate and depth of respiration are adjusted precisely, so that the rate of excretion matches the rate of formation. Carbon dioxide excretion is a complex process, involving the transport of carbon dioxide in the blood to the pulmonary capillaries, diffusion into the alveoli and ventilation. Ventilation is controlled by the medullary respiratory centre, which receives input from peripheral and central chemoreceptors. Carbon dioxide retention can occur as a consequence of malfunction of either the excretory mechanism or its control. Some of the causes of respiratory acidosis are indicated in [Box 5.3](#).

Compensatory responses in respiratory acidosis

Buffering. The role of erythrocytes in converting carbon dioxide to bicarbonate and buffering the hydrogen ions produced has been discussed above. This process is extremely effective: in health, the arteriovenous difference in hydrogen ion concentration is only ~3 nmol/L. It is salutary to examine the efficacy of this process in more detail. In the absence of any buffering, were an increase in PCO_2 sufficient to cause an increase in bicarbonate concentration of only 1 mmol/L to occur (acutely, an increase of little more than 1 kPa is required to do this), it would be expected that hydrogen ion concentration would increase by the same amount, that is, 1 mmol/L. The fact that the increase is only a matter of a few nanomoles is almost entirely due to buffering by haemoglobin. Buffering of hydrogen ions by haemoglobin takes place rapidly, but the amount of haemoglobin available to buffer hydrogen ions is limited. The maximum increase in plasma bicarbonate concentration that occurs in acute respiratory acidosis is of the order of 4 mmol/L. In chronic carbon dioxide retention, buffering by other

BOX 5.3 Some causes of respiratory acidosis**Defects in the control of respiration**

 - Poliomyelitis
 - Guillain–Barré syndrome
 - Motor neuron disease
 - Neurotoxins

Defects in respiratory function

- Mechanical
 - Myasthenic syndromes
 - Myopathies
 - Thoracic trauma and deformities
 - Pneumothorax, pleural effusion
- Pulmonary disease
 - Restrictive defects (extensive fibrosis, pulmonary oedema, infiltrative tumours)
 - Obstructive defects (chronic bronchitis, emphysema, severe asthma)
 - Impaired perfusion (massive pulmonary embolism)

intracellular buffers occurs, and, as discussed below, increased renal ammonium excretion plays an important (albeit indirect) part in controlling the hydrogen ion concentration. Buffering of hydrogen ions by bone occurs to a lesser extent in chronic respiratory acidosis than in metabolic acidosis.

Hyperventilation. Although the increase in PCO_2 will stimulate the respiratory centre, the underlying disease will mean that the respiratory apparatus is unable to respond adequately to this stimulus. Therapeutic measures to improve respiratory function may lower PCO_2 , but in chronic carbon dioxide retention, this may have undesirable consequences, as is discussed in the section on treatment, below.

Renal hydrogen ion excretion. In sustained carbon dioxide retention, renal bicarbonate reabsorption is maximal and phosphate is excreted almost entirely in the dihydrogen form. There is also a marked increase in urinary ammonium excretion. This has the effect of compensating for the increase in hydrogen ion formation from carbon dioxide, and may even restore blood hydrogen ion concentration to normal. It is accompanied by a further increase in plasma bicarbonate concentration (in addition to that generated directly by the erythrocyte mechanism). Although this is usually considered to be a consequence of increased renal hydrogen ion excretion (since bicarbonate is generated *pari passu* with hydrogen ions in renal tubular cells), it is probably also partly a result of diversion of ammonium from ureagenesis, requiring decreased buffering by bicarbonate of hydrogen ions produced during this process. Practically, it is important

to appreciate that this compensation evolves over several days of carbon dioxide retention. If an attempt is made to reduce PCO_2 rapidly, for example by artificial ventilation, temporary persistence of the compensatory process may result in the development of an alkalosis (Post-hypercapnic alkalosis, see p. 83).

There is a limit to which changes in renal acid excretion and in ammonium metabolism can compensate for an increase in PCO_2 ; if this rises above 8 kPa, arterial hydrogen ion concentration will always be increased.

Biochemical characteristics of respiratory acidosis

The cardinal features of respiratory acidosis are an increased blood PCO_2 and a high, or high-normal, hydrogen ion concentration; bicarbonate concentration is increased. The hydrogen ion and bicarbonate concentrations for any PCO_2 depend on the extent of the compensatory increase in renal hydrogen ion and ammonium excretion (see above). In an acute disturbance, the increase in bicarbonate is only of the order of 2–4 mmol/L, even with massive increases in PCO_2 , but in compensated disturbances the increase is much greater.

Systemic effects of respiratory acidosis

In patients with respiratory acidosis, the manifestations of the underlying disorder and of hypoxaemia, if present, usually dominate the clinical findings, but effects due to acidosis and to hypercapnia may also be present. Hypoxaemia causes breathlessness, cyanosis and drowsiness. The consequences of acidosis have been discussed above. The effects of hypercapnia are seen predominantly in the central nervous and cardiovascular systems.

The neurological effects of hypercapnia cover a spectrum from anxiety and confusion through to impaired consciousness and coma. Particularly in chronic carbon dioxide retention, headache, papilloedema, extensor plantar responses and myoclonus may occur. Most of these effects are due to the increased cerebral blood flow that is a consequence of the vasodilatory action of carbon dioxide.

Systemic vasodilatation also occurs, but the cardiac output is increased so that blood pressure is usually maintained. The skin is warm and arterial pulses are bounding. The acidosis may cause venous constriction and chronic hypoxaemia may cause pulmonary hypertension and cor pulmonale, rendering the patient very susceptible to pulmonary oedema should intravenous fluids be given injudiciously.

Management

The logical management of respiratory acidosis is to treat the underlying cause and thus restore PCO_2 to normal. This may not be possible and, in chronic carbon dioxide retention, if compensatory processes have restored the blood hydrogen ion concentration to normal or near normal, it may not be necessary. In practice, the management of respiratory disorders is usually dictated by the necessity to maintain an adequate arterial PO_2 . As mentioned above, rapid correction of an elevated PCO_2 in a patient with chronic carbon dioxide retention is

potentially dangerous. The compensatory changes can persist for several hours, or even a few days, and may cause the patient to become alkalotic.

This demonstrates the fact that the compensatory process in a respiratory acidosis can be regarded as the *physiological* generation of a non-respiratory alkalosis, although the patient's hydrogen ion concentration does not fall *below* normal, that is, the patient does not become frankly alkalotic, as long as the PCO_2 remains elevated.

Non-respiratory alkalosis

This disorder can develop because of excessive loss of hydrogen ions, decreased generation of hydrogen ions or exogenous alkali administration. Some of the causes are indicated in **Box 5.4** and some of the more important of these are discussed later.

Non-respiratory alkalosis is characterized by an increase in plasma bicarbonate concentration. Since this bicarbonate is filtered at the glomerulus and, therefore, available for urinary excretion, the persistence of a non-respiratory alkalosis implies that it is being perpetuated by inappropriate reabsorption of filtered bicarbonate. Indeed, in healthy subjects, it is very difficult to produce a sustained alkalosis by the administration of, for example, sodium bicarbonate, whether orally or intravenously, because the excess is excreted in the urine. In considering the body's responses to non-respiratory alkalosis, it is therefore necessary to take into account not only the

BOX 5.4 Some causes of non-respiratory alkalosis

Saline responsive (chloride depletion)

- Gastrointestinal causes
 - Vomiting
 - Gastric drainage
 - Congenital chloride-losing diarrhoea
- Exogenous alkali administration
 - Sodium bicarbonate, lactate, acetate especially if GFR reduced
- Contraction alkalosis
- Renal causes
 - Poorly reabsorbable anion therapy (e.g. carbenicillin)
 - Diuretics (secondary to ECF volume contraction)
 - Post-(chronic)hypercapnia, especially in congestive cardiac failure, nephrotic syndrome, cirrhosis, i.e. decreased 'effective intravascular volume'

Saline unresponsive

- Associated with hypertension
 - Primary aldosteronism
 - Cushing syndrome
 - Secondary aldosteronism
 - Liquorice, carbenoxolone
- Not usually associated with hypertension
 - Bartter, Gitelman syndromes
 - Refeeding after starvation
 - Potassium depletion^a (except in renal tubular acidosis, acetazolamide and pancreatic fistula)
 - Magnesium depletion^a

^aWhen diuretic induced, may respond to saline.

underlying cause, but also the factors responsible for its perpetuation. Three such factors appear to be important:

- extracellular volume contraction
- potassium deficiency
- mineralocorticoid excess.

These are discussed further below.

Compensation for non-respiratory alkalosis

Buffering. A fall in blood hydrogen ion concentration results in the release of buffered hydrogen ions and, in consequence, the blood bicarbonate concentration increases. The excess bicarbonate could be excreted by the kidneys but, as mentioned above, this process is impeded in sustained alkalosis.

Hypoventilation. In a systemic alkalosis, decreased stimulation of chemoreceptors would be expected to decrease the respiratory drive, leading to compensatory retention of carbon dioxide. However, any increase in PCO_2 will tend to stimulate respiration and lessen the extent of the acute compensatory response. With the passage of time, this response may increase, because the central respiratory centre appears to become less sensitive to an increase in PCO_2 . However, hypoventilation will tend to decrease arterial PO_2 and should the extent of this be so severe as to cause hypoxaemia, the stimulus of this will override any inhibitory effect of a low hydrogen ion concentration. Significant tissue hypoxia is, however, uncommon in the absence of respiratory disease: although alkalosis causes a left shift in the oxyhaemoglobin dissociation curve, chronically this is offset by a decrease in red cell 2,3-DPG, which reduces the affinity of haemoglobin for oxygen (see p. 90).

Renal bicarbonate excretion. As indicated above, persistence of a non-respiratory alkalosis implies continued and inappropriate renal bicarbonate reabsorption. This could be achieved by the combination of a fall in the glomerular filtration rate (GFR) with maintenance of normal rates of tubular bicarbonate reabsorption, or by enhanced tubular reabsorption with a normal GFR. In many patients with non-respiratory alkalosis, there is both a decrease in the GFR and increased bicarbonate reabsorption.

A decrease in ECF volume may lead to a decrease in the GFR. If this is associated with chloride deficiency, the requirement to maximize tubular sodium reabsorption may cause an obligatory increase in the reabsorption of filtered bicarbonate to maintain electrochemical neutrality, to the extent that the urine may become acidic. (Priority is given to the control of ECF volume over that of acid-base status.) In the majority of patients with non-respiratory alkalosis, correction of the alkalosis follows repletion of ECF volume by the infusion of an isotonic sodium chloride solution (hence 'saline-responsive' non-respiratory alkalosis).

Non-respiratory alkalosis is frequently associated with potassium deficiency, but the fact that, in many instances, the alkalosis can usually be corrected by volume expansion without replacement of potassium casts doubt on the precise role of potassium. However, potassium depletion can contribute to the maintenance of a non-respiratory alkalosis through an effect on bicarbonate reabsorption. Severe potassium depletion enhances

proximal bicarbonate reabsorption. Distal tubular sodium reabsorption takes place in exchange for potassium and hydrogen ions; particularly when there is enhanced distal sodium reabsorption, potassium depletion may result in an increased secretion of hydrogen ions into the tubular fluid.

The third factor that can maintain a non-respiratory alkalosis is an increase in mineralocorticoid activity. This promotes distal tubular sodium reabsorption and results in increased excretion of both potassium and hydrogen ions. The effect is potentiated by potassium depletion, increased distal sodium delivery (as with diuretic treatment) and by the presence of non-resorbable anions, which accentuate the negativity of the luminal aspect of tubular cells. Increased mineralocorticoid secretion can occur secondarily to ECF volume contraction or be primary, as in Conn and Cushing syndromes. In these two conditions, ECF volume is expanded and the alkalosis, unusually, is not corrected by saline infusion.

Biochemical characteristics of non-respiratory alkalosis

The blood hydrogen ion concentration is low and the bicarbonate concentration increased; respiratory compensation may increase PCO_2 , but not to more than about 8 kPa. Hypokalaemia is almost always present. Paradoxically, for the reasons explained above, the urine may be acidic and urinary potassium excretion increased.

Systemic effects of alkalosis

In general, the effects of alkalosis are the opposite of those of acidosis. The effects on the cardiovascular system are, however, less in alkalosis and infrequently of clinical consequence. Alkalosis is rarely sustained over a long period and there is no evidence of any adverse effects on bone.

Chronic non-respiratory alkalosis is frequently associated with potassium depletion and hypokalaemia. In addition to any contribution from the causative condition (e.g. gastric secretions contain approximately 10 mmol/L potassium), this is related to increased distal tubular secretion of potassium as a consequence of decreased hydrogen ion secretion. Thus, alkalosis can cause potassium depletion and potassium depletion sustain alkalosis. If sodium depletion is also present, the stimulation of maximal distal tubular sodium reabsorption will also contribute to potassium depletion.

Neuromuscular hyperexcitability is present frequently in patients with acute respiratory alkalosis, manifest as paraesthesia, muscle cramps and tetany. It is unusual in non-respiratory alkalosis, except when the hydrogen ion concentration falls rapidly, as has been reported in patients with chronic respiratory acidosis treated with mechanical ventilation. Grand mal convulsions have been reported in such patients, and alkalosis can precipitate a fit in patients with epilepsy. This is, at least in part, a result of buffering of hydrogen ion by plasma proteins, particularly albumin, which decreases in alkalosis, leading to increased binding of calcium to protein, thus lowering the plasma ionized calcium concentration.

Management of non-respiratory alkalosis

Management should be directed towards treatment of the underlying cause of the alkalosis, when possible. As mentioned above, treatment can also be directed towards the correction of any factors tending to sustain the alkalosis. Most patients will respond to expansion of the ECF volume with isotonic saline. The demonstration of a low urinary chloride concentration reliably predicts those patients who will respond to this treatment. This is frequently combined with potassium replacement, although, in many instances, the alkalosis can be corrected by the administration of saline alone, even if there is potassium depletion (which may require correction in its own right).

Administration of saline is inappropriate (and potentially dangerous) in patients with saline-unresponsive causes of non-respiratory alkalosis. Management must be directed towards the underlying cause, for example removing the source of excessive mineralocorticoid secretion (or blockade of mineralocorticoid action) or replacement of potassium or magnesium, as appropriate.

Specific causes of non-respiratory alkalosis

Loss of gastric acid. The most severe non-respiratory alkalosis is seen in patients losing unbuffered acid from the stomach because of either gastric drainage or prolonged vomiting, particularly in association with pyloric stenosis, which prevents the concomitant loss of alkaline secretions from the proximal small intestine. The acid is hydrochloric acid so that patients become chloride depleted. The hydrogen ions are derived from carbonic acid, *pari passu* with bicarbonate. Initially, renal excretion of the excess bicarbonate may prevent the development of alkalosis, but with ECF volume contraction, the requirement to maximize renal sodium reabsorption in the face of hypochloreaemia necessitates increased reabsorption of sodium with bicarbonate. Indeed, in severe cases, renal bicarbonate reabsorption may be complete in spite of the high plasma concentration, resulting in the excretion of an acidic urine. Potassium is lost in gastric fluid, but increased aldosterone secretion may result in significant loss of potassium in the urine as well, exacerbating the potassium depletion and the alkalosis. Thus all three of the factors mentioned above can be involved in the maintenance of the alkalosis. The alkalosis usually responds to re-expansion of the ECF volume with isotonic saline; isovolaemic infusion of saline prevents the development of alkalosis in patients whose gastric fluid is being drained (e.g. because of postoperative ileus).

Post-hypercapnic alkalosis. It has been pointed out that the rapid lowering of a chronically elevated PCO_2 can result in the compensatory processes causing a frank non-respiratory alkalosis. If PCO_2 falls to normal over a few days, bicarbonate is excreted and an alkalosis does not develop, but if this occurs in patients with contraction of the ECF volume, for example as a result of diuretic treatment, alkalosis may become apparent and persist. It can be treated by administration of isotonic saline, though with caution because these patients frequently have secondary cardiac disease.

Mineralocorticoid excess. Syndromes of actual or apparent mineralocorticoid excess are almost invariably associated with non-respiratory alkalosis, for reasons that have been outlined above. Extracellular fluid volume is increased and patients are usually hypertensive. Expansion of the ECF should oppose the effect of potassium depletion on proximal bicarbonate reabsorption, and it is likely that the alkalosis is maintained largely by increased distal reabsorption.

Miscellaneous. Several other conditions can cause non-respiratory alkalosis as a result of increased renal excretion of hydrogen ions, but are not associated with hypertension. They include Bartter and Gitelman syndromes, and magnesium and potassium depletion. Refeeding after starvation is also sometimes associated with transient non-respiratory alkalosis, the cause of which is unclear, but which may be perpetuated by concomitant hypovolaemia and avid renal sodium reabsorption.

Respiratory alkalosis

Respiratory alkalosis is a consequence of the rate of excretion of carbon dioxide exceeding the rate of production, leading to a decrease in PCO_2 . This is usually due to stimulation of the respiratory centre: the stimulus may be toxic, reflex, psychogenic or related to the presence of an intracranial lesion. The exception is mechanical ventilation, when normal respiratory control is overridden. It is a common abnormality in the critically ill. Some of the causes of respiratory alkalosis are indicated in [Box 5.5](#).

Compensatory responses in respiratory alkalosis

Buffering. In acute respiratory alkalosis, the fall in PCO_2 causes a decrease in hydrogen ion concentration and a slight fall in bicarbonate. Other buffers release hydrogen ions, so tending to counter the effect of the fall in PCO_2 ; some of these hydrogen ions will combine with bicarbonate, causing its concentration in the blood to fall further. A new steady state can be attained rapidly and can persist for approximately six hours, after which the effect of changes in renal hydrogen ion metabolism become detectable.

BOX 5.5

Some causes of respiratory alkalosis

- Voluntary hyperventilation
- Mechanical ventilation
- Reflex hyperventilation
 - Decreased pulmonary compliance
 - Disease affecting chest wall
 - Irritative lesions of the air passages
- Other stimuli to respiratory centre
 - Cortical influences (pain, fever, anxiety etc.)
 - Local disease (trauma, tumours)
 - Drugs and toxins (salicylate poisoning, hepatic failure)
 - Hypoxaemia (ascent to altitude, right-to-left shunts, pulmonary disease, carbon monoxide poisoning etc.)
- Non-respiratory acidosis (during recovery)

Hypoventilation. Correction of a respiratory alkalosis is only possible if the rate of excretion of carbon dioxide can be restored to normal. The fact that an alkalosis develops (other than with mechanical ventilation) indicates that the inhibitory effect of the decrease in PCO_2 on respiration is being overwhelmed by whatever stimulus is causing the hyperventilation.

Renal hydrogen ion excretion. If a low PCO_2 persists for more than a few hours, decreased renal generation of bicarbonate (for which carbon dioxide is a substrate) will decrease urinary acidification and effect further compensation for the alkalosis, further lowering the plasma bicarbonate concentration.

Biochemical features of respiratory alkalosis

The cardinal feature of an acute respiratory alkalosis is a decrease in arterial PCO_2 , a decrease in hydrogen ion concentration and a small decrease in bicarbonate concentration, though not to less than about 18 mmol/L. In a chronic respiratory alkalosis, renal compensation may result in arterial hydrogen ion concentration being only marginally decreased, while the bicarbonate concentration falls further, but not to less than about 12 mmol/L. The finding of bicarbonate concentrations less than these values suggests the additional presence of a non-respiratory acidosis.

If the stimulus to hyperventilation is hypoxaemia, arterial hydrogen ion concentration may be affected predominantly by a resulting non-respiratory acidosis. The interpretation of measured acid-base parameters in mixed disorders of hydrogen ion homeostasis is discussed in a later section.

Systemic effects of respiratory alkalosis

The manifestations of the underlying disorder often predominate in patients with respiratory alkalosis. In acute hypocapnia, cerebral vasoconstriction reduces cerebral blood flow, and light-headedness, confusion, impaired intellectual function, syncope and seizures may occur. In patients with sickle cell disease, hypocapnia has been recorded as causing strokes, presumably as a result of cerebral hypoxaemia engendered by the vasoconstriction. Perioral and peripheral paraesthesiae are common, in part at least, because of a fall in ionized calcium concentration. These features usually remit if the hypocapnia persists.

In contrast, cardiovascular changes can occur with both acute and chronic hypocapnia. They include an increase in heart rate, non-specific chest pain or even frank angina.

Mild hypokalaemia can occur with respiratory alkalosis; plasma phosphate concentration is often significantly reduced.

Management

Where possible, treatment should be directed at the underlying cause. In a psychogenically induced acute respiratory alkalosis, rapid symptomatic relief may be obtained by getting the patient to rebreathe from a paper bag.

If the alkalosis is severe, and the nervous or cardiovascular features are giving cause for concern, it may occasionally be necessary to sedate the patient or prevent the hyperventilation by resorting to mechanical ventilation, always being sure that adequate oxygenation is maintained.

The interpretation of acid–base data

Many approaches to the diagnosis of disorders of hydrogen ion homeostasis have been promulgated. These may involve the mathematical manipulation of data, or the plotting of data on a diagram that shows the ranges of the variables in the various disorders. Three points are worth emphasizing in this context. First, although the use of diagrams may facilitate the rapid diagnosis of an acid–base disturbance, it cannot add to the information that is available from an analysis of the data on which the diagrams are based. Second, diagnosis should be based on measured variables and not on secondarily derived data. Third, acid–base variables must always be assessed in their clinical context: this is particularly important in mixed disorders, in which results may be indistinguishable from those that can occur during the physiological compensation of single disorders.

The most logical acid–base diagram is thus a graph of hydrogen ion concentration against partial pressure of carbon dioxide, as shown in Figure 5.6. This shows the zones in which combinations of PCO_2 and $[H^+]$ occur in the various disorders that have been described. If a pair of data for a patient falls outside one of these areas, it suggests that there is a mixed acid–base disorder. Such diagrams may be useful not only to help in defining the acid–base disorder in an individual patient, but also, when serial plots are made, to follow the response to treatment.

It will be apparent that diagnosis of the type of acid–base disorder requires only knowledge of PCO_2 and $[H^+]$;

FIGURE 5.6 ■ The relationship between arterial hydrogen ion concentration ($[H^+]$) and partial pressure of carbon dioxide (PCO_2). The ranges of values typical of the major disturbances of hydrogen ion homeostasis are shown. Note that, in acute respiratory disturbances, the variation of $[H^+]$ with PCO_2 is rectilinear.

this must follow from the fact that, as shown by Equation 7, bicarbonate concentration depends on PCO_2 and $[H^+]$ and cannot vary independently of them.

In Figure 5.6, the plot of $[H^+]$ against PCO_2 is rectilinear in acute respiratory disorders. This fact makes it possible to diagnose acid–base disorders without recourse to diagrams. The slope of the plot is such that, in an acute respiratory disturbance (that is, before there has been time for significant compensation to occur), for every 1 kPa change in PCO_2 , $[H^+]$ would be expected to change by 5.5 nmol/L, an increase in PCO_2 increasing $[H^+]$ and a decrease in PCO_2 decreasing $[H^+]$ by this amount.

Thus, in a patient whose PCO_2 is abnormal, it is possible to calculate whether the observed $[H^+]$ is what it would be expected to be if the respiratory disturbance were acute, that is, in the absence of any compensation. Suppose, for example, a patient has a PCO_2 of 7.5 kPa and $[H^+]$ of 52 nmol/L – plotting these figures on Figure 5.6 suggests that the patient has an acute respiratory acidosis. But this can also be appreciated by calculation: assuming a normal PCO_2 of 5.3 kPa and $[H^+]$ of 40 nmol/L, an acute increase in PCO_2 to 7.5 kPa would be expected to increase $[H^+]$ to $[40 + (5.5 \times 2.2)] = 52$ nmol/L, as is observed. Were the observed $[H^+]$ to be higher, it would indicate that the acidosis had a non-respiratory as well as a respiratory component. Were the observed $[H^+]$ to be lower than expected from the PCO_2 , it would indicate the presence of a non-respiratory alkalosis in addition to the respiratory acidosis.

In this latter instance, however, an alternative explanation could be that the respiratory acidosis had been partly compensated. As has been indicated, the compensatory processes in disturbances of hydrogen ion homeostasis can be regarded as the generation of opposing disturbances. Indeed, in respiratory disturbances, in which the development of compensation lags behind the development of the primary disorder, the presence and nature of the compensation is made explicit if the primary abnormality is corrected rapidly, leaving the persisting compensatory process as the sole acid–base abnormality (see Post-hypercapnic alkalosis, above).

As previously mentioned, it is important to appreciate that examination of PCO_2 and $[H^+]$, or of data derived from them, in isolation from clinical information and other, independent, laboratory data, may not permit differentiation between a compensated disorder of hydrogen ion homeostasis or the simultaneous existence of two primary disorders having opposing effects on hydrogen ion concentration. In the descriptions of the major acid–base disorders, the maximum extent to which compensation can occur was indicated, and if data lie outside these limits then a mixed disturbance must be present; however, such a disturbance can be present even if the data lie within the limits of normal compensation.

The approach to the interpretation of acid–base data described above is essentially physiological; it does not require the use of derived data which, as explained in an earlier section, do not provide additional, independent, information.

An alternative approach, which is essentially physicochemical in nature, is provided by the strong ion theory, originally developed by Stewart (1978). This was based

on in vitro studies of the dissociation of water (and hence hydrogen ion concentration) in the presence of various solutes and carbon dioxide, and led to the conclusion that $[H^+]$ is determined by three independent variables. These are the 'strong ion difference' (SID, the sum of the concentrations of sodium, potassium, magnesium and calcium ions less than that of the sum of the concentrations of chloride, sulphate and organic acid anions); the total concentration of weak acids, i.e. phosphate and proteins (A_T) and the partial pressure of carbon dioxide.

Strong ion difference is further differentiated into 'apparent' SID (SID_a) and 'effective' SID (SID_e). The former is provided by $([Na^+] + [K^+]) - [Cl^-]$; the latter is the sum of $[HCO_3^-]$ and non-bicarbonate buffers, that is, the anionic equivalences of albumin and phosphate. The difference between the two is the 'strong ion gap' (SIG). The normal value of SIG is zero. The various quantities are either measured or read from nomograms based on the solutions of a series of complex equations.

This approach defines additional primary acid–base disorders in addition to the four described above. There are two respiratory disorders (as with the physiological approach), but in non-respiratory acidosis, although SID_e is always low, this can occur with a high SIG (as in lactic acidosis) or a normal SIG (as with bicarbonate loss); in non-respiratory alkalosis, SID_e is high and SIG normal, but both acidosis and alkalosis can also be due to abnormal value of A_T (hyperalbuminaemic acidosis and hypoalbuminaemic alkalosis, respectively). The contribution of differences in plasma protein concentration is not considered to be of significance in the physiological approach (and indeed, changes in plasma albumin concentration in vivo do not affect $[H^+]$).

Although the strong ion theory has its proponents, it has not been widely adopted. It is considerably more complex than the physiological approach; it is derived entirely from observations made in vitro; it does not provide any quantitative data concerning the compensatory responses to primary disorders and, although there are some data suggesting that it better predicts outcome in critically ill patients than traditional approaches, most studies have failed to do this. (The interested reader will find further information and discussion of this topic in the Further reading section, below.)

Mixed disorders of hydrogen ion homeostasis

Mixed acid–base disorders, that is, disorders with both respiratory and non-respiratory components, occur frequently. Some examples are shown in Box 5.6. They can be classified according to whether the component disturbances are additive or opposing in their effects on hydrogen ion concentration.

The presence of a mixed disorder can be inferred from any change in hydrogen ion concentration not being as predicted from the PCO_2 . In a mixed respiratory and non-respiratory acidosis, PCO_2 will be elevated, but $[H^+]$ will be higher than would be predicted from the PCO_2 . In a mixed respiratory and non-respiratory alkalosis, PCO_2 will be decreased, but $[H^+]$ will be lower than predicted. In each case, the plot of $[H^+]$ and PCO_2

BOX 5.6 Some causes of mixed acid–base disorders

Additive disorders

- Non-respiratory acidosis + respiratory acidosis
 - Respiratory failure
 - Cardiac arrest
 - Poisoning, e.g. with ethanol, methanol
- Non-respiratory alkalosis + respiratory alkalosis
 - Vomiting and congestive cardiac failure
 - Vomiting or diuretic therapy and, for example, hepatic failure or pneumonia

Counterbalancing disorders

- Non-respiratory acidosis + respiratory alkalosis
 - Salicylate poisoning
 - Septicaemia ± renal failure
 - Acute hepatic failure, hepatorenal syndrome
 - Ketoacidosis and pneumonia
- Non-respiratory alkalosis + respiratory acidosis
 - Diuretic therapy or vomiting and chronic obstructive airways disease
 - Severe potassium depletion
- Non-respiratory acidosis + non-respiratory alkalosis
 - Vomiting and renal failure
 - Diuretic therapy and ketoacidosis
 - Severe vomiting in ketoacidosis

Triple disorders

- See text

on the acid–base diagram (Fig. 5.6) will fall in the regions between those shown for the appropriate non-respiratory and acute respiratory disorders.

The diagnosis of mixed disorders in which the component disturbances have opposite effects on hydrogen ion concentration is less straightforward. As discussed above, the problem is that the changes in $[H^+]$ and PCO_2 may be exactly the same as may be found as a result of physiological compensation. This stems from the fact that the compensatory process itself disturbs acid–base homeostasis, albeit advantageously, tending as it does to restore $[H^+]$ towards normal. Usually, careful consideration of the clinical findings and other data that may be available will allow the correct diagnosis to be made. It should also be appreciated that the efficacy of compensatory processes is limited, particularly in non-respiratory disorders. Compensation restores the hydrogen ion concentration *towards* normal, but restoration *to* normal is only seen with mild chronic respiratory acidosis and chronic respiratory alkalosis. With more severe disturbances, compensation is incomplete. Overcompensation does not occur so that, for example, a patient with a slightly elevated $[H^+]$ and a low PCO_2 , must have a partially compensated non-respiratory acidosis and cannot have compensated respiratory alkalosis.

Since the causes of respiratory acidosis and alkalosis are retention and excessive excretion of carbon dioxide, respectively, these two disorders cannot coexist. However, several mechanisms can be responsible for the development of non-respiratory disorders, and the

existence of a process producing an acidosis need not exclude the presence of one producing an alkalosis. Thus, a patient could have renal failure (a cause of acidosis) and be vomiting excessively (a cause of alkalosis). Whether the patient is actually acidotic or alkalotic will depend on which process predominates, but examination of $[H^+]$ and PCO_2 alone will not reveal this type of mixed disturbance. It may only be inferred from clinical observations coupled with other biochemical data – particularly, for example, the anion gap – or become apparent when the predominant disorder is treated appropriately and apparent ‘over-swing’ occurs, for example the patient, having had a mild non-respiratory acidosis, becomes severely alkalotic.

Exceptionally, triple acid–base disorders can occur. Patients have been described with a severe non-respiratory alkalosis (usually due to prolonged vomiting), accompanied by a respiratory acidosis or alkalosis, in whom a high anion gap suggests a component of non-respiratory acidosis (e.g. a lactic acidosis). The $[H^+]$ (low) and PCO_2 (also low) in such patients may suggest a partially compensated acute respiratory disturbance, but the clinical features will be inconsistent with this as the sole diagnosis.

In practice, because mixed acid–base disorders frequently develop in patients who are severely ill, the management of the acid–base disorder per se will usually be less important than that of the underlying illness. Indeed, the management of any acid–base disorder should include measures to correct the cause where possible, though, as has been indicated above, specific measures relating to the acidosis or alkalosis may also be necessary.

TISSUE OXYGENATION

Introduction

The process whereby atmospheric oxygen is made available to mitochondria, where the oxidation of carbon and hydrogen releases energy, is a complex one, depending on adequate alveolar ventilation and function, pulmonary and tissue blood flows, and the ability of the blood itself to take up oxygen in the alveoli and release it to tissues. Tissue oxygenation can be compromised by disease affecting any of these functions. Until relatively recently, the only readily available index of tissue oxygen supply was the arterial partial pressure of oxygen, PaO_2 . This measurement is still regarded as essential, but it has a number of limitations. It requires access to arterial blood, either by direct puncture or through an indwelling catheter; blood samples must be collected with considerable care and analysis performed without delay, but, perhaps most importantly, measurement of PaO_2 provides incomplete information on oxygen transport. It is a measure of partial pressure, not of the oxygen *content* of blood nor the *delivery* of oxygen to tissues. However, although tissue oxygenation depends upon factors other than PaO_2 , maintenance of an adequate PaO_2 is a prerequisite for normal tissue oxygenation. This is illustrated in the following sections, which discuss the transport of oxygen from the inspired gas to the tissues, where it is used for oxidative metabolism.

Pulmonary function

The lungs have two principal functions: to transfer oxygen from inspired gas to the blood, and to remove carbon dioxide from the blood to the expired gas. As discussed above, the latter is critical to hydrogen ion homeostasis, and is compromised by hypoventilation. Hypoventilation invariably leads to decreased oxygen uptake into the blood, but, as will be seen, impaired oxygenation can occur in the absence of hypoventilation.

Alveolar ventilation

The partial pressure of oxygen in arterial blood, PaO_2 , depends on the alveolar oxygen tension (PAO_2), which is in turn dependent on the fraction of the inspired gas comprising oxygen (FiO_2), the arterial carbon dioxide tension ($PaCO_2$), the respiratory quotient (RQ), atmospheric barometric pressure (P_B) and the partial pressure of water vapour (PH_2O) such that:

$$PaO_2 = FiO_2 \times (P_B - PH_2O) - PaCO_2 / RQ \quad (29)$$

This is the alveolar gas equation. The respiratory quotient depends on the relative proportions of free fatty acids, carbohydrate and protein being used as energy substrates by the tissues, but it varies through only a small range, even in disease. Alveolar air is always saturated with water so that PH_2O is constant. It follows that PAO_2 can increase significantly as a result of either an increase in P_B (requiring a hyperbaric chamber) or FiO_2 (requiring the administration of oxygen) or a decrease in $PaCO_2$ (requiring an increase in ventilation). Only the last two are readily available to treat patients with a low PAO_2 . Inspection of Equation 29 will indicate that the effect of a change in $PaCO_2$ on PAO_2 will be greater if FiO_2 is normal than if it is raised; an increase in $PaCO_2$ (usually accepted as being equal to $PaCO_2$) can significantly decrease PAO_2 at normal values of FiO_2 , but it will have a lesser effect if the FiO_2 is increased.

Oxygen uptake into blood

The continuous delivery of mixed venous blood of low oxygen content to the alveolar capillaries, and diffusion of oxygen down the concentration gradient from the alveolar space to the blood, result in a constant tendency for PAO_2 to fall that is prevented by the delivery of oxygen to the alveoli by ventilation. In healthy young individuals, oxygen diffuses readily from alveoli into the plasma and PaO_2 is usually only about 1 kPa less than PAO_2 , that is (breathing room air at sea level) about 13.3 kPa. The gradient increases with age and the approximate normal value is given by $(PAO_2 - PaO_2) = (0.06 \times \text{age in years})$ kPa so that it may reach nearly 4 kPa in healthy 60-year-olds. Pulmonary disease that impairs diffusion is a potential cause of an increase in $(PAO_2 - PaO_2)$ and hence a decrease in PaO_2 , but the nature of the alveoli is such that any impairment of diffusion must be considerable before it affects PaO_2 at rest.

The maintenance of a normal PaO_2 also requires a normal relationship between the perfusion of alveoli and

their ventilation: the effects of a disturbance in this relationship (ventilation–perfusion imbalance) are further considered below.

In health, a small proportion of the blood reaching the lungs from the tissues bypasses the alveoli and does not take part in gas exchange (a right-to-left shunt). This is because the bronchial veins drain directly into the pulmonary veins, while some blood that perfuses the myocardium drains directly into the cavity of the left ventricle. Any increase in shunting due to a pathological process will tend to decrease PaO_2 .

The final factor that can affect PaO_2 is the oxygen tension in the blood reaching the lungs, that is, mixed ('mixed' because this blood is derived from all the veins draining into the right side of the heart) venous PO_2 or PvO_2 . If this is low, increased alveolar oxygen transport will be necessary to allow maximal PaO_2 . In health, increased tissue oxygen requirements (as, e.g. during exercise) result in a fall in PvO_2 , and the increased oxygen requirement is met by hyperventilation. Tissue oxygen requirements are often increased in disease, for example as a result of sepsis or the metabolic response to trauma, but, at the same time, the physiological responses leading to hyperventilation may be attenuated. Other factors that can contribute to a low PvO_2 include decreased oxygen saturation, anaemia and a decrease in cardiac output, all of which, as will be discussed below, can decrease the delivery of oxygen to tissues.

In summary, a low PaO_2 , that is, hypoxaemia, can be caused by any of the following:

- a decrease in PAO_2 (whether due to a decrease in the proportion of oxygen in the inspired gas, an increase in $PACO_2$ or a decreased barometric pressure)
- hypoventilation
- decreased diffusion
- imbalance of ventilation and perfusion
- an increase in shunting
- a decrease in PvO_2 .

Hypoxaemia caused by hypoventilation or a decrease in PAO_2 or PvO_2 can be distinguished from the other causes by calculating the alveolar–arterial oxygen gradient ($PAO_2 - PaO_2$). PAO_2 can be calculated from arterial blood gas measurements using the alveolar gas equation. The gradient is increased when hypoxaemia is a result of impaired diffusion, shunting or imbalance between ventilation and perfusion. In these conditions, $PaCO_2$ is often normal. However, when, as in hypoxaemia caused by alveolar hypoventilation, $PaCO_2$ is increased, ($PAO_2 - PaO_2$) is typically normal.

Hypoxaemia becomes recognizable clinically when it is sufficiently severe to cause central cyanosis. This requires a deoxygenated haemoglobin concentration of more than 50 g/L (saturation <75% at normal haemoglobin concentrations). In patients with severe anaemia, the low haemoglobin may result in significant hypoxaemia being present without there being discernible cyanosis; conversely, patients with polycythaemia may have central cyanosis, despite a relatively normal oxygen saturation.

Peripheral cyanosis will always be present if there is central cyanosis, but peripheral cyanosis can occur in the absence of central cyanosis as a consequence of reduced peripheral circulation.

The role of haemoglobin in oxygen transport

Although the amount of oxygen present in physical solution in the blood is directly related to PaO_2 (0.225 mL/L per kPa), only a small amount of oxygen is carried in this way (at normal PaO_2 , approximately 3 mL per litre of plasma). Oxygen is principally transported in the blood bound to haemoglobin. One gram of haemoglobin can bind 1.34 mL of oxygen when fully saturated. The normal PaO_2 of arterial blood is approximately 13.3 kPa, at which haemoglobin is approximately 97% saturated. Total arterial oxygen content (CaO_2) is given by the sum of the dissolved and haemoglobin-bound fractions:

$$CaO_2 = ([Hb] \times SaO_2 / 100) \times 1.34 + (0.23 \times PaO_2) \quad (30)$$

where [Hb] is the haemoglobin concentration (g/L) and SaO_2 is the percentage saturation of haemoglobin with oxygen. At sea level, CaO_2 is normally about 200 mL/L. SaO_2 can be measured using a co-oximeter; these instruments also measure haemoglobin concentration and thus allow calculation of arterial oxygen content, which provides far more information than PaO_2 alone. Modern blood gas analysers often incorporate a co-oximeter, and such instruments are widely used in intensive therapy units. Arterial oxygen content can also be measured non-invasively (transcutaneously) using a pulse oximeter. It is beyond the scope of this book to discuss in detail the analytical principles utilized in these instruments, but a summary is provided in a later section (see p. 91).

The familiar sigmoid relationship between Hb saturation and oxygen tension (Fig. 5.7) has a number of important clinical consequences. First, a considerable reduction in PaO_2 below normal has little effect on the amount of oxygen carried in the blood. Saturation only falls below 90% when PaO_2 falls below 8 kPa. If PaO_2 falls further, however, oxygen saturation (and thus the amount of oxygen carried) decreases sharply. A further consequence is that, because haemoglobin is saturable, increasing PaO_2

FIGURE 5.7 ■ The oxygen–haemoglobin dissociation curve. At a normal arterial PO_2 (point 'a'), haemoglobin is about 97% saturated ($SaO_2 = 97\%$). Point 'y' represents the normal venous PO_2 , at which haemoglobin is 75% saturated ($SvO_2 = 75\%$). A decrease in arterial PO_2 to 8 kPa (point 'x') is associated with a decrease in SaO_2 to only 90%, but a further decrease will have a proportionately greater effect on SaO_2 and thus on arterial oxygen content.

above that necessary to provide complete saturation has relatively little effect on arterial oxygen *content*, since only the small fraction present in solution is significantly increased.

The effects of pulmonary disease on oxygen uptake into blood

The effects of alveolar hypoventilation and impaired diffusion on pulmonary function have been described above. Two other functional defects, shunting and ventilation–perfusion imbalance, can also have profound effects on the oxygenation of blood.

Shunting

Haemoglobin is only about 97% saturated in normal arterial blood. This is, in part, because of physiological shunting. In some conditions (e.g. lobar pneumonia, pulmonary oedema, adult respiratory distress syndrome), some alveoli become filled with fluid and do not take part in gas exchange, although they are still perfused with blood. Shunting is thereby increased and this leads to arterial hypoxaemia. Atelectasis (collapse of a lung or part of a lung so that it is not aerated) has the same effect. Under such circumstances, increasing PAO_2 by increasing FiO_2 has little effect on overall PaO_2 . This is because no gas exchange will be taking place in the alveoli that are acting as shunts, while haemoglobin in blood leaving normally functioning alveoli will already be fully saturated with oxygen. Increasing FiO_2 will increase only the small proportion of oxygen held in physical solution in this blood, and this will have little effect on total arterial oxygen content.

Ventilation–perfusion imbalance

The fact that haemoglobin is not fully saturated in normal arterial blood is also related to an imbalance between alveolar ventilation and perfusion. At rest, ventilation is about 4.2 L/min and pulmonary blood flow is about 5.5 L/min, so that the overall ventilation–perfusion ratio (\dot{V}/\dot{Q} ratio) is approximately 0.8. However, this ratio is not uniform throughout the lungs, ranging between the approximate limits 0.5 and 3.0. Some alveoli are better ventilated than they are perfused ($\dot{V}/\dot{Q} > 1$), so that a proportion of ventilation is ‘wasted’ and the effect is an increase in ‘dead space’; in others, \dot{V} and \dot{Q} are in balance. In both cases, effective oxygenation of the blood takes place. However, in those alveoli in which perfusion exceeds ventilation ($\dot{V}/\dot{Q} < 1$), complete oxygenation of the blood is impossible. Because haemoglobin is saturable, oxygen transport in the well-ventilated and normally ventilated alveoli cannot compensate for decreased oxygenation of blood in poorly ventilated alveoli. Many pulmonary diseases, notably chronic obstructive pulmonary disease and interstitial pulmonary disease, give rise to an increase over the normal imbalance of ventilation and perfusion. However, in contrast to disease in which significant shunting occurs, increasing the FiO_2 in such conditions, because it will increase oxygen transport in poorly ventilated alveoli, can increase overall PaO_2 .

Differential effects of pulmonary disease on $PaCO_2$ and PaO_2

It will be instructive at this point to compare the effects of respiratory disease on $PaCO_2$ and PaO_2 . Carbon dioxide is transported in blood effectively in physical solution (albeit mostly in the form of bicarbonate). In contrast to the oxyhaemoglobin dissociation curve, the curve relating the carbon dioxide content of blood to partial pressure is almost linear over the physiological range. As a result, a significant change in $PaCO_2$ will always cause a significant change in the carbon dioxide content of blood. In contrast, as has been seen, considerable changes in PaO_2 can occur with little effect on the blood’s oxygen content.

$PaCO_2$ is determined by alveolar ventilation: in health, any increase in carbon dioxide formation (e.g. during exercise) can be matched by an increase in excretion and PaO_2 is not affected. In contrast, in pulmonary disease, if $PaCO_2$ is increased, then PaO_2 will always be decreased. Thus, if hypoventilation causes hypercapnia, it will also cause hypoxaemia. However, hypercapnia is not always present in patients who are hypoxaemic. Carbon dioxide can diffuse between the blood and the alveolar air more readily than oxygen; defects in diffusion rarely cause hypercapnia, although they can cause hypoxaemia. Shunting causes a decrease in PaO_2 , but this will stimulate ventilation, increasing the excretion of carbon dioxide from ventilated alveoli and preventing a rise in $PaCO_2$ or even causing hypocapnia. Only with extensive shunting will the $PaCO_2$ be increased.

In pulmonary disease causing an increase in \dot{V}/\dot{Q} imbalance, there is a tendency for PaO_2 to fall, for the reasons discussed above; this will stimulate respiration but, while the increased ventilation of well-perfused alveoli cannot compensate for the impaired oxygenation, it can increase carbon dioxide excretion and $PaCO_2$ fall. With more severe disease, however, hypoxaemia will be accompanied by hypercapnia.

Respiratory failure, defined by PaO_2 being < 8 kPa or $PaCO_2$ being > 7 kPa, is thus divided into two types: type I, in which PaO_2 is low and $PaCO_2$ is normal or low (typically seen in condition such as pneumonia, pulmonary oedema and acute lung injury, where lung tissue is damaged) and type II, in which PaO_2 is low but $PaCO_2$ is high (typically seen in chronic obstructive pulmonary disease and conditions causing hypoventilation).

Oxygen transport to tissues

Oxygen delivery

The transport of oxygen to tissues depends not only on adequate transfer of oxygen from the inspired gas to the alveolar capillaries, but also on an adequate cardiac output. The total amount of oxygen delivered by the cardiopulmonary apparatus (DO_2) is given by the product of oxygen content (CaO_2) and cardiac output (CO):

$$DO_2 = CaO_2 \times CO \quad (31)$$

However, the amount of oxygen available to tissues will depend upon local perfusion and the affinity of haemoglobin for oxygen, which determines how readily oxygen can be released.

Oxygen uptake

Oxygen is taken up into tissues because their PO_2 is lower than that of the blood, and oxygen diffuses down its concentration gradient. However, examination of the oxyhaemoglobin dissociation curve indicates that the amount of oxygen taken up will depend on the haemoglobin saturation (SO_2) at a given PO_2 . Mixed venous oxygen saturation (SvO_2) at rest is approximately 75%, corresponding to a PvO_2 of 5.3 kPa and permitting the uptake of 46 mL of oxygen from each litre of blood. Resting cardiac output is approximately 5 L/min, and total tissue uptake of oxygen is about 250 mL/min at rest. However, if the oxyhaemoglobin curve were to shift to the left, less oxygen would be released from haemoglobin for the same fall in pO_2 , whereas a right shift would increase the availability of oxygen.

Such shifts occur physiologically. An increase in PCO_2 or $[H^+]$ (both of which occur as blood traverses the capillary beds) causes a right shift, as does an increase in temperature. The position of the curve is also determined by the concentration of 2,3-DPG in erythrocytes. An increase in 2,3-DPG concentration (normally about 4 mmol/L of red cells) causes a right shift. This occurs in chronic hypoxia and thus facilitates oxygen uptake by tissues. These effects are illustrated in Figure 5.8. The position of the oxyhaemoglobin saturation curve can be defined by P_{50} , the partial pressure of oxygen at which haemoglobin is 50% saturated. It is normally about 3.7 kPa.

Hypoxia

Tissue hypoxia can be due to a disturbance occurring at any stage in the delivery of oxygen to the cells where it is utilized (Table 5.4), to increased demand or to deficient

TABLE 5.4 Factors affecting tissue oxygenation and causes of hypoxia

Factor	Cause of hypoxia	Type of hypoxia
Inspired oxygen content (FiO_2)	Low inspired PO_2 Low barometric pressure (P_B)	Hypoxic
Alveolar oxygen tension (PAO_2)	Hypoventilation Increased oxygen consumption Increased $PACO_2$	Hypoxic
Arterial oxygen tension (PaO_2)	Venous-arterial shunting V/Q imbalance Impaired diffusion capacity	Hypoxic
Oxygen-carrying capacity of blood	Low haemoglobin Low P_{50}	Anaemic
Blood supply to tissues	Low cardiac output Vasoconstriction	Stagnant
Impaired utilization of oxygen	Metabolic poisons	Histotoxic

oxygen uptake. The rational treatment of hypoxia obviously depends on knowing the cause.

Measurement of oxygen delivery to tissues

This requires determination of arterial oxygen content, preferably from measurements of haemoglobin and SaO_2 , and of cardiac output. SaO_2 can be calculated from PaO_2 , using an assumed value for P_{50} , but direct measurement, by oximetry, is more reliable. It may be possible to infer the adequacy of cardiac output from clinical observation, but it can be measured directly by the thermodilution

FIGURE 5.8 ■ The oxygen–haemoglobin dissociation curve. An increase in PCO_2 , $[H^+]$ or red cell 2,3-diphosphoglycerate (2,3-DPG) causes a right shift in the curve, decreasing the affinity of haemoglobin for oxygen (P_{50} increased) and increasing the amount of oxygen available to the tissues. A decrease in PCO_2 , $[H^+]$ or red cell 2,3-DPG causes a left shift, which has the opposite effect.

method using a pulmonary artery (Swan–Ganz) catheter incorporating a thermistor.

Oximeters – instruments that measure the saturation of haemoglobin with oxygen – are of two types. Co-oximeters measure the optical absorbance of blood in vitro at multiple wavelengths; because oxyhaemoglobin and deoxygenated haemoglobin (and, indeed, carboxyhaemoglobin and methaemoglobin) have different absorbance characteristics, these instruments can be calibrated to quantitate these species separately, and thus to measure SaO_2 . Pulse oximeters are non-invasive. They have sensors that are usually placed on a thin part of the patient's anatomy (e.g. a finger tip or ear lobe) that direct light of two wavelengths (660 and 940nm) through the tissue to a detector that measures the relative absorbance and hence haemoglobin and oxyhaemoglobin. The influence of absorption by tissues and venous and capillary blood is minimized by measuring the *changing* absorption (hence pulse oximetry) that is due to haemoglobin in arterial blood alone. Reflectance pulse oximeters are also available, but are less widely used.

Pulse oximeters do not detect carboxyhaemoglobin and other haemoglobin variants and may thus give misleading results if these are present. For example, while the saturation may be normal (e.g. 97%), if 12% of the haemoglobin were to be in the form of carboxyhaemoglobin, the true percentage of oxyhaemoglobin would only be 85% of the total. Pulse co-oximeters that combine the two techniques and allow more reliable non-invasive measurement of SaO_2 have been developed.

Most blood gas analysers provide an estimate of SaO_2 based on measurements of $[H^+]$, PaO_2 and empirical equations. This approach relies on a number of assumptions that may not be valid in individual patients, with the result that these estimates can vary significantly from measured values, particularly if abnormal haemoglobins (e.g. carboxy-, methaemoglobin) are present. Direct measurements are to be preferred. Blood gas analysers may also provide a value for arterial oxygen content, but as with saturation, these are only estimates, not true measurements.

Detection of tissue hypoxia

Although the accumulation of lactic acid is a consequence of severe tissue hypoxia, the development of hyperlactataemia is a relatively late phenomenon, and by the time it is detectable, hypoxic tissue damage may already have occurred. Furthermore, it can occur for other reasons, for example impaired hepatic function, strenuous muscle contraction (not only in exercise but also due to rigors or convulsions) and as a result of improved perfusion of *previously* poorly perfused tissue ('washout' phenomenon).

The measurement of mixed venous oxygen saturation (SvO_2) is now widely used in the assessment of the critically ill. SvO_2 can be measured either in vitro in a blood sample taken through a pulmonary artery catheter or in vivo using a catheter containing fibre-optic bundles, which transmit light of appropriate wavelength to the blood and transmit reflected light back to

FIGURE 5.9 ■ Oxygen delivery to, and consumption by, tissues. Normally, consumption is independent of delivery; when delivery falls below a critical level, it results in decreased consumption.

a measuring device. It reflects the difference between arterial oxygen supply and tissue consumption. SvO_2 is normally of the order of 75%, but frequently falls to 50% or less when there is anaerobic metabolism, although such a fall can also be due to appropriately increased tissue uptake of oxygen or to a decrease in cardiac output. Because the measured SvO_2 is effectively a mean value of venous blood from all tissues, it can be affected by changes in the relative distribution of blood between different tissues. Measurements of SvO_2 can be misleading; in severe sepsis, reduced tissue oxygenation is sometimes associated with a high SvO_2 , as a result of impaired oxygen extraction and local arterio-venous shunting.

Oxygen delivery to tissues (approximately 16 mL/kg body weight/min at rest) normally exceeds demand, so that if delivery falls demand may still be met and consumption be independent of supply. However, if supply falls below a critical level (approximately 8 mL/kg per min), oxygen consumption becomes supply dependent (Fig. 5.9). If this occurs, it may be possible to improve oxygenation by the use of inotropes or red cell transfusion (to improve supply) or sedation (to reduce consumption).

Management of respiratory failure

It is beyond the scope of this book to discuss this topic in detail. Appropriate measures, depending on the cause, may include treatment of any airways obstruction, infection or pulmonary oedema, increasing FiO_2 , improving alveolar hypoventilation to decrease $PACO_2$, using inotropic drugs to stimulate cardiac output, increasing the oxygen-carrying capacity of the blood by red cell transfusion and the use of measures to increase tissue perfusion or reverse the effects of toxins. Hypophosphataemia is a sometimes unrecognized cause of respiratory muscle weakness, especially in the critically ill, as is malnutrition. In patients with chronic hypercapnia who are hypoxaemic, it has long been thought that increasing the FiO_2 is potentially dangerous. The rationale for this notion

is that acquired insensitivity of the respiratory centre to carbon dioxide can cause hypoxaemia to be providing the major stimulus to respiratory effort, and that its abolition would lead to respiratory arrest. However, hypoxaemia is a greater threat to life than hypercapnia, and this danger is now thought too have been exaggerated.

There are many techniques for improving alveolar hypoventilation, including the provision of invasive respiratory support through the use of a mechanical ventilators or even extracorporeal oxygenation techniques. Ventilators may be used in a variety of modalities, for example to take over completely a patient's breathing (e.g. when there is paralysis of the respiratory muscles or in deep coma leading to absent or poor respiratory effort) or to provide assistance to inspiratory efforts initiated by the patient. However, mechanical ventilation, although a potentially life-saving technique in critical hypoxia, is not without its disadvantages, including impaired cardiac filling (and hence a decrease in cardiac output); too rapid a fall in P_{aCO_2} ; depressing the normal respiratory drive; dilutional hyponatraemia due to inappropriate anti-diuresis, and a risk of mechanical damage to the airways and lungs (which may already be damaged). Oxygen in high concentrations is potentially toxic, and the lowest concentration compatible with reversing and preventing hypoxia should be used.

Ventilatory support is not synonymous with invasive mechanical ventilation. Patients able to breathe spontaneously may be helped by the maintenance of continuous positive airways pressure (CPAP) through the use of tight-fitting nasal or facial masks. The increased pressure aids gas entry during inspiration and reduces airways collapse during expiration.

CONCLUSION

Disorders of hydrogen ion metabolism and of tissue oxygenation are frequently encountered in clinical practice and may coexist, often because of a common aetiology,

but sometimes because of a direct effect of one upon the other. For both groups of disorders, a sound understanding of the physiological principles governing homeostasis in normal individuals is essential for correct diagnosis and effective management. These principles are essentially simple, and pertain no matter how complex any particular disturbance may appear.

APPENDICES 121

CALCIUM METABOLISM

Biological role of calcium

Calcium is a divalent cation with multiple roles in vertebrate physiology, which can be grouped as either structural or metabolic. Its structural role is in the skeleton where calcium deficiency leads to skeletal disease, either in the form of osteoporosis or osteomalacia. Its metabolic roles are more numerous.

The extracellular concentration of calcium ions influences the threshold for nerve action potentials, a high calcium raising the threshold and a low calcium having the opposite effect. The extracellular calcium concentration appears to alter the gating of sodium and potassium channels, possibly the result of calcium ions being attracted to and 'screening' the negative charge on the cell surface in the region of these channels.

Calcium has a key role in intracellular signalling. The depolarization of nerve or muscle cells, or the binding of a hormone or cytokine to its receptor on the surface of other types of cell, results in an increase in cytosolic calcium concentration via either one or both of two mechanisms: the influx of calcium through plasma membrane channels and the release of calcium from intracellular stores (e.g. the sarcoplasmic or endoplasmic reticulum). The latter pathway depends on receptor-activated hydrolysis of inositol phospholipids in the plasma membrane, leading to the release of inositol trisphosphate into the cytosol. This compound binds to a receptor on the endoplasmic reticulum resulting in the release of calcium into the

cytosol. The regulation of a variety of cell functions can then follow, some enzymes being directly affected by the cytosolic calcium concentration (e.g. protein kinase C) and others indirectly by the calcium receptor protein, calmodulin. These pathways are integral to muscle contraction, neuroendocrine secretion, cell metabolism and growth.

Distribution of calcium

The total body calcium in a human adult is approximately 1 kg, 99% of which is contained in the skeleton. Approximately 1% of skeletal calcium is freely exchangeable with calcium in the extracellular fluid (ECF). Calcium ions diffuse freely throughout the extracellular space, where their concentration is approximately 1.2 mmol/L. The plasma *ionized* calcium concentration is the same, but the plasma *total* calcium is approximately two-fold higher because of protein binding of calcium. Calcium also forms complexes with phosphate, citrate and bicarbonate in plasma and interstitial fluid (Table 6.1). It is the ionized calcium concentration that is physiologically important and closely regulated.

Calcium is principally an extracellular ion; cytosolic concentrations are of the order of 10^{-4} to 10^{-3} mmol/L. The low intracellular calcium concentration is necessary for calcium to function as an intracellular messenger. It is maintained by calcium pumps and exchangers on cell membranes. The endoplasmic reticulum and the mitochondria also have the capacity to remove calcium from the cytosol.

Total (2.2–2.6 mmol/L)	100

Calcium fluxes

Three principal organs are involved in the body's handling of calcium: the gastrointestinal tract, bone and the kidneys (Fig. 6.1).

Gastrointestinal tract

Intestinal absorption of calcium is mediated by two mechanisms. One is an active transcellular process, regulated by calcitriol (1,25-dihydroxyvitamin D; $1,25(\text{OH})_2\text{D}$) in the duodenum. This involves uptake of calcium into the enterocyte by TRPV6 (membrane calcium channel transient receptor potential cation channel, subfamily V, member 6), followed by intracellular binding of calcium to the calcium-binding protein CaBP-9k, then energy-dependent transport of the calcium across the basolateral membrane via PMCA1b, an alternatively spliced transcript of plasma membrane Ca^{2+} -ATPase. 1,25-Dihydroxyvitamin D increases gene expression of TRPV6 and CaBP-9k, thus increasing

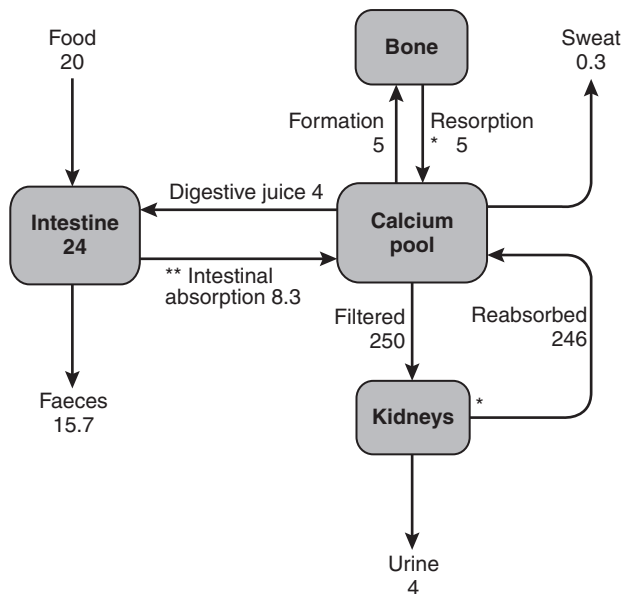

FIGURE 6.1 ■ Representative calcium fluxes (mmol/24h) in a healthy adult (70kg body weight) in zero calcium balance. The rapid exchange of calcium on bone surfaces and the exchange in soft tissues are not illustrated in this diagram. The major sites of action of parathyroid hormone (*) and 1,25(OH)₂D (**) are indicated. (Modified from Wilkinson R. Absorption of calcium, phosphorus and magnesium. In: Nordin B E C (ed). Calcium, phosphorus and magnesium metabolism. Edinburgh: Churchill Livingstone; 1976, with permission).

calcium absorption. Calcium is also absorbed passively throughout the small intestine and possibly in the colon. Because the duodenum is relatively short compared to the rest of the small bowel, it may account for less than half of the calcium absorbed at normal dietary intakes, despite its greater absorptive capacity per unit length. At low calcium intakes, active absorption predominates, but this is saturable, and at higher intakes, the change in net absorbed calcium in relation to any change in intake is relatively small and mediated by passive paracellular absorption.

The gut not only absorbs calcium but also secretes it in the digestive juices. The unabsorbed portion of this secreted calcium (approximately 2–3 mmol/24h) is known as the endogenous faecal calcium. Thus at very low intakes, the absorbed dietary calcium will be less than that lost from secretion in digestive juice and the net calcium absorption will be negative. Net calcium absorption is positive in healthy adults when their daily calcium intake is greater than 5 mmol.

The absorption of calcium is influenced by other dietary constituents. The presence of anions such as phosphate, oxalate (found in some fruit and vegetables) and phytate (found in some unrefined cereals) diminishes calcium solubility and thus net absorption. Gastrointestinal absorption of calcium tends to decline with age, but is increased during pregnancy and lactation. The principal regulator of intestinal absorption is 1,25(OH)₂D, and so either deficiency or excess of this hormone is associated with parallel changes in calcium absorption.

The average calcium intake of healthy adults consuming a Western diet is about 20 mmol/day, of which 20–40% is absorbed. The principal source of calcium in the Western diet is dairy products. There are significant amounts of calcium in some green vegetables such as spinach, though the bioavailability is lower.

Kidneys

The ionized and complexed fractions of plasma calcium are filtered at the glomeruli, amounting to approximately 250 mmol/24h. Of this, ~98% is reabsorbed, mostly in the proximal tubules. Calcium reabsorption in the proximal tubules is through a paracellular, therefore passive, process, which is closely linked with that of sodium and does not appear to be hormonally regulated. The fine-tuning of calcium excretion occurs in the distal parts of the nephrons where ~15% of the filtered load is reabsorbed. This section consists of the distal convoluted tubules, the connecting tubules and the initial portion of the cortical collecting ducts. In these distal sites, calcium reabsorption is active and occurs against an electrochemical gradient.

Active calcium reabsorption is a multistep process with initial passage of Ca^{2+} across the luminal membrane through the epithelial channel TRPV5 (membrane calcium channel transient receptor potential cation channel, subfamily V, member 5), then cytosolic diffusion bound to vitamin D-sensitive calcium-binding proteins (calbindins), and finally active extrusion across the opposite basolateral membrane by a Na^+ , Ca^{2+} -exchanger (NCX1)

and/or Ca^{2+} -ATPase (PMCA1b). This active calcium reabsorption is subject to hormonal regulation – principally by parathyroid hormone (PTH) and extracellular calcium itself, but possibly also by $1,25(\text{OH})_2\text{D}$, calcitonin, oestrogens and androgens.

Urine calcium excretion is increased in subjects consuming a high protein diet, because of acid production in the metabolism of sulphur-containing amino acids and sequestration of calcium by sulphate in the urine, resulting in inhibition of calcium reabsorption. Sodium intake can also influence calcium excretion by affecting proximal tubular sodium and calcium reabsorption (increased sodium intake increasing calcium excretion). Other factors that increase renal tubular calcium reabsorption are hypovolaemia, alkalosis and thiazide diuretics, whereas volume expansion, acidosis and loop diuretics (e.g. furosemide) have the opposite effect.

Bone

In the mature adult, the movement of calcium into bone equals its rate of efflux and bone mass remains constant. The situation is different in both growth and senescence. In spite of this constancy of adult bone mass, there is an active exchange of calcium between bone and the ECF. This can take place as a result of bone remodelling (see Chapter 31), or it can be accomplished by a process of mineral exchange between bone and the ECF, without local changes in bone matrix. Bone remodelling accounts for the changes in bone density that take place with ageing or disease. In the healthy adult, about 5% of the entire skeleton is remodelled in one year. In contrast, radioisotope studies have indicated that 1–2% of total body calcium can be exchanged between the bone and ECF over a period of several days. The precise mechanisms of this exchange and the factors influencing it are not known, but the quantities of calcium involved suggest that it may be an important part of normal calcium homeostasis.

Calcium losses in sweat are in the order of 0.3 mmol/24h. Breast milk has a high calcium content (~7.5 mmol/L) and a breast-feeding woman can lose 4–8 mmol/24h in her milk.

Regulation of calcium metabolism

Plasma calcium concentration is principally controlled by PTH and $1,25(\text{OH})_2\text{D}$. Calcitonin may also be regarded as a calcitropic hormone, although it has no clearly defined physiological function in humans. Many other hormones, growth factors and cytokines can influence bone metabolism.

Parathyroid hormone

Parathyroid hormone is an 84-amino acid, single-chain polypeptide secreted by the parathyroid glands. The gene is on chromosome 11 and consists of three exons encoding a peptide of 115 amino acids (pre-pro-PTH), which is cleaved to produce pro-PTH (90 amino acids) and subsequently the mature peptide (84 amino acids), before secretion. Most of the biological activity of PTH appears to reside in the 34 amino acids at the N-terminal end of the peptide.

The principal regulator of PTH secretion is the ECF ionized calcium concentration: low concentrations stimulate secretion and high concentrations inhibit it. This regulation is mediated by the calcium sensing receptor (CaSR), a cell membrane-bound, G-protein-coupled receptor. The relationship between PTH secretion and ionized calcium concentrations is not linear. Marked hysteresis is evident from experiments where ionized calcium concentrations are raised or lowered. The PTH concentration at any given concentration of plasma ionized calcium is lower when the ionized calcium concentration is rising than it is when ionized calcium is falling (Fig. 6.2). Plasma PTH concentrations exhibit a diurnal variation. They are stable during the afternoon and evening, but then rise by about 50% to peak at around 02.00 h and subsequently fall to values approximately 50% below afternoon values around 09.00 h. The zenith to nadir difference (in healthy men) is ~2.3 pmol/L, using an intact PTH assay.

Many other factors have been shown to influence PTH secretion, including $1,25(\text{OH})_2\text{D}$, adrenergic agonists, prostaglandins and magnesium, but whether any of these are physiologically important is debatable. Severe magnesium deficiency can produce a state of reversible hypoparathyroidism.

Parathyroid hormone binds to cell surface receptors in its target tissues. The PTH receptor has seven transmembrane domains, an extensive extracellular domain involved in hormone binding and an intracellular domain regulating intracellular signalling. In its two principal target tissues, bone and kidney, this results in activation of both adenylate cyclase (with production of cyclic adenosine

FIGURE 6.2 ■ Mean concentrations of plasma intact PTH in relation to plasma ionized calcium concentration in response to infusions of citrate (■) and calcium gluconate (●), and during recovery from hypocalcaemia (□) and hypercalcaemia (○). For any given ionized calcium concentration, the PTH concentration is lower when the ionized calcium is rising than when it is falling. (Data from Conlin P R et al. *Journal of Clinical Endocrinology and Metabolism* 1989; 69:593–599, with permission of the Endocrine Society).

monophosphate, cAMP) and phospholipase C (with production of inositol trisphosphate) and subsequent mobilization of intracellular calcium.

In bone, PTH receptors are present on cells of osteoblastic lineage. The osteoblasts in turn regulate osteoclast maturation through production of RANKL (receptor activator of nuclear factor κ -B ligand), which binds to the receptor, RANK, on pre-osteoclasts, leading to their maturation to osteoclasts. This process is modulated by osteoblast production of osteoprotegerin (OPG), which can also bind RANK-ligand, thus reducing its binding to RANK and so the stimulation of osteoclastogenesis.

Parathyroid hormone has three principal actions on the kidneys. It reduces proximal tubular reabsorption of phosphate, increases distal tubular reabsorption of calcium and increases the activity of the 25-hydroxyvitamin D 1α -hydroxylase enzyme in proximal tubular cells. It also decreases proximal reabsorption of bicarbonate, leading to a mild hyperchloraemic acidosis in states of PTH excess.

Measurement of circulating parathyroid hormone.

The development of assays for PTH has greatly simplified the investigation of patients with abnormal plasma calcium concentrations, but these assays do have limitations. The parathyroid gland secretes both the intact 84-amino acid peptide and inactive PTH fragments. Hepatic and renal metabolism of intact PTH results in the appearance of mid-region and carboxy-terminal peptides in the circulation. In vivo, the principal biologically active peptide is intact parathyroid hormone, which is present at a low concentration (1–5 pmol/L) and has a short half-life (2–4 min). However, mid-molecule and carboxy-terminal fragments have significantly longer half-lives and accumulate in concentrations 5–20 times greater than that of the intact peptide. These inactive fragments are cleared by the kidneys and their concentrations increase substantially in the presence of renal insufficiency. Although these fragments are not biologically active, they may be immunoreactive, if they cross-react with the particular antibodies used in the immunoassay. Assays that detect inactive fragments, therefore, report higher PTH concentrations than those that detect the intact molecule.

In recent years, two-site and immunoassays of 'intact' PTH, which purportedly measure only the biologically active intact peptide, have been widely used. However, there is evidence that these first-generation assays for intact PTH also detect non-(1–84)-PTH peptides, in particular PTH 7–84, which may have different biological actions from the full-length peptide. Assays based on antibodies directed at the first four amino acids of PTH (second-generation intact PTH assays) reveal that non-(1–84)-PTH peptides account for about 15% of circulating immunoreactive PTH (as detected by first-generation assays) in healthy patients, and at least 30% in patients with either primary or secondary hyperparathyroidism. There is also evidence that some non-intact peptides might be biologically active, possibly antagonizing the actions of the intact hormone. Whether assays based on antibodies directed at the extreme N-terminus of PTH offer important clinical advantage in the management of either primary hyperparathyroidism or renal bone disease

over the widely available first-generation intact PTH immunoassays remains uncertain.

Both mid-molecule and intact PTH assays show an increase in reference values with age, though this is more marked for the mid-molecule assays because of increased fragment accumulation secondary to the age-related decline in renal function. Because of the effect of renal function on measurements using mid-molecule and carboxy-terminal PTH assays, their interpretation must always take into account the patient's estimated GFR. Owing to the heterogeneity of PTH immunoassays currently in use, it is important that laboratories use assay-specific data for reference ranges and the ranges of values to be expected in hyperparathyroidism, hypercalcaemia of malignancy, hypoparathyroidism and renal disease. Failure to do so may result in inappropriate management of patients with renal disease.

The action of PTH on the kidney causes cAMP to appear in the urine. 'Nephrogenous' cAMP has been used in the past as a surrogate measure of PTH. Its current use is limited to the evaluation of PTH resistance (see [Appendix 6.3](#), below).

Classification of hyperparathyroidism. Increases in plasma concentrations of PTH are seen in a variety of circumstances. It is useful clinically to distinguish conditions in which the increased secretion of PTH is a normal physiological response to hypocalcaemia (secondary hyperparathyroidism) from those in which hypersecretion of PTH is the principal abnormality (primary hyperparathyroidism). If secondary hyperparathyroidism persists over long periods then the parathyroids can become hyperplastic. A gradual rise in plasma calcium accompanies this change and overt hypercalcaemia can develop. This is known as tertiary hyperparathyroidism, and arises chiefly in long-term dialysis patients, but it has also been described in patients with malabsorption syndromes. This classification is unsatisfactory in some respects. For example, the kidney transplant recipient with hypercalcaemia due to hyperparathyroidism that developed while on dialysis is difficult to categorize.

An alternative classification, which has the attraction of being more closely related to treatment stratagems, is to describe hyperparathyroidism in relation to the prevailing plasma calcium concentration. Thus, hyperparathyroidism can be described as hypocalcaemic, normocalcaemic or hypercalcaemic.

Vitamin D

Synthesis and metabolism. Vitamins are defined as essential organic compounds that the body cannot synthesize, and are therefore a vital component of the diet. The term 'vitamin D' is a misnomer as the majority of vitamin D is synthesized in the skin by the action of ultraviolet light on 7-dehydrocholesterol ([Fig. 6.3](#)). This produces cholecalciferol (vitamin D₃). Vitamin D is present in a variety of foodstuffs. It can be added to food in the form of ergocalciferol (vitamin D₂ – an additive to margarine and some breakfast cereals and, in the USA, to milk) or may occur naturally in animal products in the form of cholecalciferol. Fish oils are the richest dietary source of cholecalciferol.

FIGURE 6.3 ■ A summary of vitamin D metabolism. Factors stimulating (+) or inhibiting (–) metabolic conversions are indicated. All the dihydroxylated metabolites of renal or hepatic origin are further metabolized before excretion. Ultimately, most vitamin D is excreted through the bile into the faeces, in the form of inert metabolites. FGF23, fibroblast growth factor 23; GH, growth hormone.

In most respects, these two forms of vitamin D have similar metabolism and action. The calciferols are fat soluble and large quantities can be stored in adipose tissue. They are virtually without biological activity unless they have been hydroxylated. Hydroxylation by the enzyme vitamin D 25-hydroxylase (CYP2R1), takes place in the liver producing 25-hydroxyvitamin D (25(OH)D, calcidiol), which is the principal circulating metabolite and the prohormone for 1,25(OH)₂D (calcitriol). The dependence on dermal synthesis for provision of vitamin D is well illustrated by the marked variation in plasma 25(OH)D concentrations through the year in non-tropical areas of the world, where values are significantly higher in summer and autumn than in winter and spring. The vitamin D metabolites circulate in plasma bound to an α-globulin, vitamin D-binding protein and, to a lesser extent, to albumin (Table 6.2).

Most of the circulating 25(OH)D is metabolized in the liver via intermediates such as 23,25(OH)₂D and 25,26(OH)₂D into inactive metabolites that are excreted into the bile. A small proportion of circulating 25(OH)D undergoes further hydroxylation in the cells of the

proximal renal tubules to produce either 1,25(OH)₂D or 24,25(OH)₂D (secalciferol). The principal active metabolite of vitamin D is 1,25(OH)₂D. Although circulating concentrations of 24,25(OH)₂D are normally ten times greater than those of 1,25(OH)₂D, it has no definite physiological role.

In contrast to hepatic 25-hydroxylation, renal 1α-hydroxylation is closely regulated, being enhanced by low circulating concentrations of phosphate and 1,25(OH)₂D, and by high concentrations of PTH, and suppressed by high concentrations of the bone-derived hormone fibroblast growth factor 23 (FGF23). When the plasma concentration of phosphate is high and PTH low, 1α-hydroxylase activity (enzyme CYP27B1) decreases and that of 24-hydroxylase (enzyme CYP24B) becomes greater. Other factors may also influence renal hydroxylation of vitamin D. In vitro, low calcium can stimulate 1α-hydroxylation independently of PTH, although whether this is significant in vivo is not known. Direct or indirect effects of growth hormone, prolactin, oestrogens and calcitonin have also been described.

1,25-Dihydroxyvitamin D is inactivated by the formation of more polar metabolites, which are excreted primarily into bile. Over 96% of all vitamin D is ultimately eliminated through the bile into the faeces. Since this excretion is largely in the form of inactive metabolites, it is doubtful if there is any enterohepatic recycling of physiological importance.

Although the kidneys are undoubtedly the major source of production of 1,25(OH)₂D, there is evidence from anephric haemodialysis patients that small quantities can be synthesized extrarenally. In pregnancy, 1,25(OH)₂D is synthesized in the placenta, and in a variety of granulomatous diseases (sarcoidosis, tuberculosis, berylliosis) the macrophages of the granulomata can also 1α-hydroxylate vitamin D. In these circumstances, the synthesis is substrate dependent, meaning that the more 25(OH)D that is available, the more 1,25(OH)₂D is synthesized.

Actions. Vitamin D metabolites act via a cytosolic receptor that is translocated to the nucleus where it regulates gene expression. The vitamin D receptor is similar in structure to the steroid and thyroid hormone receptors, having an amino-terminal domain, a central DNA-binding domain with ‘zinc fingers’ and a carboxy-terminal hormone-binding domain. 1,25-Dihydroxyvitamin D has an affinity for the vitamin D receptor that is approximately 1000 times greater than that of 25(OH)D, which in turn is an order of magnitude more potent than 24,25(OH)₂D. However, the circulating concentration of 25(OH)D is substantially greater than that

TABLE 6.2 Circulating concentrations of vitamin D metabolites

Metabolite	Concentration	% Bound to DBP ^a	% Bound to albumin	% Free
Calciferol	2.5–5.0 nmol/L			
25-hydroxyvitamin D	50–125 nmol/L ^a	88	12	0.03%
1,25-hydroxyvitamin D	50–150 pmol/L ^b	85	15	0.5%
24,25-hydroxyvitamin D	1.3–3.8 nmol/L			

^aHigher in summer/autumn than winter/spring; ^bhigher in pregnancy and during puberty.

^cVitamin D binding protein. Interconversions: 10 nmol ≡ 4 μg ≡ 160 international units.

of $1,25(\text{OH})_2\text{D}$, so it is possible that this metabolite has some biologically significant effect.

The principal site of action of $1,25(\text{OH})_2\text{D}$ is the intestine, where it stimulates the production of the calcium channels TRPV6 and TRPV5, and the calcium-binding protein CaBP-9k. In bone, it is a potent osteolytic factor *in vitro*, acting through osteoblast RANK-ligand production to bring about fusion of osteoclast precursors to form mature osteoclasts. The physiological importance of its bone resorbing effect is uncertain. $1,25$ -Dihydroxyvitamin D also has direct effects on the liver and kidney. In the liver, it enhances the production of inactive $25(\text{OH})\text{D}$ derived metabolites that are excreted in the bile, and in the kidney it stimulates the $24,25$ -hydroxylase – both these mechanisms protect against chronically high $1,25(\text{OH})_2\text{D}$ concentrations.

Several cells and tissues other than those involved in calcium and phosphorus metabolism, including macrophages, activated T-lymphocytes, the placenta and keratinocytes, express vitamin D receptors and/or the 1α -hydroxylase enzyme, suggesting that their functions might be regulated by components of the vitamin D system. Many malignant cells also express the vitamin D receptor. There is evidence that $1,25(\text{OH})_2\text{D}$ decreases the growth of several cancer cell lines, and slows or prevents the growth and/or development of cancers and autoimmune diseases in rodents. Genetic ablation of vitamin D signaling, by deleting the genes encoding either the vitamin D receptor or 1α -hydroxylase, leads to renin-dependent hypertension and an increased propensity to tumour development. The consequences of complete absence of vitamin D signaling in rodents, however, are likely to be very different from minor decreases in $25(\text{OH})\text{D}$ in humans. At present, there is no robust clinical trial evidence that vitamin D supplements or bioactive vitamin D analogues favourably influence important outcomes such as cancer, hypertension or autoimmune diseases. Accordingly, vitamin D supplements are not indicated in the management of non-skeletal diseases.

Synthetic vitamin D analogues. A variety of $1,25(\text{OH})_2\text{D}$ analogues have been synthesized. 1α -Hydroxyvitamin D_3 (alfacalcidol) is rapidly metabolized by the liver into $1,25(\text{OH})_2\text{D}$ and, although having roughly half the potency of $1,25(\text{OH})_2\text{D}$ on a weight basis, is similarly useful in conditions where the 1α -hydroxylation step is impaired. A similar preparation, 1α -hydroxyvitamin D_2 (doxercalciferol) is also marketed. Other analogues such as $26,27$ -hexafluorocalcitril are more potent calcaemic agents.

A number of analogues with attenuated calcaemic properties have also been developed. Examples include calcipotriol (used in the treatment of psoriasis), paricalcitol (used in some countries in the treatment of hyperparathyroidism in chronic renal failure) and eldecalcitol (which has been investigated in osteoporosis). The divergent effects of these analogues on cell differentiation, PTH secretion and calcium homeostasis probably reflect pharmacokinetic differences rather than distinct $1,25(\text{OH})_2\text{D}$ -sensitive pathways, since there is no evidence that they act through different receptors.

Measurement of vitamin D metabolites. Measurements of $25(\text{OH})\text{D}$ and $1,25(\text{OH})_2\text{D}$ can be of value in clinical practice, though the indications for $1,25(\text{OH})_2\text{D}$ measurement are relatively few (e.g. obscure causes of hypercalcaemia). 25 -Hydroxyvitamin D is the best measure of vitamin D status. While its synthesis is dependent upon 25 -hydroxylation in the liver, even advanced liver disease does not seem to be a limiting factor in its production. Free concentrations are normal in most patients with cirrhosis, though total concentrations may be low because of associated hypoproteinaemia. $1,25$ -Dihydroxyvitamin D is present in concentrations only 1000th of those of its precursor (see Table 6.2). Its production is closely regulated and so is not tied to concentrations of its precursor, except in patients with severe vitamin D deficiency or in granulomatous disease. Renal disease has a major impact on its circulating concentrations, as do states of parathyroid over- or underactivity.

A variety of assays have been used in the past, and a number have been withdrawn from the market because of unsatisfactory performance characteristics. Cross-calibration of available assays has not always been within acceptable limits. The reference method uses liquid chromatography with tandem mass spectrometry (MS/MS), but as this is an expensive assay to run, many laboratories use immunoassays based on automated platforms. The acceptability of this compromise depends on the performance characteristics and calibration of the particular assay platform. Some of the commercially available assays have limited ability to measure $25(\text{OH})\text{D}_2$, which may be important when supplementation has been provided in the form of vitamin D_2 . It is evident that significant variation can occur in measurement of vitamin D metabolites, as a result both of differences between the available assays and in the implementation within individual laboratories.

Calcitonin

Calcitonin is a 32-amino acid peptide produced in humans in the parafollicular cells (C cells) of the thyroid gland. It contains a disulphide bridge and a proline-amide group at the C-terminus. Both of these and the full amino acid sequence are necessary for biological activity. It is metabolized in the kidneys and has a plasma half-life of approximately 5 min.

Secretion of calcitonin is stimulated by an increase in plasma calcium concentration and it is also released in response to a number of gut hormones (e.g. gastrin, glucagon, secretin, cholecystokinin-pancreozymin). It reduces plasma calcium concentration by a direct effect on osteoclasts, which have a cell surface calcitonin receptor linked to adenylate cyclase. It causes contraction of osteoclasts and an acute reduction in osteoclastic bone resorption. It also acts on the kidneys, where it decreases renal tubular reabsorption of calcium and phosphate.

Despite these clearly documented actions, its physiological significance is uncertain because its actions appear to be transient. Furthermore, chronic calcitonin deficiency (as in patients post-thyroidectomy) or excess (as in medullary carcinoma of the thyroid) do not result in significant changes in bone or mineral metabolism.

There are a number of different forms of calcitonin in the circulation, many of which are not biologically active. Thus, different immunoassays may detect different molecular species. The measurement of calcitonin does not form a significant part of the clinical evaluation of calcium metabolism, but it is an important tumour marker for medullary carcinoma of the thyroid.

Procalcitonin. Procalcitonin, the 116 amino acid peptide precursor of calcitonin, is produced not only by thyroid C-cells but also by the neuroendocrine cells of the lung and the intestine. The amount of procalcitonin produced by the cells of the lung and the intestine increases in response to proinflammatory stimuli, especially of bacterial origin. Measurement of procalcitonin can be used as a marker of severe sepsis and generally correlates well with the degree of sepsis.

Other hormones

A number of hormones influence calcium and bone metabolism *in vitro*, in normal physiology or in specific pathological circumstances. The oestrogen deficiency that develops at the time of the menopause results in increases in cytokine production which leads to increases in bone resorption. Direct effects of oestrogen on osteoclasts and on osteoblastic production of RANKL and osteoprotegerin are also important. Calcium absorption in the gut and reabsorption in the kidney are both reduced, and plasma calcium concentrations rise. These changes lead to a reduction in bone mass, but are reversible with oestrogen replacement therapy. Similarly, testosterone deficiency in men predisposes to osteoporosis, partly through loss of its direct anabolic effects on muscle and on osteoblasts, and partly through diminished conversion to oestrogen. Glucocorticoids can cause marked osteoporosis. These hormones act at a number of sites and reduce osteoblastic activity, induce apoptosis of osteoblasts and osteocytes, reduce intestinal calcium absorption, increase urinary calcium loss and probably increase bone resorption. In children, glucocorticoid excess causes marked growth retardation. Glucocorticoid deficiency may be associated with hypercalcaemia.

Growth hormone accelerates linear growth in children and increases plasma phosphate concentration by increasing renal tubular reabsorption of phosphate. These effects are probably mediated by growth hormone-induced changes in the production of insulin-like growth factor 1 (IGF-1, somatomedin C). There is controversy as to the effect of the growth hormone–somatomedin axis on bone density.

Subjects with high total body fat mass have been shown to have higher bone densities. This appears to be mediated by a number of hormonal mechanisms. Insulin is anabolic to bone *in vitro*, and obesity is usually associated with hyperinsulinaemia. At least two other anabolic peptides, amylin and preptin, are co-secreted with insulin and may contribute to the relationship. Leptin has been shown *in vitro* to stimulate osteoblast growth directly and to inhibit osteoclast development, so it is also likely to be an important factor. In contrast, when leptin is administered into the third ventricle of the brains of

experimental animals, there is a profound reduction in appetite and fat mass, with resultant loss of bone mass. There is some evidence that central leptin administration activates the sympathetic nervous system and that this might also contribute to bone loss.

Thyroid hormones are potent stimulators of bone resorption, and thyrotoxicosis can be associated with decreased bone density and hypercalcaemia. Prostaglandins of the E series also stimulate bone resorption *in vitro*. Parathyroid hormone-related peptide (PTHrP) is a 141-amino acid peptide that is responsible for a large proportion of cases of humoral hypercalcaemia of malignancy. Eight of the 13 amino-terminal amino acids are identical to those found in PTH itself, and it appears to act on the PTH receptor. There is evidence for its production in both the fetal parathyroids and in the lactating breast, raising the possibility that it has a physiological role in these contexts. A carboxy-terminal fragment of PTHrP may act as an inhibitor of osteoclastic bone resorption. Direct measurement of PTHrP by immunoassay is possible, but is rarely necessary in clinical practice, since the malignant disease underlying humoral hypercalcaemia is frequently evident at the time that the elevated plasma calcium is recognized.

Biochemical assessment of calcium metabolism

In addition to the assays of calcitropic hormones discussed above, estimation of calcium concentrations in the circulation and of calcium fluxes in the gut and kidney are of value in assessing patients with disorders of calcium metabolism.

Plasma calcium

As indicated previously, total plasma calcium comprises protein-bound, complexed and ionized fractions. Thus changes in plasma protein concentrations or acid–base status will affect the relationship between ionized and total calcium. Total serum calcium remains the most commonly measured index. It should always be accompanied by a measurement of the serum albumin concentration from which a ‘corrected serum calcium’ can be calculated:

$$\begin{aligned} \text{corrected serum concentration (mmol/L)} = \\ \text{measured calcium concentration} + \\ 0.02(40 - \text{albumin concentration (g/L)}) \end{aligned}$$

Laboratories should derive their own correction formulae based on their own particular calcium and albumin assays, as both the mean normal albumin concentration (assumed here to be 40 g/L) and the amount of calcium bound to each gram of albumin (assumed here to be 0.02 mmol/g) can vary. The corrected calcium is only an approximation, and when there are significant dysproteinaemias or acid–base disturbances, ionized calcium should be measured directly. This measurement is also useful in patients to whom large quantities of citrated blood products have been administered, since these individuals have an increased proportion of plasma calcium complexed to citrate. Ionized calcium is

FIGURE 6.4 ■ Diurnal variation in total plasma calcium (dotted line), ionized calcium (solid line) and phosphate (broken line) in healthy subjects. (From Markowitz M et al. 1981 *Science* 213:672–674, with permission from the American Association for the Advancement of Science).

measured using an ion-selective electrode. Specimens must be obtained anaerobically to minimize changes in specimen pH. The pH is also usually measured and results adjusted to a pH of 7.4.

There are diurnal variations in both total and ionized plasma calcium concentrations (Fig. 6.4). Significant changes in plasma calcium take place following the ingestion of a calcium-rich meal or of calcium supplements. Posture and the application of tourniquets, both of which can influence plasma protein concentrations, may also influence total calcium estimations. Total plasma calcium rises significantly (by approximately 0.1 mmol/L) at the menopause.

Intestinal calcium absorption

This is not routinely measured in clinical practice, but knowledge of it is sometimes of value, e.g. in some patients with kidney stones and hypercalciuria. In the past, it was measured by metabolic balance, which required a period of 7–10 days as an inpatient, during which time subjects were given a diet with a constant calcium intake, and calcium absorption was estimated from precise measurements of faecal and urinary calcium output.

Calcium absorption can be measured with a variety of stable or radioisotope techniques in which an oral calcium load with a tracer is administered in the fasting state and absorption efficiency is estimated from the rate of appearance of the isotope in the blood. The size of the oral calcium load accompanying the isotope is important. Low doses reflect better the active duodenal transport, whereas high doses better reflect net intestinal absorption. The increment in urine calcium following the administration of a known calcium load has also been used as an index of calcium absorption (see Appendix 6.1, below). The clinical utility of these tests is limited and they are rarely used nowadays.

Urinary calcium

Calcium can be measured either in a 24 h urine or in urine collected after an overnight fast. In the latter instance, the subject empties the bladder on rising, has a glass of water and then collects the urine sample at any time between 30 min and 2 h later. In both instances, acid (usually 6 M hydrochloric acid) is added either before collection or subsequently, to prevent crystallization of calcium salts. Creatinine is usually measured on both 24 h and fasting urine samples – in the former case to allow assessment of completeness of collection and in the latter as a denominator in relation to which the concentration of calcium (and other urinary constituents) can be expressed.

The reference range for 24 h urine calcium is 1–7.5 mmol/24 h in men and 1–6.25 mmol/24 h in women. In the steady state, this reflects the absolute dietary intake of calcium and the net proportion absorbed from the intestine. Urine calcium excretion is usually increased with hypercalcaemia of any cause, and its measurement contributes little to the differential diagnosis of hypercalcaemia, except in the diagnosis of familial hypocalciuric hypercalcaemia.

Fasting urine calcium can be expressed as a simple molar ratio to creatinine (reference values 0.10–0.30 in adults). This is considered to be an index of bone resorption, but newer markers of bone resorption are preferred in clinical practice (see Chapter 31). If the calcium:creatinine ratio is multiplied by the plasma creatinine concentration, the resulting product is the calcium excretion per litre of glomerular filtrate (Ca_E). This is useful in assessing the contribution of abnormal renal tubular handling of calcium to disorders of plasma calcium homeostasis (see Appendix 6.2, below).

Indices of bone turnover

Disorders of plasma calcium are often accompanied by abnormalities of bone turnover, so assessment of bone turnover can be useful. These measures are discussed in more detail in Chapter 31.

Hypercalcaemia

Hypercalcaemia develops when the rate of entry of calcium into the ECF from bone and gut exceeds the capacity of the kidney to excrete it. Diminished excretory capacity can be the result of either increased renal tubular reabsorption (an important component, for example, in the hypercalcaemia of primary hyperparathyroidism and familial hypocalciuric hypercalcaemia) or of a reduction in glomerular filtration rate (in sarcoidosis, for example, hypercalcaemia is more frequently encountered in subjects with impaired renal function). However, hypercalcaemia itself can affect these processes, thus initiating a vicious cycle with worsening hypercalcaemia. By its actions on the kidney, hypercalcaemia leads to polyuria, volume depletion and thus to a reduction in glomerular filtration rate and enhanced proximal tubular reabsorption of sodium, which carries calcium with it. This situation, termed ‘dis-equilibrium hypercalcaemia’, is a medical emergency. It is important both to recognize this and to differentiate it from ‘equilibrium hypercalcaemia’ (e.g. due to mild

primary hyperparathyroidism or familial benign hypercalcaemia), where the plasma calcium remains stable.

Whether hypercalcaemia causes symptoms depends both upon the degree of elevation of plasma calcium and the rate at which it has risen. When plasma calcium is <3.0 mmol/L, a large proportion of patients are asymptomatic. The clinical features of severe hypercalcaemia are summarized in [Box 6.1](#).

Causes of hypercalcaemia

[Box 6.2](#) lists the most frequently encountered forms of hypercalcaemia.

Primary hyperparathyroidism. Primary hyperparathyroidism is the most common cause of hypercalcaemia presenting outside hospital. Prior to the advent of large automated analysers, it was regarded as a rare disease, but is now a common incidental finding. Its prevalence is approximately 1 per 1000 and it is most frequently diagnosed in the 6th decade of life, when it is two or three times as common in women as in men. To some extent, this can be explained by the postmenopausal rise in plasma calcium concentration. The normal distribution curve is shifted to the right and, therefore, a higher proportion of postmenopausal women must necessarily have plasma calcium concentrations above the upper limit of normal for younger people. In younger patients, the sex incidences are equal.

In 90% of patients, primary hyperparathyroidism is attributable to a single parathyroid adenoma, and most of the remaining cases are attributable to four gland hyperplasia, sometimes as a part of the multiple endocrine neoplasia (MEN) syndrome type 1 (see Chapter 41). This syndrome accounts for the majority of patients with familial hyperparathyroidism. Parathyroid carcinoma, which

BOX 6.2 Differential diagnosis of most frequently encountered forms of hypercalcaemia

Most common

Primary hyperparathyroidism

- Sporadic
- Familial (see [Table 6.3](#))

Malignant disease

- Humoral hypercalcaemia of malignancy (PTHrP)
- Widespread skeletal metastases (most commonly breast cancer)
- Haematological malignancy (multiple myeloma, adult T cell leukaemia/lymphoma)^a

Less common

- Granulomatous disease^a (e.g. sarcoidosis, tuberculosis, histoplasmosis, leprosy)
- Toxicity with vitamin D or its derivatives
- Persistent hyperparathyroidism after renal transplantation
- Severe thyrotoxicosis

Rarer causes of hypercalcaemia are summarized in [Table 6.4](#)

^aHypercalcaemia is typically steroid-responsive.

usually presents with severe hypercalcaemia and very high PTH concentrations, accounts for $<1\%$ of all cases.

Adenomatous primary hyperparathyroidism appears to have a clonal origin. Two genetic mechanisms have been elucidated ([Table 6.3](#)). The PTH gene is located on the opposite side of the centromere of chromosome 11 from the gene (*PRAD1*) that encodes cyclin D1, a proto-oncogene that regulates cell growth. In about 20% of sporadic parathyroid tumours, it has been shown that while one chromosome is intact, the other copy has undergone centromeric inversion, a rearrangement that places the PTH regulatory elements under the influence of cyclin D1, allowing deregulated parathyroid gland growth.

Germline mutations underlie several of the inherited syndromes that include primary hyperparathyroidism. The mutated gene in multiple endocrine neoplasia 1 (*MEN1*) is also located on chromosome 11, and encodes a protein, menin, that acts as a tumour suppressor. Rare instances have been reported of kindreds with germline *MEN1* mutations in which primary hyperparathyroidism is the only clinical feature. Primary hyperparathyroidism is less frequently (~20%) a feature of the MEN 2 syndromes, which result from activating mutations of the gene encoding the RET tyrosine kinase receptor. Germline mutations in the tumour suppressor gene *CDC73*, which encodes the protein parafibromin, causes the inherited disorder, hyperparathyroidism-jaw tumour syndrome. Somatic mutations in this gene are also present in a high proportion of sporadic parathyroid carcinomas.

Primary hyperparathyroidism may present with the symptoms of hypercalcaemia outlined in [Box 6.1](#), but frequently patients are symptom-free. The prevalence of osteoporosis is probably increased in patients with primary hyperparathyroidism, especially at skeletal sites enriched for cortical bone. The classic skeletal manifestations of

BOX 6.1 Clinical features and associations of hypercalcaemia

(Typically only present if hypercalcaemia is ≥ 3 mmol/L)

Neuropsychiatric

- Lethargy, depression
- Confusion, coma
- Hypotonia, hyporeflexia, muscle weakness

Gastrointestinal

- Anorexia, nausea, vomiting
- Abdominal pain
- Constipation
- Pancreatitis

Cardiovascular

- Electrocardiographic changes (reduced QT interval, prolonged PR interval)
- Arrhythmias

Renal

- Polyuria, polydipsia, volume depletion
- Reduced glomerular filtration rate
- Calculi, nephrocalcinosis

AD, autosomal dominant; AR, autosomal recessive; CaSR, calcium sensing receptor

primary hyperparathyroidism, which include subperiosteal phalangeal resorption, a 'salt and pepper' appearance in the skull and bone cysts ('brown tumours') of the long bones or jaw (collectively termed 'osteitis fibrosa cystica'), are features of severe, longstanding disease, and are now uncommon in the developed world. Approximately 15% of patients have renal complications in the form of nephrolithiasis or nephrocalcinosis.

Familial hypocalciuric hypercalcaemia. Familial hypocalciuric hypercalcaemia (FHH) (also known as benign familial hypercalcaemia) is an autosomal dominant condition in which mild hypercalcaemia with relative hypocalciuria is present throughout life. Patients with this disorder are most frequently heterozygous for inactivating mutations in the calcium sensing receptor (CaSR). The 'set-point' for PTH release is raised, and mild PTH-dependent hypercalcaemia results. The CaSR is also expressed in the renal tubules, where it regulates renal tubular calcium reabsorption in a PTH-independent fashion. The inactivating *CASR* gene mutation promotes inappropriately avid tubular calcium reabsorption in the face of hypercalcaemia, explaining the relative hypocalciuria. Patients with FHH are usually asymptomatic, although non-specific symptoms of lethargy and polydipsia have been observed in some instances. There may be an increased incidence of pancreatitis, but the frequency of nephrolithiasis and peptic ulcer disease is the same as in the general population. In most cases, the condition follows a benign course and the greatest danger to patients is being misdiagnosed as having adenomatous primary hyperparathyroidism and thus having inappropriate parathyroidectomy. Familial hypocalciuric hypercalcaemia accounts for about 2% of asymptomatic hypercalcaemia.

Neonatal severe primary hyperparathyroidism occurs in newborns who have inherited two inactivating *CASR* mutations – one from each parent. It presents as severe, life-threatening hypercalcaemia. Urgent total parathyroidectomy is indicated.

Hypercalcaemia of malignancy. Malignancy can result in hypercalcaemia by four general mechanisms:

- by the secretion into the circulation of factors that increase bone resorption and/or decrease urine calcium loss (humoral hypercalcaemia of malignancy, HHM)
- as a result of osteolytic metastases that lead to local bone destruction
- osteolysis from bone marrow infiltration in haematological disorders
- more rarely, accelerated conversion of plasma 25(OH)D to 1,25(OH)₂D by some haematological malignancies, leading to vitamin D-dependent hypercalcaemia.

Parathyroid hormone-related peptide is the main mediator of humoral hypercalcaemia of malignancy. It is synthesized and secreted by a number of tumours, particularly those of epithelial cell origin (e.g. squamous cell carcinoma of the bronchus, renal cell carcinoma, breast carcinoma) and produces biochemical changes similar to those of primary hyperparathyroidism, although the degree of hypercalcaemia is often more severe in HHM, and plasma 1,25(OH)₂D concentrations tend to be normal or low rather than increased.

Hypercalcaemia associated with osteolytic metastases is most commonly seen in advanced breast cancer, but can occur with other solid tumours that spread to bone. Hypercalcaemia is very common in some haematological malignancies, particularly multiple myeloma and acute human T cell leukaemia-lymphoma virus (HTLV)-1-associated disease. The bone destruction is mediated by

osteoclasts, activated by factors released by the tumour. A number of different cytokines have been implicated, including RANKL and TNF- α . In addition, bone formation may be impaired at sites of myelomatous skeletal disease, as a result of inhibition of Wnt signalling through the lipoprotein receptor-related protein 5 (LRP5). In contrast to the hypercalcaemia associated with metastases from solid tumours, hypercalcaemia associated with haematological malignancy typically responds rapidly to glucocorticoid treatment. In the rare cases of patients with hypercalcaemia associated with haematological malignancies that elaborate 1 α -hydroxylase, the hypercalcaemia also responds rapidly to glucocorticoid treatment.

Granulomatous disease. The macrophages in granulomata occurring in sarcoid tissue, pulmonary tuberculosis and berylliosis are capable of 1 α -hydroxylating 25(OH)D, independently of normal homeostatic regulation. The production of 1,25(OH)₂D is dependent on disease activity and circulating 25(OH)D concentrations. Thus, during the summer months, patients with active disease have increased intestinal calcium absorption. This is usually evident as hypercalciuria, but some patients, usually those with some pre-existing renal impairment, become hypercalcaemic. 1,25-Dihydroxyvitamin D production can be rapidly suppressed (and hypercalcaemia corrected) by glucocorticoids, chloroquine or ketoconazole.

Vitamin D toxicity. Excessive intake of vitamin D or its analogues can produce hypercalcaemia. This may be iatrogenic or the result of self-medication. On withdrawal of vitamin D, hypercalcaemia resolves. The rate of reversal

is much more rapid in patients intoxicated with alfalcidol or calcitriol than it is in patients intoxicated by calciferol. In the former instances, plasma calcium reverses with a half-time of 1–5 days, but in the latter, the half-time is of the order of 10–30 days. Women being treated with vitamin D or its analogues for hypoparathyroidism may become hypercalcaemic during lactation or after stopping exogenous oestrogen therapy.

The vast majority of adult hypercalcaemic patients (>98%) will have one of the above diagnoses, but there are rarer causes of hypercalcaemia (summarized in Table 6.4). Hypercalcaemia in dialysis and kidney transplant recipients is discussed in Chapter 31. Hypercalcaemia in infants and children is much less common than in adults, and a different range of diagnoses needs to be considered (Box 6.3).

Investigation of hypercalcaemia

Figure 6.5 sets out an approach to the investigation of hypercalcaemia. Having confirmed that true hypercalcaemia exists, a clinical assessment will in many cases, point to the appropriate diagnosis by revealing evidence of underlying diseases or medications that may be contributing. The next stage is biochemical assessment, in which PTH measurement is pivotal. The currently available assays of intact PTH will usually produce either an elevated or suppressed value in hypercalcaemic subjects, thus establishing or excluding the parathyroids as the cause of the hypercalcaemia.

A normal intact PTH concentration in the face of an elevated plasma calcium may be consistent with either primary hyperparathyroidism or with FHH. The ratio of calcium clearance to creatinine clearance in a 2 h fasting

TABLE 6.4 Uncommon causes of hypercalcaemia

Cause	Probable mechanisms	Other biochemical features (plasma)	Treatment	Comments
Thiazides	↑ Renal tubular reabsorption	–	Withdrawal	Often coexisting primary hyperparathyroidism
Lithium	? Enhanced sensitivity to PTH or ↑ PTH secretion	–	Withdrawal	Often coexisting primary hyperparathyroidism
Oestrogens/tamoxifen	↑ Bone resorption	–	Transient hypercalcaemia only	In women with skeletal metastases from breast cancer
Vitamin A toxicity	↑ Bone resorption	–	Withdrawal	Also described with retinoic acid derivatives
Immobilization	↑ Bone resorption	↓ [PTH], ↑ [phosphate]	Mobilize or inhibitors of bone resorption	Occurs in individuals with high bone turnover rate (e.g. tetraplegia, extensive Paget disease)
Acute kidney injury (AKI) – diuretic phase	↑ Calcium absorption	↑ [1,25(OH) ₂ D]	Resolves spontaneously	Occurs in recovery phase of AKI induced by rhabdomyolysis
Multiple organ dysfunction/systemic inflammatory response syndrome	Unknown	? ↑ [1,25(OH) ₂ D]	Resolves spontaneously	Poor response to bisphosphonates
Islet cell tumours/phaeochromocytoma	? ↑ Bone resorption	? ↑ [PTHrP]	Surgery or inhibitors of bone resorption	–
Addison disease	↑ Renal tubular reabsorption	↓ [Na ⁺], ↑ [K ⁺]	Fluids, steroid replacement	–
Milk-alkali syndrome	↑ Calcium intake	–	Withdrawal	Often coexisting primary hyperparathyroidism

BOX 6.3 Causes of hypercalcaemia in infants and children**Hyperparathyroidism**

- Severe neonatal hyperparathyroidism (bi-allelic *CASR* mutations)
- Multiple endocrine neoplasia type 1
- Parathyroid carcinoma

Malignancy

- Acute leukaemia
- Solid tumours

Syndromic

- Williams–Beuren syndrome (microdeletion of contiguous genes on chromosome 7q11.23)
- Jansen syndrome (mutation of PTH/PTHrP receptor)

Vitamin D-related

- Iatrogenic
- Infantile hypercalcaemia (inactivating *CYP24B* mutations)
- Granulomatous disease (tuberculosis, sarcoidosis)

Immobilization**Miscellaneous**

- Hypophosphatasia (*TNSALP* mutations)
- Subcutaneous fat necrosis
- Congenital lactase deficiency
- Primary hyperoxaluria type 1

urine collection is useful in distinguishing between these two possibilities – in FHH the ratio is usually < 0.01. However, clear distinction between adenomatous primary hyperparathyroidism and FHH is not always possible on biochemical grounds. Studying family members and/or sequencing the *CASR* gene may be necessary.

If plasma PTH concentration is low, then a variety of other investigations can be pursued. The order in which these are undertaken will be determined by the clinical clues. Cancer-associated hypercalcaemia is almost always a late complication of the disease, which is therefore either known or readily diagnosed when the hypercalcaemia is recognized. A search for malignancy may include radioisotope bone scanning, chest and abdominal imaging and serum and urine protein electrophoresis. Assays for PTHrP are now available, but are rarely needed in the evaluation and treatment of hypercalcaemia. Plasma PTHrP concentrations are elevated in most patients with humoral hypercalcaemia of malignancy, and are low in healthy subjects (<2 pmol/L). Parathyroid hormone-related peptide concentrations are also increased in about half of women with lytic bone metastases from breast cancer, irrespective of whether they are hypercalcaemic. In difficult cases, measurement of 1,25(OH)₂D may be of value. Elevated concentrations are seen in granulomatous disease, some lymphomas and sometimes in primary hyperparathyroidism, and subnormal concentrations are usually found in HHM. Measurement of 25(OH)D will allow confirmation of vitamin D intoxication, but not if it is caused by 1 α -hydroxylated compounds such as alfacalcidol, calcitriol, paricalcitol or calcipotriol.

A number of investigations previously used in the differential diagnosis of hypercalcaemia have limited utility. Hypophosphataemia is a feature of both primary hyperparathyroidism and HHM, and phosphate concentrations tend to be increased in sarcoidosis and vitamin D toxicity or when there is renal impairment. Measurement of plasma chloride has been used because of the mild metabolic acidosis associated with primary hyperparathyroidism. While chloride concentrations do tend to be higher in primary hyperparathyroidism than in HHM, this measurement has very little clinical utility in individual patients. The same considerations apply to plasma magnesium concentrations. Although plasma magnesium is higher in FHH than in primary hyperparathyroidism, it is of limited diagnostic value. Since both PTH and PTHrP stimulate renal adenylate cyclase, measurement of cyclic adenosine monophosphate excretion has no discriminant value.

Skeletal radiology may be of help, showing myeloma deposits (that may be missed by bone scintigraphy) or showing evidence of other malignancy or revealing the changes of hyperparathyroidism. Occasionally, use is still made of the glucocorticoid suppression test (prednisolone 30 mg/day for a period of ten days). In primary hyperparathyroidism, no change in plasma calcium occurs, but in granulomatous disease, vitamin D intoxication and in haematological malignancies, a significant fall in plasma calcium usually occurs. The analysis of renal tubular calcium handling (see [Appendix 6.2](#), below) can provide information on the mechanisms underlying hypercalcaemia, but does not help to differentiate primary hyperparathyroidism from HHM.

In summary, measurement of intact PTH, accompanied by clinical history and examination and targeted radiological investigations will allow the cause of hypercalcaemia to be ascertained quite quickly in the vast majority of patients.

Treatment of hypercalcaemia

Specific details of the treatment of hypercalcaemia are beyond the scope of this text, but its principles will be reviewed. In patients with mild asymptomatic primary hyperparathyroidism, long-term follow-up has revealed stability of plasma calcium and renal function, and low rates of disease complications. Consequently, some authorities feel that no intervention is necessary in patients who have not had renal stones and are at low fracture risk, although this remains an area of controversy. Either medical treatment with bisphosphonates or surgical correction are effective treatments for improving bone mineral density in patients with primary hyperparathyroidism who are at increased risk of fracture. When definitive treatment is necessary, as in patients who develop urolithiasis or severe hypercalcaemia (>3 mmol/L), removal of the causative adenoma by an experienced surgeon is usually curative. Recurrence is rare, except patients in whom hyperparathyroidism is caused by multiglandular hyperplasia, as in the type 1 multiple endocrine neoplasia syndrome. Calcimimetic drugs, such as cinacalcet, which act as allosteric agonists of the CaSR present on the parathyroid chief cells, suppress PTH secretion and lower plasma calcium in PTH-dependent hypercalcaemia. Studies indicate that treatment with

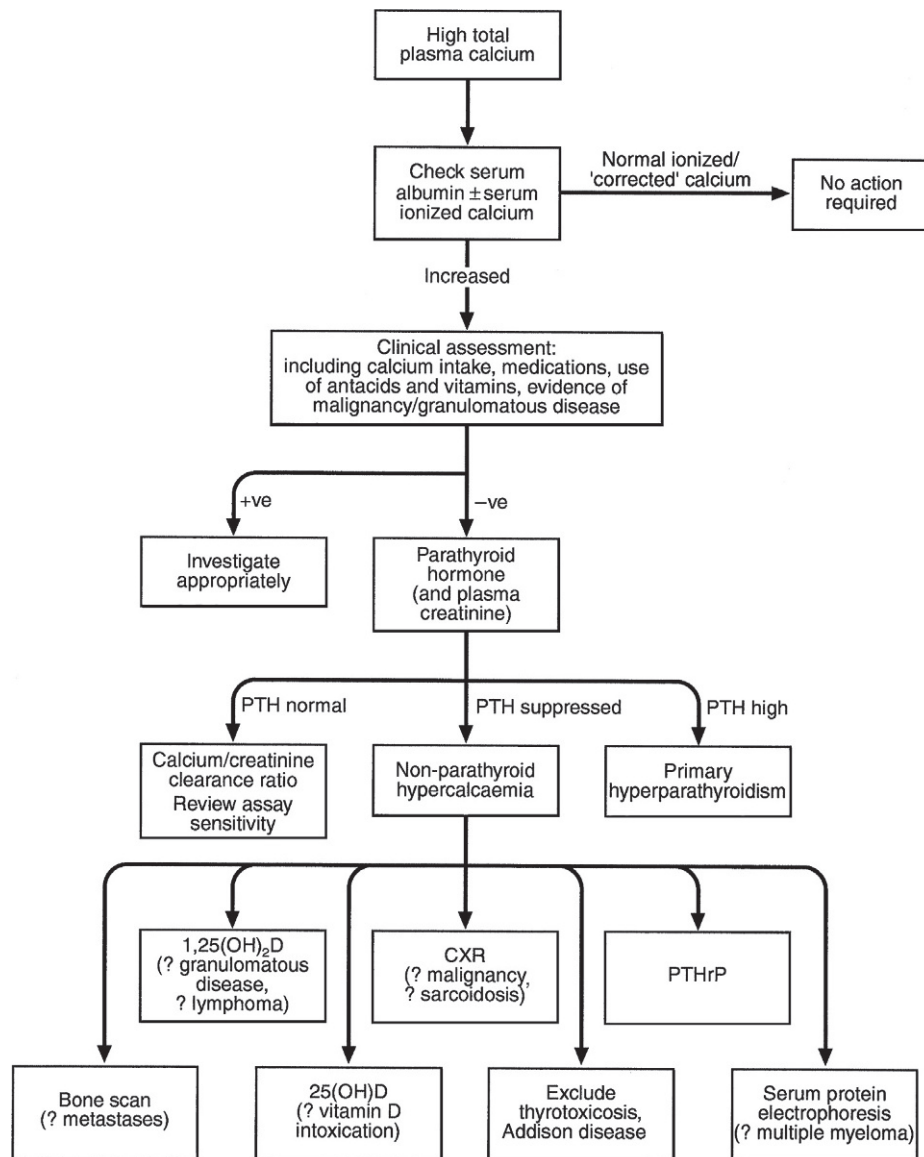

FIGURE 6.5 ■ A flow diagram for investigation of hypercalcaemia.

cinacalcet can maintain normocalcaemia for at least five years in the vast majority of patients with mild primary hyperparathyroidism, and that it is moderately effective in lowering plasma calcium in patients with severe, symptomatic PTH-dependent hypercalcaemia. Thus, the calcimimetics may acquire a role in the future in treating patients with severe, symptomatic primary hyperparathyroidism or parathyroid cancer in whom surgery has either failed or is not possible. In FHH, no therapy is required.

Individuals with disequilibrium hypercalcaemia are almost invariably volume depleted, and the first step in their management is rehydration with intravenous normal saline. This will be associated with increased renal blood flow and a resultant increased clearance of calcium through the kidneys. In those in whom hypercalcaemia is secondary to increased bone resorption, therapy with an inhibitor of bone resorption is appropriate. This is now satisfactorily achieved with intravenous infusions of bisphosphonates (e.g. pamidronate or zoledronate), with the majority of patients gradually returning to normocalcaemia within about a week.

In the past, forced saline diuresis has been used to increase renal clearance of calcium. This is potentially hazardous, particularly in the elderly, in whom congestive cardiac failure and electrolyte imbalances may cause significant morbidity. The infusion of phosphate, which can cause widespread metastatic calcification, is another dangerous and redundant therapy for hypercalcaemia. Steroids are helpful in haematological malignancies and in sarcoidosis.

Hypocalcaemia

Hypocalcaemia is a relatively uncommon finding, but true hypocalcaemia usually indicates a significant underlying abnormality requiring diagnosis and treatment.

Clinical features

Hypocalcaemia results in increased excitability of neuromuscular tissue. This may become clinically manifest as tetany, usually presenting as carpopedal spasm or, in

milder cases, as paraesthesiae in the perioral region or fingers. Laryngeal stridor and seizures may also occur. The electrocardiogram shows prolongation of the QT and ST intervals, and patients may develop arrhythmias, heart block and congestive heart failure.

In longstanding hypocalcaemia, calcification of the basal ganglia, psychiatric disturbances and cataracts may occur. Hypocalcaemic children may show abnormalities in dental development.

Causes of hypocalcaemia

Causes of hypocalcaemia are set out in [Box 6.4](#). Because hypoalbuminaemia is observed in patients with a wide variety of other diagnoses, it is mandatory to make allowance for the plasma albumin concentration or to measure ionized calcium when entertaining the diagnosis of hypocalcaemia. The common causes of chronic hypocalcaemia relate to abnormalities in the synthesis, secretion or action of PTH or $1,25(\text{OH})_2\text{D}$, or both these hormones.

Hypoparathyroidism. The most common type of hypoparathyroidism is that occurring after surgery to the thyroid or, occasionally, to other structures in the neck. It varies widely in severity and, in some patients, is tran-

BOX 6.4 Differential diagnosis of hypocalcaemia

Hypoparathyroidism

- Genetic (see [Table 6.5](#))
- Idiopathic
- Post-surgical, post-neck irradiation
- Severe hypomagnesaemia
- Infiltrative
 - β -thalassaemia (iron)
 - Wilson disease (copper)
 - Malignancy

Parathyroid hormone resistance

- Pseudohypoparathyroidism (types Ia, Ib, Ic, II)

Abnormalities of vitamin D metabolism

- Vitamin D deficiency
- Deficient 1α -hydroxylation
 - Renal impairment
 - Acidosis
 - Vitamin D-dependent rickets, type I

Vitamin D resistance

- Vitamin D-dependent rickets, type II
- Severe gluten enteropathy

Other causes

- Acute pancreatitis
- Hyperphosphataemia
- Acute rhabdomyolysis
- Multiple transfusions of citrated blood
- Severe acute illness (e.g. toxic shock syndrome, Gram-negative sepsis)
- Osteoblastic metastases (e.g. prostate, breast)
- Neonatal hypocalcaemia
- Abrupt inhibition of bone resorption (hungry bone syndrome)

sient, with plasma calcium returning to normal in the weeks after surgery. Overt hypocalcaemia can be precipitated in previously asymptomatic patients with partial hypoparathyroidism by therapy with exogenous oestrogens or proton pump inhibitors.

Spontaneous hypoparathyroidism is rare. It may occur as an isolated disorder or be part of a congenital disease complex. The most frequently encountered forms are listed in [Table 6.5](#).

The complex forms are usually the result of mutation in or deletions of genes encoding transcription factors regulating pharyngeal pouch development.

Idiopathic isolated hypoparathyroidism is also likely to have a genetic basis. Mutations in or near the genes *PTH* and *GCMB* (encoding 'glial cell missing'; a master regulator of parathyroid development) have been described in kindreds with both autosomal recessive and autosomal dominant inheritance. A rare X-linked recessive form has also been described.

It is important to distinguish autosomal dominant hypocalcaemia with hypercalciuria (ADHH) from other forms of hypoparathyroidism. This is usually caused by activating mutations in the gene encoding the CaSR and is the genetic and phenotypic converse of familial hypocalciuric hypercalcaemia: PTH concentrations are low in the face of hypocalcaemia, and there is relative hypercalciuria. Most patients with this syndrome are asymptomatic or minimally symptomatic, and do not require treatment. Treatment to raise plasma calcium should not be given to individuals known to have ADHH unless they are symptomatic, because it causes hypercalciuria, which can lead to nephrolithiasis and renal impairment.

Autoimmune hypoparathyroidism may occur alone or in association with additional features, including mucocutaneous candidiasis and adrenal insufficiency, as a component of the autoimmune polyglandular syndrome type 1 (APS-1) or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome. This may be sporadic or familial with an autosomal recessive inheritance pattern. Less commonly, it may also be seen as part of the autoimmune polyglandular syndrome type 2 (APS-2), which is characterized by adult-onset adrenal insufficiency associated with type 1 diabetes and thyroid disease and is believed to be a polygenic disorder with apparent dominant inheritance. The parathyroid glands are an infrequent target for autoimmunity; antibodies directed against the parathyroid CaSR may have a direct pathogenetic role.

Hypoparathyroidism is characterized by hypocalcaemia, with plasma total calcium concentrations as low as 1.25 mmol/L being found. Urine calcium excretion is subnormal and the TmP/GFR (see [p. 111](#)) is increased, leading to hyperphosphataemia. Bone turnover is reduced, as are intestinal calcium absorption and circulating concentrations of both $1,25(\text{OH})_2\text{D}$ and intact PTH. Some PTH immunoassays are not able to distinguish low concentrations from those within the reference range.

Pseudohypoparathyroidism. This term refers to a heterogeneous group of rare conditions characterized by the combination of resistance to the actions of PTH and, variably, other glycoprotein hormones, and Albright hereditary osteodystrophy (short stature, obesity, short

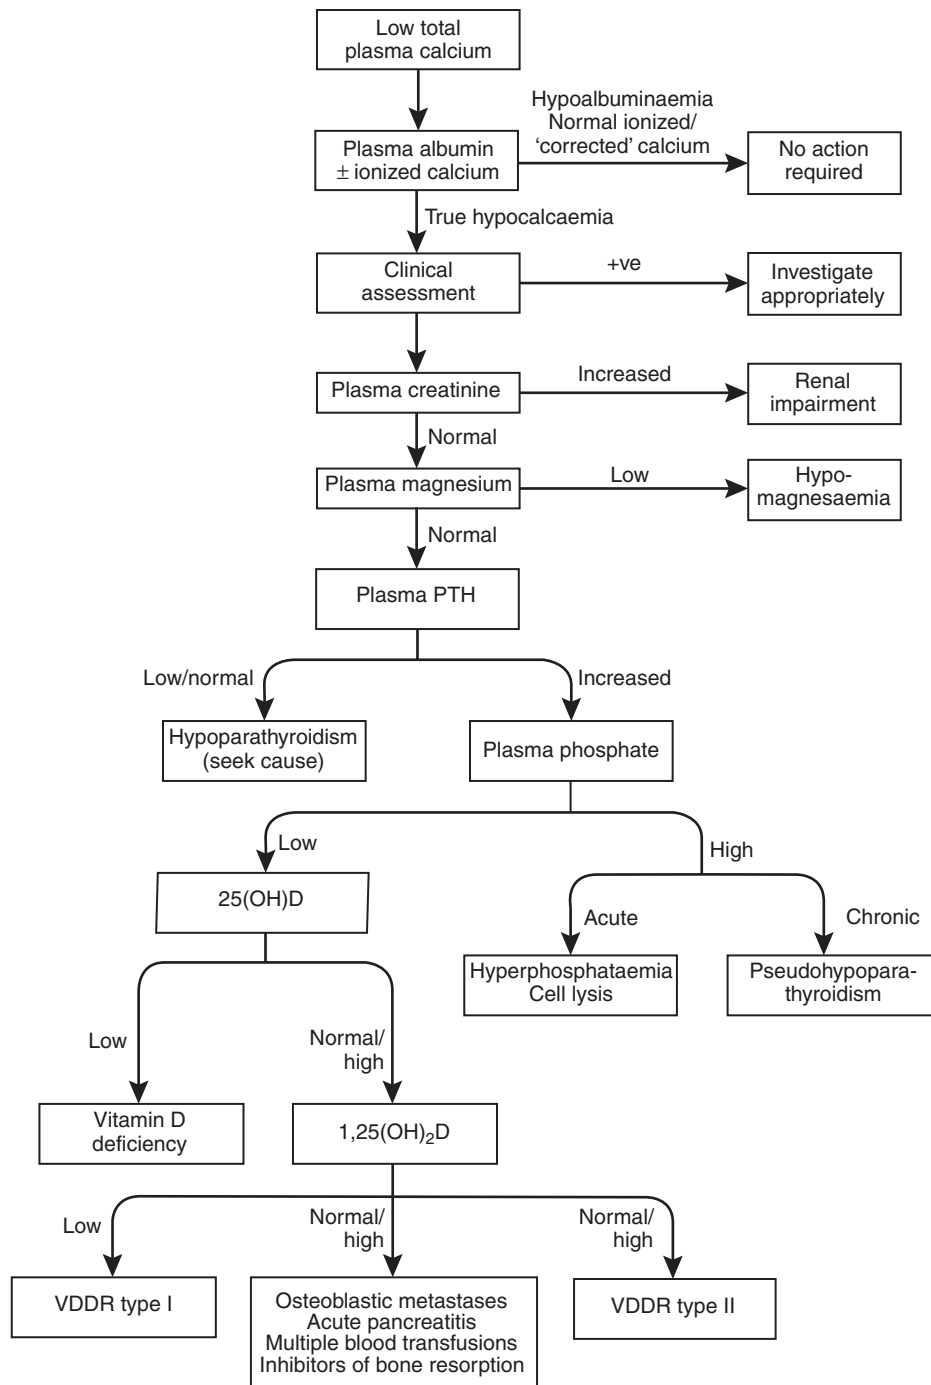

FIGURE 6.6 ■ A flow diagram for investigation of hypocalcaemia. (For abbreviations, see text.)

and the infusion of large quantities of citrate as a result of blood transfusions has a similar effect. Some radiographic contrast dyes contain either citrate or the calcium chelator EDTA, and can also produce hypocalcaemia. These mechanisms, together with magnesium deficiency, which impairs both PTH secretion and action, contribute to the hypocalcaemia observed in 25–50% of patients admitted to intensive care units.

In patients with widespread osteoblastic metastases, modest hypocalcaemia may occur secondarily to increased incorporation of calcium into bone around the secondary deposits. Severe, prolonged hypocalcaemia

may occur in patients following parathyroidectomy for longstanding hyperparathyroidism (hungry bone syndrome). Hypocalcaemia is sometimes seen in the neonatal period, being more common in premature infants and in the offspring of diabetic and hyperparathyroid mothers. Its aetiology is varied (see Chapter 25).

Investigation of hypocalcaemia

Figure 6.6 sets out an approach to the differential diagnosis of hypocalcaemia. Clearly, the first step is to confirm that hypocalcaemia is not just a reflection of low plasma

albumin concentration. An ionized calcium measurement may be necessary, particularly in acutely ill patients in whom calcium binding to albumin or other components of plasma may be abnormal. A number of the causes of hypocalcaemia shown in [Box 6.4](#) are easily distinguished clinically. The acutely ill patient is clearly distinguishable from someone with chronic hypocalcaemia. The family history may be contributory, there may be an abnormal phenotype, evidence of other hormonal abnormalities associated with autoimmune hypoparathyroidism, a past history of thyroid surgery, clinical evidence of osteomalacia etc. Data gained at this point may allow some of the investigations outlined below to be bypassed, or may direct the clinician towards specific diagnoses.

In the absence of such clues, serum creatinine and magnesium should be measured at an early stage, since renal failure and magnesium deficiency are relatively frequent causes of hypocalcaemia. Parathyroid hormone should also be assayed to determine whether parathyroid gland hypofunction is the cause. Serum phosphate measurement is useful, the phosphate concentration being high in hypoparathyroidism, syndromes of PTH resistance and when hyperphosphataemia is the primary disturbance, and (provided renal function is adequate) low in states of abnormal vitamin D activity and/or secondary hyperparathyroidism.

The plan of investigations outlined in [Figure 6.6](#) is only a guide, and some patients will have multiple pathologies, which complicate the interpretation of their biochemistry. This is particularly true in those with acute illness or malignancy.

Some investigations not shown in this scheme may also be of value. A measurement of TmP/GFR is useful in confirming the diagnosis of hypoparathyroidism, and the modified Ellsworth–Howard test in the diagnosis of pseudohypoparathyroidism. Plasma alkaline phosphatase activity is normal or low in hypoparathyroidism, but elevated in most patients with secondary hyperparathyroidism.

Treatment of hypocalcaemia

A detailed discussion of treatment is beyond the scope of this text, but the principles involved will be outlined. Clearly, the underlying condition needs to be sought and, in some cases, appropriate treatment of that will correct the hypocalcaemia. In acute symptomatic hypocalcaemia, intravenous calcium treatment may be necessary. A typical regimen in an adult would be to give 10–20 mL 10% calcium gluconate over 5 min (2.26–4.52 mmol calcium), followed by a continuous intravenous infusion supplying 9–18 mmol calcium in 2 L of fluid over 24 h.

In vitamin D deficiency, treatment should be with vitamin D itself, for reasons of both cost and safety. Repletion of vitamin D does not bypass the body's homeostatic control of plasma calcium concentration, as will occur if 1α -hydroxylated vitamin D metabolites are used. In an adult, adequate vitamin D stores can be achieved by administering 50 000 IU cholecalciferol monthly.

1α -Hydroxylated vitamin D derivatives are preferred in those conditions in which 1α -hydroxylation is impaired and pharmacological doses of vitamin D would otherwise

be needed, such as hypoparathyroidism, pseudohypoparathyroidism and vitamin D-dependent rickets (VDDR) type I. Typical doses for an adult would be 1–4 μ g/day of alfacalcidol or 0.75–2.25 μ g/day of calcitriol. Calcium supplements are not usually required. The aim is to get the plasma calcium concentration just high enough to relieve symptoms, and this is usually achieved around the lower limit of the reference range. Running the plasma calcium concentration higher than this increases the risk of vitamin D toxicity.

PHOSPHORUS METABOLISM

Distribution of body phosphorus

Phosphorus accounts for about 1% of the weight of the elementary composition of the human body; about 23 mol in a 70 kg adult human. Of this, the bulk (85%) is in the skeleton and teeth (largely in the form of hydroxyapatite) and some 14% is located within the cells of the soft tissues. Within different cell types, the phosphorus content may vary from 300 to 1300 mmol/kg. Only 1% of total body phosphorus is present in extracellular fluids ([Box 6.5](#)).

In the blood, phosphorus is present in both organic forms (phosphoproteins, phospholipids etc.) and the inorganic form (as phosphate). The inorganic moiety, which is what is measured routinely in laboratories, exists predominantly in the form of the ions HPO_4^{2-} and H_2PO_4^- in a ratio of about 4:1. Some 15–20% of inorganic phosphate is non-covalently bound to plasma proteins and is not ultrafilterable.

Intracellular phosphorus

Phosphorus is important in the metabolism of all cells. It is a key component of a wide array of biological molecules, including the phospholipids of cell membranes and intracellular organelles, nucleic acids, enzyme cofactors and glycolytic intermediaries. Phosphorylation or dephosphorylation induces dramatic shifts in the activity of many enzymes and cellular signalling proteins. Organophosphate compounds such as adenosine triphosphate (ATP), creatine phosphate and diphosphoglycerate store chemical energy in their high energy phosphate bonds. Hydrolysis of ATP provides the main energy source for many metabolic processes and for

BOX 6.5 Distribution of body and blood phosphorus

Body phosphorus

- Bone ~85%
- Soft tissue cells ~14%
- Extracellular fluid ~1%

Blood phosphorus

- Organic (covalently bound) ~70%
- Inorganic

 - Protein-bound (non-covalent) ~5%^a

^aThe phosphorus content in plasma that is commonly measured and described as phosphate concentration.

muscle contraction. In muscle, ATP is replenished by the donation of phosphate groups from creatine phosphate. In the mitochondria, phosphate-containing proteins play essential roles in the electron transport system. Other phosphate-containing intracellular molecules include cyclic adenosine monophosphate and inositol triphosphate, which act as second messengers.

Although organically-bound phosphorous concentrations within cells are much greater, non-organically bound intracellular phosphate also has important direct effects on cellular energy metabolism. For example, glucose uptake, lactate production and quantity of ATP all vary directly with the intracellular phosphate concentration. The amount of intracellular phosphate is also an important regulator of enzyme activity in the glycolytic pathway. Within red cells, the concentration of 2,3-diphosphoglycerate (2,3-DPG) plays a crucial role in oxygen availability to the tissues. In severe phosphate deficiency, 2,3-DPG synthesis is decreased, which increases the affinity of oxygen to haemoglobin and thus decreases the release of oxygen to the tissues.

Cytoplasmic inorganic phosphate concentrations are similar to those in the extracellular fluid (ECF) (1–1.3 mmol/L), but are not in simple equilibrium. The electrical potential of cells in relation to the ECF means there is a negative potential across the membrane, tending to repel phosphate ions from the cytoplasm. An active process pumps phosphate ions into cells against this membrane potential in order to maintain cytoplasmic phosphate concentrations.

Cytoplasmic inorganic phosphate concentrations change in response to shifts in the balance between the organic phosphorous pool and cytosolic phosphate. Examples of this are in skeletal muscle, when an increase in workload leads to the net degradation of creatine phosphate and generation of cytoplasmic phosphate. In cells in which glycolysis is taking place, such as erythrocytes, a rise in cytoplasmic hydrogen ion concentration stimulates glycolysis. Glycolytic intermediaries, which are organic phosphates, accumulate in the cytoplasm and cause a marked depletion of cytoplasmic phosphate.

Although cells can regulate their steady-state concentrations of phosphate metabolites in the face of changes in extracellular phosphate, severe hypophosphataemia can deplete intracellular phosphate. Large fluxes of phosphate across the cell membrane can, in turn, affect extracellular phosphate concentrations. Various intracellular metabolic disturbances, hormones and hydrogen ion shifts can all cause clinically significant redistribution of phosphate. Examples of mechanisms that permit shifts of phosphate into cells include systemic alkalosis, the stimulation of adrenoreceptors by catecholamines or sympathomimetic agents, and the insulin-mediated entry of glucose into cells.

Phosphate homeostasis

The main sources of phosphate transfer to and from the plasma pool are the intestine, bone, soft tissues and the kidneys. Under steady-state conditions, the net intestinal phosphorus absorption equals the net urine excretion (Fig. 6.7). Small amounts of phosphate (~1 mmol/24 h)

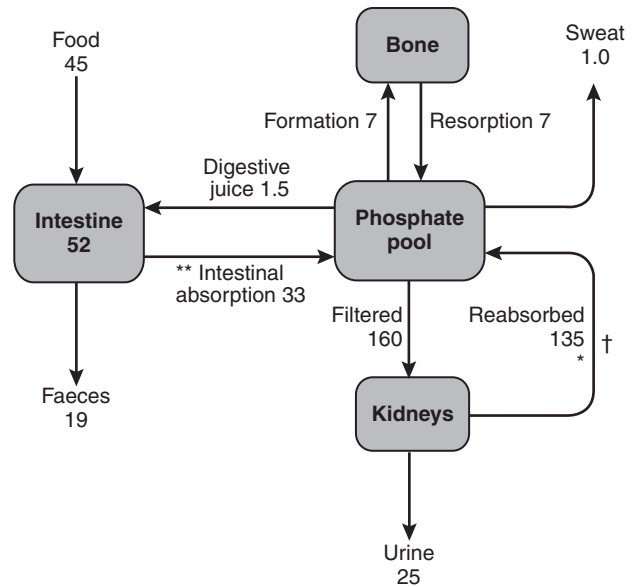

FIGURE 6.7 ■ Representative fluxes (mmol/24 h) in a healthy adult (70 kg body weight) for phosphate. The exchanges with soft tissues are not illustrated in this diagram. For phosphate metabolism the major sites of action of parathyroid hormone (*), FGF23 (†) and 1,25(OH)₂D (**) are indicated. Parathyroid hormone and FGF23 reduce renal tubular reabsorption of phosphate and increase urine phosphate excretion. (Modified from Wilkinson R. Absorption of calcium, phosphorus and magnesium. In: Nordin B E C (ed). Calcium, phosphate and magnesium metabolism. Edinburgh: Churchill Livingstone; 1976, with permission).

may be lost in the sweat. The phosphate content of breast milk is ~1.8 mmol/L, and a fully breast-feeding woman will lose ~1.4 mmol/24 h in the milk.

There are two interrelated mechanisms that react to variations in phosphate status in order to maintain phosphate homeostasis, despite fluctuations either in supply (diet, intestinal absorption) or demand (growth, mineralization, cellular metabolism). These two mechanisms are mediated by:

- 1,25(OH)₂D, synthesis of which occurs in response to hypophosphataemia through the 1 α -hydroxylation of 25(OH)D by the cells of the proximal tubules of the kidney
- fibroblast growth factor 23 (FGF23), synthesis and release of which is stimulated by hyperphosphataemia.

1,25-Dihydroxyvitamin D regulates plasma phosphate primarily by its stimulatory action on intestinal phosphate absorption, whereas FGF23 primarily regulates plasma phosphate by decreasing renal tubular phosphate reabsorption. The two hormonal systems interact: FGF23 production is activated by 1,25(OH)₂D, and in turn potently inhibits the activity of 1 α -hydroxylase required for synthesis of 1,25(OH)₂D. Fibroblast growth factor 23 is most highly expressed in bone, particularly by differentiated osteoblasts and osteocytes, but is also expressed in thymus, brain and heart. It signals through a co-receptor complex comprising the FGF receptor 1 and the β -glycosidase-like protein, klotho, and is catabolized intracellularly by subtilisin-like enzymes that cleave the native protein at a specific site to generate fragments that are thought to be biologically inert. Murine transgenic experiments demonstrate a critical role for FGF23

in phosphate homeostasis: deletion of the *FGF23* gene is accompanied by hyperphosphataemia, enhanced renal tubular reabsorption of phosphate, and elevated concentrations of $1,25(\text{OH})_2\text{D}$; overexpression of the protein causes renal phosphate wasting, decreased concentrations of $1,25(\text{OH})_2\text{D}$ and osteomalacia. Fibroblast growth factor 23 induces phosphaturia by decreasing expression of the two active phosphate transporters in the luminal membrane of the proximal renal tubule, the types 2a and 2c sodium-phosphate co-transporters (NaPi-2a and NaPi-2c, respectively). It further lowers plasma phosphate by inhibiting the activity of renal 1α -hydroxylase and increasing the activity of the $25(\text{OH})\text{D}$ -24-hydroxylase, thereby decreasing synthesis of $1,25(\text{OH})_2\text{D}$, and intestinal phosphate absorption. The concentration of FGF23 rises in response to an increase in plasma phosphate as glomerular function declines, and, by directly promoting an increase in urinary phosphate excretion and indirectly reducing intestinal phosphate absorption, allows the maintenance of normal plasma phosphate concentration in early renal failure.

Fibroblast growth factor 23 is the best characterized of a group of circulating compounds that induce phosphaturia, collectively termed 'phosphatonins'. Other putative phosphatonins, such as the skeletal product matrix extracellular phosphoglycoprotein (MEPE), and secreted frizzled-related protein 4, may be involved in the pathogenesis of pathological states of renal phosphate wasting, hypophosphataemia and osteomalacia (including X-linked hypophosphataemic rickets and oncogenic osteomalacia), but no evidence currently exists for a role of either in physiological phosphate homeostasis.

Dietary phosphate and intestinal absorption

Phosphate is present in a wide range of foodstuffs, so that if the diet is adequate in other nutrients, it is usually also adequate in phosphate. A typical Western diet contains around 0.65 mmol/kg body weight/24 h. There is a considerable capacity to adapt to low phosphate intake, so it is difficult to establish a minimum dietary requirement. Hypophosphataemia resulting solely from inadequate dietary intake is extremely rare. A measurable increment in $1,25(\text{OH})_2\text{D}$ production, one of the adaptive responses, occurs when dietary phosphate is reduced to <0.32 mmol/kg per 24 h.

Phosphate absorption takes place most efficiently in the duodenum and jejunum, though the ileum contributes most in absolute quantity because of its greater length. Approximately 67% of dietary phosphate is absorbed from the jejunum and ileum even under conditions of phosphate repletion, by a passive non-saturable mechanism. Thus, net absorption increases in parallel with dietary phosphate content. The active, $1,25(\text{OH})_2\text{D}$ -dependent, saturable component of phosphate absorption mainly increases jejunal uptake. The bioavailability of intestinal phosphate is reduced by a high calcium intake, as calcium forms insoluble complexes with phosphate in the intestinal lumen. Aluminium salts react similarly. Phosphate is secreted in the digestive juices at a rate of ~0.1 mmol/kg per 24 h, about 67% of which is reabsorbed

from the intestine. Phosphate fluxes are summarized in Figure 6.7.

The renal tubular reabsorption of phosphate

A high proportion of the phosphate in plasma is ultrafilterable and about 75% of filtered phosphate is reabsorbed by the proximal tubules. A further 5–20% is reabsorbed in the distal tubules and/or cortical collecting ducts and the remainder (20–30 mmol/24 h in an adult) appears in the urine.

If phosphate is infused intravenously and the urinary excretion rate of phosphate measured, then above a certain plasma concentration of phosphate all additional increments in the filtered load will be paralleled by the same increment in urinary phosphate; that is, the relationship between the phosphate excretion rate and the plasma phosphate is linear, with a slope that equates to glomerular filtration rate at high (saturating) filtered loads. Extrapolating this line back to where the urine phosphate excretion rate is zero defines the threshold of glomerular filtrate (and hence plasma) phosphate concentration (T_{mP} , tubular maximum for phosphate) that the renal tubular homeostatic mechanism is seeking to maintain, in relation to glomerular filtration rate (GFR). In vivo, this can be determined by calculating the clearance of phosphate relative to that of creatinine on a fasting urine sample and using the nomogram of Walton and Bijvoet (1975), which relates this value to the prevailing plasma phosphate concentration (T_{mP}/GFR). This is performed fasting to avoid changes in plasma phosphate due to food intake, and requires a urine sample and a plasma sample (see Appendix 6.4, for method).

Factors regulating T_{mP}/GFR . A number of endocrine and non-endocrine factors are involved in the regulation of T_{mP}/GFR and hence plasma phosphate (Table 6.7). The most important are FGF23 and PTH. Fibroblast growth factor 23 production is affected by perturbations in plasma phosphate, such that a rise in its concentration stimulates an increase in FGF23 production, which in turn increases urinary phosphate loss. It is not clear whether plasma phosphate concentrations directly affect FGF23 production, or do so by an as yet unknown intermediary pathway. Changes in plasma phosphate do not directly affect PTH secretion, but PTH acts on the renal tubules, to reduce T_{mP}/GFR . Plasma phosphate concentrations are thus usually low when there is an elevation in PTH (e.g. in primary hyperparathyroidism or secondary hyperparathyroidism due to vitamin D deficiency) and renal function is normal. T_{mP}/GFR is increased when PTH concentrations are low, or there is insensitivity to the hormone (e.g. in hypoparathyroidism or pseudohypoparathyroidism). Parathyroid hormone-related peptide has similar effects to PTH on renal phosphate handling. The phosphaturic effects of PTH and PTHrP result from action at multiple sites along the nephrons and are mediated through cAMP production.

The high T_{mP}/GFR seen in childhood and in acromegaly is mediated through insulin-like growth factor

TABLE 6.7 Factors and disorders affecting TmP/GFR

Factor	Increased TmP/GFR	Decreased TmP/GFR
Endocrine	Hypoparathyroidism Pseudohypoparathyroidism Growth hormone/IGF-1 Recovery from vitamin D deficiency Lactation	Hyperparathyroidism PTH-related peptide Corticosteroids Oestrogen replacement therapy

Numbers in brackets refer to Online Mendelian Inheritance in Man (OMIM) catalogue number.

1 (IGF-1). TmP/GFR is increased in thyrotoxicosis and decreased by corticosteroids.

The increase in plasma phosphate seen after the menopause is abolished by oestrogen replacement therapy. There is little evidence that $1,25(\text{OH})_2\text{D}$ greatly affects renal phosphate handling. Calcitonin, given in pharmacological doses, acutely decreases the TmP/GFR. In general, acidosis (whether respiratory or metabolic) reduces renal tubular phosphate reabsorption, whereas alkalosis has the opposite effect. Calcium itself can affect phosphate transport in the kidneys. In healthy subjects, this is difficult to demonstrate because of concurrent changes in PTH, but calcium infusion in hypoparathyroid subjects ultimately increases urinary phosphate losses and reduces plasma phosphate by reducing TmP/GFR.

Various drugs may induce changes in TmP/GFR. In general, these changes are small, the exceptions being glucocorticoids and acetazolamide, which reduce TmP/GFR, and the bisphosphonate, etidronate which, when given at doses of 10 mg/kg, causes a dose-dependent increase in TmP/GFR and plasma phosphate.

Renal phosphate handling may also be affected by haemodynamic changes. Patients with a single kidney (e.g. transplant recipients or live kidney donors) have a high filtered load per nephron and lower TmP/GFR as an adaptation. Phosphaturia also accompanies the natriuresis that follows volume loading, poorly controlled diabetes or diuretic use, because renal phosphate transport is related to sodium transport. Parathyroid hormone is needed for the full expression of this phenomenon.

Disorders of renal phosphate metabolism. There are a number of conditions that share as a central feature a combination of low TmP/GFR, hyperphosphaturia, hypophosphataemia and osteomalacia: the defect may be inherited or acquired. The clinical manifestations depend on the severity of the renal phosphate leak, the degree of response of the 1α -hydroxylase enzyme to the ensuing hypophosphataemia, the age at onset and associated defects. In some instances (e.g. in some patients with idiopathic hypercalciuria), the primary defect appears to be a low TmP/GFR with modest hypophosphataemia and, in response to this, there is an appropriate increase in $1,25(\text{OH})_2\text{D}$ production. Intestinal absorption of calcium and phosphate is enhanced and the extra calcium that is absorbed appears in the urine, predisposing to renal stones.

There are several syndromes of hyperphosphaturia and hypophosphataemia, accompanied by inappropriately low concentrations of $1,25(\text{OH})_2\text{D}$ and osteomalacia, including autosomal dominant hypophosphataemic rickets (ADHR), X-linked hypophosphataemic rickets (XLH) and oncogenic osteomalacia (OOM) (Table 6.7). In most instances, an abnormality in FGF23 metabolism underlies the phenotype.

Oncogenic osteomalacia is a paraneoplastic syndrome, in which tumours of mesenchymal origin elaborate and secrete excess amounts of FGF23, and possibly other phosphatonins, such as MEPE or secreted frizzled-related protein 4. Detection and removal of the tumour reduces FGF23 concentrations and corrects the biochemical and skeletal phenotype. In autosomal dominant hypophosphataemic rickets, affected individuals harbour a mutation in

the gene encoding FGF23, which renders the full-length protein resistant to normal (inactivating) proteolysis. Patients with X-linked hypophosphataemia carry a mutation in the *PHEX* (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) gene, which encodes an endopeptidase that is believed to sequester and stabilize a secreted FGF23-stimulating bone matrix protein. Inactivation of *PHEX* allows accumulation of the matrix-bound FGF23-stimulating protein and an increase in local, and then systemic, FGF23 production. Whether the *PHEX* endopeptidase also inactivates FGF23 in vivo is currently uncertain, but thought to be unlikely.

In all three of these phosphaturic syndromes, circulating concentrations of FGF23 are typically elevated. Circulating concentrations of FGF23 can also be elevated in patients with polyostotic fibrous dysplasia/McCune-Albright syndrome (caused by somatic activating mutations in *GNAS1*) in 50% of whom renal phosphate wasting occurs. Two autosomal recessive conditions are associated with FGF23-dependent hypophosphataemia. In type 1, autosomal recessive hypophosphataemic rickets (ARHR), inactivating mutations of *DMP1*, which encodes an osteocyte protein that restrains FGF23 production, produce a phenotype similar to that of ADHR. Inactivating mutations of *ENPP1*, which encodes an enzyme important in regulating hydroxyapatite deposition, cause type 2 autosomal recessive hypophosphataemic rickets. This is a rare syndrome of generalized arterial calcification of infancy and, in those who survive to adulthood, FGF23-dependent hypophosphataemia.

The recessively inherited condition, hereditary hypophosphataemic rickets with hypercalciuria, is caused by inactivating mutations in the gene *SLC34A3*, which encodes the NaPi-2c transporter. In this hypophosphataemic disorder, which is not mediated by FGF23, chronic hypophosphataemia is accompanied by an appropriate increment in 1α -hydroxylase activity and plasma $1,25(\text{OH})_2\text{D}$. In a few patients, a milder phenotype of hypophosphataemia with nephrolithiasis and osteopenia has been associated with mutations in NaPi-2a. The bone diseases associated with hypophosphataemia are discussed in Chapter 31.

Plasma phosphate concentrations

There are marked age-related changes in plasma phosphate, with the highest concentrations seen in early infancy when growth velocity is highest. Throughout childhood and adolescence, plasma phosphate concentrations remain higher than in adults. In adulthood, a decline in fasting plasma phosphate concentrations is seen in men after the age of 40. In women, there is little change, but a small increment (~ 0.07 mmol/L) occurs after the menopause. Plasma phosphate does not change during pregnancy, but is increased during lactation. The age- and lactation-related changes in plasma phosphate are mediated through changes in TmP/GFR (Table 6.8).

There is marked diurnal variation in plasma phosphate. During the day, concentrations are substantially higher in the mid-afternoon than in the early morning and there is a second peak in the early hours of the morning (see Fig. 6.4). This early morning peak is attenuated with age.

TABLE 6.8 Plasma phosphate concentrations according to age and sex

Age	Sex	Reference range for plasma phosphate (mmol/L)
Last trimester in utero	M, F	0.8–1.4
1 day	M, F	1.0–2.6
1 day–1 month	M, F	1.8–3.2
1–12 months	M, F	1.4–2.1
1–14 years	M, F	1.2–1.7
14–18 years	M, F ^a	1.0–1.6
18–45 years	M, F	0.8–1.4
>45 years	F	0.8–1.4
>45 years	M	0.7–1.2
Lactation	F	1.1–1.5

^aThe decline in plasma phosphate concentrations from adolescent to adult values occurs, on average, two years earlier in girls than boys. Adult concentrations are reached around age 15 in girls and age 17 in boys. This parallels the earlier start and finish to the adolescent growth spurt in girls.

Plasma phosphate rises after food and subsequently falls as phosphate either enters cells or is excreted. The fall in plasma phosphate after a meal is partly attributable to insulin-dependent stimulation of glycolysis, which increases intracellular phosphate utilization.

Hyperphosphataemia

The major causes of hyperphosphataemia are listed in Box 6.6. Hyperphosphataemia may arise through an increase of phosphate input into the blood or decreased

BOX 6.6 Causes of hyperphosphataemia

Pseudohyperphosphataemia

- Haemolysed specimen
- Myeloma
- Delayed separation from red cells

Increased phosphate input

- Intravenous phosphate
- Rectal phosphate

Shift from intracellular to extracellular fluid

- Cell death
 - Tumour lysis syndrome
 - Rhabdomyolysis
 - Malignant hyperpyrexia
 - Heat stroke

Diminished phosphate excretion

- Reduced GFR
 - Acute kidney injury
 - Chronic kidney disease
- Increased TmP/GFR
 - Physiological (normal childhood, lactation, recovery from vitamin D deficiency)
 - Pathological (reduced PTH or PTH resistance), vitamin D toxicity, thyrotoxicosis, acromegaly, etidronate, tumoral calcinosis (genetic conditions, see text)

excretion. The latter may result from a reduction in GFR or an increase in TmP/GFR. Conditions in which the TmP/GFR is raised, generally cause modest hyperphosphataemia (plasma phosphate 1.4–2.4 mmol/L). Tumoral calcinosis in non-uraemic subjects is a rare recessively inherited disorder associated with a high TmP/GFR, elevated 1,25(OH)₂D₃ concentrations and hyperphosphataemia; a biochemical phenotype that is the mirror image of autosomal dominant hypophosphataemic rickets. It is most commonly caused by inactivating mutations in the *GALNT3* gene. *GALNT3* encodes a glycosyltransferase known as ppGalNac-T3. This enzyme O-glycosylates the subtilisin-like proprotein convertase recognition site in the FGF23 protein, thereby protecting FGF23 from proteolytic cleavage and permitting intact FGF23 to be secreted. In the absence of this enzyme, most FGF23 is processed into inactive fragments before secretion, leading to low or undetectable circulating concentrations of biologically active FGF23. Tumoral calcinosis can also result from mutations in the genes encoding FGF23 or *klotho*, leading to impaired secretion of FGF23, and resistance to the actions of FGF23, respectively. A feature of tumoral calcinosis is the presence of large periarticular calcific masses, which are subject to breakdown and chronic inflammation.

Renal impairment, whether acute or chronic, can cause hyperphosphataemia, but this does not usually occur until the GFR falls below 30 mL/min. As renal function deteriorates further, plasma phosphate rises sharply and may reach 6 mmol/L in established renal failure. Other abnormalities of phosphate metabolism that present early in the course of chronic kidney disease are important in the aetiology of hyperparathyroidism and are discussed further in Chapter 31.

The diet rarely contains sufficient phosphate to cause significant postprandial hyperphosphataemia, but excessive input of phosphate can occur with the use of intravenous phosphate salts or phosphate enemas. The latter is particularly liable to occur with children unless the dose of phosphate in the enema is reduced. Massive cell death with release of intracellular phosphate can cause hyperphosphataemia. Examples of the latter include rhabdomyolysis and the tumour lysis syndrome, seen, for example, after the initiation of chemotherapy in childhood leukaemia. It should be emphasized that, as with hypercalcaemia, an increased input of phosphate into the circulation is much more likely to cause severe hyperphosphataemia if there is coexistent renal impairment and thus a reduced capacity to excrete phosphate. This is often the case in critically ill patients.

Plasma phosphate may be artefactually raised (by ~30%) in very haemolysed samples or if separation from red cells is delayed. Pseudohyperphosphataemia has also been described with certain chromogenic assay methods of automated analysis in patients with paraproteinaemia or hypertriglyceridaemia.

Consequences of hyperphosphataemia

No specific symptoms are directly attributable to hyperphosphataemia. However, when the product of the calcium and phosphate concentrations in blood exceeds the

solubility product (approximately 4.85×10^{-6} molar units), soft tissue (metastatic) calcification occurs. This is seen most frequently in chronic kidney disease, where calcification occurs in blood vessels, the skin, heart, lungs, kidneys, conjunctivae and around joints. Interstitial calcification of the kidneys is of particular importance, since it impairs renal function further and reduces the ability to excrete phosphate loads. The deposition of calcium phosphate salts in the skin is thought to contribute to the pruritus of chronic uraemia, a symptom that may improve with better control of hyperphosphataemia. The syndrome of progressive ischaemic skin ulceration (calciophylaxis) in patients with established renal failure has also been attributed to calcium phosphate deposition. In this syndrome, ulcers spread rapidly with secondary infection of the necrotic tissues. Histologically, there is extensive arterial and arteriolar calcification and thrombosis. These lesions do not respond to local therapy, but do heal after parathyroidectomy (which reduces the [calcium]×[phosphate] product acutely). Urgent parathyroidectomy is indicated in this condition.

If plasma phosphate rises acutely, then plasma calcium concentrations fall by a mass action effect; this is seen, for example, with the tumour lysis syndrome and rectal or intravenous phosphate administration. This was the basis of the former use of intravenous phosphate in the management of malignant hypercalcaemia. However, the perils of soft tissue calcification induced by this treatment outweigh any benefit.

Diagnostic approach to hyperphosphataemia

The clinical history should reveal excessive exogenous phosphate supply (intravenous or rectal). Massive cell death in, for example rhabdomyolysis or the tumour lysis syndrome, should also be evident from the clinical setting. Rhabdomyolysis can be confirmed by measurement of serum creatine kinase activity.

Diminished excretion of phosphate due to severe renal impairment is evident from measurement of the plasma creatinine. The most convenient method of detecting changes in TmP/GFR is to use the nomogram of Walton and Bijvoet (see Appendix 6.4, below). Other measures of urinary phosphate clearance have theoretical failings compared with the TmP/GFR. In interpreting the result, it is important to bear in mind the normal age-related changes in this index. There is no diagnostic value in measuring the 24 h urine phosphate excretion which, in steady-state conditions, reflects the product of dietary phosphate content and fractional phosphate absorption.

Therapeutic approach to hyperphosphataemia

Hyperphosphataemia due to a raised TmP/GFR is rarely high enough to require specific action. Phosphate control is, however, important in patients with established renal failure, both to limit damaging metastatic and vascular calcification and to control the development of hyperparathyroidism. There are various salts of aluminium, magnesium and calcium which, when administered orally, bind phosphorus in the intestine and

limit its absorption. Aluminium hydroxide is the most effective of these agents, but significant quantities of aluminium, which has toxic effects on bone, may be absorbed. Calcium-based phosphate binders (such as calcium acetate or calcium carbonate) are generally used in preference to aluminium salts. However, calcium-based phosphate binders tend to worsen hypercalcaemia in dialysis patients, and have been linked to adverse vascular outcomes, so calcium-free phosphate-binding agents, such as lanthanum carbonate and sevelamer hydrochloride are increasingly used. In dialysis patients, inadequate phosphate control may be due to a number of factors (see Box 31.6).

Acute kidney injury can complicate the tumour lysis syndrome and is attributable to phosphate and urate released from cells. Maintaining a brisk saline diuresis at the time chemotherapy is begun reduces the risk of developing acute kidney injury.

Hypophosphataemia

Mechanisms

Hypophosphataemia can arise by any one or combination of three mechanisms:

- inadequate phosphate absorption from the intestine
- shifts of phosphate from extracellular fluid into cells
- abnormal urinary phosphate losses (Table 6.9).

As indicated earlier, it is very rare that the diet is so inadequate in phosphate that, on its own, it can cause hypophosphataemia. However, chronic malnutrition

can result in a deficit of whole body phosphate such that, when conditions occur in which there is a shift of phosphate from the extracellular to the intracellular compartment, such as during refeeding, profound hypophosphataemia may develop. Inadequate dietary phosphate may thus be a predisposing factor to, rather than a direct cause of, hypophosphataemia. Clinically significant hypophosphataemia due to the use of phosphate-binding antacids has been described, but this is now rare because of the availability of alternative therapies for peptic ulcer disease.

Hypophosphataemia can result from the acute shift of phosphate into cells. Less than 1% of total body phosphate is in the extracellular space, so small shifts of no more than 6 or 7 mmol can induce significant changes in plasma phosphate concentrations. If this occurs without prior intracellular phosphate depletion, then the condition is usually benign and self-limiting. The most frequently encountered conditions in which this phenomenon occurs are the following.

- *Refeeding syndrome.* Providing sufficient calories, protein and other nutrients to malnourished patients allows accelerated tissue accretion. The cellular uptake and utilization of phosphate increases, initially for the purpose of phosphorylation of glucose and fructose, and ATP synthesis. When insufficient quantities of phosphate are provided, an acute state of severe hypophosphataemia, with intracellular phosphate depletion, occurs. The clinical and metabolic consequences can be serious. Examples of situations in which this mechanism can operate, include the treatment of diabetic ketoacidosis and during parenteral nutrition.

TABLE 6.9 Mechanisms underlying common causes of hypophosphataemia

Aetiology of hypophosphataemia	↑ Cellular uptake			↓ Gastrointestinal input		↑ Urinary loss	
	Respiratory alkalosis	Refeeding	Muscle	Inadequate intake	Poor absorption	↓ TmP/GFR	
Primary hyperparathyroidism						•	Plasma phosphate typically 0.35–0.80 mmol/L
Vitamin D deficiency with secondary hyperparathyroidism				•	•	•

Diabetic ketoacidosis – recovery		•				(•) ^c	
Hyperalimentation		•		•			
Hepatic failure	•	•		•	•		
Long distance running			•				

^aContribution of phosphate malabsorption depends on 1,25(OH)₂D response to hypophosphataemia.

^bDue to β-agonist use.

^cPhosphaturia associated with glycosuria.

- *Respiratory alkalosis.* Hyperventilation due to any cause will reduce the carbon dioxide content of the blood and cells. Intracellular hydrogen ion concentration falls, which activates the enzyme phosphofructokinase, which in turn accelerates phosphorylation of glucose. Phosphate is taken up rapidly from the plasma and hypophosphataemia results. Examples of clinical situations in which this mechanism may occur include liver failure, severe burns, salicylate poisoning, alcoholic ketoacidosis, alcohol withdrawal and sepsis. Hyperventilation in these situations may be the result of either direct metabolic effects or simply fear and pain. It is commonly observed in hospitalized patients, but is typically mild and transient and does not require specific treatment; correction of the underlying cause of hyperventilation also corrects the hypophosphataemia.
- *Increased muscle uptake.* Prolonged intense exercise can increase uptake of phosphate into muscle in an attempt to replenish creatine phosphate stores. This has caused profound hypophosphataemia in marathon runners.

Increased urinary phosphate loss is usually a chronic phenomenon resulting from a low TmP/GFR and gives rise to moderate hypophosphataemia and osteomalacia (see above, and Chapter 31). In uncontrolled diabetes, osmotic diuresis causes loss of phosphate in the urine, and this contributes to the occurrence of hypophosphataemia once insulin therapy is begun. A reduction in TmP/GFR also contributes to the hypophosphataemia that can occur in paracetamol overdose, even in the absence of significant hepatic damage. A reduction in TmP/GFR, along with other renal tubular function abnormalities, may be seen in patients with severe alcohol dependency. It reverses on abstinence.

Consequences of hypophosphataemia

Mild to moderate hypophosphataemia (0.35–0.80 mmol/L in an adult) is not harmful in the short term, but if chronic it may induce osteomalacia. When plasma phosphate concentrations fall below 0.35 mmol/L, the syndrome of acute phosphate deficiency may develop. The major manifestations are listed in Table 6.10.

Diagnostic approach to hypophosphataemia

The acute phosphate deficiency syndrome often arises in patients who are critically ill from other causes, and the symptoms of phosphate deficiency may mimic features of these illnesses. Examples of this include deteriorating mental function simulating encephalopathy in the hepatic failure patient, and tremor and irritability simulating alcohol withdrawal symptoms. The detection of severe phosphate deficiency thus depends on anticipating the circumstances in which it might occur and requesting laboratory confirmation. In these circumstances, measurement of plasma phosphate is usually sufficient, but assessments of recent dietary and intravenous phosphate intake may also be helpful. In all patients with severe acute hypophosphataemia, phosphate disappears from the urine so little information can be gained from its measurement.

In the case of chronic hypophosphataemia causing osteomalacia, the critical investigation is determination of the TmP/GFR. An inappropriately low TmP/GFR should prompt evaluation for one of the causes of renal phosphate wasting, discussed under Disorders of renal phosphate metabolism (see p. 112). Measurement of serum concentrations of FGF23 can be helpful in identifying FGF23-dependent causes of hypophosphataemia. Development of FGF23 immunoassays is continuing; there is an assay that measures the full-length peptide only and a C-terminal assay that recognizes both full length and the cleaved C-terminal fragment.

Nuclear magnetic resonance has been used to detect changes in intracellular phosphate metabolism and has proved particularly valuable in research into muscle diseases. The technique is not, however, generally available for clinical practice. Isotopic tests of intestinal phosphate absorption have also been used in research, but have little practical clinical application.

Therapeutic approach to hypophosphataemia

Mild to moderate acute hypophosphataemia secondary to redistribution (plasma phosphate 0.35–0.80 mmol/L in adults) is usually transient and requires no specific

TABLE 6.10 The acute phosphate deficiency syndrome

System affected	Mechanism/site	Clinical consequence
Haemopoietic system	↓ 2,3-DPG in red cells, reduced O ₂ release to peripheral tissues	Tissue hypoxia
	↑ Red cell fragility Abnormal leukocyte function Abnormal platelet function	Haemolysis (plasma phosphate <0.1 mmol/L) ↓ Resistance to infection ↓ Platelet survival, abnormal clotting
Striated muscle	↓ Contractility of diaphragm, heart, skeletal muscles	Respiratory failure ↓ Stroke work Stiffness, weakness, debility
	Rhabdomyolysis	Muscle pain, weakness ↑ Plasma creatine kinase
Nervous system	Brain	Lethargy, confusion, irritability, dysarthria, tremor, seizure, coma
	Peripheral nerves	Paraesthesiae
Gastrointestinal	↓ conduction velocity	
	Smooth muscle	Gastric atony, ileus

treatment. Severe hypophosphataemia (<0.35 mmol/L) occurs only when there has been a cumulative net loss of ~100 mmol phosphate. Symptoms of hypophosphataemia appear when net losses reach ~300 mmol. However, the deficit in total body phosphate cannot be predicted reliably from the plasma phosphate concentration.

Treatment may be given orally in the form of sodium or potassium hydrogen phosphate (100 mmol phosphate daily in divided doses for a week), but often with critically ill patients, intravenous replacement is necessary, particularly in those with symptomatic acute hypophosphataemia. Intravenous therapy can safely be undertaken using monobasic potassium phosphate (KH_2PO_4) in a dose of 50–100 $\mu\text{mol/kg}$ body weight in half normal saline by continuous infusion over 12 h. This can be repeated every 12 h with monitoring of plasma calcium, phosphate and potassium. Intravenous administration can be stopped when plasma phosphate has risen above the symptomatic watershed of 0.35 mmol/L, assuming the rest of the deficit can be replaced orally.

Prevention is appropriate for at-risk patients. For example, many patients receiving parenteral nutrition require about 0.5 mmol phosphate/kg body weight/24 h, and occasionally more. Malnourished alcoholic patients receiving intravenous glucose should receive phosphate supplementation too.

The complications of intravenous phosphate administration include hyperphosphataemia, hypocalcaemia, hyperkalaemia and acidosis. Oral phosphate is a laxative that may induce diarrhoea.

MAGNESIUM METABOLISM

Most magnesium is in the mineral phase of bone or within the cells of the soft tissues. After potassium, it is the most abundant intracellular cation. Within cells, magnesium is a cofactor in over 300 enzymatic reactions, involving energy metabolism, control of various calcium and potassium channels, membrane stabilization and neuromuscular excitability, protein and nucleic acid synthesis and oxidative phosphorylation. It is of particular importance in those processes involving the formation and utilization of ATP. All enzymatic reactions involving ATP have an absolute requirement for magnesium. Less than 0.5% of total body magnesium is present in the plasma, although, for practical purposes, measurements of plasma ionized or total magnesium are the only widely used methods for determining magnesium status. However, such measurements may not accurately reflect whole body magnesium status. The body distribution of magnesium in an adult is summarized in Table 6.11. The magnesium content of infants is lower than adults (approximately 10 mmol/kg body weight, compared with 16 mmol/kg body weight in adults).

Plasma magnesium

In plasma, ~60% of the total magnesium is in the ionized form and ~15% complexed (with phosphate, citrate or bicarbonate), the remainder (~25%) being protein-bound,

TABLE 6.11 Magnesium content and distribution in a typical 70 kg adult

	Total (mmol)	Concentration
Bone	600	100 mmol/kg dry weight
Intracellular		
Soft tissues	500	12–18 mmol/kg
Red cells	5.5	2.7 mmol/L
ECF		
Interstitial fluid	7.0	0.7 mmol/L
Plasma	2.5	0.8–1.0 mmol/L
Ionized	1.5	0.5–0.6 mmol/L

mainly to albumin. Plasma magnesium concentrations can be adjusted for albumin concentration by the formula:

$$\text{Mg}_C^{2+} = \text{Mg}_T^{2+} + 0.005(40 - \text{Alb});$$

where Mg_C^{2+} is the corrected value and Mg_T^{2+} is the measured total value. The ionized and complexed magnesium fractions are ultrafilterable. The precise distribution of magnesium in the various plasma fractions may, as in the case of calcium, be altered by changes in protein and hydrogen ion concentrations. Plasma magnesium concentrations do not show any major changes with age or between the sexes, apart from a small increment at the menopause of ~0.06 mmol/L. Plasma magnesium falls to premenopausal concentrations with oestrogen replacement, in the same way that calcium does.

Magnesium homeostasis

Magnesium is widely distributed in foods. Being the mineral ion of chlorophyll, green vegetables are an important source. Daily intakes range from 6 to 20 mmol, with a median of ~12 mmol. Hard water contains an appreciable amount of soluble magnesium (up to 5 mmol/L), which may be more available than some of the intracellular magnesium in particular foods. Food processing can remove much of the magnesium from cereals and carbohydrate foodstuffs. The wide reference range for 24 h urinary magnesium excretion (2.0–7.5 mmol) largely reflects different magnesium intakes.

Of the typical dietary intake of 12 mmol, 6 mmol is absorbed, mainly in the small intestine. There are two separate transport systems. One, an active transport, is saturated at low intraluminal concentrations; the other is a passive diffusion mechanism that absorbs a constant fraction (~7%) of ingested magnesium. Some magnesium can be absorbed from the large bowel, as demonstrated by the occurrence of hypermagnesaemia after the use of magnesium-containing enemas. About 2 mmol magnesium is secreted into the intestine, thus the net daily intestinal absorption is ~4 mmol, which is balanced by excretion of this amount into the urine.

Approximately 75% of the total plasma magnesium is filtered through the glomeruli. Of that, ~20% is reabsorbed in the proximal tubules by paracellular absorption. The majority of the ultrafilterable magnesium (~65%) is reabsorbed in the cortical thick ascending limb of the loop of Henle. This is a passive paracellular process, driven by a positive transepithelial

voltage gradient and mediated by a tight-junction Mg^{2+} pathway, which involves the molecules claudin-16 and claudin-19.

The distal convoluted tubules regulate the final urinary magnesium excretion by active transcellular reabsorption of Mg^{2+} (~5–10% of ultrafilterable magnesium). Active magnesium reabsorption is a multistep process. A negative membrane potential maintained by the voltage-gated K^+ channel $Kv1.1$ provides the driving force for Mg^{2+} transport across the apical, epithelial channel, TRPM6 (transient receptor potential cation channel M6). Epidermal growth factor regulates active Mg^{2+} transport through TRPM6 in a paracrine/autocrine manner. The Na^+,K^+ -ATPase situated in the basolateral membrane generates a local negative membrane potential helping to drive Mg^{2+} across the TRPM6 channel in the basolateral membrane. The transcription factor HNF1 β (hepatocyte nuclear factor 1 β) affects the expression of the regulatory protein γ -subunit that binds and modulates Na^+,K^+ -ATPase. There is a probable active extrusion mechanism, either via a Mg^{2+} pump or a Na^+-Mg^{2+} exchanger, with the transmembrane protein CNNM2 (cyclin M2) a likely candidate.

There is no significant reabsorption in the collecting ducts. Between 3% and 5% of the filtered magnesium finally appears in the urine. The kidney has a maximal limit for tubular reabsorption ($TmMg$), above which all the ultrafilterable magnesium is excreted. Calculating either the $TmMg$ or the fractional urinary magnesium excretion from magnesium infusion experiments can be helpful in characterizing genetic hypomagnesaemic disorders.

Renal magnesium clearance is increased by osmotic diuretics, loop diuretics and thiazides. The kidneys of the premature newborn differ from those of adults in that the proximal tubules can reabsorb up to 70% of the ultrafilterable magnesium.

There are clear homeostatic mechanisms for regulating magnesium status, although the magnesium 'sensor' has not been characterized. The kidneys appear to be the prime organs in the fine regulation of magnesium homeostasis. In times of magnesium deprivation, the kidneys can reduce magnesium excretion to <1 mmol/24h. There is intestinal adaptation too, with the proportion of dietary magnesium absorbed higher (up to 75%) when the diet is magnesium-depleted, but lower (down to 25%) when the load is greater. Intestinal magnesium absorption can be inhibited by binding agents such as cellulose phosphate. Faecal magnesium output is normally <15 mmol/24h.

Magnesium appears to regulate parathyroid hormone secretion in a manner similar to calcium, but is only one-half to one-third as potent. Parathyroid hormone secretion is thus stimulated by modest hypomagnesaemia and suppressed by hypermagnesaemia. Paradoxically, profound hypomagnesaemia actually inhibits parathyroid hormone secretion. Although PTH may enhance the renal tubular reabsorption of magnesium, it is probably of little importance in the overall regulation of magnesium metabolism.

Magnesium losses through sweat may be great. At high temperatures, 10–15% of total magnesium output can be

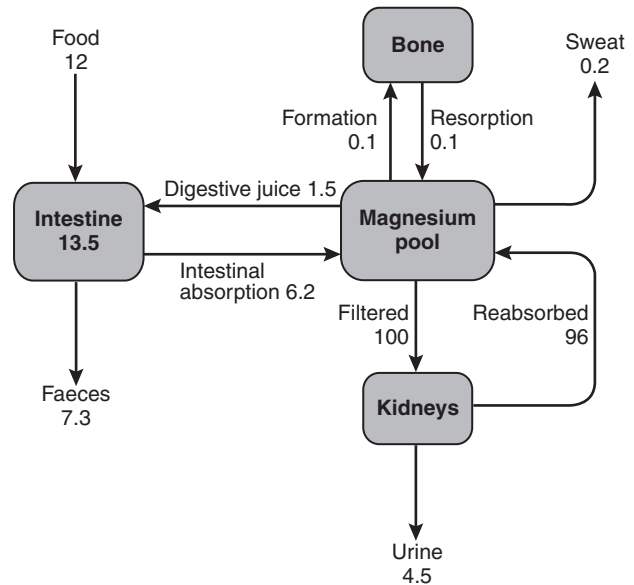

FIGURE 6.8 ■ Representative fluxes (mmol/24h) in a healthy adult (70 kg body weight) for magnesium. The exchanges with soft tissues are not illustrated in this diagram. (Modified from Wilkinson R. Absorption of calcium, phosphorus and magnesium. In: Nordin B E C (ed). Calcium, phosphate and magnesium metabolism. Edinburgh: Churchill Livingstone; 1976, with permission).

found in the sweat. Typical magnesium fluxes in an adult are illustrated in Figure 6.8. The magnesium content of breast milk is ~1.6 mmol/L, and a breast-feeding woman may lose up to 1.2 mmol/24h through this route.

Hypomagnesaemia

Causes

Hypomagnesaemia may arise through inadequate absorption (or intake), by excessive urinary or gastrointestinal losses, or by redistribution of magnesium from extracellular to intracellular sites. Hypomagnesaemia in adults is usually an acquired condition, the major causes of which are listed in Box 6.7. It is important to recognize that several drugs can cause symptomatic hypomagnesaemia, and that withdrawal of the drug concerned will resolve the problem. Most drugs associated with hypomagnesaemia affect renal tubular magnesium reabsorption. The exceptions are proton pump inhibitors (PPI), which probably affect intestinal transport or increase intestinal loss. This is a class effect and hypomagnesaemia will recur if a second PPI is substituted for the first. In adults, severe symptomatic hypomagnesaemia (<0.35 mmol/L) is seen in patients having platinum-based chemotherapy or taking proton pump inhibitors, or who are very unwell in intensive care settings.

There are a number of familial disorders (predominantly affecting renal tubular magnesium handling) that have helped understanding of magnesium homeostasis (Table 6.12). The recessively-inherited forms tend to be more severe and present in infancy or childhood. The dominantly inherited forms tend to be milder (although hypomagnesaemia can be severe with *KCNA1* mutations, plasma calcium is often unaffected).

BOX 6.7 Acquired causes of hypomagnesaemia**Inadequate intake**

- Alcoholism
- Protein calorie malnutrition
- Prolonged infusion or ingestion of low Mg solutions or diet

Malabsorption

- Inflammatory bowel disease
- Proton pump inhibitor treatment (may be excessive gut loss rather than malabsorption)^a
- Gluten enteropathy
- Intestinal bypass
- Radiation enteritis

Renal tubular dysfunction

- Alcoholism
- Hyperaldosteronism
- Hyperparathyroidism
- Post renal obstruction
- Post renal transplant
- Nephrotoxic drugs (amphotericin^a, cisplatin^a, ciclosporin^a, cetuximab, amikacin, gentamicin, laxatives, pentamidine, tobramycin, tacrolimus and carboplatin)
- Potassium depletion
- Diuretics (non-potassium-sparing)
- Osmotic diuresis

Intracellular shift

- Post-myocardial infarction
- Post-parathyroidectomy
- Recovery from diabetic ketoacidosis
- Recovery from starvation (refeeding syndrome)
- Acute pancreatitis

^aMost common causes of severe drug-induced hypomagnesaemia.**Consequences**

Symptoms directly attributable to hypomagnesaemia occur at plasma concentrations <0.5 mmol/L and include anorexia, nausea, tremor, apathy, depression, agitation and confusion. Severely hypomagnesaemic patients usually have coexistent hypokalaemia and a cellular potassium deficit; probably because of reduced activity of the magnesium-dependent Na⁺,K⁺-ATPase system of cell membranes. Potassium is lost from cells into the ECF and is then lost in the urine because magnesium deficiency also impairs the renal conservation of potassium. If severe hypomagnesaemia is prolonged then hypocalcaemia may also develop, principally because of impaired parathyroid hormone secretion. With the development of hypocalcaemia, neuromuscular signs such as muscle weakness, tremor and twitching, a positive Chvostek sign, delirium, convulsions and ultimately coma may occur.

The effects of hypomagnesaemia on the excitability of nerve, muscle and cardiac cells appear not to be direct since, as far as is known, magnesium is not involved in the normal action potential, in conduction or contraction. The effects appear to be mediated by inhibition of the Na⁺,K⁺-ATPase enzyme and, in practice, it is difficult to distinguish direct neuromuscular and cardiac effects of

severe hypomagnesaemia from those secondary to alterations in potassium and calcium metabolism.

Cardiac effects. Hypomagnesaemia of a more modest degree (0.5–0.8 mmol/L) is not uncommon and, while it is not associated with obvious symptoms, it is not necessarily benign. In patients admitted to coronary care units, there is a relationship between hypomagnesaemia and the incidence of serious dysrhythmias (including multifocal atrial tachycardia, ventricular tachycardia, ventricular fibrillation and torsades de pointes). However, hypomagnesaemia is strongly associated with hypokalaemia, and this is itself a potent cause of dysrhythmias. The association between low plasma concentrations of magnesium and potassium is again explicable by reduced membrane ATPase activity, a loss of intracellular potassium and subsequent urinary losses. The ratio of intra- to extracellular potassium, which largely determines the resting membrane electrical potential, is reduced with a consequent increase in electrical excitability. Hypokalaemia can be refractory to replacement therapy while magnesium deficiency persists. Some cardiac dysrhythmias are less responsive to antidysrhythmic therapy in the presence of hypomagnesaemia. In addition to the dysrhythmias, magnesium depletion is associated with other electrocardiographic abnormalities, including PR and QT interval prolongation and T-wave flattening. Following acute myocardial infarction, plasma magnesium concentrations typically fall and are at their lowest 12–24 h after admission to hospital. Drug therapy, particularly non-potassium-sparing diuretics, may exacerbate this hypomagnesaemia by increasing urinary losses.

Diagnostic approach to hypomagnesaemia

Plasma magnesium concentration remains the only widely available measure of magnesium status. Attempts to assess intracellular magnesium more reliably have included the measurement of erythrocyte, monocyte and muscle cell concentrations, but these experimental approaches are not widely available. Hypomagnesaemia is common in the critically ill, occurring in up to 50% of such patients. However, only about 25% have low ionized magnesium concentrations.

A magnesium retention test, which aims to detect a total body deficit, has been proposed. The urinary excretion of magnesium is measured over 24 h following the parenteral administration of 0.1 mmol/kg magnesium (in the form of magnesium sulphate). Normally 75–80% of the dose is excreted, but less if there is magnesium deficiency (see [Appendix 6.5](#), for method).

To assess renal magnesium handling in patients with suspected renal tubular abnormalities, the fractional urinary magnesium (FE_{Mg}) can be estimated on fasting urine (U) and plasma (P) samples:

$$FE_{Mg} (\%) = \frac{U_{Mg} \times P_{creat}}{(0.75 \times P_{Mg}) \times U_{creat}} \times 100$$

Values >2%, while the patient is hypomagnesaemic, suggest renal magnesium wasting. Renal tubular

TABLE 6.12 Genetic causes of hypomagnesaemia

Disorder	OMIM ^a	Inheritance locus	Gene	Mutated protein	Mechanism	Phenotype
Hypomagnesaemia 1 (HOMG1)	602014	AR 9q21	<i>TRPM6</i>	Transient receptor potential channel M6 (TRPM6)	Reduced absorption of Mg from distal convoluted tubule and impaired intestinal Mg absorption	Neonatal convulsions, tetany

^bIndicates an activating mutation; all others are thought to be inactivating.

magnesium handling can be assessed more rigorously by magnesium infusion testing. It is possible to combine an infusion test to determine TmMg with a magnesium retention test to determine if there is a magnesium deficit (see [Appendix 6.6](#), for a suggested protocol).

Where hypomagnesaemia is due to inadequate intake or malabsorption, urinary magnesium falls rapidly to <0.7 mmol/24h from the usual 2–7 mmol/24h.

The main diagnostic step must remain thinking of hypomagnesaemia as a potential problem and making a request for plasma measurement. Studies comparing

physician-initiated testing and ‘routine’ measurement have shown that hypomagnesaemia is very common in hospitalized patients, that it is frequently associated with hypokalaemia and that only about 10% of hypomagnesaemic patients are identified by physician-initiated requests. This has been used as an argument for including magnesium among the routine hospital analyses of plasma ‘electrolytes’.

The ingestion of large quantities of magnesium (in the form of antacids or laxatives) can induce diarrhoea. In magnesium-related diarrhoea, the faecal magnesium

BOX 6.8 Conditions that may benefit from magnesium supplementation

- Ventricular tachyarrhythmias
- Hypokalaemia unresponsive to potassium supplementation
- Neurological manifestations of hypomagnesaemia
- Hypomagnesaemia without clinical manifestations
- Diuretic therapy
- Hypocalcaemia unresponsive to calcium supplementation

From Reinhart R A 1988 Magnesium metabolism. Archives of Internal Medicine 148:2415–2420.

content is high (>15 mmol/24h). This measure is of occasional value in the diagnosis of factitious diarrhoea.

Therapeutic approach to hypomagnesaemia

Conditions that may benefit from magnesium repletion are listed in Box 6.8. The amount and rate of magnesium administration depends on the cause and severity of the magnesium depletion and on renal and intestinal function.

Symptomatic deficiency is best treated by the intravenous route. Adults with good renal function should be given 12 mmol magnesium (in the form of magnesium sulphate in saline or 5% dextrose) over 2–3 h and a further 12 mmol infused slowly over the following 24 h. This regimen may need to be repeated over several days, as the tissue magnesium deficit takes longer to correct than the plasma concentration. If the plasma concentrations are increased too much, urinary magnesium losses increase. In infants, replacement is given in a similar manner, but the dosage should be reduced to 0.2–0.3 mmol/kg. Plasma magnesium concentrations need to be monitored during and after replacement therapy. The intramuscular route can also be used for replacement, but the injections are painful.

Where feasible, magnesium supplements may also be given orally (5–10 mmol/24 h, in divided doses). Suitable preparations include magnesium oxide and its sulphate and carbonate salts, which are available as antacids or purgatives. Higher doses may cause diarrhoea.

With drug-induced hypomagnesaemia, the offending agent should of course be withdrawn.

Hypermagnesaemia

The kidneys normally excrete excess magnesium very efficiently and can handle loads of up to 400 mmol/24 h, so hypermagnesaemia as a clinical problem is largely restricted to patients with acute or chronic renal failure. Hypermagnesaemia is, however, seen in familial hypocalcaemic hypercalcaemia (FHH), and can also occur with magnesium-containing enemas and cathartics. In subjects with renal failure, the potential sources of excess magnesium loads are the dialysate, magnesium-containing antacids (as phosphate-binding agents) and, in acute kidney injury, release of magnesium from tissues.

Hypermagnesaemia in patients with renal impairment can also occur with the use of citrate-gluconic acid solutions. These solutions, which contain substantial quantities of magnesium salts, are used either for bladder irrigation or are infused into the renal pelvis through a nephrostomy tube for the dissolution of renal stones.

Hypermagnesaemia in the order of 1.5–2.5 mmol/L may be associated with hypotension but is commonly asymptomatic. In the range 2.5–5.0 mmol/L, areflexia may be present and electrocardiographic changes occur (prolonged PR and QRS interval, peaked T waves). At higher concentrations, respiratory paralysis and cardiac arrest ensue: concentrations >8 mmol/L (almost always iatrogenic) are frequently fatal. At these very high plasma concentrations, magnesium has direct effects on neuromuscular cells; inhibiting acetylcholine release and causing peripheral blockade. Use is made of this in the pharmacological management of seizures associated with eclampsia of pregnancy, where an effective remedy is the parenteral administration of magnesium sulphate to maintain plasma concentrations at 3–4 mmol/L.

The treatment of hypermagnesaemia initially consists of cessation of magnesium administration. In an emergency, intravenous calcium gluconate (10 mL, 10% solution; 2.2 mmol calcium) will reverse the effects of hypermagnesaemia. Dialysis is also effective.

CONCLUSION

The physiology and pathology of calcium, phosphate and magnesium are closely related. The principal hormones involved in calcium and phosphate homeostasis are 1,25-dihydroxyvitamin D, FGF23 and parathyroid hormone. The great majority of calcium and phosphate is present in the skeleton, as is over half the magnesium, but all three ions have many other vital functions.

Pathological increases and decreases in concentrations of calcium, phosphate and magnesium can occur, and all can have serious consequences. For each disorder, a relatively small number of conditions account for the majority of presentations.

APPENDIX 6.1: CALCIUM ABSORPTION TEST

This test was originally described by Broadus et al. (1978) for use in the investigation of hypercalcaemia, but it can also be used to estimate intestinal calcium absorption in other contexts. The patient takes a low calcium diet (10 mmol (400 mg)/24 h) for one week and is studied after an overnight fast (distilled water only). A water intake of 250 mL/h is maintained from 1 h before the test until its completion. The test consists of three consecutive 2 h urine collections for measurement of calcium and creatinine, with a plasma calcium and creatinine measurement at the midpoint of the first and third of these

collections. At the beginning of the second urine collection, a 1 g (25 mmol) oral calcium load is taken.

Interpretation

Reference values:

$$\begin{aligned} \text{rise in urine calcium output} &= 0.18 - 0.73 \text{ mmol} / 2 \text{ h} \\ \text{rise in plasma calcium} &= 0.07 - 0.30 \text{ mmol} / \text{L} \end{aligned}$$

Reference

APPENDIX 6.2: ANALYSIS OF TUBULAR HANDLING OF CALCIUM

The relationship between urine calcium excretion per litre of glomerular filtrate (Ca_E) and plasma calcium has been established from calcium infusion experiments in healthy subjects. The renal tubular handling of calcium can be assessed by reference to this normal relationship. Ca_E is estimated from:

$$\frac{\text{urine [calcium]} \times \text{plasma [creatinine]}}{\text{urine [creatinine]}}$$

obtained from the second void sample after rising in the morning, while still fasting. All these concentrations are expressed as mmol/L. The units of Ca_E are mmol/L glomerular filtrate.

Interpretation

Hypercalcaemic patients falling to the right of the reference range (Fig. 6.9) are excreting less calcium than

FIGURE 6.9 ■ Renal tubular handling of calcium (see text). (From Nordin B E C. Diagnostic procedures. In: Nordin B E C (ed). Calcium, phosphate and magnesium metabolism. Edinburgh: Churchill Livingstone; 1976, with permission).

expected for their prevailing plasma calcium concentration. Provided that this is documented at a time when the patient is not volume depleted, it can then be inferred that abnormally high renal tubular calcium reabsorption is contributing to the patient's hypercalcaemia. Typically, this is seen in primary hyperparathyroidism, familial hypocalciuric hypercalcaemia and malignant hypercalcaemia due to PTHrP. Similar considerations apply in the investigation of hypocalcaemia. Patients in whom Ca_E falls to the left of the reference range are excreting more calcium than would be predicted from the low plasma calcium concentration, and it can be inferred that abnormally low renal tubular calcium reabsorption is contributing to the hypocalcaemia (typically seen in hypoparathyroidism).

APPENDIX 6.3: CLASSIFICATION OF PSEUDOHYPOPARATHYROIDISM

This protocol is a modification of the Ellsworth-Howard and Chase-Auerbach tests. It measures the response of urine cAMP and TmP/GFR to an injection of synthetic human PTH (1-34).

The test is performed in a fasting patient, who ingests 250 mL/h of water between 06.00 and 12.00 noon. Two 30 min urine collections are collected before 09.00, at which time PTH (1-34), 0.625 µg/kg (maximum dose 25 µg) is infused intravenously over 15 min. Consecutive urine collections are made from 09.00-09.30; 09.30-10.00; 10.00-11.00 and 11.00-12.00, with blood samples taken at 09.00 and 11.00.

Analysis

Urine specimens: cAMP, creatinine, phosphate concentrations. Blood specimens: creatinine, phosphate concentrations. cAMP excretion is expressed as nmol/L glomerular filtrate (GF):

$$\frac{\text{urine [cAMP]} \times \text{plasma [creatinine]}}{\text{urine [creatinine]}}$$

Urine and plasma creatinine concentrations are expressed in the same units.

Phosphate excretion expressed as TmP/GFR (mmol/L glomerular filtrate; see Appendix 6.4).

Interpretation

Normal response:	10-20-fold increase in cAMP excretion, fall in TmP/GFR of 20-30%
Pseudohypoparathyroidism:	Type I, <5-fold increase in cAMP Type II, normal increase in cAMP Both types, <10% fall in TmP/GFR

Reference

APPENDIX 6.4: ESTIMATION OF TMP/GFR

A fasting, second voided urine sample is obtained in the morning. The convention is that this should be a 2 h collection, but the timing is in fact immaterial since time does not enter into the calculation. A plasma sample is obtained at the same time.

Measurements: plasma phosphate and creatinine; urine phosphate and creatinine (all expressed in the same units).

The ratio of the clearance of phosphate ($C_{\text{phosphate}}$) to the clearance of creatinine ($C_{\text{creatinine}}$) is calculated:

$$\frac{C_{\text{phosphate}}}{C_{\text{creatinine}}} = \frac{\text{urine [phosphate]} \times \text{plasma [creatinine]}}{\text{plasma [phosphate]} \times \text{urine [creatinine]}}$$

The tubular reabsorption of phosphate (TRP) = $1 - (C_{\text{phosphate}}/C_{\text{creatinine}})$.

TmP/GFR is read from the nomogram which relates the prevailing plasma phosphate concentration [PO_4] to TRP (Fig. 6.10).

A straight line through the appropriate values of plasma phosphate and TRP (or $C_{\text{phosphate}}/C_{\text{creatinine}}$) passes through the corresponding value of TmP/GFR. It should be noted that TmP/GFR and plasma phosphate concentrations are expressed in the same units. Two scales have been given: the 0.0–2.0 scale is suitable for estimating values of TmP/GFR close to the reference range expressed in SI units (0.80–1.35 mmol/L glomerular filtrate) and the 0.0–5.0 scale for values expressed in mass units (2.5–4.2 mg/100 mL glomerular filtrate).

FIGURE 6.10 ■ Estimation of TmP/GFR (see text). (From Walton R J, Bijvoet O L M 1975 Lancet 2: 309–310, with permission).

APPENDIX 6.5: MAGNESIUM RETENTION TEST

Suggested schema for clinical use of magnesium tolerance test in normomagnesaemic patients:

1. Collect baseline urine (spot or timed) for magnesium/creatinine molar ratio
2. Infuse 0.1 mmol MgSO_4 /kg lean body weight in 50 mL dextrose saline over 4 h

3. Collect urine for 24 h (starting with infusion) for measurement of excretion of magnesium and creatinine (Cr) (both in mmol)
4. Calculate % Mg retained using the following formula:

$$1 - \left(\frac{\text{postinfusion urine [Mg]} - (\text{preinfusion urine [Mg]} - ([\text{Mg}]/[\text{Cr}] \times \text{postinfusion urine [Cr]})}{\text{total elemental Mg infused}} \right)$$

5. Criteria for Mg deficiency: >50% retention at 24 h.

Reference

From Ryzen E, Elbaum N, Singer FR, Rude RK. Parenteral magnesium tolerance testing in the evaluation of magnesium deficiency. *Magnesium* 1985;4:137–47. With permission of the publishers Karger, Basel.

APPENDIX 6.6: RENAL TUBULAR REABSORPTION OF MAGNESIUM

1. A fasting urine and blood sample are obtained after an overnight fast.
2. A loading dose of 0.4–0.8 mmol magnesium is infused (1–2 mL 10% MgSO_4 solution), and then a continuous infusion of 8 mmol over 2 h (in 50 mL 5% dextrose) is begun.
3. Over the third and fourth hours of the test, 16 mmol magnesium are infused.
4. For the fifth and sixth hours of the test, 32 mmol magnesium are infused. (Quantities shown are for an adult.)
5. Urine specimens are collected hourly for the measurement of magnesium and creatinine concentrations. Blood specimens are collected at the midpoint of each hour for the measurement of magnesium and creatinine.
6. A graph is plotted of magnesium excretion/litre of glomerular filtrate (Mg_{excr} : y-axis) vs ultrafilterable plasma magnesium (ufMg: x-axis).

$$\text{Mg}_{\text{excr}} = (\text{urine [magnesium]} \times \text{plasma [creatinine]}) / \text{urine [creatinine]}$$

$$\text{ufMg} = 0.75 \times \text{plasma [magnesium]}$$

The graph should show a line roughly parallel to the line of identity. The TmMg is the vertical distance between these parallel lines. A typical normal value is ~0.6 (meaning that when ufMg is less than 0.6 mmol/L, virtually all filtered magnesium is reabsorbed). In patients with impaired renal tubular reabsorption, TmMg values may be close to zero.

It is possible to combine both retention and tubular reabsorption tests in hypomagnesaemic patients, if the volume of each of the six urine samples is measured.

In addition to calculating magnesium excretion/litre of glomerular filtrate (as above) for each collection, the total amount of magnesium excreted over the 6 h of the test can be calculated. A collection is then made of the next 18 h urine to calculate 24 h urine excretion for determination of magnesium retention (as in Appendix 6.5).

ANATOMY

Gross anatomy

The kidneys are located against the posterior abdominal wall on either side of the vertebral column. They lie anterior to the diaphragm and various muscles; their anterior surfaces are covered by parietal peritoneum. The left kidney is posterior to the stomach, pancreas, spleen and descending colon, and the right to the liver, the second part of the duodenum and the ascending colon. Their superior poles are covered by the suprarenal (adrenal) glands. In the adult, the kidneys are about 11–13 cm long, 6 cm wide and 4 cm thick. They weigh approximately 150 g each, yet together receive about 25% of the resting cardiac output. This blood is supplied by the renal arteries, which are branches of the aorta. Venous drainage is into the renal veins, which drain into the inferior vena cava. The kidneys are innervated by sympathetic nerves arising from the sympathetic chains and by parasympathetic fibres arising from the vagus nerve.

Each kidney is covered by a poorly distensible capsule. This limits the swelling that can occur during acute inflammation, and in such circumstances there is an increase in tissue pressure that tends to decrease the glomerular filtration rate (GFR).

Congenital absence of one kidney occurs in approximately 1 in 2400 individuals; this is only of significance if renal surgery is contemplated for any reason. The remaining kidney usually undergoes compensatory hypertrophy. Another common (approximately 1 in 10 000) congenital anomaly is the single ‘horseshoe’ kidney, in which the lower poles of the potential two kidneys are conjoined; renal function is normal but, occasionally, ureteric obstruction may predispose to calculus formation and infection.

Microstructure

Each kidney contains approximately one million functional units, called nephrons. These are tubular structures, consisting of various histologically and functionally

distinct elements. Each nephron has a single glomerulus, which is located in the outer part of the kidney (the cortex) and is responsible for the ultrafiltration of the blood. The remainder of the nephron consists of several contiguous tubular structures that progressively modify the composition of the ultrafiltrate before it is passed out as urine. These structures (Fig. 7.1) are:

- the proximal convoluted tubule, also located in the cortex
- the loop of Henle, which has the configuration of a hairpin and extends into the deeper part of the kidney (the medulla), then doubles back on itself to return to the cortex
- the distal convoluted tubule, located in the cortex
- the collecting duct, which extends down through the medulla to the renal papillae, whence the urine drains into the renal pelvis. The renal pelvises are drained by the ureters, and the right and left ureters themselves drain into the urinary bladder, where urine is stored prior to voiding.

The glomerulus

Each glomerulus consists of a tuft of capillaries that protrudes into the dilated, blind end of the nephron (the Bowman capsule) (Fig. 7.2). The nephron is composed of epithelial cells, and these and the endothelial cells of the glomerular capillaries are separated by a

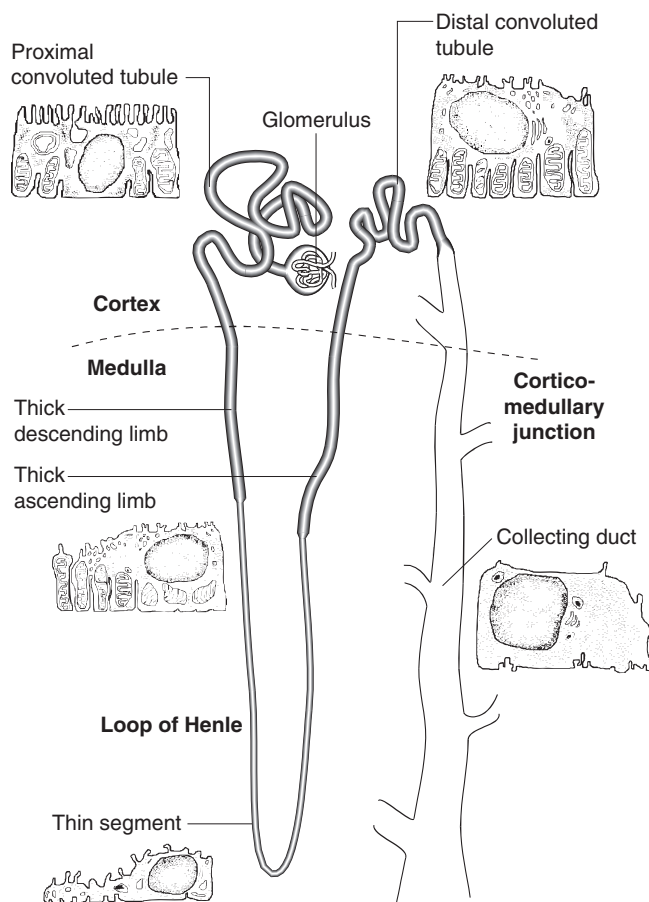

FIGURE 7.1 ■ Diagram of a nephron showing the structure of typical tubular cells.

basement membrane. This visceral basement membrane is continuous with a parietal basement membrane associated with the epithelial cells forming the outer part of the Bowman capsule, which are continuous with the epithelium of the proximal convoluted tubule. The microstructure of the glomerulus is described in detail in Chapter 8.

The glomerular filtrate is formed by the passage of fluid from the capillaries through fenestrations in the endothelial cells and through the basement membrane. This is covered on its epithelial aspect by the interdigitating foot processes of the epithelial cells, or podocytes, and the ultrafiltrate passes across a thin membrane (the epithelial slit diaphragm) into the filtration slits between the foot processes and then into the Bowman space, which is continuous with the lumen of the nephron. The selective retention of different constituents of the blood occurs at different stages. The endothelial fenestrations are too small to permit significant passage of erythrocytes, leukocytes or platelets; the major barrier to the filtration of proteins is mechanical and provided by the inner layer of the basement membrane, but the anionic surface layer also selectively retards anionic proteins. Finally, the foot processes and slit diaphragms also act as a mechanical barrier. The relative rate of progression of the constituents of the plasma into the Bowman space, therefore, depends on molecular mass, shape and charge. Glomeruli also contain mesangial cells. These stellate cells are contractile, are involved in the regulation of glomerular filtration and have phagocytic properties. The basement membrane does not extend between the mesangial cells and endothelial cells. This facilitates their ability to phagocytose large particles from the plasma. Their ability to ingest immune complexes plays an important part in the pathogenesis of certain forms of glomerular disease.

The proximal convoluted tubule

This structure is about 15 mm long and is composed of a single layer of inter-digitating epithelial cells united at their apices by tight junctions. The luminal surfaces of these cells have microvillous brush borders that provide the large surface area required for the absorptive function of the proximal tubule. The proximal tubule drains into a short straight segment directed towards the outer medulla and continuous with the descending limb of the loop of Henle.

The loop of Henle

The descending limb of the loop of Henle (Fig. 7.1) is composed of flat epithelial cells. The majority of the loops, whose glomeruli lie in the outer part of the cortex, are relatively short, but those with more deeply situated glomeruli have longer loops (up to 14 mm), which extend down into the medullary pyramids.

The thin descending limb turns back on itself, ascending towards the medulla, and the epithelial cells become cuboid, rich in mitochondria and have an invaginated luminal surface. The thick ascending limb extends towards the glomerulus of the same nephron and then leads into the distal convoluted tubule.

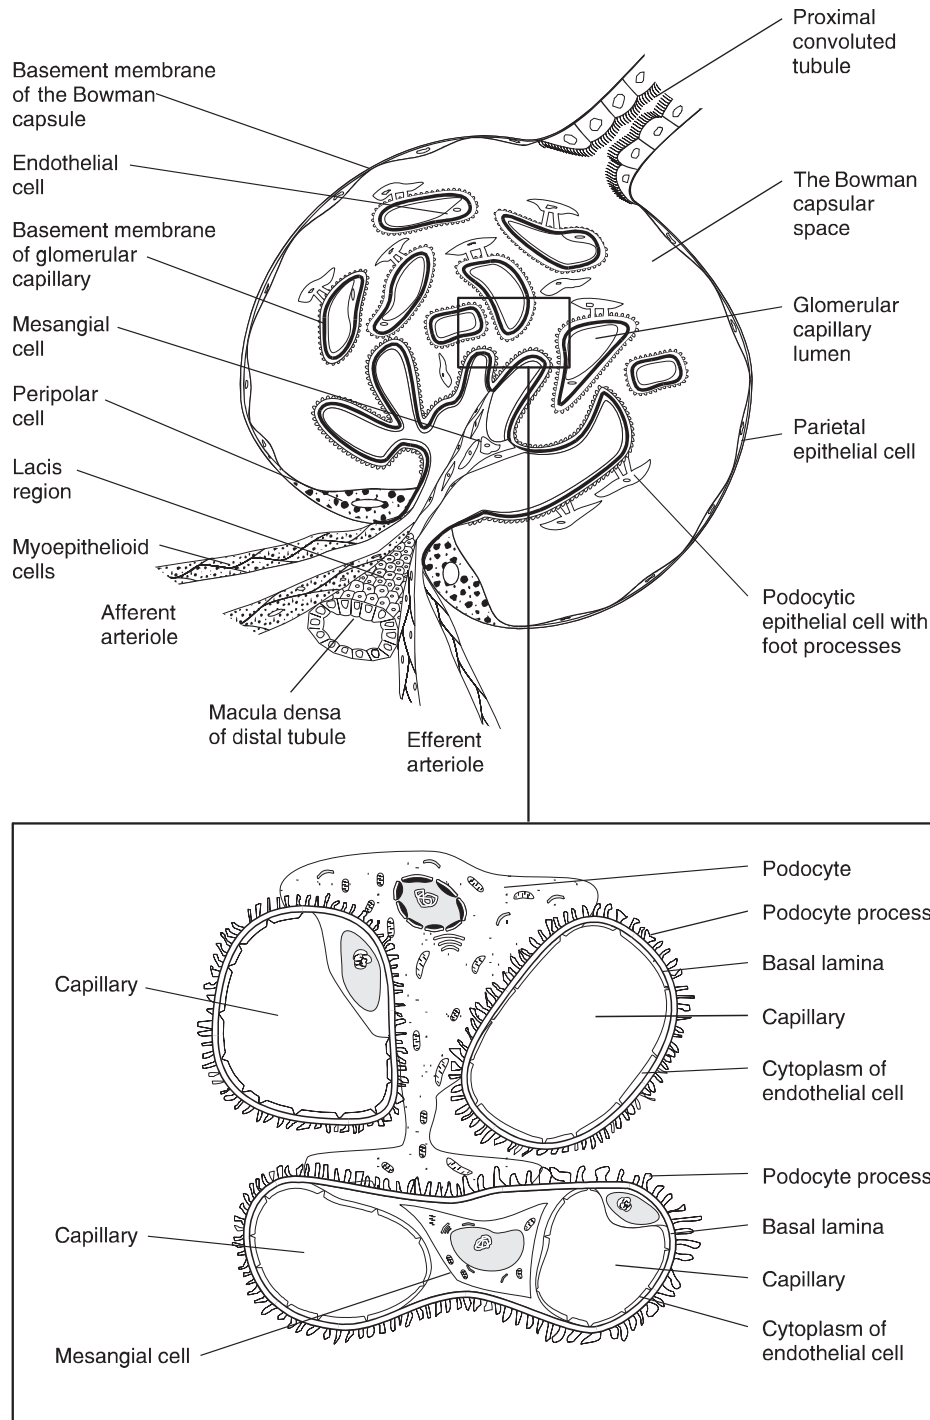

FIGURE 7.2 ■ Diagram of a glomerulus with detailed enlargement to show the cellular relationships.

The distal convoluted tubule and collecting duct

The distal convoluted tubule is about 5 mm long and is made up of typical absorptive epithelial cells, although without a brush border. It passes close to the afferent and efferent arterioles of the same nephron. The tubular epithelial cells in this area have a special function in relation to the control of renin secretion and are known as the macula densa. Renin is secreted by myoepithelioid juxtaglomerular cells in the walls of the afferent arterioles.

These cells, together with those of the macula densa and some other nearby cells (lacis cells), constitute the juxtaglomerular apparatus.

The distal convoluted tubule also contains intercalated (I) cells, responsible for the secretion of acid.

The collecting ducts are composed of I cells and also principal (P) cells, which become permeable to water under the influence of vasopressin. The ducts descend from the cortex down through the medulla, opening to the renal pelvis from the renal papillae.

Other specialized cells

In addition to the cells of the nephron and blood vessels, the kidneys contain medullary interstitial cells. These characteristically contain lipid droplets and secrete prostaglandins.

Blood vessels

Blood leaving glomerular capillary tufts passes not into venules, but into efferent arterioles. Those draining the cortical glomeruli divide into a capillary plexus that enmeshes the renal tubules. Those draining the juxtamedullary glomeruli form the vasa recta; these are bundles of vessels that plunge into the medulla to varying depths, forming capillary plexi that envelop the loops of Henle and then rejoin to form the ascending vasa recta, which eventually drain into the renal veins. The vasa recta form a countercurrent exchange system (see below), which is essential to the formation of both concentrated and dilute (with respect to plasma) urine.

RENAL FUNCTION

The principal functions of the kidneys are to excrete water-soluble (mostly nitrogenous) waste products and toxins from the body, and to control the volume and composition of the extracellular fluid (ECF). The kidneys also have important endocrine functions. It is perhaps surprising that the kidneys produce some 170 L of glomerular filtrate per 24 h, but only 1–2 L of urine. The bulk of the solvent and solute filtered is reabsorbed, but the control of the processes responsible gives considerable scope for the composition and volume of the urine to be adjusted to meet the physiological needs of the individual.

The physiology of the kidneys is well described in many standard physiology textbooks and will not be recounted in detail in this chapter. Rather, a brief summary is given and certain features that are pertinent to an understanding of the investigation of renal function and the mechanisms and consequences of renal impairment are emphasized.

Renal blood flow and its control

At rest, 20–25% of the cardiac output flows through the kidneys (1.1–1.3 L/min). The bulk of this blood perfuses the cortex; indeed, the flow rate to the medulla is actually less than to most other tissues.

The process of glomerular filtration is essential to renal function and is dependent on an adequate renal perfusion pressure. Autoregulatory mechanisms allow maintenance of renal blood flow and GFR within narrow limits in the face of a wide variety of external variables, including arterial pressure, venous pressure, ureteric hydrostatic pressure and plasma oncotic pressure. Renal blood flow and GFR are independent of mean arterial blood pressure over the range 80–200 mmHg. This is achieved by intrinsic, and humorally and neurally mediated, alterations in the tone of the renal blood vessels and, in particular, of the efferent glomerular arterioles.

Renal hypoperfusion stimulates the release of renin from juxtaglomerular cells. This enzyme converts circulating angiotensinogen to angiotensin I, which is in turn converted by angiotensin-converting-enzyme to angiotensin II, a powerful vasoconstrictor. This contributes to the maintenance of systemic blood pressure and, in the kidney, by causing efferent arteriolar vasoconstriction, helps to maintain the intraglomerular pressure despite a reduction in perfusion pressure. Various other mechanisms are involved in the maintenance of systemic blood pressure, but in the poorly perfused kidney, release of prostaglandins causes vasodilatation which, at least in mild hypotension, helps to maintain renal blood flow. A perfusion pressure of at least 50–60 mmHg is required to overcome the combined hydrostatic and oncotic pressures that oppose filtration; if mean arterial pressure falls below 80 mmHg, renal blood flow and GFR decline rapidly.

Glomerular function

Glomerular filtration is fundamental to the production of urine and to the homeostatic functions of the kidney. Techniques for measuring the GFR, the amount of filtrate formed per unit time, are described in a later section (p. 131).

The glomerular filtration rate is determined by the balance of pressures across the filtration barrier in the glomerulus, and the physical nature and extent of the barrier itself. The forces include the difference between afferent and efferent glomerular arteriolar pressures (promoting filtration) opposed by the difference in osmotic pressures between the ultrafiltrate and the plasma, and the hydrostatic pressure in the Bowman space. The net filtration pressure is normally approximately 15 mmHg at the afferent end of the capillaries, falling to zero at the efferent ends. Factors influencing the GFR are summarized in [Box 7.1](#).

A decrease in the area available for filtration can occur in many renal diseases in which there is glomerular damage. It can also result from contraction of mesangial cells mediated by agents such as angiotensin II, vasopressin, noradrenaline (norepinephrine), thromboxane A₂ and prostaglandin F₂; dopamine, natriuretic peptides and prostaglandin E₂ have opposite effects. A reduction in filtration area may be an important physiological mechanism for reducing GFR and thus conserving fluid.

BOX 7.1 Factors affecting glomerular filtration rate

- Renal blood flow
- Glomerular capillary hydrostatic pressure
 - Systemic blood pressure
 - Afferent/efferent arteriolar vasoconstriction
- Hydrostatic pressure in the Bowman space
 - Ureteric obstruction
 - Renal oedema (with restricting capsule)
- Plasma protein concentration
- Glomerular ultrafiltration coefficient
 - Glomerular permeability
 - Number of glomeruli

Tubular function

The proximal convoluted tubule

The proximal tubules are responsible for the active reabsorption of the bulk of filtered solute, accompanied by an iso-osmotic amount of water. Thus, virtually all the filtered glucose, amino acids, bicarbonate and potassium are absorbed here, together with some two-thirds of the filtered sodium. Absorption of solutes is an active, energy-requiring process and is isotonic, so that an equivalent amount of water is also absorbed and the fluid entering the descending limb of the loop of Henle is isotonic with plasma.

Transport occurs by way of ion channels, exchangers, co-transporters and pumps; filtered proteins are taken up into tubular cells by endocytosis and broken down into their constituent amino acids. Transport mechanisms have finite capacities and these may be exceeded in some circumstances. For example, glucose begins to be excreted in the urine if the plasma concentration exceeds about 10 mmol/L. Isolated or generalized disorders of renal tubular function result in the excretion of solutes normally reabsorbed in the proximal tubule even at normal plasma concentrations, as discussed further in Chapter 9.

The sodium content of the ECF is the primary determinant of ECF volume, the maintenance of which is critical to life. Given that about 26000 mmol of sodium are filtered at the glomeruli each day (equivalent to some 8–9 times the total body sodium), it is clearly essential that most of the filtered sodium is reabsorbed. Indeed, the bulk of sodium reabsorption is obligatory. However, an increase in GFR (which potentially could lead to a massive increase in sodium excretion) results in increased proximal tubular sodium absorption and *vice versa*. This process, termed *glomerulo-tubular balance*, is thought to be mediated largely through changes in the oncotic pressure in the peri-tubular capillaries. This increases when the GFR increases, owing to the increase in the volume of water removed from the plasma. The re-absorption of several other solutes is affected similarly. Normal kidneys are capable of excreting between virtually zero and more than 400 mmol of sodium per 24h. The fine control of sodium excretion is achieved in the distal convoluted tubule, where sodium reabsorption is stimulated by aldosterone.

Most of the filtered bicarbonate is absorbed in the proximal convoluted tubule, although indirectly. Hydrogen ions are generated in the tubular cells and are secreted into the tubular lumen (mainly in exchange for sodium) where they combine with the filtered bicarbonate ions. Bicarbonate ions are formed *pari passu* with hydrogen ions and are co-transported with sodium across the basolateral membranes of the tubular cells into the interstitial space (see Chapter 5).

Some substances are secreted into the urine from the proximal tubule. Examples include penicillins, creatinine, certain steroids and their glucuronides and derivatives of hippuric acid, for example *p*-aminohippuric acid (PAH). This property of PAH allows physiologists to use measurements of PAH clearance to determine renal plasma flow, but this is not an investigation that is used clinically.

The loop of Henle

This structure provides the countercurrent multiplier that generates the medullary hypertonicity that is essential for the regulation of water excretion and the production of concentrated urine.

Essentially, the process involves the active transport of solute (principally chloride and sodium ions) out of the thick ascending limb of the loop of Henle. This solute is not accompanied by water. As a result, the fluid within the lumen becomes hypotonic and the interstitial fluid surrounding the loop becomes hypertonic. Since water can diffuse out of the thin descending limb, but not the thick ascending limb, the net effect is that the fluid within the loop of Henle and the surrounding interstitial fluid become progressively hypertonic from the corticomedullary junction down into the medulla. There is further sodium and chloride absorption from the thick ascending limb. As water cannot diffuse out of the thick limb, the fluid entering the distal convoluted tubule is hypotonic with respect to plasma.

The anatomical disposition of the vasa recta allows them to act as a countercurrent exchanger, maintaining (though not actively contributing to) the osmotic gradient. The flows of water and solutes in the nephron are summarized in Figure 7.3. Whereas 60–70% of the filtered loads of solute and water have been reabsorbed from the glomerular filtrate at the beginning of the loop of Henle, a further 15% of water is removed during passage through this structure, so that only 10–20% of filtered water and somewhat less solute reach the distal convoluted tubule.

Tubuloglomerular feedback. There is a reciprocal relationship between the rate of flow of fluid through the ascending limb of the loop of Henle and the first part of the distal convoluted tubule of individual nephrons, and the rate of glomerular filtration through the same nephron. Thus, a decrease in flow rate increases filtration and vice versa. This process tends to result in a constant load of solute being presented to the distal convoluted tubule.

FIGURE 7.3 ■ Changes in the fraction of the filtered amounts of substances remaining in the tubular fluid along the length of the nephron.

Feedback is mediated through constriction and dilatation of the afferent arteriole by factors such as renal prostaglandins, adenosine and the renin–angiotensin system, in response to changes in chloride absorption in the macula densa. This mechanism becomes more sensitive when ECF volume is decreased and vice versa.

Tubuloglomerular feedback should not be confused with glomerulotubular balance, the change in proximal tubular sodium reabsorption in response to changes in GFR that has been discussed above and in Chapter 4.

The role of urea. Urea has an essential role in the generation of medullary hypertonicity. The thick ascending limb of the loop of Henle is permeable to urea (and sodium) but not to water. Movement of urea down its concentration gradient into the interstitium contributes significantly to medullary hypertonicity; the inner medullary portion of the collecting duct (see below) is also permeable to urea. The poor concentrating ability of the kidneys in the newborn is due to the decreased availability of urea to maintain medullary hypertonicity. In adults, renal concentrating power is dependent on an adequate protein intake (the source of urea) and is lower on a low protein diet.

The distal convoluted tubule

This part of the nephron is responsible for the ‘fine tuning’ of urinary composition. Aldosterone stimulates sodium reabsorption, generating an electrochemical gradient that allows the secretion (and thus excretion) of potassium and hydrogen ions. Normal distal tubular function is essential to the maintenance of hydrogen ion homeostasis.

The collecting duct

These structures extend from the ends of the distal convoluted tubules to the renal papillae. Their main function is to permit the reabsorption of solute-free water and thus regulate the osmolality of the urine. This is achieved through the action of vasopressin (antidiuretic hormone). The cells of the collecting ducts are normally impermeable to water. Under the influence of vasopressin, aquaporin-2 water channels are inserted into the tubular wall, such that they become permeable, allowing water to move out of the hypotonic fluid in the tubular lumen into the hypertonic interstitium, so producing concentrated urine. In the absence of vasopressin, no water is removed and the urine is hypotonic.

The extremes of achievable urine osmolality are 30–1400 mmol/kg. When maximally dilute, as much as 13% of the filtered water is excreted and the rate of urine production is about 16 mL/min; when maximally concentrated, <0.5% of filtered water is excreted and urine production is as little as 500 mL/24 h.

Some solute is also absorbed in the collecting ducts. In the cortical portion, sodium reabsorption takes place in exchange for potassium and hydrogen ions, as in the distal convoluted tubules. The medullary segment is partially permeable to urea, which moves passively out into the interstitium and helps to maintain the high osmolality of the medulla.

Diuresis. While the maximal urine flow rate when a water load is being excreted is approximately 16 mL/min (assuming an average solute load), higher rates are attainable if there are increased quantities of non-reabsorbed solutes in the tubules. This osmotic diuresis is due to the direct osmotic effect of the solutes and to a secondary effect on sodium reabsorption. The retention of water in the lumen of the proximal tubules increases the concentration gradient against which sodium must be reabsorbed; the same factor limits sodium reabsorption in the thick ascending part of the loop of Henle, thus interfering with the generation of medullary hypertonicity. This is the explanation for the diuresis characteristic of hyperglycaemia.

RENAL DISEASE AND ITS PRESENTATION

Introduction

There are many specific renal diseases; these may present with clinical features clearly referable to the kidneys (e.g. a decrease or increase in urine output), but frequently have systemic manifestations (e.g. the ‘uraemic syndrome’ (see p. 142) and hypertension). The kidneys can also be involved in multisystem disease, for example diabetes mellitus, the connective tissue disorders and amyloidosis.

Manifestations of renal disease

There are relatively few cardinal manifestations of renal disease and none is specific to any one underlying disorder. They include anuria, oliguria and polyuria; respectively a complete absence, decreased production and excessive production of urine. Polyuria may come to notice only by virtue of causing excessive production of urine at night (nocturia). These are usually symptoms of disordered renal function, although anuria and oliguria can be secondary to obstruction of the urinary tract and polyuria can be due to extrarenal disease that impairs the ability of the kidneys to concentrate the urine.

Urinary frequency (the passing of urine more frequently than normal, but in normal total 24 h volumes) must be distinguished from polyuria; it is often related to irritation of the urinary tract, for example by infection, but can also be due to prostatic enlargement. Irritation of the urinary tract is frequently accompanied by dysuria – pain on micturition. Patients with renal disease may experience loin pain or have tenderness in the loins. Renal or ureteric colic, an intermittent pain of considerable severity, is characteristic of the passage of urinary calculi.

Patients with renal disease may present with systemic abnormalities, including hypertension, pyrexia, oedema and the ‘uraemic syndrome’. This latter term is used to describe the protean manifestations of renal failure. The urine may appear abnormal in renal disease; the causes are discussed in a later section (p. 130).

Finally, renal disease may be revealed for the first time by the finding of a biochemical abnormality, particularly an elevated plasma creatinine or urea concentration, or positive urine dip-stick tests for protein or blood.

Diseases affecting the kidneys

Although patients with renal disease frequently present with an obvious functional abnormality, for example increased plasma creatinine or proteinuria, these are not specific to any one renal disease.

A full discussion of the nature of individual renal diseases is beyond the scope of this chapter. Many renal diseases specifically affect one part of the kidney. Glomerulonephritis, which is often of immunological origin, can manifest by decreases in the GFR or changes in glomerular permeability (e.g. causing proteinuria). Glomerulonephritis may be of primary renal origin, or occur secondarily to an extrarenal disorder (see Chapter 8).

A considerable number of conditions, both inherited and acquired, limited to the kidneys and having extrarenal manifestations, can cause disorders of renal tubular function. They are discussed in detail in Chapter 9.

The kidneys can be affected by infection, tumours and infiltrative and degenerative disorders. Generalized disorders, particularly shock, hypertension, connective tissue diseases and diabetes, are also frequent causes of renal dysfunction. The kidneys are also susceptible to the effects of toxins, including many widely used drugs (e.g. the aminoglycoside antibiotics and some cytotoxic drugs), as well as industrial and other toxins, and exposure to such agents is another frequent cause of renal dysfunction.

The major part of this chapter is devoted to a discussion of generalized renal failure, both acute and chronic. These are potentially life-threatening conditions and the clinical biochemistry laboratory plays a major part in their diagnosis and management.

THE ASSESSMENT OF RENAL FUNCTION

Introduction

Many techniques are of value in the investigation of the kidneys and renal function. The major groupings of techniques are laboratory tests, particularly biochemical and immunological, radiological imaging and the histological examination of renal tissue usually obtained by percutaneous biopsy.

Imaging techniques: standard radiography, ultrasonography, computed tomography, magnetic resonance imaging, the use of radionuclides and duplex scanning, can provide valuable anatomical information. Such techniques can be used to diagnose, for example, structural abnormalities, tumours, hydronephrosis, polycystic disease and the scarring of pyelonephritis. Radionuclide techniques can also provide information concerning renal function, particularly divided function (the separate function of the two kidneys) and glomerular function. Duplex scanning is a good screening test to assess renal blood flow before proceeding to magnetic resonance angiography or renal angiography.

Useful immunological markers include the detection in serum of antiglomerular basement membrane antibodies (positive in Goodpasture syndrome), antineutrophil cytoplasmic antibodies (in vasculitis), antinuclear antibodies and double-stranded DNA antibodies (in systemic

lupus erythematosus), complement components (in various types of glomerulonephritis) and antistreptolysin O antibodies (in post-streptococcal glomerulonephritis). Immunological techniques are also widely used in the histological examination of renal tissue. However, given the pivotal role of the kidneys in body fluid homeostasis, it is not surprising that biochemical investigations that indicate derangements of homeostasis are the most widely used tests of renal function. The remainder of this section covers such tests.

Biochemical tests of renal function

Urinalysis

The assessment of renal function should start with examination of the urine. Simple observations on the urine still contribute to the investigation of patients with suspected renal disease. To be valid, they must be made on a freshly passed sample.

Appearance. The normal colour of urine is due to urochrome pigments, and the deepness of the colouration, which can vary from a pale straw colour to deep amber, depends on urinary concentration. There are many causes of abnormal colouration of the urine, some of the more frequently encountered of which are indicated in [Box 7.2](#). In some cases, the colour is pH dependent. The distinction between haemoglobin or myoglobin and other causes of a reddish-brown urine can simply be accomplished by testing the urine with a suitable reagent stick; both myoglobin and haemoglobin will give a positive reaction for 'blood'.

Turbidity in a fresh sample suggests infection, but can also be due to the presence of fat in patients with the nephrotic syndrome. The presence of chyle in the urine may cause turbidity so severe that the urine appears milky. Anything more than a scant amount of foaming

BOX 7.2 Some causes of abnormal urinary colouration

Blue-green

- Methylene blue
- *Pseudomonas* infection
- Riboflavin

Pink-orange-red

- Haemoglobin
- Myoglobin
- Phenolphthalein
- Porphyrins
- Rifampicin

Red-brown-black

- Haemoglobin
- Myoglobin
- Red blood cells
- Homogentisic acid
- Levodopa
- Melanin
- Methyl dopa

when the urine is shaken, suggests proteinuria. The most frequent abnormal odour is that of ammonia, owing to the presence of urea-splitting microbes, either because the patient has a urinary infection or, in stale samples, because of contamination.

Specific gravity and osmolality. Both of these give an indication of the concentration of the urine. When this needs to be known accurately, for example in tests of renal concentrating ability, measurements of osmolality are essential. A reagent stick assessment of specific gravity may sometimes help in the interpretation of a screening test for proteinuria, since false negative results can occur with very dilute urine and vice versa. However, these reagent sticks detect ionic species only, and underestimate the specific gravity if other substances, for example glucose, are present.

pH. Normal urine is acidic, except after meals. Measurements of urine pH are important in the investigation of renal stone formers and as part of a test of urinary acidification in the investigation of suspected renal tubular acidosis.

Glucose. Glycosuria can occur either because of an increase in blood glucose concentration or because of a low renal threshold for glucose, owing to impaired proximal tubular reabsorption. In the latter instance, the blood glucose concentration will be normal. Renal glycosuria is discussed further in Chapter 9.

Protein. Proteinuria is an important feature of renal disease. Normal urine protein excretion is <200 mg/24 h and is not detectable with standard reagent sticks (e.g. 'Albustix'). Pathological proteinuria may be:

- overflow (due to raised plasma concentrations of low molecular weight proteins)
- glomerular (due to increased glomerular permeability to protein)
- tubular (due to decreased tubular reabsorption of filtered protein or saturated reabsorption)
- secreted (derived from the epithelium of the urinary tract).

Further details of the causes, detection and investigation of proteinuria are discussed in Chapter 8 and will not be considered further here.

Urinary sediment. Microscopic examination of the sediment obtained by centrifuging a freshly passed sample of urine frequently reveals a few cells (e.g. erythrocytes, polymorphonuclear leukocytes and cells derived from the kidney and urinary tract), hyaline (or rarely granular) casts composed of uromodulin (Tamm-Horsfall protein), and sometimes fat droplets, mucus threads and pigment granules.

Increases in any of these may occur in renal diseases. Abnormal casts are also frequently present. These are accretions of uromodulin with other material, for example cells or cellular debris. Red cell casts imply haematuria from glomerular disease, and white cell casts, the presence of white cells within the renal tubules. In acute pyelonephritis, there is an increase in polymorphs and various types of cast, in contrast to lower urinary tract infection where

polymorphs, but not casts, are increased. Microbiological examination in acute pyelonephritis will usually reveal bacteriuria. In acute glomerulonephritis, haematuria causes the urine to appear reddish-brown or smoky, and the sediment contains large numbers of red and white blood cells, and red cell, haemoglobin and other casts. In chronic glomerulonephritis, the amount of sediment is much less, but there is usually an excess of dysmorphic red blood cells, which suggests that red cells have passed through the glomerular membrane. Red cell and haemoglobin casts are sometimes present. Granular casts are seen in the urinary sediment in many renal diseases, but particularly in acute tubular necrosis; in this condition, casts containing tubular cells are also often present, but red cell casts are uncommon. Characteristic crystals may be seen when specific substances are present in excess or the pH of the urine promotes crystallization, for example, hexagonal cystine crystals, birefringent calcium oxalate crystals, calcium phosphate or uric acid crystals (see Chapter 9).

Other substances. Many other substances can be detected in the urine in appropriate circumstances, for example drugs or bilirubin. Their presence is due to the normal excretory function of the kidneys and is not a reflection of renal dysfunction, so they will not be considered further here.

Measurement of glomerular filtration rate

Glomerular filtration is essential to renal function, and investigations designed to measure the GFR are the most frequently performed tests of renal function. The factors that determine the GFR have been discussed above. Its measurement is based on the concept of clearance – the determination of the volume of plasma from which a substance is completely removed (the plasma is 'cleared' of the substance) by glomerular filtration during its passage through the kidney. Clearance is a theoretical concept – no substance is cleared completely from the plasma in this way – but can nevertheless be used as a valid measure of the GFR.

For the clearance of a substance to equal the GFR, it must be freely filtered by the glomeruli and eliminated from the body solely by this route (e.g. it must not be metabolized by the liver or secreted into or reabsorbed from the urine). The substance should be non-toxic and accurate measurement should be easily available in a routine laboratory. The clearance of a substance requires measurements of the plasma concentration and urinary excretion rate:

$$\text{Clearance} = (U \times \dot{V}) / P$$

where U is the concentration of the substance in the urine, \dot{V} is the rate of formation of urine and P the plasma concentration of the substance. It should be noted that \dot{V} is a rate; it has the dimensions (volume/time) and its determination requires the collection and measurement of the total amount of urine formed over a known period of time. The units of the various quantities are usually adjusted so that the clearance is expressed as mL/min.

TABLE 7.1 Properties of substances used to assess glomerular filtration rate

Property ^a	Urea	Creatinine	Inulin	^{99m} Tc-DTPA
Not protein bound	Yes	Yes	Yes	Yes
Freely filtered by glomerulus	Yes	Yes	Yes	Yes
Neither secreted nor absorbed in nephron	Flow-related reabsorption	Some secretion	Yes	Yes
Produced endogenously at constant rate	No	Yes	No	No
Easily measured	Yes	Yes	No	No

^aThe ideal substance would have all these properties. DTPA, diethylenetriaminepentaacetic acid.

The critical properties of some of the substances used in clearance measurements to assess GFR are shown in Table 7.1.

Clearance can also be used to determine renal plasma flow, using a substance such as *p*-aminohippuric acid, which is almost completely cleared from the blood in a single passage through the kidneys by a combination of glomerular filtration and secretion.

Inulin clearance. Inulin is a plant polysaccharide that satisfies all the physiological criteria mentioned in the previous section. The measurement of inulin clearance remains the 'gold standard' for the estimation of GFR. However, it is a relatively complex procedure and, although test kits are commercially available, it is infrequently used in clinical practice. In essence, the test involves the injection of a bolus dose of inulin, followed by a maintenance infusion designed to produce a constant plasma concentration. Once this has been achieved, a series of timed urine samples is collected and blood is drawn for the measurement of inulin at the midpoints of the collection periods. The GFR is taken as the mean of the inulin clearances for each period.

Creatinine clearance. Creatinine is an endogenous substance, a normal product of muscle metabolism. Its rate of production is fairly constant from day-to-day, being determined by muscle bulk rather than by activity. Creatinine is removed from the body mainly by glomerular filtration and its clearance can be measured as an index of GFR, although in the UK, it is much less frequently used than previously.

Creatinine is actively secreted into the urine, so that its clearance tends to overestimate the GFR. This effect is of little significance at normal filtration rates, the ratio (creatinine clearance/inulin clearance) being between 1.1 and 1.2, but in advanced renal disease the contribution of active secretion to the total amount of creatinine excreted in the urine becomes high in relation to the amount filtered, and creatinine clearance may significantly overestimate the true GFR. This is despite the fact that in established renal failure, bacterial degradation of creatinine secreted into the gut may contribute approximately 2 mL/min to the total clearance.

Inaccuracies arising from methodological problems with creatinine measurement have largely been overcome, but the major cause of inaccuracy in the determination of GFR by creatinine clearance is the accurate measurement of urine volume. Traditionally, patients have been required to collect urine over a 24h period. This is a

convenient time, but requires the patient to void their urine completely at the beginning of the 24h period and collect all the urine passed over the ensuing 24h, making a final collection at the end of this period. The possibilities for mistakes resulting in an incomplete collection are considerable and even under ideal conditions, for example in a metabolic unit with highly motivated patients, the coefficient of variation for repeated measurements in the same individual is >10%. The critical difference (the amount by which two estimates must differ to give a 95% probability that there has been a true change in GFR) is therefore >33%. The accuracy of estimates of the GFR by measurement of creatinine clearance may be improved by making two or more consecutive 24h urine collections, but this is often not practical even if it is acceptable to the patient.

There is, however, nothing special about the 24h period. The use of shorter periods, although more convenient for the patient, may reduce accuracy through inadequate bladder emptying, but a good compromise is to make a collection overnight. As long as the bladder was emptied at the beginning of the test (before retiring) and when the final collection was made (on rising), the urine production rate can be calculated and substituted in the $(U \times V)/P$ formula.

It is essential that a reliable method is employed to measure plasma and urine creatinine concentrations. Colorimetric assays tend to overestimate creatinine since they detect non-creatinine chromogens. But even when reliable methods are used, it should be appreciated that the creatinine clearance is based on four measurements: plasma and urine creatinine concentrations, urine volume and time. Each has an inherent inaccuracy and the overall analytical variance will be the sum of the individual variances.

Plasma creatinine concentration. The way in which creatinine is handled by the kidney, coupled with the fact that, in any one individual, the rate of production is relatively constant from day-to-day, means that the plasma creatinine concentration alone can be used as an index of renal function. But, although it is widely used, it has a number of disadvantages and these must be borne in mind when interpreting plasma creatinine concentrations. Perhaps the most important becomes apparent from considering the familiar $(U \times V)/P$ formula for deriving the GFR. Plasma creatinine concentration is *inversely* related to GFR, not *directly* related. This means that a plot of plasma creatinine concentration against GFR has the form of a hyperbola (Fig. 7.4). At any concentration of creatinine,

FIGURE 7.4 ■ Relationship between creatinine clearance and plasma creatinine concentration. As the clearance is related to the reciprocal of the plasma concentration, considerable loss of renal function can occur without the plasma creatinine concentration rising above the reference range (shaded).

halving the GFR will double the plasma creatinine concentration. But given the wide reference range for plasma creatinine concentration in the healthy population, this means that in an individual, the plasma creatinine concentration could be within the reference limits, yet the GFR be only one-half of normal.

This is of critical importance to clinical practice, since in early renal disease (when it might be supposed that therapeutic intervention would be most beneficial), the plasma creatinine concentration may be ‘normal’ – that is, within the reference range – in spite of the GFR being reduced. Plasma creatinine concentration is thus a relatively insensitive index of mild renal functional impairment. At low values of GFR, however, it becomes extremely sensitive, although its accuracy declines because of the increased contribution of tubular secretion to overall renal excretion.

Other factors that must be taken into account in assessing the significance of plasma creatinine concentrations include muscle mass, diet (a recent meal including meat, particularly if stewed, may cause a transient increase in plasma creatinine concentration) and the presence in the plasma of substances that interfere with the assay. Ketones, bilirubin, cephalosporins and spironolactone have all been implicated, depending on the method used, but especially in Jaffé-(picric acid) based assay systems. Enzymatic assays for creatinine are said to be more specific than older colorimetric methods, but they are still prone to interference by certain drugs such as acetylcysteine and phenindione.

The importance of muscle mass is exemplified by the changes that occur with age. In healthy individuals, GFR, and thus creatinine clearance, declines with increasing age from about the end of the 4th decade, at a rate of approximately 1 mL/min per year. However, plasma creatinine concentration does not normally rise with age; this is because of a decrease in production rate, thought to reflect the tendency for muscle mass to fall with age.

Although comparison of a measured plasma creatinine concentration with a reference range can be misleading, the fact that *intraindividual* variation is less than *interindividual*

variation means that the detection of a *change* in creatinine concentration in an individual provides a more sensitive indication of a change in renal function. Nevertheless, the biological and analytical variance (even using the best assays) results in a critical difference of about 17% (20 μmol/L at a plasma creatinine concentration of 120 μmol/L).

In patients with advancing renal disease, the progressive loss of renal function with time can be expressed as a graph of reciprocal plasma creatinine concentration against time (since GFR is proportional to $1/[\text{plasma creatinine}]$). A steady loss of renal function will cause this plot to be rectilinear (Fig. 7.5). Such plots are useful in patients with irreversibly declining renal function to help predict when renal replacement will become necessary, so that, for example appropriate means for vascular access for haemodialysis can be provided.

Given the problems associated with the measurement of plasma creatinine concentration and creatinine clearance, the practical application of these measurements to patients with, or suspected of having, renal disease is not straightforward. Since the rate of creatinine production is relatively constant in most individuals (the essential assumption being that lean body mass is constant), one approach is to measure the GFR (preferably by a reliable technique, see below) and the plasma creatinine concentration simultaneously and then to follow progress with serial plasma creatinine measurements.

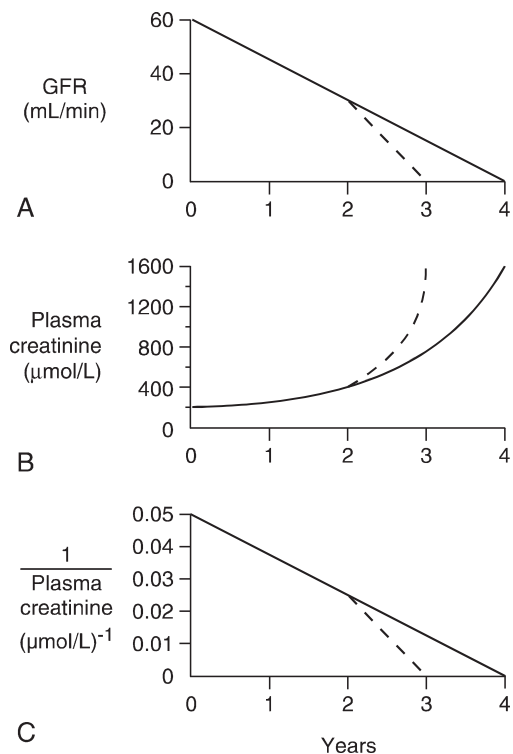

FIGURE 7.5 ■ The progression of chronic kidney disease. Hypothetical curves to show (A) the decline in glomerular filtration rate (GFR); (B) the increase in plasma creatinine concentration and (C) the decrease in reciprocal plasma creatinine concentration. The broken lines show the changes that might be expected if the decline in function was to accelerate for any reason (see Box 7.6).

Calculated creatinine clearance and estimated glomerular filtration rate. Given that the creatinine cleared by the kidney is almost entirely derived from muscle, and that muscle mass is related to body mass and to age, it is possible to derive formulae to estimate the creatinine clearance, and hence the GFR, from the plasma creatinine concentration. More than 25 different formulae have been suggested to correct for age, weight, gender and ethnic origin. The empirically derived equation of Cockcroft and Gault is one of the earliest and the best known of these. However, this and all similar formulae depend on measurements of plasma creatinine, and their accuracy can be impaired by all the factors that affect this. The early formulae, including that of Cockcroft and Gault, were derived using Jaffé based methods for the measurement of creatinine. Laboratories should take into account the relationship between their creatinine assay and the original assay used to derive any equation before advising clinicians on interpretation. None of the correction equations performs well in the physiological range of GFR, which limits their usefulness, for example in monitoring patients with diabetes or assessing potential kidney donors.

Cockcroft and Gault. The Cockcroft and Gault formula for males is:

$$C_{cr} = [1.224 \{ (140 - \text{age}) \times \text{wt} \} / C_{r_p}] \text{ mL/min}$$

where C_{cr} is creatinine clearance, C_{r_p} is plasma creatinine concentration in $\mu\text{mol/L}$, age is measured in years and wt is body weight in kilograms. For females, C_{cr} is 15% less than for males, so that the figure 1.224 in the above formula is replaced by 1.04.

Modifications to the formula are required before it can be used in children or obese adults as it assumes that increasing weight is related to increasing muscle rather than fat mass. The formulae developed for children are particularly useful, since there are considerable practical difficulties in making quantitative urine collections in this age group. The commonest estimation used in the UK is the Schwartz formula:

$$\text{GFR} = 49 \times \text{length} / C_{r_p} \text{ mL/min} / 1.73 \text{ m}^2$$

where length is measured in centimetres and plasma creatinine in $\mu\text{mol/L}$.

MDRD. The UK has adopted the system originally devised in the USA for deriving an estimate of GFR (eGFR), which can be used for population screening for kidney disease. This is based on the abbreviated MDRD (Modification of Diet in Renal Diseases) study equation. It is a useful estimate of GFR in adults up to a value of 60 mL/min per 1.73 m² body surface area. The equation was developed from measurements in an independent sample of 1070 individuals. Over 90% of the estimates were within 30% of the measured GFR (using ¹²⁵I-iothalamate), with only 2% having an error of more than 50%.

There are four variables (age, sex, race and creatinine concentration), but the equation only requires one biochemical value. The equation is being validated in other

patient groups, including patients with type 1 diabetes without microalbuminuria, those with mild decreases in renal function or a normal GFR, and non-US populations, for example Indian and Chinese.

The original MDRD equation included an additional two variables (albumin and urea), but there is very little advantage in using it, as any small gain in accuracy is offset by the increase in variability from the extra measurements.

The abbreviated MDRD formula for Caucasians is:

$$\text{eGFR (mL/min/1.73 m}^2) = 175 \times \{ (\text{plasma [Cr] in } \mu\text{mol/L}) / 88.4 \}^{-1.154} \times (\text{age in years})^{-0.203}$$

The factor 88.4 is required to convert $\mu\text{mol/L}$ to mg/dL (the units for which the formula was derived). This equation applies to males; for females, the result is multiplied by 0.742; for African-Caribbeans, it is multiplied by 1.212.

The original abbreviated MDRD formula had 186 as the multiplier rather than 175; the change was made to align the formula with measurements of creatinine by methods whose calibration is traceable to the reference method (isotope dilution with mass spectrometry).

In a study of serum creatinine measurements in laboratories, the method group mean bias for a specimen with an assigned value of 79.7 $\mu\text{mol/L}$ varied from -5.25 to +27.4 $\mu\text{mol/L}$. In order to standardize values for eGFR, UKNEQAS (UK National External Quality Assessment Service) has calculated additional corrections (slope and intercept adjusters) to align individual manufacturers' methods to the reference method.

It should be noted that the MDRD equation for eGFR has not been validated for use in children, acute kidney injury, pregnancy, oedematous states, muscle wasting diseases, amputees or malnourished individuals. It is less accurate in obese than in lean individuals. When the eGFR is >60 mL/min, many laboratories report the value as >60 mL/min per 1.73 m², owing to decreasing precision and accuracy at higher values of GFR. Values above 90 mL/min should never be reported as an absolute figure, because the correlation with measured GFR is poor.

CKD-EPI. The Chronic Kidney Disease Epidemiology Collaboration group produced a set of formulae based on pooled data from several studies, which correlate better with measured GFR than the original MDRD formula, especially at values >60 mL/min per 1.73 m². However, GFR is overestimated in certain groups of patients, especially those with a low body mass index. Different formulae are applied depending on the value of the serum creatinine. Further details are available on the websites of various renal organizations.

Definition of CKD using eGFR. A persistent reduction in eGFR (<60 mL/min) is defined as chronic kidney disease (CKD). However, patients with markers of kidney damage, like persistent albuminuria or abnormalities on imaging (such as polycystic kidneys) or on renal biopsy, are defined as having CKD even if their eGFR is normal.

The stage of CKD can be assigned based on the degree of renal GFR reduction, irrespective of diagnosis, according to the Kidney/Disease Outcomes Quality Initiative (K/DOQI) classification (see Table 7.2), and used to guide the appropriate management.

Cystatin C. This is a low molecular weight (13.4kDa) protein, a cysteine protease inhibitor that is present on the surface of all nucleated cells and from which it is shed into the plasma and excreted by glomerular filtration. Its plasma concentration is much less dependent than that of creatinine on weight and height, muscle mass, age or sex, and many studies have suggested that its plasma concentration is a more sensitive index of mild renal impairment than that of creatinine. Estimates of GFR based on either cystatin C measurements alone or combined with creatinine, are more accurate than those based on creatinine alone. Plasma cystatin C concentration may be increased in malignancy, hyperthyroidism and by treatment with corticosteroids (a disadvantage in kidney transplant recipients), independently of the GFR. However, its greatest drawback is that it has to be measured by immunoassay, which is much more expensive than the usual colorimetric or enzymatic techniques used to measure creatinine. Although not widely available in routine laboratories in the UK, measurement may have a role in the detection of early renal impairment in patients with extremes of muscle bulk, such as body builders and small elderly women and in postpubertal teenage boys, for whom children's reference ranges for creatinine are inappropriate.

Plasma urea concentration. Although of great historical importance and still widely used as a test of renal function, the measurement of plasma urea concentration suffers from many disadvantages for this purpose. Although the plasma urea concentration can provide useful information in some circumstances, particularly when it can be compared with the plasma creatinine concentration, the latter, in spite of the problems discussed above, is the more reliable test of renal function.

Urea is the end-product of the metabolism of many nitrogenous substances, particularly amino acids. It is freely filtered at the glomerulus, but its plasma concentration is dependent in part on its rate of formation, which can vary

widely according to the overall rate of protein turnover and can also be affected by hepatic function. For example, plasma urea concentration frequently rises following a gastrointestinal bleed, owing to increased urea formation from the digestion of the blood in the gut, irrespective of any effect of the blood loss on GFR, while patients with combined hepatic and renal failure may have normal plasma urea concentrations because of decreased production despite decreased excretion. There is significant passive reabsorption of urea from the lumen of the nephron, and this increases at high plasma urea concentrations (as in renal failure) and if the rate of flow of fluid through the nephron is low (as when GFR is decreased by dehydration). The familiar observation that the plasma urea concentration tends to rise before the creatinine in patients with 'prerenal' renal impairment (see p. 137) reflects this latter fact.

Plasma β_2 -microglobulin. This protein, a component of the major histocompatibility (HLA) complex, is shed into the plasma at a constant rate and, having a molecular weight of only 11 815 Da, passes freely through the glomeruli. As a result, its plasma concentration is normally very low (<2 mg/L), but it rises if renal function is impaired and can reach 40 mg/L. There is a direct relationship between plasma β_2 -microglobulin concentration and GFR, but its measurement has not been widely adopted for estimating the GFR for methodological reasons. Further, there are a number of conditions in which the production of β_2 -microglobulin is increased (e.g. lymphoid tumours and some inflammatory diseases) and these can result in increased plasma concentrations that do not reflect decreased clearance.

Isotopic techniques for measuring glomerular filtration rate. A number of radiolabelled compounds that are excreted entirely or largely by glomerular filtration have been used in tests designed to measure the GFR. These include ^{51}Cr -labelled ethylenediaminetetraacetic acid (EDTA), ^{125}I -iodothalamate and $^{99\text{m}}\text{Tc}$ -diethylenetriaminepentaacetic acid (DTPA). The Cr-EDTA-derived GFR is the accepted isotopic gold standard and is used when a very accurate estimate of GFR is required, for example in the work-up of potential kidney donors. In the

TABLE 7.2 Stages of chronic kidney disease

Stage	Description	eGFR ^a (mL/min per 1.73 m ²)	Action ^b
1	Kidney damage with normal or \uparrow GFR	≥ 90	Diagnosis and treatment, treatment of comorbid conditions, slowing progression, cardiovascular disease risk reduction
2	Kidney damage with mild \downarrow GFR	60–89	Estimating progression
3a	Moderate \downarrow GFR	45–59	Evaluating and treating complications
3b		30–44	
4	Severe \downarrow GFR	15–29	Preparation for renal replacement therapy
5	Established renal failure	<15 (or dialysis)	Replacement therapy (if uraemia present)

The suffix 'p' is used for all stages of CKD to denote the presence of proteinuria confirmed by laboratory testing.

^aeGFR is the estimated GFR.

^bIncludes action from preceding stages. Table based on the National Kidney Foundation K/DOQI chronic kidney disease classification with modifications recommended by UK NICE guidelines.

simplest type of test, a single bolus injection is given and accurately timed blood samples are collected over 2 h (longer may be necessary in patients with renal impairment). The logarithm of plasma radioactivity is plotted against time and extrapolated back to zero time, to allow calculation of the notional initial volume of distribution. The GFR is then given by:

$$\text{GFR} = V_0 \times (\log_e 2) t_{1/2}$$

where V_0 is the notional initial volume of distribution and $t_{1/2}$ is the half-life for the decrease in plasma radioactivity.

Such methods compare reasonably well with the results of inulin clearance, but their accuracy is enhanced if classic clearance techniques are used. For this, the marker compound is given during a water diuresis and a series of measurements of plasma and urine radioactivity are made. The clearance formula is used to calculate individual clearances and the GFR is taken as the mean of these.

^{99m}Tc -DTPA is also used as a renal scanning agent (although the dose of radioactivity required is approximately ten times greater than for measurement of GFR). However, gamma camera scanning following the administration of this agent can be used to measure the individual contribution of each kidney to the overall GFR.

Other tests of renal function

Tests of proximal tubular function include the measurement of phosphate reabsorption (see Chapter 6) and the detection of aminoaciduria and glycosuria. The causes of glycosuria are discussed in Chapters 9 and 15. Amino aciduria can be due to increases in plasma amino acid concentration ('overflow amino aciduria'), as occurs in several inherited disorders of amino acid metabolism, or to decreased renal tubular reabsorption of normally filtered amounts of amino acids ('renal amino aciduria'). Renal amino aciduria can be due to isolated defects of amino acid transport or to generalized proximal tubular dysfunction, and is discussed in Chapter 9.

Tests of distal tubular function include formal tests of urinary concentration and dilution and of urinary acidification. These are discussed in Chapters 4 and 9. The assessment of urinary sodium excretion in relation to physiological requirements plays an important part in the investigation of renal function in certain circumstances, as discussed in the section on acute kidney injury (see later). In general, however, tests of renal tubular function are employed much less frequently than tests of glomerular function in the investigation of renal disease.

ACUTE KIDNEY INJURY (ACUTE RENAL FAILURE)

Introduction

Acute kidney injury (AKI) has now replaced the term acute renal failure. The new terminology enables health-care professionals to consider the disease as a spectrum of injury. This spectrum extends from less severe forms of injury to more advanced injury requiring renal replacement therapy (RRT). Clinically, AKI is characterized by

a rapid reduction in kidney function resulting in a failure to maintain fluid, electrolyte and acid-base homeostasis. Acute kidney injury is potentially a life-threatening condition and, developing as it often does in patients who are already severely ill, it has a high mortality, despite the widespread availability of effective renal replacement therapy.

In many patients with AKI, there is oliguria (a urine flow rate of <15 mL/h in the adult). However, this is not universally present. In particular, non-oliguric AKI may be seen in patients with burns, liver disease and drug-induced renal damage. Occasionally, there is no urine production at all (anuria). This can occur with particularly severe renal disease but is more frequently due to urinary tract obstruction (to which it is an important clue).

It is important to appreciate that a diagnosis of AKI on its own is incomplete and does not imply any particular cause. The principal clinical features of AKI are summarized in Table 7.3.

The use of the adjective 'acute' tends to emphasize the importance of the period of time over which the condition develops. While it is true that this time is usually only a few hours (in contrast to that for chronic kidney disease, CKD), a more fundamental difference between these two syndromes is that AKI is usually potentially reversible, whereas in CKD, there is progressive, irreversible loss of renal function over a period that can range from months to tens of years, leading eventually to established renal failure, a condition in which renal replacement (e.g. long-term dialysis or transplantation) is required for continued survival.

Classification and causes

As has been discussed above, the primary determinants of the GFR are the hydrostatic pressure of blood in the glomerular capillaries, the intrinsic physical properties of the glomeruli and the hydrostatic pressure of fluid in the lumina of the nephrons. It follows that changes in

TABLE 7.3 Metabolic and clinical features of acute kidney injury

Metabolic feature	Clinical feature
Retention of nitrogenous waste products (↑ plasma urea and creatinine)	Nausea, vomiting, hiccoughs, clouding of consciousness, gastrointestinal bleeding etc.
Retention of sodium and water (usually with hyponatraemia)	Peripheral and pulmonary oedema, ascites, pleural effusion
Retention of potassium (with hyperkalaemia)	Typical electrocardiographic changes (peaked T waves, flattened P waves, QRS depression, widened QRS complex)
Retention of acid (metabolic acidosis, ↑ [H ⁺], ↓ pH, ↓ [HCO ₃ ⁻], ↓ PCO ₂)	Muscle weakness, paralysis, risk of cardiac arrest Kussmaul breathing, hypotension

any one or more of these may cause a decrease in GFR. Acute kidney injury has traditionally been classified into prerenal (due to impaired renal perfusion), intrinsic renal and postrenal (obstructive) causes (Box 7.3). This classification, though particularly useful in formulating an approach to diagnosis and management, has limitations; in any patient, more than one factor may be contributing to the development of renal failure. Furthermore, both 'prerenal' and 'postrenal' AKI can lead to the development of intrinsic renal damage. Also, intrinsic renal disease can have both detrimental effects on renal perfusion and lead to obstruction of urinary flow. Finally, the syndrome of acute kidney injury can develop in patients

BOX 7.3 Some causes of acute kidney injury

Prerenal

- Hypovolaemia
 - Haemorrhage
 - Gastrointestinal fluid loss
 - Diuresis
 - Burns
- Decreased cardiac output
 - Cardiogenic shock
 - Massive pulmonary embolus
 - Cardiac tamponade
- Other causes of hypotension
 - Sepsis
 - Vasodilator drugs
- Interference with autoregulation of renal blood flow
 - Angiotensin-converting-enzyme inhibitors
 - Prostaglandin inhibitors (e.g. non-steroidal anti-inflammatory drugs)

Intrinsic renal

- Glomerulonephritis
- Vascular disease
- Severe hypertension
- Ischaemia
- Nephrotoxins
 - Aminoglycoside antibiotics
 - Non-steroidal anti-inflammatory drugs
 - X-ray contrast media
 - Heavy metals
 - Animal and plant toxins
- Hypercalcaemia
- Infiltrative disorders
 - Sarcoidosis
 - Lymphoma, leukaemia

Postrenal

- Bilateral ureteric obstruction (or unilateral if there is only one functioning kidney)
 - Calculi
 - Papillary necrosis
 - Tumours
 - Retroperitoneal fibrosis
 - Surgical mishap
- Bladder outflow/urethral obstruction
 - Urethral stricture
 - Benign prostatic hypertrophy
 - Carcinoma of prostate
 - Neurogenic bladder

with CKD as when, for example, complete bladder outflow obstruction leads to retention of urine and AKI in a man who already has chronically impaired renal function as a result of partial obstruction due to prostatic hypertrophy.

Prerenal acute kidney injury

This type of injury is characterized, at least in its early stages, by a lack of structural renal damage, preservation of normal tubular function (e.g. concentrating ability, sodium reabsorption) and rapid reversibility provided that the underlying cause is managed appropriately. In essence, it is a consequence of reduced renal perfusion, secondary to either cardiovascular insufficiency (hypovolaemia and hypotension) or a derangement of intrarenal haemodynamics. Some causes are indicated in Box 7.3. In many hospitals, a significant proportion of cases of acute kidney injury follows trauma or surgery and may be exacerbated by the administration of nephrotoxic drugs or coexistent medical conditions.

In health, renal blood flow and GFR remain unchanged over a wide range of renal perfusion pressures, but a fall in perfusion pressure below a mean of about 80 mmHg leads to a reduction in renal blood flow and GFR.

Homeostatic mechanisms involved in the defence of ECF volume include increased sodium reabsorption and increased water retention. The major stimulus to sodium reabsorption is through angiotensin II-induced secretion of aldosterone. Water reabsorption is stimulated by increased vasopressin secretion; stimuli to vasopressin secretion in this context may include hypovolaemia, angiotensin II and, if hypovolaemia is due to hypotonic fluid loss, increased plasma osmolality. In addition, vasoconstriction of efferent glomerular arterioles by angiotensin II increases the filtered fraction of the plasma, thus increasing the protein content (and oncotic pressure) of blood in these vessels and in the peritubular capillaries, so enhancing proximal tubular reabsorption of water.

Diagnosis

The accurate diagnosis of prerenal AKI is important, since rapid intervention may prevent progression to intrinsic AKI. In prerenal AKI, the plasma urea concentration is usually increased disproportionately to that of creatinine. As urine flow rate falls, the diffusion of urea from the lumen of the nephron into the interstitial fluid increases. An increase in urea may also be related to the increased catabolism that frequently is present as a result of the underlying disorder. In contrast, in intrinsic kidney injury, plasma urea and creatinine concentrations tend to rise in parallel.

Urinalysis may be informative and should be performed in all patients with AKI. As discussed on page 130, abnormalities apart from the presence of hyaline casts are uncommon in prerenal AKI, but are invariably present in intrinsic AKI. The fact that tubular function is intact in prerenal AKI underlies a number of diagnostic tests (see Table 7.4). In prerenal AKI, the homeostatic responses to hypovolaemia described above should

TABLE 7.4 Diagnostic tests of potential value in differentiating prerenal and intrinsic renal acute kidney injury

Test	Result	
	Prerenal	Intrinsic renal
Urine [Na ⁺]	<20 mmol/L	>40 mmol/L
Urine osmolality/plasma osmolality	>1.5	<1.1

maximize renal sodium reabsorption and water retention. In consequence, the urine will tend to be concentrated and have a low sodium content, whereas if there is tubular damage, there will be a failure of this response, and the urine will be dilute and contain significant quantities of sodium. Although in general these theoretical conclusions are supported by clinical observations, considerable overlap may occur in the results obtained in patients with prerenal and established AKI. It must be emphasized that the tests are only useful if there is oliguria, and may be vitiated if the patient has been given a diuretic (which will increase sodium excretion, even in prerenal AKI), or mannitol or an X-ray contrast medium, both of which increase urine osmolality even in intrinsic AKI.

Although these tests are of help in management, the diagnosis of intrinsic AKI may only be made on the basis of an inexorably rising plasma creatinine concentration despite correction of any 'prerenal' factors that may have been identified.

Management

The management of prerenal AKI involves rapid restoration of euvoemia, discontinuation of potentially nephrotoxic drugs and increasing tubular flow to prevent tubular obstruction. Delay in achieving euvoemia increases the risk of progression to intrinsic kidney injury. Fluid replacement must be done with a view to achieving adequate cardiac output but avoiding fluid overload. In patients with shock, it may be necessary to infuse vasoactive substances to achieve an adequate blood pressure.

Intrinsic acute kidney injury

Intrinsic AKI can be a progression from a prerenal phase, but many conditions causing AKI do so without a prerenal component. Nephrotoxins, intrinsic renal disease (e.g. glomerulonephritis) and systemic disease affecting the kidneys (e.g. septicaemia) are all important causes of kidney injury (see [Box 7.3](#)).

The term 'acute tubular necrosis' is sometimes used synonymously with 'intrinsic AKI', but should not be. Ischaemic injury and many nephrotoxins cause acute tubular necrosis, but in other cases of renal injury, the brunt of the damage is borne by the glomeruli. Although the treatment in such patients will involve management of the kidney injury per se, the prognosis often depends on the underlying cause.

Diagnosis

The distinction between prerenal and intrinsic AKI has been discussed above. In addition, proteinuria is usually present in intrinsic injury. The urinary sediment frequently contains epithelial cells, both free and in casts, and in kidney injury due to glomerulonephritis, haematuria and red cell casts are present.

The plasma biochemical disturbances are similar in all types of kidney injury though without intervention, they become more severe if prerenal AKI progresses to intrinsic injury. The plasma urea and creatinine concentrations then tend to rise in parallel.

Special investigations that may be of value (but will not be required in all cases) include radiology (ultrasound, isotopic scanning, CT and MRI scans) and renal histology.

Ultrasound is helpful in the exclusion of urinary tract obstruction. It shows the size and cortical thickness of the kidneys (small kidneys imply chronicity). Asymmetry of renal size may suggest renovascular disease. This can be confirmed by duplex scanning. If poor images are obtained, blood flow can be determined by magnetic resonance angiography (MRA). This technique does not require the use of X-ray contrast media, but in patients with eGFR <30 mL/min, the gadolinium which is used as a contrast agent for MRI scanning has been implicated in the development of a condition known as nephrogenic systemic fibrosis. There is no known cure for this condition. Computed tomography (CT) scanning is also useful in further definition of anatomical renal tract abnormalities. Contrast-enhanced CT scanning can, however, exacerbate renal impairment by causing contrast nephropathy. It should, therefore, be used with caution in patients with acute kidney injury.

Renal biopsy is not required if the cause of AKI is obvious (e.g. post-trauma), but will inform management if the development of kidney injury is unexpected and if intrinsic renal disease, for example glomerulonephritis, is suspected.

Acute tubular necrosis

Pathogenesis. While the reduction in GFR that occurs with renal hypoperfusion is readily explicable, the cause of its persistence after restoration of the circulation is a more complex issue, which is still not fully understood. Several mechanisms may be involved ([Fig. 7.6](#)). These include continued renal vasoconstriction due to the intrarenal release of vasoactive substances, such as endothelin and prostaglandins, and to angiotensin II (renin secretion may remain high secondary to decreased delivery of solute, especially sodium, to the macula densa); direct damage to the glomeruli resulting in decreased filtration, and physical obstruction of the lumina of nephrons by swollen tubular cells or tubular debris. Diffusion of fluid from the lumina of nephrons into the interstitial tissue through damaged tubular walls (stimulated by the difference in oncotic pressures), will tend to oppose the process of glomerular filtration.

There is evidence from experimental models to support all these mechanisms. In all probability, all are

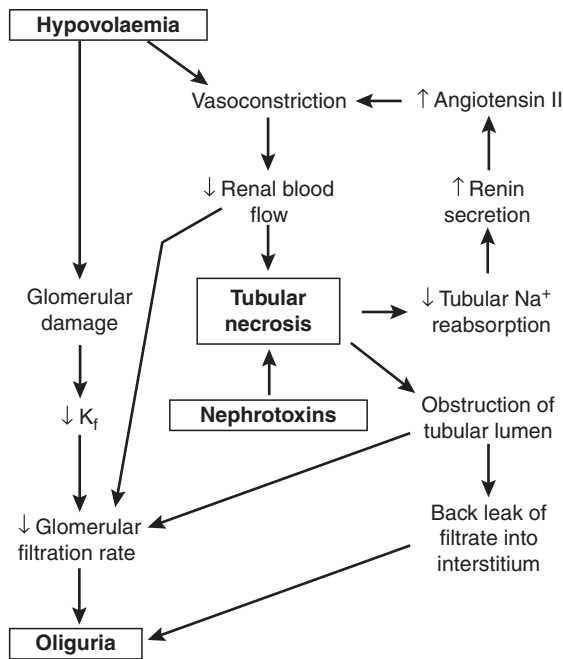

FIGURE 7.6 ■ Factors involved in the pathogenesis of oliguria in acute tubular necrosis. K_f , glomerular ultrafiltration coefficient.

involved in the pathogenesis of acute tubular necrosis, but the relative contributions of the various mechanisms are likely to differ in each case.

Whatever the cause, however, injury, whether nephrotoxic or ischaemic, appears to be central to the development of acute tubular necrosis, and the restoration of normal renal function requires not only restoration of glomerular filtration, but also regeneration of the tubular epithelium of nephrons.

Natural history. The natural history of acute tubular necrosis (ATN) can be divided into three phases: the initial, oliguric phase; a diuretic phase, as glomerular filtration begins to recover, but a combination of persisting tubular damage and a high osmotic load causes a diuresis, and a recovery phase. The time course is variable between a few days and several months. Although patients who survive usually recover normal renal function, a small number develop renal cortical necrosis, from which functional recovery is not possible.

Exceptions occur and some patients do not have an oliguric phase. The details of management of each phase are different although the principles – avoidance of complications and the provision of renal replacement therapy as required – are common to all patients with AKI.

The mortality of AKI has decreased considerably with the widespread availability of renal replacement treatment, but remains in the region of 50%. It is related not only to the severity of the kidney injury and the efficiency of treatment, but also to the underlying cause and any comorbidities, for example multiple trauma. Acute kidney injury frequently occurs in patients who are already severely ill. The prognosis is generally better in non-oliguric AKI than when oliguria is present.

Obstructive (postrenal) kidney injury

The possibility of an obstructive cause must be considered in any patient with AKI. The history and examination (e.g. previous symptoms suggestive of prostate disease, or a palpable bladder on clinical examination) may provide a clue. Ultrasonography may reveal dilatation of the ureters if there is ureteric obstruction.

Obstructive AKI may be due to urethral (e.g. benign prostatic hypertrophy), bilateral ureteric (e.g. calculi, retroperitoneal fibrosis) or intrarenal (e.g. light chain precipitation in myeloma) obstruction. Any of these conditions can also cause chronic kidney disease.

The procedures involved in the diagnosis of obstructive AKI often reveal the cause. Management is directed at restoring a normal flow of urine, for example by percutaneous nephrostomy, or removal or ultrasonic destruction of calculi. Relief of obstruction often leads to a temporary diuresis and natriuresis, and the urine output should be monitored closely to guide fluid replacement therapy.

Acute kidney injury in the setting of chronic kidney disease

Acute kidney injury can occur and precipitate presentation in patients with pre-existing (chronic) kidney disease. Clues to this possibility are indicated in [Box 7.4](#). In practice, it is often necessary to manage the acute event and investigate the patient for chronic renal disease later.

Hepatorenal syndrome

Patients with liver disease can develop acute kidney injury. The causes may be common (e.g. paracetamol (acetaminophen) toxicity), or independent. Prerenal and intrinsic renal disease can occur. The hepatorenal syndrome is a unique form of AKI that can develop in patients with chronic liver failure. It is discussed in detail in Chapter 14. The hepatorenal syndrome can progress to acute tubular necrosis; this has a particularly poor prognosis and recovery usually only occurs if there is some improvement in hepatic function.

BOX 7.4

Factors suggesting an element of chronicity in acute kidney injury (i.e. acute on chronic kidney disease)

- Absence of acute illness
- Long duration of symptoms
- Nocturia
- Anaemia
- Bone disease
- Sexual dysfunction
- Neuropathy
- Skin disorders
- Small kidneys demonstrated by radiological imaging

Metabolic consequences and management of acute kidney injury

The importance of prevention has already been emphasized. Many cases of AKI occur in patients at predictably high risk of developing the condition.

Accurate diagnosis is essential in the management of acute kidney injury. It is essential to consider the following possibilities:

- is there a prerenal component?
- is there any urinary tract obstruction?
- is there any intrinsic renal disease?
- is there a chronic component?

The approaches to answering these questions have been discussed above.

If renal function is not rapidly restored to normal despite appropriate management of any antecedent condition, the aim of treatment becomes the prevention of the consequences of the condition. There are two aspects to management: general measures and, if these alone are insufficient, renal replacement therapy. Specific measures to treat the underlying cause should, of course, be continued. All patients require rigorous clinical and laboratory monitoring throughout.

General management

Fluid and electrolyte balance. The prevention of fluid overload or electrolyte imbalance is crucial to the management of AKI. In calculating fluid balance, allowance must be made for endogenous water production of some 500 mL/24h and insensible losses (approximately 0.5 mL/kg body weight/h, but significantly higher if there is pyrexia). Endogenous production derives from oxidative metabolism and will be increased if (as is usual) the patient is catabolic.

Objective assessment of extracellular fluid (ECF) volume, preferably using flow-based measurements (or, alternatively, central venous pressure), is valuable, and in many patients is essential. Sodium intake must be limited in oliguric patients and special note taken of any covert sodium administration if drugs are given as their sodium salts. In patients with non-oliguric AKI and during the diuretic phase of acute tubular necrosis, adequate fluid replacement is required and should be informed by continuous assessment of urinary volume.

Hyperkalaemia is a life-threatening complication of AKI and frequent monitoring of plasma potassium concentration is essential. Several factors contribute to the increase in plasma potassium concentration, including decreased renal excretion, acidosis and loss of intracellular potassium to the ECF as a result of catabolism. Potassium intake should be minimized; intravenous calcium chloride can be used to antagonize the effects of hyperkalaemia. An infusion of dextrose and insulin may temporarily reduce the plasma potassium concentration, but persistent significant hyperkalaemia is an indication for renal replacement treatment.

Other disturbances that may occur in AKI include hyperphosphataemia, hypocalcaemia, hyperuricaemia and hypermagnesaemia. Hypercalcaemia may develop, particularly in patients with AKI related to crush injuries,

owing to release of calcium from damaged muscle and increased synthesis of calcitriol as falling phosphate concentrations decrease the inhibition of renal 1α -hydroxylase.

Acid–base balance. Since the kidneys are the only organs capable of excreting significant amounts of hydrogen ions, and the net daily acid load that has to be excreted is of the order of 40–80 mmol, patients with AKI are usually acidotic. Acid–base status may also be adversely affected by comorbid conditions, for example lactic acidosis secondary to sepsis.

Nutrition. Active nutritional management is a vital part of the management of patients with AKI, whether being treated conservatively or with renal replacement. The aim is to maintain nutritional status where it is adequate and to improve it where it is compromised, in order to limit catabolism, promote the healing of any wounds and enhance resistance to infection. The mainstay of nutritional management is to provide adequate energy substrates to obtain positive energy balance. Nitrogen requirements are variable and there are few reliable data to guide the amount of protein or amino acids that should be provided. In established renal failure, an increase in plasma urea concentration not associated with an increase in creatinine suggests excessive provision of nitrogen. It is important to provide adequate vitamins and trace elements.

If possible, the enteral route should be used to provide nutrients. In patients who cannot eat, or eat enough, proprietary liquid feeds may be given through a nasogastric tube. For patients with intestinal failure, and for those in whom enteral feeding is contraindicated for some other reason or in whom enteral feeding cannot, on its own, provide sufficient energy, parenteral feeding will be required.

The principles of nutritional management in AKI are no different from those in any other condition: an adequate regimen must be provided; a suitable route for its provision must be available, and the patient's response must be carefully monitored (see Chapter 11). It should be appreciated that patients receiving renal replacement in general have increased requirements for nutrients, since there will be loss from the bloodstream into the dialysate.

There is no reason not to use lipid emulsions together with glucose solutions as an energy source in patients with AKI receiving parenteral feeding, unless there is a problem with lipid utilization; this will be apparent from simple inspection of the plasma, which will appear lipaemic.

Other measures. Infection is a frequent cause of death in patients with AKI, even if it has not precipitated the condition. It is essential to treat any infection early and adequately and to take every practicable step possible to prevent infection developing. When prescribing drugs, including antibiotics, care must be taken to avoid any that are potentially nephrotoxic. The dosages of any drugs that are excreted by the kidneys should be reviewed and, where appropriate, dosage guided by measurement of plasma concentrations.

Renal replacement treatment

Major indications for renal replacement include the following:

- fluid overload (e.g. pulmonary oedema)
- the need to 'create space' to allow provision of parenteral nutrition or other solutions in the oliguric patient
- severe hyperkalaemia (plasma potassium >7.0 mmol/L)
- severe acidosis (arterial $[H^+]$ >70 nmol/L, pH <7.15 or plasma bicarbonate <12 mmol/L).

Haemodialysis. This technique is discussed on page 149. It is usually performed intermittently, each treatment lasting approximately 4 h. Clearance rates of more than 30 mL/min can be achieved. Intermittent haemodialysis is an efficient technique, but there is a danger of 'disequilibrium syndrome' due to too rapid removal of metabolites leading to osmotic imbalance between body fluid compartments with consequent rapid shifts of fluid. Headache, vomiting and, occasionally, fits may occur.

Because excess fluid is removed intermittently, the provision of continuous parenteral feeding may be more difficult with haemodialysis than with the filtration techniques described in the following sections.

Continuous venovenous haemofiltration (CVVH).

This technique (see p. 150) allows clearance rates of approximately 10 mL/min. In haemofiltration, large volumes of fluid are removed, but over a longer period of time, thus minimizing the risks of circulatory imbalance. There is, therefore, ample scope for the provision of parenteral nutrition when required, although other fluid replacement may usually be required in addition.

Continuous venovenous haemodiafiltration (CVVHDF).

In this technique, the filter is also perfused by dialysis solution. This combines the advantages of continuous filtration (particularly the ease of removal of fluid) with those of dialysis (higher clearances). Correction of metabolic imbalances, for example hyperkalaemia, is more easily achieved with CVVHDF than CVVH.

Peritoneal dialysis. Peritoneal dialysis (see p. 150) is a simpler technique than haemodialysis or haemofiltration, and does not require access to the circulation. However, it is less efficient than haemodialysis (clearance rates approximately 20 mL/min) and so is less suitable for hypercatabolic patients. Considerable quantities of protein (up to 40 g) can be lost into the dialysate at each session and there is a risk of peritonitis. Nevertheless, if the requirements needed to set up haemodialysis or filtration are not immediately available, this technique is valuable in the management of patients with AKI.

CHRONIC KIDNEY DISEASE

Introduction

Chronic kidney disease is a syndrome of persistent renal impairment involving loss of both glomerular and tubular function such that the kidneys' homeostatic functions

are compromised. It usually has a gradual onset and, in many cases, progresses inexorably to a critical state (established or end-stage renal failure) in which the patient's continued survival requires the initiation of renal replacement treatment, either by some form of dialysis or by renal transplantation. Although there are many causes of CKD, the clinical features of the condition tend to be similar regardless of the cause, being in effect due to a decrease in the number of functioning nephrons. Despite this, it is, as discussed below, important to attempt to determine the cause, although this is not always possible.

Although CKD may be discovered early, before it has given rise to any clinical disturbance (e.g. by the routine assessment of renal function in patients at risk of developing CKD), it frequently presents late, with a GFR already <20 mL/min. Some patients will also have clinical features of the 'uraemic syndrome'. This term is used to describe the clinical features that can occur in patients with CKD, but is caused by the retention of many substances, of which urea itself is relatively unimportant, and by other (e.g. endocrine) abnormalities that arise as a result of renal dysfunction.

Aetiology and pathogenesis of chronic kidney disease

Some of the more frequent causes of CKD are indicated in Box 7.5. As alluded to above, it is not always possible to determine the cause; patients presenting with advanced uraemia frequently have small, shrunken kidneys (unless diabetes, amyloid or polycystic disease is the cause of the condition) and specific diagnostic features may not be discernible even in a biopsy. It is, however, important to try to determine the cause, particularly in patients with less advanced disease. This may reveal a condition that is susceptible to treatment, so that progression can be delayed or even halted. The cause will, to some extent, determine the prognosis and allow planning of the eventual need for renal replacement and, if transplantation is contemplated, of the likelihood of recurrent disease in the grafted kidney. Finally, the identification of a familial cause (e.g. polycystic disease) may usefully lead to screening of other members of the family.

Successful treatment of the underlying cause of CKD does not always arrest the progress of the condition. It appears that, once started, the loss of nephrons in CKD itself contributes to disease progression. This has important therapeutic implications and the possible mechanisms have been extensively investigated.

BOX 7.5 Some causes of chronic kidney disease (CKD)

- Glomerulonephritis
- Pyelonephritis
- Interstitial nephritis
- Diabetes mellitus
- Hypertension
- Polycystic kidney disease
- Nephrotoxic drugs
- Multisystem disease

The progression of loss of renal function

If 80% of a rat's renal mass is removed, the animal develops proteinuria, hypertension and progressive renal failure; glomerular sclerosis is demonstrable in the renal remnant. Before hypertension and histological changes develop, there is a massive increase in renal blood flow, owing to a decrease in afferent arteriolar resistance. This leads to an increase in capillary hydrostatic pressure, increased capillary permeability and passage of macromolecules, including plasma proteins and lipoproteins, through the capillary wall. Some of the protein appears as proteinuria, but some is scavenged by mesangial cells, and it is thought that overloading of these phagocytic cells may cause functional derangement and cellular proliferation and contribute to the glomerular sclerosis. Increased numbers of macrophages may liberate growth factors, also stimulating cellular proliferation, and direct endothelial damage may lead to platelet activation and intraglomerular thrombosis, with consequent fibrosis and liberation of platelet-derived growth factor and other stimulants of cellular proliferation.

Systemic hypertension is common in chronic kidney disease (though less so if the underlying pathology is in the medulla, e.g. reflux nephropathy, than in the cortex, e.g. glomerulonephritis), owing to salt and water retention and inappropriate release of renin and, thus, formation of angiotensin I. This hypertension itself has a harmful effect on renal function, by exacerbating the processes described above and by causing arteriolar damage and ischaemic glomerular sclerosis.

Chronic kidney disease causes hyperphosphataemia, and the phosphate retention can contribute to further renal damage. Dyslipidaemia is a frequent finding in chronic renal disease, and the accumulation of lipids in the glomeruli is also thought to contribute to the progression of renal disease and suggests another possible therapeutic manoeuvre that may retard this process.

In addition to these factors, incidental conditions can contribute to the progression of renal failure in patients with renal disease (see [Box 7.6](#)). As the homeostatic capacity of the kidneys decreases, so the patient becomes more susceptible to what might otherwise be easily tolerated events.

BOX 7.6 Incidental factors which can contribute to the progression of CKD

- Hypertension
- Hypovolaemia
 - Vomiting, diarrhoea, excessive use of diuretics etc.
- Urinary tract infection
- Congestive cardiac failure
- Drugs

The uraemic syndrome

The clinical syndrome associated with CKD is protean in its manifestations. None is specific to the condition, but the overall clinical disturbance is characteristic. Disorders of the cardiovascular, neurological, skeletal, gastrointestinal, endocrinological, haematological and immunological systems are of particular clinical importance, but any system can be affected. The clinical features are summarized in [Box 7.7](#).

BOX 7.7 Some clinical features of the uraemic syndrome

Cardiovascular

- Pericarditis
- Hypertension
- Congestive cardiac failure

Dermatological

- Pruritus
- Pigmentation
- Slow wound healing

Endocrinological

- Glucose intolerance
- Impaired growth
- Sexual dysfunction

Gastrointestinal

- Hiccough
- Nausea
- Vomiting
- Anorexia
- Gastritis

Haematological

- Anaemia
- Bleeding diathesis

Immunological

- Increased susceptibility to infection
- 'Burn out' of immunological disease (e.g. systemic lupus erythematosus)

Neurological

- Confusion, coma
- Dementia
- Headache
- Peripheral neuropathy
- Flapping tremor
- Muscle weakness

Pulmonary

- Pulmonary oedema

Skeletal

- Vertebral fractures

Other

- Nocturia
- Thirst
- General malaise

BOX 7.8 Uraemic toxins

- Urea
- Creatinine
- Oxalate
- Guanidines
 - Methylguanidine
 - Guanidinosuccinic acid
- Indoxyl sulphate
- *p*-Cresol and *p*-cresylsulphate
- Hippuric acids
 - Hippuric acid
 - *o*- and *p*-hydroxyhippuric acid
- Peptides
 - Parathyroid hormone
 - β_2 -microglobulin
- Polyamines
 - Spermine
 - Putrescine etc.

These changes result to a considerable extent from the effects of the retained 'uraemic toxins'; no single substance is responsible, although some, for example parathyroid hormone, appear to be particularly important. **Box 7.8** indicates some of the toxins that have been identified, but it should be emphasized that not only is it incomplete, but many uraemic toxins still await identification. In addition, deficiencies, for example of the hormones erythropoietin and calcitriol, contribute to the uraemic syndrome; while dialysis may relieve the clinical features of the syndrome by removing toxins, those related to deficiencies (e.g. anaemia) require treatment by specific supplementation.

Clinical features

A comprehensive discussion of the clinical manifestations of CKD is beyond the scope of this chapter. In the cardiovascular system, hypertension, congestive cardiac failure and accelerated atherosclerosis are all frequently encountered. The neurological involvement can include both the central nervous system (uraemic encephalopathy) and the peripheral nervous system. The skeletal features of CKD, which used to be called renal osteodystrophy, but is now called chronic kidney disease – mineral and bone disorder (CKD-MBD), comprise a complex amalgam of osteomalacia, secondary hyperparathyroidism, osteosclerosis and osteopenia; they largely stem from the impaired production of calcitriol (1,25-dihydroxycholecalciferol), the hormone derived from vitamin D. More recently, fibroblast growth factor 23 (FGF-23) and klotho, a transmembrane protein produced by the osteocyte, which is required for FGF-23 receptor activation, have been identified as being important in this area, but their exact roles are still under investigation. Renal bone disease is discussed in more detail in Chapter 31. Gastrointestinal problems include hiccoughs, anorexia and gastritis, which can all cause great distress to the patient; gastrointestinal bleeding can be life-threatening.

The anaemia of CKD is usually normochromic and normocytic (see p. 147); fragmented ('burr') cells may be present on the blood film. A multifactorial bleeding

diathesis is often present, with disturbances of platelet function and of coagulation. Depression of both the humoral and cellular arms of the immune system are frequent in CKD and patients have increased susceptibility to infection, are more likely to develop cancers and – a possibly beneficial effect – may experience remission of immunologically mediated disease.

Metabolic disturbances in CKD

Retention of nitrogenous waste products. Patients with CKD invariably have high plasma concentrations of urea and creatinine, but both can be affected by extrarenal factors. Thus, plasma urea concentration can be significantly reduced, even in advanced disease, by restriction of dietary protein, or in patients with chronic liver disease, and a sudden increase may occur if the patient suffers a gastrointestinal haemorrhage. Patients with CKD often have muscle wasting, which results in decreased creatinine production.

Hyperuricaemia is usually present in patients with CKD, although the concentration does not often exceed 600 $\mu\text{mol/L}$ and attacks of acute gout solely due to the CKD are rare.

Potassium metabolism. Potassium balance can often be maintained in CKD until the GFR falls to <5 mL/min. This is because of an adaptive response whereby distal tubular potassium secretion is increased; the mechanisms include increased aldosterone secretion and increased sodium delivery to the distal nephron, but there is also a poorly understood direct effect on potassium excretion. Furthermore, colonic potassium excretion, which is not usually a major route of potassium loss, becomes quantitatively important in patients with CKD.

Hyperkalaemia tends to occur earlier in patients with hyporeninaemic hypoaldosteronism, for example secondary to diabetes, and if there is significant acidosis. Hyperkalaemia is a life-threatening complication of CKD and can be precipitated by the injudicious administration of potassium or a drug that interferes with potassium excretion, for example potassium-sparing diuretics, angiotensin-converting-enzyme (ACE) inhibitors or β -adrenergic blockers.

Acid-base metabolism. In health, the kidneys excrete some 40–80 mmol of hydrogen ions per 24 h, this being the net rate of production on a normal diet. In CKD, renal hydrogen ion excretion is impaired, and once the GFR falls to below ~30 mL/min, systemic acidosis is likely to develop. This is despite the fact that the pH of the urine can usually be reduced to the lowest level achievable in health. The causes of the acidosis are discussed in detail in Chapter 5, but in summary are primarily due to reduced phosphate excretion, which diminishes the buffering capacity of the urine, and reduced ammoniogenesis which, albeit indirectly, also decreases renal hydrogen ion excretion.

In addition, there is often a partial defect in the reabsorption of filtered bicarbonate, a consequence, in part, of the expanded ECF volume and, in part, of the increased secretion of parathyroid hormone (see below). Severe

acidosis is, however, uncommon in CKD and, despite a continuing positive hydrogen ion balance, the blood hydrogen ion concentration tends to remain stable for weeks or even months at a time. This appears to be due to the extensive buffering of hydrogen ions that occurs in bone.

Although the usual acid–base disturbance in CKD is a non-respiratory acidosis, the ability of the kidneys to excrete excess bicarbonate is also decreased, and patients in whom there is excessive non-renal loss of acid, for example due to vomiting, may occasionally develop alkalosis.

Calcium, phosphate and magnesium metabolism and renal bone disease. These topics are reviewed in detail in Chapters 6 and 31. In essence, CKD leads to a progressive decrease in the synthesis of calcitriol from 25-hydroxycholecalciferol, as a result of both inhibition of the enzyme by retained phosphate (an effect that becomes apparent as the GFR falls to <60–70 mL/min) and, in more advanced disease, a decrease in the amount of enzyme as the renal mass decreases. A lack of calcitriol leads to decreased absorption of calcium from the gut, exacerbated by a low dietary intake of calcium, common in patients with CKD. There is thus a tendency to hypocalcaemia which, in health, should be corrected by increased secretion of parathyroid hormone (PTH) and mobilization of calcium from bone. In CKD, although the plasma PTH concentration is characteristically increased, often to a very high level (secondary hyperparathyroidism), there is resistance to its action, probably because of the low calcitriol concentrations. In consequence, plasma calcium concentration is usually below normal.

It should be noted that the results of older assays for PTH may be misleading, owing to metabolism of the hormone and selective retention of the biologically inactive C-terminal fragment in CKD. Assays that measure only intact PTH are more reliable indicators of parathyroid activity.

As discussed in detail in Chapter 6, hypercalcaemia can occur in CKD if parathyroid autonomy develops or after successful renal transplantation (tertiary hyperparathyroidism).

Plasma phosphate concentrations are usually normal, but can be low in early CKD. Despite a decrease in the number of functioning nephrons, the fractional excretion of phosphate by each is increased due to the elevated PTH. In more advanced disease, further loss of nephrons leads to the characteristic phosphate retention.

Plasma magnesium concentrations tend to be increased in CKD. Although toxic concentrations do not occur in uncomplicated cases, problems have been encountered in patients given magnesium salts therapeutically, for example as antacids.

Protein metabolism. Patients with CKD tend to be mildly catabolic, although this process can be accelerated by the development of intercurrent illness. Although the limitation of protein intake is an important aspect of the conservative management of CKD (see p. 148), it must not be so severe that it becomes a contributory factor to the loss of body protein.

Endocrine disturbances in CKD

There is good reason to expect endocrine disturbances in renal disease since the kidneys are an important site of hormone production, action and clearance (Table 7.5). Quite apart from the effect of the kidneys themselves on the production, excretion and activity of various hormones, impairment of non-endocrine renal function can secondarily affect the endocrine system. For example, CKD causes significant alterations in the internal environment that may influence the secretory control of hormones, their transport, activation and degradation, the relative amounts of free and protein-bound hormones in plasma and the responsiveness of hormone receptors at the cellular or subcellular level. Thus, in addition to renal clearance, the extrarenal clearance of some hormones may be abnormal in CKD, for example impaired hepatic degradation of biologically active PTH or diminished breakdown of insulin by skeletal muscle. Also, the function of endocrine organs may be influenced by treatment such as dietary restriction, drug therapy and renal replacement treatment.

The major mechanisms whereby chronic kidney disease influences endocrine function are outlined in Table 7.6. When kidney disease becomes advanced, the plasma or tissue concentrations and/or the functions of most hormones are altered, resulting in a number of well-recognized endocrine abnormalities (Box 7.9).

Growth retardation

Short stature is common among children with advanced kidney disease; its pathogenesis is multifactorial (Box 7.10). From an endocrine point of view, growth is a complex process involving primarily growth hormone (GH), but it is also dependent upon normal adrenal, thyroid and sex hormone function as well as an adequate supply of nutrients. In CKD, plasma immunoreactive GH concentrations rise in proportion to the decline in creatinine clearance and probably also to protein malnutrition.

TABLE 7.5 Functions of the kidneys involving hormones

Function	Hormones
Endocrine organ	Erythropoietin Angiotensin I and II 1,25-Dihydroxycholecalciferol Prostaglandins Kinins
Endocrine target organ	Parathyroid hormone Arginine vasopressin Aldosterone Calcitonin Atrial natriuretic peptide
Excretion of hormones	Cortisol Aldosterone Catecholamines Thyroid hormones Sex hormones
Catabolism of hormones	Parathyroid hormone Calcitonin Arginine vasopressin Insulin 1,25-Dihydroxycholecalciferol

TABLE 7.6 Mechanisms by which chronic kidney disease influences endocrine function

Mechanism	Example
Damage to renal parenchyma	Reduced synthesis of hormones Reduced clearance of hormones Reduced action of hormones
Disturbance of fluid and electrolyte balance	Activation of homeostatic mechanisms, e.g. renin–angiotensin system; PTH secretion in response to hypocalcaemia
Inappropriate secretion of hormones	Hypersecretion of hormones, e.g. prolactin
Appropriate homeostatic feedback mechanisms	Secretion of LH in response to reduced testosterone
Impaired extrarenal catabolism	Accumulation of hormones, e.g. PTH, insulin
Reduced hormonal function	Presence of multimolecular forms with varied biological activity, e.g. glucagon and calcitonin Accumulation of hormones with opposing actions Accumulation of metabolic inhibitors
Renal loss of binding proteins	Disturbance of bound:free ratio
Target organ resistance to hormonal action	Abnormal receptor binding, e.g. 1,25-dihydroxyvitamin D Abnormal postreceptor events, e.g. PTH, insulin
Reduced clearance of drugs	May interfere with endocrine function
Specific drug therapy, e.g. steroids	May interfere with endocrine function or induce endocrine disease, e.g. Cushing syndrome
Malnutrition	May have profound effects on endocrine function, e.g. growth and reproductive function
Increased susceptibility to sepsis	May have profound effects on endocrine function

BOX 7.9 Major endocrine abnormalities seen in CKD

- Anaemia
- Endocrine hypertension
- Glucose intolerance
- Growth retardation
- Hypergastrinaemia
- Hyperlipidaemia
- Renal osteodystrophy
- Sex hormone dysfunction
- Thyroid hormone abnormalities

BOX 7.10 Pathogenesis of growth retardation in CKD

- Malnutrition
- Anaemia
- Uraemia
- Renal tubular dysfunction
- Renal osteodystrophy
- Steroid therapy

This rise in GH is because of reduced clearance and consequently increased plasma half-life. Growth failure in the presence of raised plasma GH concentrations indicates a resistance to the actions of GH in peripheral tissues. The homeostatic mechanisms regulating GH secretion also appear to be abnormal in CKD, with exaggerated GH responses to arginine, thyrotrophin releasing hormone (TRH) and insulin-induced hypoglycaemia.

The skeletal growth-promoting actions of GH are mediated by the insulin-like growth factors (IGFs). In CKD, the plasma concentrations of IGFs tend to be normal, but their bioavailability is reduced. This is probably because of increases in the plasma concentrations of their respective binding proteins.

Sexual dysfunction

Impaired sexual function is a frequent and distressing symptom in both male and female patients with advanced CKD. In men, the major problem is impotence, which persists despite dialysis. This may have a multifactorial aetiology, being either directly related to the CKD or to coexistent conditions (Box 7.11). However, in many patients the organic component of impotence can be directly related to a disorder of sex hormones (Box 7.12), and several mechanisms may contribute to the hormonal abnormalities found. For example, hyperprolactinaemia is secondary both to hypersecretion and a reduction in clearance. The former is thought to be caused by a decrease in the sensitivity of lactotrophs to dopamine; chromatographic analysis of the circulating prolactin has confirmed that the majority is intact prolactin and not fragments.

In addition to problems of potency, males with CKD are frequently infertile, with evidence of defective spermatogenesis. Testicular biopsy shows maturation arrest, thickening of tubular basement membrane and interstitial fibrosis, consistent with damage to seminiferous tubules. These observations lend support to the theory that sexual dysfunction in advanced CKD is due primarily to toxic effects of circulating 'uraemic toxins' on both Leydig

BOX 7.11 Factors that may contribute to impotence in CKD

- Uraemic neuropathy
- Vascular disease
- Diabetes mellitus
- Alcoholism
- Drug therapy
- Psychogenic impotence
- Sex hormone abnormalities
- Coincident endocrine disease

BOX 7.12 Major sex hormone and prolactin abnormalities in males with CKD

- Low plasma total and free testosterone concentrations
- Low plasma total and free oestrogen concentrations
- Low plasma total and free adrenal androgen concentrations (with normal sex hormone binding globulin concentrations)
- Subnormal plasma testosterone response to human chorionic gonadotrophin administration
- Hyperprolactinaemia in 50% of patients
- Subnormal prolactin responses to TRH in 50% of patients
- Disturbance of the circadian rhythm of prolactin secretion in 50% of patients

and Sertoli cell function. The identity of these 'toxins' remains undetermined, although there is good evidence to suggest that both PTH and prolactin may play a role.

The course of progressive deterioration in testicular function is not markedly altered by either haemodialysis or peritoneal dialysis. The best treatment is renal transplantation, which restores plasma gonadotrophin and sex steroid concentrations to normal and may result in effective spermatogenesis. The immunosuppressive therapy does not appear to have any deleterious effects apart from suppression of adrenal androgen secretion by prednisolone, although there is some evidence that men treated with sirolimus based regimens have a lower sperm count than those who are not.

Other notable problems that occur in dialysed males include gynaecomastia and priapism. The former does not appear to be related to either prolactin concentrations or androgen:oestrogen ratios, and has been compared to the type of gynaecomastia that occurs in malnourished patients during refeeding. The cause of priapism is unknown, but may be related to hypovolaemia after dialysis, the use of heparin or treatment with androgens.

In children, delayed bone age and delayed puberty are found. In boys, Leydig cell function appears to be relatively normal, as shown by the normal testosterone:dihydrotestosterone ratios, suggesting that 5 α -reductase activity is normal. As might be expected, this results in normal LH concentrations, but FSH concentrations are elevated, which appears to reflect damage to the germinal cell epithelium prior to the initiation of spermatogenesis. These observations suggest that Sertoli cell damage in renal impairment occurs early while Leydig cell damage either does not occur until late or only occurs in adult patients.

In women with CKD, there is typically hypothalamic anovulation with amenorrhoea along with loss of libido and inability to reach orgasm. These women frequently exhibit hyperprolactinaemia with reduced oestrogen concentrations and elevated plasma concentrations of gonadotrophins and gonadotrophin releasing hormone (GnRH). Even in women who menstruate, the mid-cycle LH surge appears to be absent leading to anovulatory cycles and low progesterone concentrations, which in turn may cause dysfunctional bleeding. It is not surprising, therefore, that such patients are infertile. With treatment, however, premenopausal women may resume normal menstruation with ovulatory cycles and may even

become pregnant. As with males, renal transplantation produces the most satisfactory results.

Thyroid abnormalities

Patients with CKD have several clinical disturbances that could potentially affect thyroid function. For example, they are chronically ill, often malnourished and display multiple hormonal and metabolic derangements. It is, therefore, not surprising that various abnormalities of thyroid function have been well documented (Box 7.13). These may complicate the diagnosis of coexistent thyroid disease (there is an increased prevalence of goitre and an increased incidence of primary hypothyroidism in CKD, particularly in women). The development of subclinical thyroid function test abnormalities has been explained by a mixture of defects (Box 7.14), which may also be observed in other chronic illnesses and malnutrition states (see Chapter 19). The high incidence of goitre in uraemic patients suggests that there is a circulating goitrogen in CKD. This does not appear to be either TSH or autoimmune antibodies, but there is circumstantial evidence to suggest that PTH may be involved since the incidence of thyroid nodules and goitres is greatly increased at post-mortem in patients with primary hyperparathyroidism.

With peritoneal dialysis (PD), plasma total T4 concentrations are not as low as with haemodialysis (HD), but T3 concentrations are lower. The low T4 concentrations in PD may relate to low concentrations of thyroxine binding globulin (TBG), while in haemodialysis there may be an inhibitor of binding present. Continuous ambulatory peritoneal dialysis (CAPD) appears to correct unbound, plasma free T4 concentrations better than HD; TSH is normal in both groups. Following successful transplantation, the plasma concentrations of thyroid hormones return to normal, while the TSH response to TRH may either be normal or decreased.

BOX 7.13 Plasma concentrations of thyroid hormones and binding globulin in CKD

- Total T4 normal or decreased
- Total T3 decreased
- Free T4 decreased
- Free T3 decreased
- Reverse T3 normal or decreased
- Blunted and/or delayed TSH response to TRH
- Thyroxine binding globulin normal

BOX 7.14 Mechanisms contributing to subclinical thyroid abnormalities in CKD

- Defective thyroid hormone synthesis
- Minor abnormalities in pituitary feedback mechanisms
- Reduced peripheral conversion of T4-T3
- Altered transport of thyroid hormones secondary to circulating inhibitors of binding

The diagnosis of thyroid disease in patients with CKD is difficult. A diagnosis of primary hypothyroidism can only be made with confidence if the plasma TSH is unequivocally elevated. In less clear-cut cases, measurement of free T4 may be helpful, but can be unreliable. The response to treatment should be monitored using plasma free T4 concentrations. The diagnosis of hyperthyroidism in renal impairment rests on the demonstration of an elevated plasma free T4 concentration in the presence of suppressed TSH, although hyperthyroidism is extremely rare in patients with this condition.

Anaemia

In patients with established renal failure, plasma erythropoietin concentrations are usually normal or even elevated. However, these concentrations are generally inappropriately low for the degree of anaemia and so there exists a state of relative erythropoietin deficiency, which contributes to the normochromic normocytic anaemia. Other factors include depression of the erythroid marrow by 'uraemic toxins', bleeding and haemodilution due to water retention. Following renal transplantation, the anaemia improves and the plasma erythropoietin concentrations return towards normal. However, very occasionally they remain elevated and erythrocytosis develops. This is due to some residual secretion of erythropoietin from the diseased kidneys.

Endocrine control of salt and water balance

Chronic kidney disease influences the activity of a number of renal and extrarenal hormones that control salt and water balance as well as blood pressure and volume. Renin release appears to be maintained by diseased kidneys under many circumstances. Thus, depending upon fluid and electrolyte balance, the plasma renin activity (PRA) in patients with renal impairment may be low, normal or high.

Plasma renin activities and 18-hydroxycorticosterone concentrations increase in patients on CAPD more than in those treated with HD. These increased concentrations have been attributed to the continuous fluid volume depletion induced by peritoneal ultrafiltration. Aldosterone concentrations are also elevated secondarily to the hyperkalaemia; they are more effectively reduced by HD than CAPD. Renal transplantation returns PRA and aldosterone towards normal. In addition, the normal physiological responses to sodium restriction, upright position, hypo- or hypervolaemia and angiotensin-converting-enzyme inhibitors appear to be preserved.

Plasma cortisol concentrations are at the upper limit of normal in CKD and respond normally during a tetracosactide test or insulin-induced hypoglycaemia, although the prolactin and GH responses are blunted during the latter, consistent with a degree of anterior pituitary dysfunction.

Plasma catecholamine concentrations are usually elevated in advanced CKD owing to a combination of several mechanisms, including reduced clearance, catabolism and neuronal uptake, and increased sympathetic efflux. After renal transplantation, normal plasma

concentrations of noradrenaline (norepinephrine) with moderately elevated concentrations of adrenaline (epinephrine) have been found. Arginine vasopressin (AVP) is normally freely filtered by glomeruli and catabolized by tubules, so plasma AVP concentrations are elevated in CKD. The hormone is not significantly cleared by dialysis and remains elevated in response to the chronic fluid depletion. Following transplantation, both normal and elevated AVP concentrations have been reported. The plasma concentrations of natriuretic peptides (e.g. BNP, see Chapter 4) rise in direct relationship to the rise in plasma creatinine and represent a normal homeostatic response to fluid overload. Once effective dialysis is established or renal transplantation performed, the concentrations return towards normal.

Impairment of the kidneys' regulatory function results in defects in both the excretory and conservatory mechanisms for sodium and water (Fig. 7.7).

Thirst and nocturia are common features of chronic renal disease, reflecting the diminished capacity to concentrate the urine and loss of the normal diurnal variation in urine production. These effects are primarily due to the solute load causing osmotic diuresis in the remaining functional nephrons. Patients tend not to complain of polyuria; the low GFR sets a low limit on the maximum urine volume of not more than about 4L/24h. The capacity to dilute the urine may be preserved longer than that to concentrate it, but in advanced disease, neither dilution nor concentration can take place. The urine tends to have a fixed osmolality (~300 mmol/kg) and the patient is at great risk of both over- and under-hydration if fluid intake is not carefully regulated.

Early in the course of CKD, normal sodium balance may be maintained by increased excretion through the remaining functional nephrons. Particularly in patients with primarily tubular disorders, sodium conservation may be defective, leading to sodium depletion with clinical evidence of decreased ECF volume. Later, the tendency is to sodium retention, but this may not be apparent until the GFR falls below 10 mL/min and, even then, some patients continue to leak sodium. Since a fall in ECF volume can further impair renal function, careful attention to the maintenance of sodium balance is essential in the management of patients with CKD.

FIGURE 7.7 ■ The renal capability to excrete sodium and water in healthy individuals (light shading) and in patients with severely impaired renal function (dark shading). (From Davison AM et al. (eds) 2005 Oxford Textbook of Clinical Nephrology, 3rd edn. Oxford: Oxford University Press p. 1705, with permission).

Carbohydrate metabolism and lipid metabolism

Impaired glucose tolerance secondary to insulin resistance is a feature of CKD. A number of mechanisms appear to contribute to the generation of this metabolic abnormality (Box 7.15), which is only partially corrected by dialysis and may persist following renal transplantation. However, this may well be related to the effect of steroid therapy since glucocorticoids are well known for their ability to cause hyperglycaemia. Some 70% of patients with CKD exhibit abnormalities of both lipids and lipoproteins, thought to be secondary to the hyperinsulinism. Typically, there is elevation of plasma triglycerides, very low density lipoprotein and intermediate density lipoprotein, but normal total cholesterol, with high density lipoprotein being decreased. The apoprotein and lipid content of the lipoproteins is also altered.

The major defects underlying these abnormalities appear to be low activities of tissue lipoprotein lipase, hepatic lipase and lecithin-cholesterol acyltransferase. These abnormalities undoubtedly contribute to the increase in cardiovascular morbidity and mortality observed in patients with CKD.

Management

General management

This entails measures to evaluate and manage comorbid conditions, slow progression of kidney disease, reduce the risk of cardiovascular disease, prevent and treat complications of chronic kidney disease and to prepare for eventual renal replacement treatment. The measures specific to kidney disease are discussed further below. Management of comorbid conditions will not be discussed further here.

The staging of chronic kidney disease as defined by the chronic kidney disease K/DOQI classification (see Table 7.2) is used as the basis for the development of clinical management plans for individual patients.

Slowing the progression of kidney disease. If the cause of the CKD can be identified, it should of course be treated appropriately. Care must be taken to avoid conditions that may accelerate the decline in renal function, for example dehydration and infection (see Box 7.6).

BOX 7.15 Mechanisms contributing to impaired glucose tolerance in chronic kidney disease

- Metabolic acidosis
- Decreased cellular sensitivity to insulin
- Decreased glucose utilization by peripheral tissues
- Increased plasma concentrations of GH and glucagon
- Retention of Mg^{2+}

Dietary measures are important both in an attempt to retard the progression of disease and in the avoidance of complications. Dietary management should ideally be supervised by a dietitian with special training in the management of renal disease. This person will not only be able to give advice on an appropriate diet, but should be able to design one that is acceptable to the patient and monitor compliance. The essentials of dietary management include maintenance of sodium, potassium and water balance, which usually entails restriction of sodium and potassium intake; reduction in phosphate intake, and dietary protein restriction (to about 0.8 g/kg per 24 h).

Experimental work suggests that judicious reduction in protein intake may decrease the progression of CKD, even when this is well established (plasma creatinine concentration $>400 \mu\text{mol/L}$). Dietary protein restriction may protect against the progression of CKD by haemodynamically mediated reductions in intraglomerular pressure and by changes in cytokine expression and matrix synthesis. The haemodynamic effects of protein-induced hyperfiltration may be due to changes in hormones (such as glucagon and insulin-like growth factor-1), alterations in the renin-angiotensin system, and intrarenal effects, including tubuloglomerular feedback. The benefits of moderate dietary protein restriction (0.6–0.8 g/kg per day) on the progression of CKD in humans remain controversial. Current data suggest that, at best, a small reduction in the rate of decline of glomerular filtration rate (GFR) may be observed with a low protein diet.

When planning nutrition in patients being treated with dialysis, account must be taken of the loss of protein and amino acids into the dialysate. This occurs in patients both on peritoneal dialysis and haemodialysis, although the protein loss tends to be larger with the former and may be up to 40 g/24 h.

Supplementary vitamins may need to be prescribed both for patients treated conservatively and, particularly, those on dialysis. Careful clinical and biochemical monitoring of nutritional status is essential. Adequate energy intake must be maintained (at least 35 kcal/kg per 24 h) to meet energy requirements and prevent catabolism.

The need for careful attention to sodium and potassium intake should be obvious from earlier sections. There are experimental data to suggest that phosphate restriction is also desirable to prevent the development of renal metabolic bone disease, for which purpose the maintenance of plasma phosphate concentration within the reference range is the ideal. Although dietary protein restriction usually also entails dietary phosphate restriction, adequate control may be difficult to achieve. It is also important to avoid decreasing calcium intake, which may contribute to the development of bone disease. Oral aluminium salts can be given to bind phosphate in the gut and reduce its absorption; the risk of aluminium-induced neurological and bone toxicity that led to avoidance of their use may have been overstated, but if they are used, it is important to monitor the serum aluminium concentration regularly. Calcium containing phosphate binders

such as calcium carbonate are widely used, but care must be taken to avoid inducing hypercalcaemia and there is a worry that they may increase the risk of vascular calcification. Newer, non-calcium-based phosphate binders are now available.

Dyslipidaemia is frequently present in patients with CKD. There are conflicting data concerning the effect of lipid lowering therapy with statins on progression of CKD. Some studies suggest that statins slow the rate of decline in renal function in patients with mild-to-moderate renal dysfunction, while others have found that they do not. All the data evaluating the effects of statin therapy on CKD progression were based on subset analyses of trials designed to evaluate the efficacy of statin therapy on cardiovascular disease. Thus, statin therapy cannot be recommended solely for renal protection.

Prevention of complications. It is essential to avoid dehydration. Particular care with fluid balance will be required if a patient has abnormal losses, for example because of vomiting, diarrhoea, or too vigorous treatment with diuretics. Blood pressure must be monitored regularly and any hypertension treated adequately. Any infections, but particularly those of the urinary tract, must be treated promptly, preferably with non-nephrotoxic drugs. Indeed, all medication must be chosen carefully to avoid nephrotoxicity.

The prevention of bone disease involves minimizing hyperphosphataemia (see above) and the administration of 1-hydroxylated metabolites of vitamin D, with or without calcium supplements. If hypercalcaemia occurs owing to tertiary hyperparathyroidism and patients are unfit for surgery, calcimimetics (e.g. cinacalcet) can be used. These drugs act directly on the calcium-sensing receptor in the chief cells of the parathyroid glands to reduce PTH synthesis and secretion.

Recombinant erythropoietin is available for the treatment of anaemia. It is effective and can greatly increase the well-being of patients with CKD, whether treated conservatively or by dialysis. It is, however, expensive and care is needed with patient selection and with monitoring the response to ensure efficient use of the drug. Iron stores must be replete for erythropoietin to work effectively.

Renal replacement treatment

By definition, the patient reaching end-stage renal failure requires renal replacement treatment in order to survive. In the face of such severe loss of renal function, the general measures outlined above will no longer be sufficient to maintain an internal environment compatible with the maintenance of vital functions. There are essentially two options: dialysis (peritoneal or haemodialysis; haemofiltration and haemodiafiltration are related techniques) and renal transplantation. These are not exclusive; most patients will need to undergo dialysis until transplantation becomes possible and, even after transplantation, some will require dialysis until adequate graft function is established or may need it again should the graft fail.

The optimum time to start a patient on dialysis will depend on several factors:

- failure of conservative measures to allow a patient to continue with the activities of daily life, including working
- the onset of major complications (pericarditis, neuropathy, encephalopathy, persistent hyperkalaemia)
- other life-threatening or intolerable features of uraemia.

Early initiation of maintenance dialysis is now preferred to a protracted period of dietary restriction. According to the K/DOQI guidelines (see Table 7.2) dialysis should be initiated electively in those whose eGFR is <15 mL/min. Some patients in the UK are eligible for pre-emptive transplantation if dialysis is predicted to be required within six months (i.e. eGFR is predicted to fall to <15 mL/min).

Haemodialysis. The dialyser consists of two contiguous compartments separated by a semi-permeable membrane. Blood flows through one compartment and dialysis fluid flows in the opposite direction through the other compartment. Waste products diffuse down the concentration gradient from blood to dialysate; water moves according to the relative osmolalities of plasma and dialysate, and other substances that can pass through the membrane (e.g. sodium, potassium) do so in relation to their own gradients (Fig. 7.8). The most frequently employed dialysers consist of an array of hollow fibres with semi-permeable walls; blood is pumped through the fibres, which are surrounded by dialysate.

The composition of the dialysate is similar to that of interstitial fluid, but with a lower potassium concentration and a higher glucose concentration (to make the fluid hypertonic and thus remove water).

Most patients dialyse for 12–15 h/week, spread over three sessions, at home, in a satellite unit or in hospital. It may be possible to relax the dietary restrictions required during conservative management somewhat after starting dialysis, but while more protein (e.g. 1 g/kg per 24 h) may be permitted, potassium, sodium, phosphate and water intake will still require restriction.

Clinical assessment provides an important guide to the adequacy of dialysis, but is inadequate on its own. Measurements of pre- and post-dialysis urea and creatinine concentrations also have limitations. Many alternative means of assessment have been studied, of which ‘urea kinetic modelling’ (UKM) is the most widely used. Measurements of plasma urea concentration are used to calculate the total urea clearance (K) (residual clearance plus clearance by the dialyser, in mL/min). This can be used to calculate the function ‘Kt/V’, where t is the dialysis time in minutes and V the volume of distribution of urea in mL (equal to the total body water or 65% of body weight). The ideal value of Kt/V is >1.0. However, urea is not an ideal marker of renal function; estimates of V may underestimate true values and the desired clearance and actual clearance achieved may not be the same. Furthermore, it is not clear whether increasing benefit may result from the achievement of higher values of Kt/V. Thus, the use of Kt/V to guide dialysis therapy is not as straightforward as it might appear.

FIGURE 7.8 ■ The principles of haemodialysis.

Haemofiltration. While in haemodialysis, waste products are removed by diffusion, in haemofiltration they are removed by convection. Fluid crosses the filtration membrane as a result of the pressure difference. Haemofiltration membranes are generally more permeable than those used in dialysis. This has the potential advantage that larger molecules (e.g. low molecular weight polypeptides) can be cleared from the plasma than is possible with haemodialysis.

There are systems that incorporate both diffusion and convection, that is, haemodiafiltration. In haemofiltration and haemodiafiltration, the volume ultrafiltered is replaced by intravenous infusion of pre-prepared replacement fluid from bags. Replacement fluid can also be prepared on line by the dialysis machine, for which the water quality has to be ultra-pure.

Peritoneal dialysis. In this technique, the semi-permeable membrane is the peritoneal membrane. Dialysate is instilled into the peritoneal cavity through a permanent silastic dialysis catheter, allowed to equilibrate and then removed. Continuous ambulatory peritoneal dialysis, in which the process is continuous with three or four fluid changes taking place over 24 h, is widely used.

Automated peritoneal dialysis (APD) is a term used to refer to all forms of PD using a machine to assist with the delivery and drainage of the fluid. Exchanges are typically carried out overnight, which leaves the patient free during the day.

Residual renal function can contribute as much as one-third of creatinine clearance; however, it declines with time so the dialysis prescription needs to be kept under review to ensure adequate clearance.

Renal transplantation. In addition to removing the requirement for repeated dialysis, successful transplantation removes the restrictions on the patient's food and fluid intake. The patient will have to take immunosuppressive therapy for life, and, although this poses some risks (increased susceptibility to infection and incidence of lymphoproliferative disorders), they can be minimized by careful monitoring, including therapeutic monitoring of plasma immunosuppressive drug concentrations.

There are many immunosuppressive regimens. Briefly, they include a monoclonal antibody against the interleukin-2 (IL-2)-receptor (e.g. basiliximab or daclizumab) on induction, a calcineurin inhibitor (cyclosporin or tacrolimus), an antiproliferative agent (azathioprine or mycophenolate mofetil) and corticosteroids. Sirolimus is another immunosuppressive drug that is not nephrotoxic; calcineurin inhibitors are. Therapeutic monitoring of these drugs is essential (see Chapter 39). If there is graft dysfunction, toxic concentrations of calcineurin inhibitors are an important reversible cause.

Many factors influence patient survival, but rates continue to improve, and one-year survival rates of >95% for patients are now common. Typically, >88% of deceased donor grafts and >95% of live related grafts are still functioning at one year.

Following transplantation, careful monitoring is required to assess graft function, monitor the patient's hydration and to assist the early diagnosis of rejection. Regular measurements are required of urine volume, plasma creatinine, sodium, potassium, bicarbonate, glucose, calcium, phosphate and albumin concentrations, liver function tests, haemoglobin and white blood cell and platelet counts, as well as therapeutic monitoring of immunosuppressive drugs.

CONCLUSION

The kidneys have an essential role in the regulation of the composition and volume of the body fluids and in the excretion of waste products of metabolism. They also have important endocrine functions. They can be affected by disease processes confined to the kidneys, but they are frequently affected by primarily extrarenal disease.

The informed use of biochemical tests plays an important part in the investigation of renal integrity and function, although many other types of investigation are also used in the management of patients with renal disease.

Renal impairment can be acute (when it is usually potentially reversible) or chronic (when it usually progresses inexorably to established (end-stage) renal failure). In both types, there are profound systemic consequences. Conservative measures are important in management, but renal replacement treatment, by some form of dialysis or haemofiltration, is often required. In established (end-stage) renal failure, death will ensue unless the patient either undergoes successful renal transplantation or receives long-term renal replacement treatment.

Note about terminology

The terms 'acute kidney injury' and 'chronic kidney disease' have now replaced 'acute renal failure' and 'chronic renal failure', respectively.

INTRODUCTION

For over 150 years, proteinuria has been recognized as one of the cardinal signs of renal disease and it continues to be used for the diagnosis and management of patients with nephropathy. However, the use of sensitive immunoassay methods to measure urine albumin has demonstrated pathologically significant proteinuria well below the detection limit of chemical methods. Since the discovery, several decades ago, that low-level albuminuria (microalbuminuria) identifies diabetic patients with incipient nephropathy, further large-scale studies have revealed that microalbuminuria is also a risk factor for macro- and microvascular disease, in both diabetic and non-diabetic populations. Studies over the last ten years have confirmed that microalbuminuria is not only associated with cardiovascular disease but also with any acute inflammatory condition, and is a reflection of systemic vascular endothelial dysfunction. Of particular importance, is the finding that, in some conditions, microalbuminuria is reversible with interventions that protect the vascular system. Thus modern assessment of proteinuria across the full pathological range has a role not just in the diagnosis and management of primary renal disease, but also as a marker of endothelial dysfunction in a variety of non-renal conditions.

PROTEIN CONSERVATION BY THE KIDNEYS

The kidneys receive approximately 25% of the resting cardiac output, which represents approximately 1.2L/min of blood or 650mL/min of plasma. The kidneys' capacity to conserve protein can be judged from a simple calculation. Every 24h, approximately 930L of plasma containing about 70g/L of protein pass through the kidneys, representing 65 kg of protein, of which <100mg (0.00015%) appear in the urine.

The filtration process is dependent on adequate renal blood flow, which is preserved by an autoregulatory system, despite variations in blood pressure (see p. 127). This mechanism allows vasodilatation as perfusion pressure falls and vasoconstriction as pressure rises. The mediators of this process include prostaglandins, kinins and atrial peptides (vasodilators), and angiotensin II, α -adrenergic hormones, thromboxane A₂, noradrenaline (norepinephrine) and vasopressin (vasoconstrictors). In addition, renal arterioles respond within seconds to changes in vessel wall tension; thus, when renal perfusion pressure rises, vessel wall tone increases and, conversely, when renal perfusion pressure falls abruptly, there is a compensatory decrease in vessel wall tone. This phenomenon is called the myogenic reflex and helps to maintain a constant renal blood flow across a range of perfusion pressures.

A minimum intraglomerular pressure, derived from the pumping action of the heart, is required to overcome the two main opposing forces to filtration: the colloidal oncotic pressure and the hydrostatic pressure in the Bowman space. When the renal perfusion pressure falls below 50–60 mmHg, further vasodilatation does not occur and renal blood flow declines in proportion to the reduction in renal perfusion pressure. These mechanisms maintain renal blood flow, and hence glomerular filtration, independently of the normal fluctuations of blood pressure. However, recent studies suggest that chronic hypertension impairs the renal autoregulatory mechanism, which may contribute to hypertension-associated renal damage and proteinuria.

The glomerular capillary wall

The glomerular membrane consists of a modified capillary wall comprising endothelium, an acellular basement membrane and an outer specialized epithelial cell layer (Fig. 8.1). The endothelial cells are thin and fenestrated with 50–100 nm pores. The basement membrane, comprising the lamina rara interna, lamina densa and lamina rara externa, is around 300–350 nm thick and is best considered as a gel-like structure containing 3–5 nm long fibrils but no detectable pores. The numerous foot processes of the epithelial cells (also called podocytes) interdigitate and envelop the outer surface of the glomerular membrane. The foot processes are separated by slit diaphragms about 55 nm in width, which form the final barrier to plasma proteins.

The whole of the glomerular membrane carries a fixed net negative charge, which is partly owing to a glycosialoprotein coat covering both endothelium and epithelium. The charge increases in density from the lamina rara interna towards the lamina rara externa, with the greatest density at the slit diaphragms of the epithelium.

The glomerular capillaries act as high pressure filters, allowing water and low molecular weight solutes to pass

through freely and almost completely retaining plasma proteins. The concentration gradient of proteins across the glomerular membrane produces the colloidal oncotic pressure that must be overcome for filtration to take place.

The theory of molecular sieving

The glomerular membrane selectively allows passage of water and low molecular weight solutes into the tubule and restricts passage of larger molecular weight plasma proteins, based on a combination of molecular size, shape and charge. The pore size of the fenestrae of endothelial cells (50–100 nm) is too great to provide a major restriction to the passage of many proteins, which pass through to the glomerular membrane. Like the glomerular membrane, most plasma proteins carry a net negative charge, resulting in their electrochemical retention by the kidneys. The capillary side of the glomerular basement membrane (lamina rara interna) has a charge density of 35–45 mEq/L, so that electrochemical effects alone reduce the concentration of albumin to 5–10% of that in plasma. Thus, the lamina rara interna of the basement membrane is the first impediment to confront charged molecules, with the lamina densa providing the most effective size barrier to macromolecules. Some macromolecules accumulate at the slit diaphragms of the epithelium where the net negative charge is greatest, and there is evidence that some molecules are pinocytosed by the podocytes.

Based on their molecular radius, shape and charge, different proteins penetrate the glomerular membrane to a variable extent, for example, albumin (radius 3.6 nm, isoelectric point 4.7) is restricted at the lamina rara interna, while lactoperoxidase (radius 3.8 nm, isoelectric point 8.0) may reach the slit pores of the epithelial cells.

Despite the protein-retaining properties of the glomerular membrane, some protein does pass into the

FIGURE 8.1 ■ Glomerular membrane structure.

proximal tubular fluid. In healthy adults, the albumin content of glomerular filtrate is probably about 15 mg/L which, with a glomerular filtration rate (GFR) of 160 L/24h, results in 2–3 g of albumin being presented to the renal tubules each day, most of which is reabsorbed.

Tubular reabsorption of proteins

The amount of protein reaching the proximal tubules is a function of the protein's ability to cross the glomerular membrane and its plasma concentration. After reabsorption, proteins are catabolized in tubular cells and the amino acids, bound vitamins and trace metals returned to the plasma pool. For example, under normal circumstances the kidneys are responsible for about 10% of albumin catabolism, but this figure can rise to 60% when there is increased glomerular clearance of albumin such as occurs in nephrotic syndrome.

Normally, only a very small proportion of plasma proteins reaches the urine. This is primarily owing to retention of large molecular weight proteins by the glomeruli, and almost complete proximal tubular reabsorption and catabolism of any filtered lower molecular weight proteins that have passed through the glomerular membrane more easily. Thus, the renal clearance of plasma proteins represents a combination of these processes. The relative contributions of glomerular retention and tubular reabsorption to protein clearance by the kidney depend on molecular weight (Table 8.1).

The likely mechanism of proximal tubular protein reabsorption is endocytosis at the tubular epithelial apical cell membrane mediated by two receptors (megalin and cubilin) and the cooperating protein amnionless. Mutations in one or other of these components are responsible for the tubular proteinuria of Imerslund–Grasbeck syndrome (selective vitamin B₁₂ malabsorption) and Donnai–Barrow syndrome (a multisystem disorder affecting many organs that normally express megalin). Following reabsorption, proteins are transferred to lysosomes for degradation while the receptors are recycled from endosomes to the apical cell membrane. Mutations in the lysosomal and endosomal components are responsible for the tubular proteinuria in Dent disease and cystinosis; the molecular mechanism in Lowe syndrome is yet to be resolved (see Chapter 9).

Megalin and/or cubilin bind albumin and low molecular weight proteins but there is some evidence that, of the filtered proteins reaching the proximal tubule, those with lower molecular weights are reabsorbed by different mechanisms from those with higher molecular weights.

TABLE 8.1 Relative clearances of plasma proteins

Protein	Molecular weight (Da)	Clearance (%GFR)
IgG	150 000	0.01
Albumin	69 000	0.02
Amylase	48 000	3
Myoglobin	17 800	75
Lysozyme	14 500	80

For example, although increased amounts of low molecular weight proteins are excreted in tubular disease, such large increases are not seen in the urine of patients with massive glomerular proteinuria, when the reabsorptive mechanisms for large molecular weight proteins such as albumin must be saturated. Conversely, experimental induction of massive low molecular weight proteinuria through saturation of reabsorption with other low molecular weight proteins does not induce a similar increase in urine albumin.

Low molecular weight proteins, such as α_1 -microglobulin and retinol-binding protein, that are readily filtered at the glomerulus and normally >99.9% reabsorbed, can be used as sensitive markers of proximal tubular function, since even subtle tubular damage is associated with increased urinary excretion.

Glomerular diseases causing heavy proteinuria induce the release of a multitude of inflammatory and fibrogenic mediators, all of which cause tubulointerstitial fibrosis and renal scarring that contribute to renal impairment. Recent studies suggest that large proteins, such as albumin, which pass through the diseased glomerular membrane, cause tubular cell injury when they reach the proximal tubules. Reabsorption of excessive amounts of these proteins leads to overloading of lysosomes and activation of proximal tubular cells, which produce matrix metalloproteins, cytokines, leukocyte chemoattractants and vasoactive mediators, leading to interstitial inflammation and scarring. The mechanism of injury has been most studied for albumin and it appears likely that compounds attached to the protein, such as fatty acids, are major culprits. In minimal change glomerular disease with heavy proteinuria that is not associated with scarring, the albumin-fatty acid composition appears to be different from that in other glomerulopathies.

Tubular secretion of proteins

Proteins that are too large to be filtered by the normal glomerulus appear in urine either as a result of tubular secretion or from desquamation of tubular epithelial cells as part of the normal cellular turnover. Some large molecular weight proteins may also enter the urine during its postrenal passage along the urinary tract. Measurable activities of enzymes such as N-acetyl β -D-glucosaminidase (150 000 Da), γ -glutamyl transferase (120 000 Da) and lactate dehydrogenase (144 000 Da) can be found in normal urine.

The major urine protein exclusively of renal origin is uromodulin (previously known as Tamm–Horsfall glycoprotein), a heavily glycosylated protein secreted from the thick ascending limb of the loops of Henle. It has a molecular weight of 70 000 Da but is normally present in urine as a large non-covalently linked polymer. Since its isoelectric point is 3.3, it tends to precipitate as a gel during urinary acidification, forming casts by trapping whatever is in the vicinity such as albumin, red blood cells, tubular cells or cellular debris. Numerous mutations in the uromodulin gene have been identified in association with familial juvenile hyperuricaemic nephropathy and medullary cystic kidney disease type 2. These are probably different phenotypes of

the same disease and are known collectively as uromodulin storage disease, owing to accumulation of the misfolded mutated protein in cells of the thick ascending limb of the loops of Henle. They are rare, primary tubulointerstitial disorders with autosomal dominant inheritance characterized by chronic progressive kidney disease, hyperuricaemia and gout, with minimal proteinuria.

The normal biological function of uromodulin remains unclear but it probably has a protective role in trapping potentially damaging material in the urinary space, allowing excretion as casts. Microscopic differentiation of the type of casts present in urine can give useful information about pathological processes within the kidney (see Chapter 7). Experimental studies suggest that uromodulin may have a role in protecting against stone formation. Its capacity to bind type-1 fimbriated *E. coli* has led to the suggestion that its excretion has evolved as a defence against urinary tract infections.

NORMAL URINARY PROTEIN CONTENT

A normal adult excretes about 300 mg/24 h of non-dialysable material, of which <140 mg/24 h is protein, but published reference ranges for total urinary protein excretion vary considerably with the analytical method used. Plasma proteins represent only some 25 mg/24 h of total urinary protein (Table 8.2), of which about half is albumin: the remaining proteins are of renal origin, uromodulin being the major contributor (70 mg/24 h). For these reasons, and because low-level albuminuria (microalbuminuria) has prognostic value both for renal and non-renal diseases, urine albumin immunoassays should be used to assess glomerular proteinuria when protein excretion rates are low.

Determinants of urine protein excretion

Age, sex and diurnal variation

In neonates, albumin excretion tends to be higher than in older children and adults: this has been attributed to greater permeability of the neonatal glomerulus. Total

urine protein tends to fall after birth and rises with increasing age, reaching adult excretion rates by puberty. However, the urine protein/creatinine concentration ratio remains constant from 3 to 15 years of age, since urine creatinine excretion rises with increasing body mass. In children aged 4–16 years, albumin excretion rate, corrected for body surface area, rises with age and is slightly higher in females. Daytime excretion rates are higher than during the night and the sex difference disappears in overnight collections. There appears to be no sex difference in urine albumin excretion in adults, but, when expressed as a ratio to creatinine, the reference range is slightly higher in females owing to their lower muscle mass and hence lower creatinine excretion.

Posture

In both adults and children, ambulatory urine protein excretion is higher than it is overnight or during recumbency, with two- to ten-fold differences being reported for urinary albumin. Orthostatic proteinuria in otherwise healthy subjects has been the subject of controversy for some time. The discussion has been complicated by the variety and differing sensitivities of the protein assays used.

Proteinuria of <1 g/24 h has been described in 0.6–9% of healthy young adults, in the absence of urinary red cells, white cells or casts, and can be divided into ‘constant’ and ‘postural’ based on its persistence after recumbency. Renal biopsies of patients with postural proteinuria reveal that 8% have unequivocal evidence of well-defined disease and 45% have subtle alterations in glomerular structure. However, more recent studies, using non-invasive Doppler ultrasound to compare recumbent and orthostatic blood flow in the left renal veins of young people with orthostatic proteinuria, have revealed that in >50% of patients there is reduced blood flow to the left renal vein during standing owing to entrapment of the left renal vein.

The medical management of isolated or postural proteinuria in an otherwise healthy patient tends to be conservative, with annual assessment of proteinuria and renal function; biopsy is reserved for the rare patient who has evidence of progressive renal impairment.

Exercise and diet

Exercise-induced proteinuria was discovered over a century ago in soldiers after marches or drills. Five- to 100-fold increases in the excretion of proteins such as albumin, transferrin and immunoglobulins have been observed following 26-mile marathon runs, with smaller increases after less strenuous activities. The pattern of exercise-induced proteinuria is generally glomerular, although mixed glomerular and tubular proteinuria has also been described, which persists for over 3 h after exercise. The reason for exercise-induced proteinuria is unclear, but some degree of renal ischaemia owing to redistribution of blood during exercise has been suggested as a possible mechanism.

A large protein meal is associated with an increased urine albumin excretion, which appears to be secondary to an associated increase in GFR.

TABLE 8.2 Plasma proteins found in normal urine

Protein	Mean (range) excretion mg/24h
Prealbumin	0.03 (0.02–0.05)
Albumin	12.7 (8.9–21.9)
α_2 -Acid glycoprotein	0.41 (0.29–0.68)
α_1 -Antitrypsin	0.31 (0.19–0.56)
Caeruloplasmin	0.06 (0.05–0.06)
Haptoglobin	0.18 (up to 0.42)
Transferrin	0.22 (0.13–0.38)
Haemopexin	0.20 (0.14–0.29)
IgA	0.51 (0.37–0.61)
IgG	2.46 (1.97–3.01)
IgM	0.34
Light chains	
lambda (λ)	1.40
kappa (κ)	2.30
β_2 -Microglobulin	0.3

Adapted from Pesce AJ, First MJ 1979 Proteinuria: an integrated review, 1st edn. New York: Marcel Dekker, with permission.

The lowest and most reproducible estimates of urine protein excretion are obtained from an early morning urine specimen after overnight recumbency.

Pregnancy

During normal pregnancy, the urinary albumin excretion rate generally remains within the non-pregnant range, although there is some evidence for a small increase in albumin excretion during the third trimester, which may be related to increased glomerular permeability and/or GFR. Total urine protein excretion increases owing to decreased renal tubular protein reabsorption.

Hypertension in pregnancy is associated with significant maternal and fetal morbidity and mortality. The reliable detection of significant proteinuria is most important in women with new-onset hypertension during pregnancy because it distinguishes between those pregnancies with pre-eclampsia and those with gestational hypertension, the former often requiring admission to hospital owing to the severity of potential complications. In the UK, NICE guidelines for the routine antenatal care of healthy pregnant women recommend blood pressure and urine protein measurement at each antenatal visit; 660 000 women each year will have at least 7–10 such checks.

Gestational hypertension is defined as new hypertension occurring after 20 weeks of pregnancy, but without significant proteinuria. In this group, routine urine protein measurement may be performed using an automated reagent-strip reading device (more reliable than a manual reading) or by a laboratory method. If a reagent strip reading is 1+ or greater, the proteinuria should be quantitated by a laboratory measure in a spot or 24 h urine sample. Women admitted with pre-eclampsia (new hypertension presenting after 20 weeks with significant proteinuria) do not need to have repeated measures of urine protein since there is no strong evidence linking the degree of proteinuria with adverse outcome. Significant proteinuria is defined as >300 mg/24 h or >30 mg/mmol creatinine in a random sample. There are insufficient studies of urine albumin excretion to be able to define cut-offs equivalent to those defining significant proteinuria in gestational hypertension or pre-eclampsia.

PROTEINURIA IN KIDNEY DISEASE

Richard Bright, in 1836, is generally credited with noting the association between proteinuria and kidney disease. Proteinuria remains the most frequent clinical finding and quantitation of proteinuria is valuable for diagnosing, monitoring and assessing the prognosis of kidney disease. Normally, total urine protein excretion is <150 mg/24 h in adults and <140 mg/m²/24 h in children, depending on the methods employed: normal concentrations are often undetectable by chemical methods. However, sensitive immunoassay of specific proteins has extended the detection limits to urine protein concentrations within the reference range. Measurements of low concentrations of specific proteins such as albumin, predominantly reflecting glomerular function, and α_1 -microglobulin or retinol-binding protein, reflecting tubular reabsorptive

function, are now used as very sensitive and early markers of primary renal disease (e.g. glomerulonephritis) and secondary renal disease (e.g. in diabetes mellitus or hypertension). Thus, proteinuria can now be regarded as a continuum that extends from the measurable amount of protein normally excreted in urine up to the 1000-fold increases found in nephrotic syndrome.

Conventionally, proteinuria has been classified into glomerular proteinuria; tubular proteinuria; nephrogenic proteinuria (e.g. uromodulin, basement membrane and tubular proteins); proteinuria of prerenal origin (e.g. overflow proteinurias such as light chain disease, myoglobinuria, haemoglobinuria, lysozyme in leukaemia and amylase in pancreatitis), and postrenal proteinuria owing to obstruction of the urinary tract or inflammation such as occurs in urinary tract infection. This is a convenient way of differentiating the principal sites of the renal abnormality, but is an over-simplification because, for example, glomerular disease leading to large amounts of plasma proteins being presented to the renal tubules leads to inflammatory changes within the tubules and renal scarring. Nor does this classification lend itself easily to the multifactorial causes of proteinuria in some disorders, e.g. HIV-associated glomerular and tubulointerstitial disease that may be modulated by co-infection with other viruses and drug-induced interstitial nephritis.

Proteinuria in staging and prognosis of chronic kidney disease

Numerous epidemiological studies have demonstrated the association of proteinuria with poorer prognosis in people in the general population and across all stages of chronic kidney disease (CKD): any renal disease is more likely to progress, there is an increased risk of developing acute kidney injury, and both all-cause and cardiovascular mortality are increased. These outcomes hold true, whether proteinuria is assessed by dipstick testing or by formal laboratory measurement of either total protein or albumin, in timed urine collections or in random samples. The quantitation of proteinuria (in the absence of a symptomatic urinary tract infection and preferably using the first morning urine) is an essential component of CKD staging, where the suffix 'p' is used to denote its presence. The decision limit is an albumin/creatinine ratio (ACR) >30 mg/mmol (~ 300 mg/24 h) or urine protein/creatinine ratio (PCR) >50 mg/mmol (~ 0.5 g/24 h), although the continuum of risk, albeit lower, extends into the reference range. The presence of proteinuria in CKD is sufficient indication to initiate blockade of the renin-angiotensin-aldosterone system (RAS) with angiotensin-converting-enzyme inhibitors (ACEI) or angiotensin-II receptor blockers (ARB). At higher excretions (ACR >70 mg/mmol or PCR >100 mg/mmol), RAS blockade should be titrated to the highest tolerable levels and referral of the patient to specialist care considered.

Glomerular proteinuria and nephrotic syndrome

In the normal adult, the renal tubules reabsorb about 2–3 g of filtered albumin every 24 h. Thus, even total failure of

this process cannot explain albuminuria of $>3.0\text{ g}/24\text{ h}$; such losses are usually secondary to increased glomerular permeability associated with glomerular damage.

Nephrotic syndrome can be defined as proteinuria severe enough to cause hypoalbuminaemia and oedema. The degree of proteinuria varies but is generally $>3.5\text{ g}/24\text{ h}$ and is accompanied by a plasma albumin $<25\text{ g/L}$. However, it should be remembered that the amount of protein in the urine may decrease as the plasma protein concentration or the GFR falls. Causes of nephrotic syndrome are listed in Table 8.3. In addition to the nephrotic syndrome, glomerular proteinuria is a feature of several other syndromes of nephron injury, and the severity of proteinuria taken together with other clinical findings can allow useful diagnostic classification (Table 8.4).

Mechanisms underlying glomerular proteinuria

Glomerular injury can occur as a result of either primary or secondary kidney disease and there is no single pathogenetic pathway that will embrace all the possible mechanisms. The term glomerulonephritis is generally reserved

for immunologically mediated diseases and excludes other conditions associated with glomerular damage such as diabetes mellitus or amyloidosis.

Glomerulonephritis can be subdivided immunologically into conditions mediated by antibodies against antigens that are either extrinsic or intrinsic to the kidney. Extrinsic antigens include microorganisms causing infections such as bacterial endocarditis or streptococcal infections, and DNA, as in systemic lupus erythematosus (SLE). Antibodies may also develop to an intrinsic structural component, such as the glomerular basement membrane, leading to immune complex formation. Whatever the original mechanism, antigen–antibody complexes become trapped in the glomerulus, activating both the classical and alternative complement pathways and leading to the release of anaphylatoxic components such as C3a and C5a. Anaphylatoxins, together with locally released kinins, prostaglandins and leukotrienes, attract polymorphonuclear neutrophils to the basement membrane, where they release lysosomal enzymes, leading to membrane disruption and glomerular proteinuria.

Examination of renal biopsies, by light and electron microscopy, reveals a gradation of morphological changes with increasing glomerular injury. Loss of anionic charge associated with fusion of the epithelial foot processes can produce a massive but selective proteinuria, while changes in the basement membrane tend to be associated with increasingly non-selective proteinuria (see later).

Minimal change disease. Light microscopy of renal biopsies shows little or no abnormality in this condition, and no immunoglobulin or complement components are seen on immunofluorescence. Electron microscopy shows fusion of epithelial cell foot processes, and the mechanism of proteinuria probably involves loss of the fixed negative charge on the glomerular basement membrane. Although the pathogenesis of minimal change disease has not been completely clarified, clinical and experimental observations suggest that T cell dysfunction plays a role.

TABLE 8.3 Causes of nephrotic syndrome

	Children (%)	Adults (%)
Primary renal disease		
Minimal change (steroid responsive) disease	80	25
Focal segmental glomerulosclerosis	7	9
Membranous nephropathy	1	22
Membranoproliferative glomerulonephritis	10	26
Glomerular disease in systemic conditions		
Amyloidosis	–	7
Diabetic nephropathy	–	3
Systemic lupus erythematosus	–	8
Henoch–Schönlein purpura	2	<1

TABLE 8.4 Summary of clinical correlates of proteinuria

Degree of proteinuria	Clinical correlates
Massive proteinuria	Nephrotic syndrome Proteinuria $>3.5\text{ g}/24\text{ h}$, usually no haematuria, plasma albumin concentration very low, plasma lipids very high, gross oedema, blood pressure normal or low, GFR normal or increased, urine volume normal or increased
Moderate proteinuria	Nephritic syndrome (acute nephritis), acute kidney injury Proteinuria $1\text{--}3.5\text{ g}/24\text{ h}$. Moderate to marked haematuria, plasma albumin normal or low, plasma lipids normal or slightly increased, oedema absent or mild, volume overload sometimes with increased jugular venous pressure, blood pressure raised, GFR reduced, urine volume reduced Chronic kidney disease Similar to nephritic syndrome/acute kidney injury (see above) but over months or years. Moderate proteinuria may reflect reduced renal mass of functioning nephrons rather than extent of renal disease
Asymptomatic, variable/transient	Proteinuria $<1\text{ g}/24\text{ h}$, no other abnormalities, probably benign (orthostatic) proteinuria. Proteinuria $>2\text{ g}/24\text{ h}$, possibly early glomerulonephritis
Persistent low-level proteinuria/microalbuminuria	Associated with early diabetic nephropathy, tubulointerstitial disease, early cardiovascular disease, hypertension, inflammatory conditions, ischaemia and arteriopathy

In the developed world, minimal change disease, frequently of unknown aetiology, accounts for 90% of nephrotic syndrome in 2–6-year-olds and about 20% in adults. In children, there is massive selective proteinuria, which is predominantly albumin with little or no immunoglobulin. This form of nephrotic syndrome usually responds to a short course of prednisolone (steroid-responsive nephrotic syndrome) and a renal biopsy is unnecessary to confirm the diagnosis. The absence of serological evidence for complement activation gives additional confirmation. In adults, the diagnosis is more difficult and a renal biopsy is generally needed before treatment is started. Minimal change disease has a good long-term prognosis with sustained remission and preserved renal function as almost all patients are responsive to treatment.

Membranous nephropathy. This is the most frequent cause of nephrotic syndrome in adults. The common variant is idiopathic membranous nephropathy, in which 80% of patients have plasma antibodies to the phospholipase A2 receptor. These antibodies are rarely found in the secondary forms associated with SLE, hepatitis B virus and cancer. Light microscopy shows thickening of the glomerular basement membrane that is more marked in the later stages of the disease. Immunofluorescence microscopy always shows IgG deposits, but when other immunoglobulin classes (e.g. IgA, IgM) are present, the condition is more likely to be lupus nephritis. Progressive thickening of the basement membrane, demonstrated by electron microscopy, is the most frequent morphological finding in nephrotic syndrome in adults.

Over 80% of patients present with massive proteinuria that is only moderately or poorly selective, while the remaining 20% have asymptomatic proteinuria or microscopic haematuria. The course of the disease is variable, with about one-third of patients going into spontaneous remission and another third progressing to established renal failure. Risk factors for a poor prognosis include severe proteinuria, hypertension, older age, male gender and reduced GFR. Currently, treatment is aimed at lowering blood pressure to <130/80 mmHg with an ACEI or ARB, which usually reduces proteinuria over six months. If proteinuria persists, immunosuppressive treatment is generally started; steroids alone are often ineffective but there remains debate over which additional agents are most effective: these include ciclosporin, chlorambucil and cyclophosphamide.

Membranoproliferative glomerulonephritis. This is characterized by mesangial proliferation and expansion and is not a specific disease but a pattern of injury. As with all glomerulonephritides, many different diseases can produce this pattern of immunologically mediated glomerular damage, including bacterial endocarditis, group A streptococcal infections, hepatitis C virus, monoclonal immunoglobulin deposition disease and SLE. The histological pattern tends to be similar and immunofluorescence microscopy frequently shows IgA, IgG and C3 deposits; circulating complement concentrations are frequently reduced with high concentrations of immune complexes present in some conditions.

Patients with membranoproliferative glomerulonephritis have proteinuria and microscopic haematuria; approximately 50% of those with nephrotic syndrome present with an unselective proteinuria. Management involves identification and treatment of the underlying cause and the use of immunosuppressive agents.

Focal segmental glomerulosclerosis. Hyaline material is deposited in the subendothelial spaces of affected capillary loops of some, but not all, glomeruli, which is why the terms focal and segmental are used. Patients present with mild proteinuria, recurrent haematuria or nephrotic syndrome. The aetiology is not known, although there is some evidence for the presence of a soluble permeability factor and some patients have SLE. Currently, adults are treated with corticosteroids for at least 4–6 months. Efficacy of treatment is judged by monitoring proteinuria; 20–30% will respond with a decrease or cessation of proteinuria. The prognosis in these patients is good, although they may suffer a relapse. Patients whose proteinuria fails to respond to steroids generally go on to develop CKD. Optimal management of this group is currently controversial, but regimens include use of lower-dose corticosteroids with the addition of ciclosporin for 12 months or more.

IgA nephropathy and Henoch–Schönlein purpura. IgA nephropathy is the commonest primary glomerular disease in the developed world; Henoch–Schönlein purpura appears to be a systemic form of the disease occurring primarily in children. A deficiency in glycosylation enzymes leads to the production of galactose-deficient IgA1. This leaves novel glycan residues exposed, to which autoantibodies develop, leading to immune complex deposition. Nephrotic syndrome is uncommon in IgA nephropathy and proteinuria rarely exceeds 5 g/24 h. Treatment involves immunosuppression and antihypertensive therapy with an ACEI or ARB to reduce proteinuria. In Henoch–Schönlein purpura, 50% of children have renal involvement, of whom 20% have nephrotic range proteinuria and associated poorer prognosis.

Urine protein selectivity and classification of glomerulonephritis

The concept of ‘selectivity’ was based on the assumption that there may be differential filtration of large molecular weight proteins among patients with glomerular disease. Protein selectivity is based on a comparison of the relative clearance of IgG (150 000 Da) and transferrin (69 000 Da) calculated as follows:

$$\frac{\text{clearance of IgG}}{\text{clearance of transferrin}} = \frac{[\text{IgG}]_u \times [\text{Trans}]_p}{[\text{IgG}]_p \times [\text{Trans}]_u}$$

where:

- [IgG]_u = urine IgG concentration
- [Trans]_p = plasma transferrin concentration
- [IgG]_p = plasma IgG concentration
- [Trans]_u = urine transferrin concentration.

Where the selectivity index is >0.5 , the proteinuria is said to be 'non-selective', $0.3-0.5$ 'moderately selective' and <0.2 'highly selective'.

Patients with minimal change disease usually show highly selective proteinuria, while patients with membranous nephropathy and membranoproliferative glomerulonephritis do not. Patients with highly selective proteinuria tend to respond well to steroid therapy in contrast to those with non-selective proteinuria, although this is too variable to be useful to determine treatment.

In correlating glomerular disease severity with the type and magnitude of proteinuria, the assumption is made that all nephrons behave in a similar way. However, histological evidence suggests that glomerular disease can be focal with some glomeruli apparently being spared. But if only one nephron out of every 10 000 allowed unrestricted passage of large molecular weight plasma proteins, this would result in an increase in excretion of large molecular weight proteins from 18 to 800 mg/24h, resulting in an unselective proteinuria, apparently indicative of more serious disease.

In addition to glomerular filtration, renal clearances of plasma proteins also reflect tubular reabsorption. If the urine protein content were to represent the overall glomerular permeability, then it must be assumed that tubular reabsorption is entirely unselective. However, small changes in the relative proportion of filtered protein reabsorbed by the renal tubules can have a large effect on their urine concentrations. Despite these limitations, some recent studies have shown that in membranous nephropathy and focal segmental glomerulosclerosis, the selectivity index or IgG excretion predicts remission better than urine total protein. Similarly, progression to CKD is better predicted both by selectivity index or IgG excretion, and the tubular component of proteinuria (e.g. α_1 -microglobulin or retinol-binding protein) than by the total 24h urine protein excretion. However, protein selectivity studies and monitoring of tubular proteinuria are not widely used in the routine diagnosis and management of patients with glomerular disorders.

Pathophysiological consequences of glomerular proteinuria

Hypoalbuminaemia. The severe hypoalbuminaemia found in nephrotic syndrome is not simply secondary to urinary losses exceeding hepatic synthesis, because in adults the maximum hepatic synthetic capacity for albumin is around 14 g/24h, which in theory should replace urinary losses in all but the most severely proteinuric patients. In the nephrotic state, there is a decrease in the circulating albumin pool and hepatic synthesis is generally normal or increased. The loss of the fixed anionic charge on the glomerular membrane, which appears to be fundamental to the glomerular proteinuria of nephrotic syndrome, may also extend to the endothelium of all capillaries, leading to a generalized increase in capillary permeability to albumin.

Oedema and salt and water retention. Until recently, the explanation for the gross interstitial oedema associated

with nephrotic syndrome was attributed solely to hypoalbuminaemia, the consequent reduction in plasma colloidal osmotic pressure being thought to lead to an increase in fluid loss from capillaries at their arteriolar ends and a reduction in tissue fluid reabsorption distally, as predicted from the operation of Starling forces. The resultant hypovolaemia was thought to stimulate the renin-aldosterone system and vasopressin release, leading to sodium and water retention. However, recent work suggests the explanation is more complex.

Normally, about 60% of total body albumin is in the interstitial space and 40% in the vascular space. Every hour, about 8 g of albumin cycle between these two fluid compartments. The gradual loss of plasma albumin from the circulation in nephrotic syndrome leads to a fall in plasma oncotic pressure (the osmotic pressure due to proteins), which in turn is accompanied by a decrease in tissue albumin and parallel fall in interstitial oncotic pressure. The balancing of falling oncotic pressure on either side of the capillary membrane protects against a dramatic fall in blood volume as a result of movement of fluid from the hypo-oncotic vascular space into the interstitium. However, the capacity of this protective mechanism is limited, and a decrease in blood volume can be expected if plasma oncotic pressure (normally 22–28 mmHg) falls below about 10 mmHg, or if the protein loss is very sudden. This is probably because the interstitial oncotic pressure is also maintained by the glycosaminoglycans matrix.

Thus, patients with nephrotic syndrome are not usually hypovolaemic and renal perfusion is generally normal. Despite this, there is intense renal sodium and water retention, which is not mediated by the renin-aldosterone system, and which exacerbates the interstitial oedema. The mechanism is not well understood, but may involve increased sodium reabsorption by epithelial sodium channels in the collecting ducts and decreased sensitivity to natriuretic peptides. In most patients, the oedema is managed by treatment with oral loop diuretics, most often furosemide. If this fails, treatment includes salt restriction, intravenous furosemide, additional thiazide or potassium-sparing diuretics and, occasionally, in severe cases, intravenous albumin.

Abnormalities of other plasma proteins. Patients with nephrotic syndrome have changes in the concentrations of circulating clotting factors, which may be responsible for an increased risk of thrombus formation including renal vein thrombosis, inferior vena cava thrombosis and pulmonary emboli. Urinary loss of the natural anticoagulant antithrombin III is probably involved, together with increased plasma concentrations of fibrinogen and factors V, VII, VIII and X, the reasons for which are unclear.

Urinary loss of vitamin D and vitamin D-binding globulin may lead to vitamin D deficiency with low plasma ionized calcium, secondary hyperparathyroidism and renal osteodystrophy. Some national guidelines recommend vitamin D supplementation, especially in children with nephrotic syndrome. Hypochromic microcytic anaemia, resistant to iron supplements, can occur as a result of urinary loss of transferrin. Patients

with nephrotic syndrome may also lose immunoglobulins and complement components, with attendant increased risk of infections such as pneumococcal pneumonia and peritonitis.

Hyperlipidaemia. Many patients with nephrotic syndrome have massive increases in plasma cholesterol and triglyceride concentrations, which correlate inversely with the plasma concentration of albumin. Plasma very low density lipoprotein (VLDL) and low density lipoprotein (LDL) concentrations are increased, partly owing to reduced clearance and partly to increased hepatic synthesis, while high density lipoprotein (HDL) is reduced because of increased urinary loss. Very low density lipoprotein and LDL are apoB-containing lipoproteins, which are potentially atherogenic and have been linked to the pathogenetic processes that result in progressive glomerular and interstitial renal disease and increased cardiovascular risk. The activities of lecithin-cholesterol acyltransferase (LCAT) and the lipoprotein lipases are reduced in patients with nephrotic syndrome, yet increased urinary losses of these enzymes have not been demonstrated and the underlying mechanism for their reduced activity is not clear. Reduced LCAT activity may also reduce HDL production and hence, impair the patient's ability to mobilize lipid from endothelium and peripheral tissues.

Hepatic synthesis of VLDL and LDL seems to be stimulated by the reduction in plasma oncotic pressure, since treatment with albumin or dextran infusions reduces hepatic lipoprotein synthesis. These abnormalities are summarized in Table 8.5. Nephrotic hyperlipidaemia is accompanied by an increased risk of cardiovascular complications and is usually treated aggressively with statins. The impact of this intervention on cardiovascular morbidity and mortality in patients with nephrotic syndrome has still to be demonstrated.

Tubular proteinuria

Unlike glomerular proteinuria, where protein excretion can reach 20 g/24h and consists mainly of albumin, tubular proteinuria is generally <1–2 g/24h. In tubular proteinuria, although albumin remains a significant component, there is a relatively much greater increase in proteins of <60 000 Da (Table 8.6).

Low molecular weight proteins are filtered rapidly by the glomerulus, and proteins of <15 000 Da enter the Bowman space almost as easily as water and dissolved minerals. Under normal circumstances, the majority of filtered proteins and other solutes are reabsorbed by the proximal tubule, but in renal tubular disease, the reabsorption of protein together with water, ions, glucose and amino acids is impaired. The changing proportions of low and high molecular weight proteins in glomerular and tubular disease, shown in Table 8.6, can be explained by considering the renal handling of albumin (69 000 Da) and β_2 -microglobulin (11 815 Da).

Despite the large differences in plasma concentration of albumin (40 000 mg/L) and β_2 -microglobulin (2 mg/L), about 15 and 2 mg/L, respectively, appear in glomerular filtrate owing to differences in glomerular sieving. Assuming 160 L of filtrate are produced each day, 2400 mg of albumin and 320 mg of β_2 -microglobulin are filtered daily and would be excreted in the absence of tubular reabsorption. The maximum normal daily excretion of albumin is about 20 mg and of β_2 -microglobulin about 0.3 mg. Thus, in tubular disease, the increase in excretion of low molecular weight proteins is far greater than that found for larger proteins such as albumin.

Renal disorders associated with tubular proteinuria

In primary tubular proteinuria and interstitial nephritis, the renal interstitium and tubules are principally affected, rather than the glomeruli or renal blood vessels.

TABLE 8.5 Summary of lipoprotein and apolipoprotein abnormalities in nephrotic syndrome

Lipoprotein fraction	Plasma concentration	Cholesterol content	Triglyceride content
VLDL	↑ ^a	↑	↑
LDL	↑ ^a	↑	Normal
HDL	Normal/↓ ^b	↓	Normal
Apolipoprotein		Cholesterol content and triglyceride content do not apply to apolipoproteins	
AI	Normal/↓ ^b		
AII	Normal/↓ ^b		
Total A	Normal/↓ ^b		
B-48 and B-100	↑		

^aIncreased in more severe nephrotic states: inversely related to plasma albumin concentration.

^bDepends on severity of nephrotic syndrome: lower concentrations occur in severe cases.

TABLE 8.6 Typical urinary protein excretions in glomerular and tubular disease (see text for details)

Protein	Normal	Glomerular disease	Tubular disease
Total protein (mg/mmol)	<15	>250	<200
Albumin (mg/mmol)	<3	>50	<50
α_1 -Microglobulin (mg/mmol)	<1	Normal/slightly ↑	↑↑
β_2 -Microglobulin (μ g/mmol)	<30	Normal/slightly ↑	↑↑

However, recent studies have demonstrated that primary glomerular proteinuria leads to large amounts of plasma proteins being presented to the proximal renal tubules, absorption of which causes inflammation and secondary tubular damage. Thus, in addition to direct tubular toxic effects of conditions mediated by autoimmune or infective mechanisms, drugs, toxins, metabolic disorders or heavy metals, any pathology leading to glomerular proteinuria will also be associated with some degree of tubular dysfunction (Box 8.1).

Measurement of urine total protein or albumin is of limited value in differentiating between glomerular and tubular proteinuria, other than that the latter tends to be associated with proteinuria of <1–2 g/24h. Estimation of proteins that more specifically reflect tubular reabsorption is of more help in identifying primarily tubular disorders. In addition to tubular proteinuria, acute and chronic tubulointerstitial disease can lead to other tubular dysfunction with loss of water, sodium, potassium, calcium, glucose, phosphate, urate and amino acids. Bicarbonate wasting can lead to renal tubular acidosis (type 2). Tubular proteinuria, together with defective reabsorption

BOX 8.1 Causes of tubulointerstitial nephritis

- Drugs
 - Analgesics
 - Non-steroidal anti-inflammatory drugs
 - Cytotoxic agents, e.g. cis-platinum
 - Ciclosporin
- Heavy metals
 - Lead
 - Cadmium
 - Mercury
 - Bismuth
 - Copper (Wilson disease)
- Urinary tract obstruction^a
- Metabolic disease
 - Vitamin D deficiency
 - Hyperuricaemia
 - Hypercalcaemia
 - Tyrosinaemia
 - Hereditary fructose intolerance
 - Galactosaemia
 - Cystinosis
 - Sickle cell anaemia^a
 - Renal tubular acidosis
 - Lowe syndrome (oculocerebrorenal syndrome)
- Infection
 - Urinary tract infection with anatomical abnormality
 - Systemic infections (streptococcal infections, leptospirosis, toxoplasmosis, infectious mononucleosis, brucellosis, syphilis)
- Neoplastic disease
 - Multiple myeloma^a
 - Light chain disease
 - Leukaemias and lymphomas
- Immunological diseases
 - Systemic lupus erythematosus^a
 - Sjögren syndrome^a
 - Transplant rejection^a
 - Amyloidosis^a

^aMay have coexisting glomerulonephritis with proteinuria >1–2 g/24h.

described above, may form part of the Fanconi syndrome, which can be inherited or acquired (see Chapter 9).

Drug and heavy metal induced tubular damage.

In general, the renal tubules are particularly susceptible to drug induced damage because the renal concentrating mechanism leads to high drug concentrations within the tubules. Aminoglycoside antibiotics bind to phospholipids and can disrupt cellular membranes. Analgesic drugs such as phenacetin or its metabolite acetaminophen (paracetamol) damage tubular cells because they are concentrated within the renal medulla, bind to cellular proteins and deplete stores of glutathione. Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit the synthesis of renal vasodilatory prostaglandins, which can lead to unopposed vasoconstriction and ischaemia.

Arsenic, chromium, cadmium, copper, bismuth, mercury and lead have all been described as causing renal injury. Heavy metals react with membrane-bound sulphhydryl groups, altering membrane permeability and causing cellular damage. Inhalation of mercury vapour appears to cause glomerular proteinuria, while ingestion of mercury salts can produce combined glomerular and tubular proteinuria. Acute lead intoxication in children can cause tubular proteinuria, although patients with clinically apparent lead poisoning sometimes have normal protein excretion. Cadmium is taken up by renal tubules as a metallothionein complex that is more toxic than cadmium alone. Increased excretion of β_2 -microglobulin was first described in cadmium workers, and markers of tubular proteinuria are now used to monitor occupationally exposed subjects.

Methods of assessing tubular damage

Renal tubular function can be assessed in a number of ways, such as by tests of reabsorption of glucose, phosphate, bicarbonate and amino acids. Discussion here will be limited to the use of urine proteins as markers of tubular damage by measurement of either high molecular weight proteins, such as enzymes or brush border antigens released by the damaged tubules, or of low molecular weight proteins filtered at the glomerulus and normally reabsorbed by the proximal renal tubule.

High molecular weight protein markers of renal tubular damage.

Several enzymes not normally filtered by the glomeruli are released by damaged tubular cells and can be detected in the urine. They include lactate dehydrogenase, γ -glutamyl transferase and alkaline phosphatase. Their use as markers of tubular damage has been limited because of their instability in urine and the presence of urinary enzyme inhibitors.

The enzyme most widely employed for monitoring tubular damage is N-acetyl β -D-glucosaminidase (NAG), a lysosomal enzyme of 150 000 Da, which is found in high concentrations in the cells of the proximal tubule. Two isoenzymes of NAG are found in urine, one acidic and one basic: the acidic form is found in normal urine and both are excreted in patients with renal disease. Its lack of specificity limits its utility but NAG may be of value in monitoring inherited tubulopathies and in assessing tubular damage during cancer chemotherapy or treatment

BOX 8.2 Conditions associated with increased urinary N-Acetyl β -D-glucosaminidase excretion

- Nephrotic syndrome
- Glomerulonephritis
- Tubulointerstitial nephritis
- Heavy metal poisoning
- Renal transplant rejection
- Diabetes mellitus (with and without nephropathy)
- Hypertensive renal disease
- Surgery
- Ischaemia
- Hyperthyroidism
- Cancer chemotherapy

with antiretrovirals. Conditions associated with increased NAG excretion are given in [Box 8.2](#).

Low molecular weight protein markers of renal tubular disease. Ideally, a low molecular weight urine protein that can be used to monitor tubular damage should have the following characteristics:

- it should have a constant plasma concentration
- be freely filtered by the glomerulus
- its tubular reabsorption should be near saturation so that small reductions in tubular function result in significant urinary excretion
- its tubular reabsorption should be unaffected by co-existing glomerular proteinuria
- it should be stable in urine
- it should be easily measurable.

Since the plasma concentration of low molecular weight proteins filtered by the glomeruli rises as the GFR falls, the tubules of those nephrons still functioning are presented with an increased low molecular weight protein load that causes overflow into the urine and confounds the interpretation of results. The characteristics of some proteins used as tubular markers are given in [Table 8.7](#).

Lysozyme (muramidase) was the first low molecular weight marker of tubular function. Urine lysozyme excretion is increased in patients with Fanconi syndrome, but is often within normal limits in patients with nephrotic syndrome. Plasma lysozyme concentration is increased in

TABLE 8.7 Proteins used as markers of tubular damage

Protein	Molecular weight (Da)	Mean normal urinary excretion ($\mu\text{g}/\text{mmol creatinine}$)	Isoelectric point
Retinol-binding protein	21 000	8	4.7
α_1 -Microglobulin	31 000	400	3.6
β_2 -Microglobulin ^a	11 815	10	5.8

^aNote: unstable at urine pH <5.5. Requires in vivo urine alkalinization to avoid erroneous results.

inflammatory conditions and in some leukaemias, which limits its value as a tubular marker.

Increased excretion of β_2 -microglobulin was first identified in patients with cadmium poisoning and with Wilson disease. This protein is associated with the heavy chain of human leukocyte antigen surface protein on cells and is released during normal cellular turnover. Increased plasma concentrations are found in patients with liver disease and some malignancies such as myeloma and B cell lymphomas. However, β_2 -microglobulin is unstable in acidic urine (pH <5.5) owing to degradation by neutrophil elastase. This necessitates strict control of urine pH after collection, although little can be done to prevent in vivo degradation in the bladder before voiding other than oral administration of bicarbonate to alkalinize the urine.

Retinol-binding protein (21 000 Da) forms an 85 000 Da complex with vitamin A and prealbumin in plasma and hence only a small proportion is free to be filtered by the glomeruli. Plasma concentration falls in inflammatory disease and in vitamin A deficiency. Plasma α_1 -microglobulin (31 000 Da) concentrations are increased in neoplastic diseases, but are reduced in liver disease in parallel with plasma albumin. Unlike β_2 -microglobulin, retinol-binding protein and α_1 -microglobulin are relatively stable in urine and are the most commonly measured markers of tubular proteinuria.

Proteinuria of prerenal origin

Proteinuria of prerenal origin has been defined as the occurrence in the urine of abnormal amounts of protein filtered by the glomeruli in the absence of any glomerular or tubular abnormality. The term is usually applied to 'overflow' proteinuria such as Bence Jones proteinuria, haemoglobinuria and myoglobinuria, where plasma concentrations of these proteins are increased. This definition has limitations because the very presence of abnormally high concentrations of protein at the glomerulus and in the tubular lumen can cause glomerular and tubular abnormalities. Furthermore, it is becoming apparent that non-renal conditions are associated with proteinuria that disappears when the condition resolves.

Myoglobinuria and haemoglobinuria

Myoglobin is found predominantly in skeletal and cardiac muscle cells. Any disease that causes rapid destruction of striated muscle (rhabdomyolysis) results in the release of myoglobin and other muscle proteins into the circulation. Having a molecular weight of 17 000 Da, myoglobin is filtered rapidly by the glomerulus; it has a renal threshold of about 15 mg/L.

[Box 8.3](#) illustrates the diversity of causes of rhabdomyolysis, although a common factor appears to be the damaging effects on muscle cells of a failure to meet increased energy demands. Rhabdomyolysis is associated with acute kidney injury, but a causal relationship is not clear. Although myoglobin casts are found in rhabdomyolysis, infusion of pure myoglobin does not in general cause kidney damage, suggesting that there are other factors that

BOX 8.3 Causes of rhabdomyolysis and myoglobinuria

- Severe exercise
- Injury
 - Trauma
 - Electric shock
 - Crush injury
 - Surgery
- Ischaemia
- Metabolic
 - Severe hypokalaemia
 - Severe hypophosphataemia
 - Glycogen phosphorylase deficiency (McArdle disease)
 - Phosphofructokinase deficiency
 - Carnitine palmitoyl acyltransferase deficiency
 - Malignant hyperpyrexia
- Infections
 - Viral (influenza, coxsackie)
 - Bacterial (typhoid, *Shigella* spp., haemolytic streptococcus)
- Toxins
 - Carbon monoxide (leading to hypoxia)
 - Snake venoms
 - Drugs (steroids, statins, barbiturates, alcohol)
- Dermatomyositis and polymyositis

lead to the kidney injury. Purine derivatives released from damaged muscle cells are rapidly converted to uric acid, leading to very high plasma urate concentrations and intrarenal deposition. Acidosis as a result of the initiating cause of rhabdomyolysis, for example hypovolaemic shock, or from the release of organic acids from muscle cells, may potentiate the degradation of myoglobin to globin and ferrihaemate within the tubules. Ferrihaemate is toxic to tubular epithelial cells. Desquamation adds to the tubular obstruction.

Intravascular haemolysis releases free haemoglobin, which binds to circulating proteins such as haptoglobin. Since haemoglobin itself is 68 000 Da and its plasma protein-complexed form is even larger, haemoglobinuria does not occur until haemolysis is severe and plasma haemoglobin concentration exceeds 1 g/L. Pure haemoglobin is not nephrotoxic, and acidosis and dehydration are important factors determining the nephrotoxicity of severe intravascular haemolytic episodes. Haemoglobin casts are found, and ferrihaemate released from degraded

TABLE 8.8 Biochemical features associated with myoglobinuria and haemoglobinuria

Haptoglobin	Normal	↓
Urate	↑↑↑	Normal
Creatinine	↑ ^a	Normal

^aPlasma creatinine concentration disproportionately increased compared to GFR.

haemoglobin may also cause tubular epithelial cell damage.

Both myoglobin and haemoglobin possess peroxidase activity, which gives positive results for blood with reagent sticks. Measurement of urine myoglobin and haemoglobin is rarely necessary because other biochemical features give better clues to the diagnosis (Table 8.8).

Paraproteinaemias and Bence Jones proteinuria

Bence Jones proteinuria, the presence in the urine of immunoglobulin light chains, is a frequent finding in patients with multiple myeloma and may occur with other B cell malignancies (Table 8.9). This topic is considered in detail in Chapter 30.

There is an association between the presence of Bence Jones protein and the development of renal dysfunction in patients with multiple myeloma. Free light chains (molecular weight 22–24 000 Da) are normally cleared from the circulation by glomerular filtration followed by reabsorption and catabolism in the proximal tubules. Given the normal production rate of 500 mg/day and a reabsorptive capacity of 10–30 g/day, the production rate must increase substantially to cause overflow into the urine in the absence of renal dysfunction. Some light chains are toxic to the proximal tubules (a property that appears to relate to the amino acid sequence in the variable domain but is incompletely understood) and probably contribute to the development of Fanconi syndrome, renal tubular acidosis and renal

TABLE 8.9 Relative frequencies of light chain proteinuria in monoclonal paraproteinaemias

Type	Relative frequency (%)	Light chain proteinuria (%)	Renal impairment (%)
Multiple myeloma			
IgG	55	60–65	50
IgA	20–25	70	60
IgD	1–4	90–100	90
IgE	<1	100	Rare
Waldenstrom macroglobulinaemia			
IgM	14	90	Rare
Light chain disease	10–20	100	90
Heavy chain disease	<1	–	Rare
Benign monoclonal paraproteinaemia	–	<5	0

failure in patients with multiple myeloma. Patients with light chain proteinuria show increased excretion of lysozyme, retinol-binding protein, β_2 -microglobulin and albumin (with β_2 -microglobulin excretion being higher in λ light chain proteinuria), suggesting that these proteins compete for common reabsorptive mechanisms. Light chains can complex with uromodulin, producing typical myeloma casts, especially when patients are dehydrated and/or acidotic. Partial degradation of light chains can cause polymerization and the formation of damaging amyloid deposits in the glomerular and tubular basement membranes. The specific detection and quantitation of urine paraproteins and Bence Jones protein requires electrophoresis, immunofixation and urine total protein analysis although specific immunoassays for urine free light chains are now available.

MICROALBUMINURIA AS A MARKER OF RISK

The term 'microalbuminuria' was coined to describe an increase in urine albumin that is detectable by sensitive immunoassays but is below the detection limit of chemical urine protein methods and dye-binding stick tests. Microalbuminuria is defined as an albumin excretion rate of 20–200 $\mu\text{g}/\text{min}$ (30–300 $\text{mg}/24\text{h}$ or 3–30 mg/mmol creatinine). Diabetic patients with microalbuminuria are at increased risk of developing dipstick positive proteinuria and CKD. Early identification allows aggressive treatment to improve glycaemic control, blood pressure and plasma lipids and has been shown to improve outcome. More recently, large scale studies have shown that screening for microalbuminuria in non-diabetic as well as diabetic populations identifies patients at increased cardiovascular risk. Furthermore, microalbuminuria has been found to be a predictor of outcome in critically ill patients following insults such as major surgery, trauma or sepsis. The link between microalbuminuria and outcome in such apparently diverse groups of patients appears to be that microalbuminuria reflects the systemic microvascular endothelial dysfunction that, in various forms, is common to all these conditions.

Microalbuminuria and risk of diabetic complications

Diabetes mellitus is the commonest cause of established renal failure. It can affect the kidneys in a number of ways leading to glomerular disease, obstruction, tubular disease and a predisposition to infection, but it is diabetic glomerular disease that is the most important, involving about one third of patients. In the early stages of diabetic renal disease, there is hyperfiltration with an increased GFR, which may be associated with microalbuminuria. With adequate treatment, the GFR falls towards normal and microalbuminuria disappears. However, microalbuminuria returns during periods of poor glycaemic control and becomes persistent with established disease, usually after 5–20 years of diabetes. The risk of developing diabetic nephropathy can be reduced by improving glycaemic control and by treating hypertension aggressively. Once albuminuria reaches

>0.5 $\text{g}/24\text{h}$ or more, improved glycaemic control appears to have little effect on further progression.

Type 1 diabetes usually presents acutely and microalbuminuria rarely occurs within five years of diagnosis, so annual monitoring of urine albumin is generally recommended only after five years' disease duration. In contrast, type 2 diabetes will often have been present for many years prior to diagnosis, hence annual monitoring of urine albumin is recommended from the time of diagnosis. To reduce micro- and macrovascular risk, patients with persistent microalbuminuria (i.e. confirmed by two repeat measurements over 3–4 months) should be treated with an ACEI (or ARB), titrated to the maximum tolerable dose, to reduce intraglomerular pressure. Blood pressure should be maintained at <130/80 mmHg by the use of additional antihypertensives if necessary. These measures, together with aggressive management of cardiovascular risk factors, aim to reduce the rate of progression of kidney disease and prevent cardiovascular events. However, it should be noted that a diminishing urine albumin excretion rate associated with treatment does not invariably translate into prevention of progression of renal disease as assessed by GFR.

Cardiovascular risk

Microalbuminuria is a marker for generalized vascular endothelial dysfunction. In the USA and the European Community, microalbuminuria is found in 6–10% of the general population. Numerous clinical studies in non-diabetic populations have found an association between microalbuminuria and cardiovascular risk factors, target organ damage and the presence of cardiovascular disease. Although microalbuminuria interacts with other cardiovascular risk factors, it is an independent predictor of cardiovascular disease. In large population studies, the presence of microalbuminuria has been shown to be associated with raised plasma C-reactive protein (CRP) concentrations (measured using high sensitivity assays), which is consistent with the view that microalbuminuria reflects systemic endothelial dysfunction mediated by inflammatory processes. Large cross-sectional prospective studies have shown an association between urine albumin excretion and both blood pressure and cardiovascular risk that extends from within the urine albumin reference range through microalbuminuria and to clinical proteinuria. In patients with primary hypertension, the prevalence of microalbuminuria is typically 4–6%. In subjects with mild hypertension and no cardiovascular complications, urine albumin excretion is determined by the haemodynamic load, whereas in subjects with more severe hypertension and associated target organ damage, the urinary albumin leak is probably the consequence of glomerular damage.

Treatment with an ACEI or ARB reduces urine albumin excretion and may prove to be a more targeted approach to reducing cardiovascular risk. Microalbuminuria can be considered not only as a risk factor for progressive renal damage, but as providing an integrated assessment of long-term damage to the cardiovascular system, and is therefore increasingly being used in cardiovascular risk assessment clinics.

What remains to be shown is whether targeted treatment of microalbuminuria in the non-diabetic population reduces cardiovascular morbidity and mortality. However, there is general consensus that detection and quantitation of microalbuminuria is useful for the assessment of overall cardiovascular risk in hypertension, since it appears to be a cost-effective way of identifying patients at higher risk for whom additional preventive and therapeutic measures are advisable.

Microalbuminuria as a risk factor in other inflammatory processes

The emerging association between inflammation, vascular endothelial dysfunction and microalbuminuria has led to a large number of studies exploring the potential clinical value of this relationship. Interaction of activated leukocytes and the vascular endothelium is at the heart of the inflammatory process, and is normally under tight homeostatic control, preventing the local inflammatory response from becoming a systemic, life-threatening process. Yet this homeostasis can fail in patients with severe injuries, infection or multiple pathologies, resulting in systemic inflammatory response syndrome (SIRS). This is the underlying pathogenetic mechanism for the development of multiple organ failure, which is the major cause of death in the critically ill (see Chapter 20). Attempts to modulate the severe inflammatory response have been unsuccessful, partly because of the multiplicity of inflammatory pathways, such that blocking a single pathway is unlikely to be effective, and because such interventions must be given early in the evolution of SIRS to have any hope of success. Increased urine albumin excretion occurs within minutes of any acute inflammatory stimulus such as trauma, surgery, ischaemia reperfusion injury or infection, and normally returns to baseline within 6–8 h, depending on the nature and magnitude of the inflammatory insult. However, in patients who develop SIRS, microalbuminuria is sustained, reflecting systemic vascular endothelial dysfunction. Thus, serial monitoring of urine albumin during major inflammatory episodes has the potential to identify, within a few hours of onset, patients who require close monitoring in an intensive care unit, and who might be candidates for immune-modulating therapy. On the other hand, a return of urine albumin excretion to normal provides a marker of restoration of homeostatic control of inflammation, which can be used as an indicator of successful recovery from the acute inflammatory insult.

CLINICAL INVESTIGATION OF PROTEINURIA

Urine dip-sticks

For many years, proteinuria has been identified by screening random urine specimens using a semiquantitative chemical stick test. These methods are based on the colour change of indicators such as bromophenol blue, which is buffered to pH 3.0 with citrate, and changes from yellow to blue when bound to albumin. Such stick

tests for protein (that predominantly detect albumin) have a detection limit in the range 200–250 mg/L and are subject to errors, including false positives owing to alkaline pH from infection with urea-splitting organisms or contamination with antiseptics, and false negatives owing to very dilute urine and visual reading errors. With the growing awareness in diabetic medicine of the pathological significance of proteinuria at concentrations that are undetectable by conventional chemical sticks, specific semiquantitative immunoassay sticks for urine albumin have been developed that can detect albuminuria at ~30 mg/L.

Collection of urine

Measurement of urine protein or albumin as a concentration in milligrams or grams per litre makes no allowance for variations in urine flow rate. Formal correction can be made by collecting timed urine samples and expressing results in protein mass per unit time. However, this is both inconvenient for the patient and prone to urine collection errors because of misunderstanding of when the collection should start and finish. Numerous studies have demonstrated that expression of urine total protein or urine albumin as a ratio to creatinine concentration in an early morning sample is at least as reproducible as a timed urine, even if collected under ideal conditions, and is more convenient for the patient. There are now few indications for collecting timed urine specimens.

Urine protein measurement

Throughout this chapter, it has been emphasized that pathologically significant proteinuria extends from the upper reference limit for urine protein, which is in milligrams per litre, to tens of grams per litre, in nephrotic syndrome. Chemical methods used for measuring urine total protein, which are both accurate and precise, are generally adequate for monitoring patients with proteinuria >1 g/L. However, there is a clear problem with using such techniques for quantitation of proteinuria in the mg/L range. First, external quality assessment programmes have highlighted the poor performance of urine total protein methods, particularly at low concentrations. This is partly related to the variable chromogenicity for the differing urine proteins of the different dyes used in total protein methods, resulting in different total urine protein reference ranges. Second, at low total protein concentrations, the relative contribution of proteins secreted into the urine by the kidneys, such as uromodulin, becomes more significant, thus masking within the total protein estimation small, but pathologically significant increases in urine albumin and other diagnostically important proteins (Fig. 8.2).

In the US National Kidney Foundation Guidelines, urine albumin is recommended as a sensitive marker for chronic kidney disease secondary to diabetes, glomerular disease and hypertension, and α_1 and β_2 -microglobulins as sensitive markers of tubulointerstitial disease. For this reason, many laboratories now provide urine albumin as their first line test for assessing 'proteinuria', covering the range from normal values, through microalbuminuria

FIGURE 8.2 ■ Comparison of urine total protein measured by sulphosalicylic acid precipitation (SSA) with urine albumin measured by specific immunoassay. When proteinuria is in the g/L range, there is reasonably good agreement between methods, but at total protein concentrations within the reference range (<150 mg/L), pathological albuminuria (i.e. >20 mg/L) can be found. (Courtesy of Dr Robert Beetham).

to the albuminuric nephrotic range. However, at higher concentrations, the requirement for repeated dilutions of the sample for accurate measurement of albumin adds considerably to the cost. Above 0.5–1 g/L, some guidelines suggest that measurement of either urine albumin or total protein is acceptable for monitoring. In more

specialized circumstances, such as screening for urinary light chains or monitoring of tubular dysfunction, specific protein immunoassays are the most reliable.

Stepwise investigation of proteinuria

Where proteinuria is confirmed, a stepwise approach to establishing the cause of proteinuria can be applied, as summarized in Figure 8.3. Particular regard should be given to evidence of oedema, diabetes mellitus, polycystic disease, hypertension, heart failure and other cardiovascular risk factors. A full clinical and laboratory assessment at this stage will identify the cause of proteinuria in the majority of patients. For example, proteinuria may be caused by protein leakage from inflamed epithelium during urinary tract infections. In other patients, proteinuria, especially microalbuminuria, may be associated with non-renal conditions, some of which are transient and disappear with the resolution of the associated condition (Box 8.4).

A third group of patients will demonstrate persistent asymptomatic proteinuria either in isolation or accompanied by other urinary abnormalities. Red cells can enter urine or filtrate at any point along the urinary tract, leading to haematuria. Proteinuria with haematuria or tubular cell, granular or leukocyte casts is likely to originate from the nephron. When red cell casts are also found, the nephron can be implicated with more confidence and, in general, this indicates more severe renal disease.

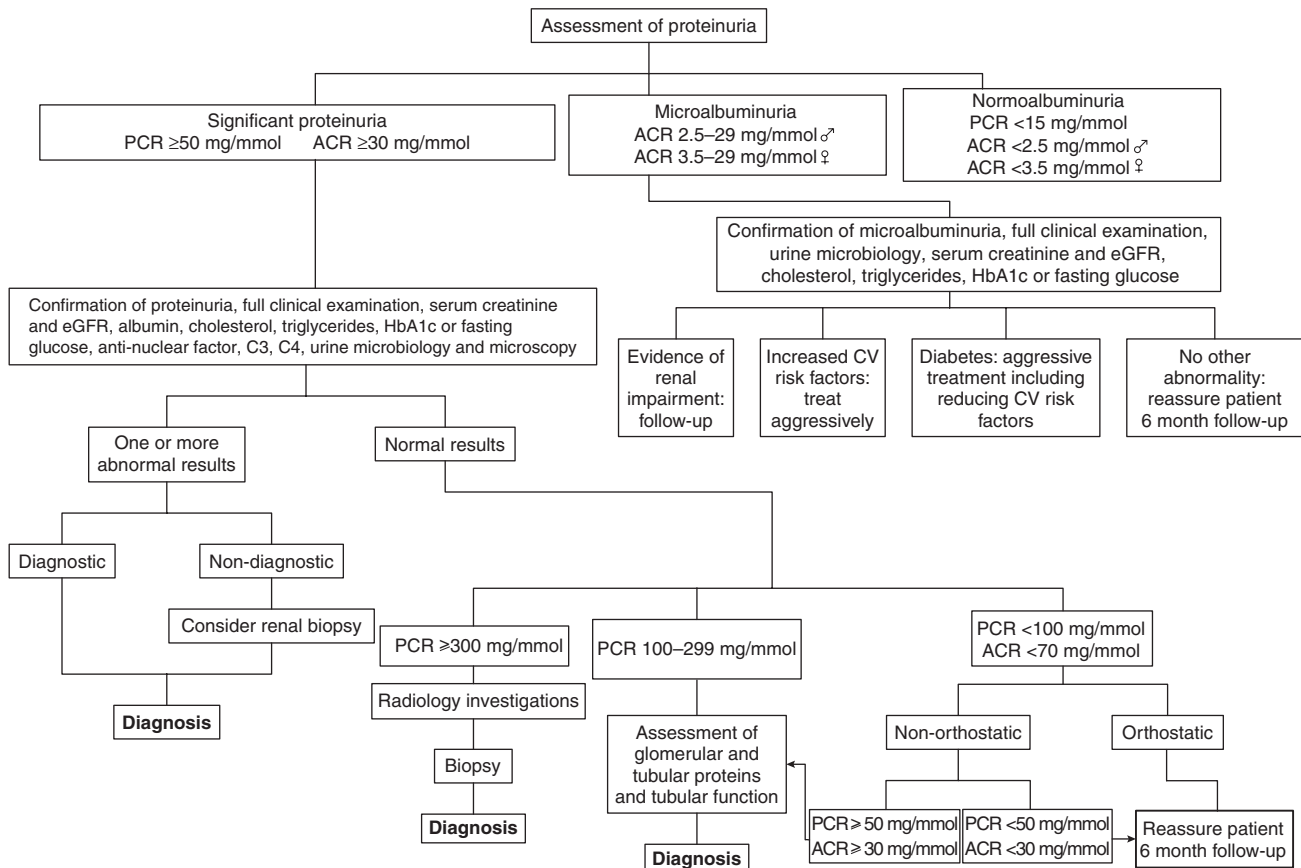

FIGURE 8.3 ■ Stepwise investigation of patients with proteinuria. Reference ranges and clinical decision points reflect current guidelines. PCR, urine protein creatinine ratio; ACR, urine albumin ratio; CV, cardiovascular.

BOX 8.4 Non-renal inflammatory conditions associated with microalbuminuria

- Trauma
- Burn injury
- Surgery
- Inflammatory conditions
 - Acute pancreatitis
 - Inflammatory bowel disease
 - Septicaemia
 - Systemic inflammatory response syndrome
- Cardiovascular disease (see text for details)
 - Myocardial infarction
 - Congestive cardiac failure
 - Intermittent claudication (especially post-exercise)
- Poisoning
 - Paracetamol (acetaminophen) overdosage

Studies have shown that ~70% of patients with asymptomatic non-orthostatic proteinuria have abnormal renal biopsies, while of those with orthostatic asymptomatic proteinuria, a much smaller proportion have abnormal biopsies. As a result, biopsy is now rarely performed in this latter group. The significance of the histological abnormalities is uncertain and the prognosis for both groups is excellent.

ACKNOWLEDGEMENT

I would like to thank Peter Gosling, who wrote this chapter for previous editions of the book.

INTRODUCTION

Most patients with renal disease have some element of renal tubular involvement, but the other manifestations of the disease tend to be clinically more obvious and important. However, in a small number of patients, the clinical picture results primarily from a disorder of renal tubular function. These disorders can be inherited or acquired, and can affect tubular handling of a limited number of specific substances or encompass more generalized defects.

Renal tubular defects are conveniently considered with renal stone formation, since calculi sometimes form as a result of one of these conditions.

RENAL TUBULAR DISORDERS

Introduction

Hereditary renal tubular disease includes certain developmental disorders of the tubules, for example polycystic renal disease and medullary cystic disease. While these can result in disorders of renal function, including renal tubular function, they will not be considered in detail here. Renal tubular physiology will be discussed briefly, followed by a discussion of some well-recognized functional disorders of the renal tubules.

Physiology

Renal function is discussed in detail in Chapter 7, but in essence the process involves filtration at the glomeruli, followed by modification of this glomerular filtrate by

both tubular reabsorption and tubular secretion. Since 170L of filtrate are formed each 24h, but only about one-hundredth this amount of urine is produced, reabsorption is quantitatively the more significant (Table 9.1). This is largely an active, energy-requiring process and explains why the kidneys account for some 6–8% of the resting oxygen consumption of the body, while representing <1% of body mass.

Some of the mechanisms by which active transport in the renal tubules occurs are shown in Figure 9.1. The control of renal tubular handling of certain substances is covered in detail in other chapters, for example sodium and water in Chapter 4. Only the renal tubular handling of substances that are important in disorders of renal tubular function will be considered further here.

Glucose is absorbed with sodium ions in the early part of the proximal tubules, in a secondary active transport process. Glucose and sodium bind to a common carrier protein (SGLT 2, see later) in the luminal membrane and sodium moves down its electrochemical gradient, carrying glucose into the cell. Na^+, K^+ -ATPase in the non-luminal (basolateral) membrane of the tubular cells pumps the sodium ions out into the interstitial fluid, while glucose is transported in the same direction by the glucose transporter GLUT 2.

Amino acids are also reabsorbed in the early part of the proximal renal tubules, again by a secondary active transport system linked to sodium reabsorption. There appear to be separate cotransporter proteins for certain groups of amino acids, although some of these probably have overlapping specificities. The process is driven by the Na^+, K^+ -ATPase in the basolateral membrane pumping sodium out of the cell, with amino acids leaving by passive or facilitated diffusion.

TABLE 9.1 Renal tubular handling of various plasma constituents

Plasma constituent	Plasma conc. (mmol/L)	Filtered	Reabsorbed/24 h (mmol)	Secreted	Excreted in the urine
Sodium	140	23800	23700	–	100
Potassium	4.0	680	650	30	60
Bicarbonate	24	4080	4080	–	0
Urea	4.0	680	320	–	360
Creatinine	0.09	15.3	–	1.0	16.3
Urate	0.3	51	50	4	5
Glucose	4.5	765	765	–	0

Figures are illustrative only, assuming 170L filtrate is formed and reduced to 1.7L of urine in an adult on a normal diet. Note, while reabsorption is quantitatively more significant, some substances are secreted into the tubules.

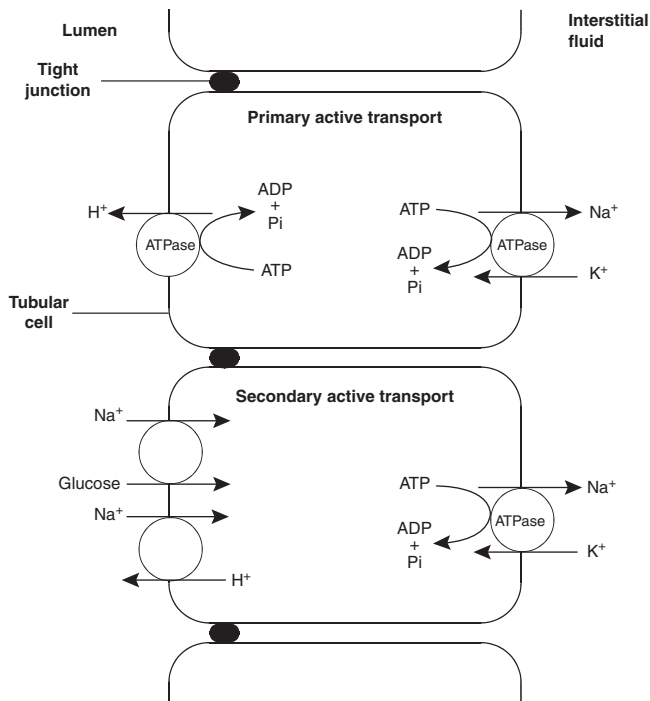

FIGURE 9.1 ■ Active transport mechanisms in the renal tubule.

Phosphate reabsorption in the renal tubules is influenced by the dietary intake of phosphate, certain hormones and a variety of other factors, and these are described in Chapter 6. In summary, about 90% of the inorganic phosphate in the plasma is freely filtered at the glomeruli, and then about 75% is reabsorbed in the proximal tubules. A small, variable amount is also absorbed in the distal tubules, but overall reabsorption is incomplete and up to 40 mmol/24h appears in normal adult urine. The rate-limiting step in reabsorption appears to be a secondary active transport system linked to sodium reabsorption, with a phosphate/sodium cotransporter located in the luminal membrane of the tubular cells.

As described in Chapter 5, the renal tubular secretion of hydrogen ions is linked to the net effective reabsorption of bicarbonate (see Figs 5.2 and 5.3). Around 4000 mmol of bicarbonate is filtered every 24h, but normal urine contains virtually no bicarbonate so the tubules must secrete 4000 mmol of hydrogen ions to achieve this. Although this mechanism prevents the loss of alkali into

the urine, it does not result in the net excretion of acid. The tubules must also secrete the hydrogen ions produced each day by normal metabolism (see Chapter 5), a further 40–80 mmol/24h.

There are two distinct mechanisms by which hydrogen ions are secreted into the tubular lumen (Fig. 9.1). A secondary active transport system linked to sodium operates in the epithelial cells of the early tubular segments, so that the Na^+, K^+ -ATPase on the basolateral membrane produces an electrochemical gradient for sodium to enter the cell from the luminal surface, but in contrast to glucose and amino acids, a hydrogen ion is simultaneously secreted into the lumen. Although a very high hydrogen ion gradient cannot be achieved, this mechanism is responsible for the bulk of hydrogen ion secretion, so that most bicarbonate reabsorption occurs in the proximal tubules. The sodium–bicarbonate cotransporter, located on the basolateral membrane of these tubular cells, mediates the transport of the generated bicarbonate into the systemic circulation. There may be other hydrogen ion secretory mechanisms in the proximal tubules, but they do not appear to be quantitatively important.

In the late tubular segments (the late distal tubules and the collecting ducts), a completely different mechanism for hydrogen ion secretion exists. This is relatively independent of tubular sodium content and occurs through primary active transport. The intercalated cells (I cells) in this part of the nephron have a hydrogen ion-transporting ATPase on their luminal surfaces and, although this accounts for <5% of the total hydrogen ions secreted, it is important because it can generate a hydrogen ion gradient of almost 1000 to 1. It is this that is responsible for the final acidification of urine and dictates the minimum achievable urinary pH of about 4.5 (or maximum hydrogen ion concentration of $\sim 32 \mu\text{mol/L}$). A chloride–bicarbonate exchanger at the basolateral membrane of the intercalated tubular cells is responsible for transporting the bicarbonate generated during this process to the systemic circulation.

Isolated abnormalities of tubular function

Glycosuria

Glucose is freely filtered at the glomeruli, but is normally then reabsorbed in the proximal tubules so that it is undetectable in urine. If plasma glucose concentrations rise to greater than $\sim 10 \text{ mmol/L}$ or if the glomerular filtration

rate increases (as in pregnancy), then the capacity of the proximal tubules to reabsorb filtered glucose is exceeded and glycosuria occurs.

Generalized defects in renal tubular function may also result in glycosuria (see later), but a small group of people appear to have an isolated defect of tubular glucose reabsorption.

Hereditary renal glycosuria. Patients with this condition excrete a variable amount of glucose in their urine at normal plasma glucose concentrations. Other aspects of carbohydrate metabolism are not affected: glucose tolerance and plasma insulin concentrations are normal. The condition is inherited in an autosomal recessive manner, and two major phenotypes have been identified (types A and B), based on the exact changes in the kinetics of glucose reabsorption. Hereditary renal glycosuria is rare, and is generally recognized to be a benign condition with no clinical sequelae.

The reabsorption of glucose in the proximal renal tubules is similar to the absorption of glucose in the intestine. There is a Na^+ ,D-glucose cotransporter on the luminal cell wall to transport glucose into the cell, with a facilitated glucose transporter (GLUT 2) on the basolateral membrane to enable the glucose to exit. The intestinal form of the Na^+ ,D-glucose cotransporter (SGLT 1) and its gene have been well characterized, but, while the corresponding renal cotransporter (SGLT 2) is known to differ from SGLT 1, its identity in humans is less well established. Nevertheless, it is assumed that mutations in the gene for SGLT 2 cause hereditary renal glycosuria by interfering with the uptake of glucose in the proximal tubules.

There is a corresponding condition affecting SGLT 1 in the gut. This cotransporter is involved in both glucose and galactose absorption, and the classic presentation is with life-threatening diarrhoea in early infancy due to glucose and galactose malabsorption (familial glucose-galactose malabsorption). There is often an associated mild renal glycosuria, although in hereditary renal glycosuria there is no corresponding effect on the gut.

Mutations affecting GLUT 2, which facilitates transport of glucose, galactose and fructose across the basolateral membrane, are another rare cause of renal glycosuria (Fanconi-Bickel syndrome).

Amino acidurias

Amino acids are normally freely filtered at the glomeruli and then almost entirely reabsorbed in the proximal convoluted tubules. There is a maximal capacity to each reabsorptive mechanism and, in most patients with amino aciduria, some extrarenal disorder leads to accumulation of amino acid(s) in the plasma, that exceeds the reabsorptive capacity of the tubules, with consequent 'overflow' amino aciduria. However, as with glycosuria, generalized defects in renal tubular function can result in amino aciduria, and there are also some isolated defects in the reabsorption of particular groups of amino acids.

Cystinuria. Cystinuria is the classic example of an amino aciduria due to a defect in renal tubular function, in that the amino aciduria occurs at normal or even low plasma concentrations of the amino acids involved.

In most patients with cystinuria, there is renal loss not only of cystine, but also of the dibasic amino acids ornithine, arginine and lysine. There is also an associated failure of intestinal absorption of the same amino acids. Inspection of their molecular structures (Fig. 9.2) shows that each has two amino groups separated by 5–7 bonds, which suggests that malfunction of a single membrane carrier protein might explain the disorder. However, the true explanation is not this simple, since the clearance of cystine may exceed the creatinine clearance, suggesting secretion of cystine into the tubules and, furthermore, since dibasic amino aciduria (e.g. lysinuric protein intolerance) or cystinuria can each occasionally occur alone.

The only known clinical manifestation of cystinuria is recurrent urinary tract stone formation, the name 'cystine' coming from the original (erroneous) assumption that the source of these stones was the bladder. Cystine stones form readily in acidic urine. They are yellow-brown in colour and are radio-opaque because of their sulphur content, although they are less radio-dense than calcium-containing stones. There may also be some calcium deposition if there is infection secondary to the calculi. They tend to occur as staghorn or multiple recurrent stones and often require some form of surgical intervention or lithotripsy (fragmentation of stones by external shock waves). Patients with cystinuria also have a higher incidence of calcium oxalate stones than the general population. All stone formers should,

FIGURE 9.2 ■ Chemical structures of the dibasic amino acids involved in cystinuria.

therefore, be screened for cystinuria, preferably by formal amino acid measurement in the urine, as qualitative screening tests are not sufficiently sensitive. The intestinal defect appears to cause no clinical problems.

Cystinuria occurs with equal frequency in both sexes, although males tend to be more severely affected. It may present at any time from the first year of life up to the ninth decade, with a peak incidence in the second and third decades. The prevalence of cystinuria varies between racial groups and according to whether the figures are taken from neonatal amino acid screening programmes or from known cystinuric stone formers (immaturity of the renal tubules in the first few months of life may lead to some heterozygous infants having urinary cystine outputs in the homozygous cystinuria range, leading to misclassification). However, the worldwide prevalence is estimated to be 1 in 7000, making it a relatively common inherited metabolic disorder.

The mode of inheritance is autosomal recessive, although in some families it appears to be incompletely recessive, with heterozygotes excreting more urinary cystine, ornithine, arginine and lysine than normal, although less than in the homozygous state. In the past, this has led to attempts to classify cystinuria into type I (homozygous for the fully recessive form) and types II and III (variants of the incompletely recessive form), based on combinations of the relative amounts of the amino acids excreted in the urine and/or the intestinal uptake of cystine and dibasic amino acids. The discovery of the genes involved in the recessive and the incompletely recessive forms of cystinuria has made this classification clearer, although the situation is not yet completely resolved.

The gene involved in type I cystinuria codes for a protein known as rBAT (a loose acronym for 'related to the b⁰⁺ amino acid transporter', with the term b⁰⁺ signifying broad specificity for neutral (0) and dibasic (+) amino acids). rBAT is a membrane glycoprotein that is one of the activating components of a heteromultimeric transporter for cystine and dibasic amino acids. The gene for rBAT (*SLC3A1*) is located at 2p16.3-p21, and, to date, more than 120 different mutations have been identified in it in patients with type I cystinuria.

A second cystinuria locus, accounting for non-type I forms of cystinuria, has been identified by linkage analysis at chromosome 19q13.1–13.2. This gene (*SLC7A9*) encodes a protein that acts as the amino acid transporting subunit of the membrane complex. More than 95 gene mutations have been identified. Most, but not all cases of cystinuria can be explained by mutations in *SLC3A1* and *SLC7A9*.

Healthy individuals excrete <10 μmol cystine/mmol of creatinine (<130 μmol/24h). Patients with homozygous cystinuria usually excrete >1700 μmol/24h and may

excrete up to 5000 μmol/24h. Heterozygotes may have an entirely normal amino acid excretion pattern in the urine or may excrete up to 1700 μmol cystine/24h, in which case they may produce stones.

Medical treatment of cystinuria begins with maintenance of a high fluid intake throughout both day and night and alkalization of the urine, both being aimed at decreasing the chance of precipitation of cystine in the renal tract. The solubility of cystine is pH dependent with a solubility limit of ~700 μmol/L at pH7, rising to ~1500 μmol/L at pH7.5. Regular monitoring is required to ensure that cystine remains well below its solubility limit throughout the day and, critically, the night. If these measures fail, then it may be possible to convert the cystine to a more soluble compound, most commonly by the use of D-penicillamine. This can form the mixed disulphide cysteine-penicillamine (Fig. 9.3), which is significantly more soluble than cystine. The aim is to keep the daily excretion of free cystine below 2000 μmol. Unfortunately, D-penicillamine frequently causes an allergic reaction and can also cause nephrotic syndrome and pancytopenia, so careful monitoring is essential. Second generation chelating agents include tiopronin (α-mercaptopropionylglycine) and captopril, although studies on the efficacy of the latter have been inconclusive. Small stones may dissolve with careful medical management, although frequent surgical intervention is required for some patients.

Occasionally, in spite of both medical and surgical treatment for stone formation, cystinuria causes sufficient renal damage to result in established renal failure. In this case, renal transplantation may be effective, since the donor kidney should not be affected by the amino acid transport defect and the patient should, therefore, remain disease free.

Hartnup disorder. A second example of an amino aciduria due to a true defect in renal tubular function, rather than an 'overflow' effect, is found in Hartnup disorder. This is named after the family in which it was first described and is again a defect of both renal and intestinal amino acid transport. The constant feature is a failure to reabsorb the neutral amino acids (Box 9.1) in the renal tubules, with their consequent appearance in the urine. The failure of reabsorption is not absolute, as renal clearances of the affected amino acids are generally lower than the creatinine clearance. Most affected individuals also have increased amounts of indoles (e.g. indican) in the urine, which originate from the bacterial breakdown of unabsorbed tryptophan in the gut. Rarely, the renal or intestinal lesions may occur alone.

FIGURE 9.3 ■ Chemical structures of cysteine, cystine and cysteine-penicillamine.

BOX 9.1 The neutral amino acids that appear in the urine in excess in Hartnup disorder

Excretion of the neutral sulphur containing amino acid methionine may also be increased.

Monoamino-monocarboxylic amino acids

- Alanine
- Serine
- Threonine
- Valine
- Leucine
- Isoleucine
- Phenylalanine
- Tyrosine
- Tryptophan
- Histidine

Monoamino-dicarboxylic amides

- Asparagine
- Glutamine

The original description of Hartnup disease included a pellagra-like skin rash, transient cerebellar ataxia and constant renal amino aciduria. Some affected individuals have also shown psychotic behaviour, while others have learning disabilities. The pellagra-like rash and its response to nicotinamide suggest that the clinical features of the disease may be due to failure to absorb tryptophan in the intestine and reabsorb it in the renal tubules, leading to a deficiency of nicotinamide. However, investigation of siblings of individuals with Hartnup disease and the results of neonatal urine amino acid screening programmes both suggest that the typical amino aciduria (Hartnup disorder) may exist without the features of Hartnup disease. It would appear that Hartnup disorder is an autosomal recessive inherited condition, but that this is not expressed clinically without the presence of certain other genetic or environmental influences, such as poor nutrition. The causative gene, *SLC6A19*, is located on chromosome 5p15.33 and codes for a sodium-dependent neutral amino acid transporter.

Familial renal iminoglycinuria. A further example of a specific abnormality in renal tubular reabsorption causing a distinct pattern of amino/imino aciduria occurs in familial renal iminoglycinuria. The primary genetic defect is a mutation in either the *SLC36A2* gene, which codes for a high affinity glycine, proline and hydroxyproline transporter, or the *SLC36A1* gene, which codes for a low affinity transporter. However, the phenotype is variable as it may be modified by mutations in at least three other genes. Some reabsorption of these amino acids can still occur via the transport system that is not affected in any individual patient.

The condition, which is benign, is autosomal recessive, although some heterozygotes are 'incomplete' and have hyperglycinuria. In some but not all homozygotes, impaired intestinal transport of proline can be demonstrated.

Neonatal screening for amino acidurias suggests that familial renal iminoglycinuria occurs in 1 in 15000 live

births in a Caucasian population. However, it should be appreciated that in healthy neonates, the renal tubular reabsorption of proline, hydroxyproline and glycine is less efficient than in adults; imino aciduria normally disappears by three months and hyperglycinuria by six months of age.

Dent disease

Also known as X-linked nephrolithiasis, Dent disease is most often caused by a mutation in the gene coding for a voltage gated chloride channel (CLC-5) expressed predominantly in the proximal renal tubules. However, a significant number of patients have a mutation in the gene usually associated with the oculocerebrorenal syndrome of Lowe, *OCRL*. Both defects are thought to cause failure of the endosomal acidification that is required to allow recycling of the proximal tubular membrane receptor, megalin, which mediates protein reabsorption. The syndrome is characterized by hypercalciuria, nephrocalcinosis, recurrent calcium-containing renal stones, low molecular weight proteinuria and chronic kidney disease eventually leading to established renal failure. Glycosuria, phosphaturia, amino aciduria and rickets may also occur in affected males. Carrier females rarely present clinically, but often have increased urinary excretion of low molecular weight proteins. Mutations of the gene encoding another voltage gated chloride channel (CLC-Kb) are responsible for some cases of Bartter syndrome (see p. 57).

Phosphate transport defects

Specific disorders of renal tubular phosphate handling can be inherited or acquired. There is reduced proximal tubular reabsorption of phosphate (in particular, the TmP/GFR is reduced, as explained in Chapter 6) and hypophosphataemia. The normal response to this would be an increase in the 1 α -hydroxylation of vitamin D, and if this is adequate, the end result would be hypercalciuria (with an increased risk of renal stones), but no bone disease. If the vitamin D response is inadequate, then the result may be bone disease with hypercalciuria (e.g. as in hereditary hypophosphataemic rickets with hypercalciuria) or bone disease alone (e.g. X-linked hypophosphataemic rickets and oncogenic hypophosphataemic osteomalacia). Inherited and acquired forms of hypophosphataemic bone disease are discussed further in Chapter 31.

The phosphate loss, and other changes in more generalized forms of renal tubular disorder, may also be severe enough to cause bone disease (see p. 174).

Renal tubular acidosis

The renal tubular acidoses (RTAs) are a group of hyperchloraemic metabolic acidoses that occur secondarily to an abnormality in urinary acidification. The plasma bicarbonate concentration is low, the plasma chloride raised and the anion gap normal, in contrast to the acidosis seen with reduction in the glomerular filtration rate in which the plasma bicarbonate is low, chloride normal and anion gap increased.

Renal tubular acidoses are classified according to the presumed site of the failure of hydrogen ion secretion. In proximal (type 2) RTA, there is a failure in bicarbonate reabsorption, while in distal RTA, there is a failure in net acid excretion. If failure of hydrogen ion secretion is the sole defect in the distal nephron, it is known as classic distal (type 1) RTA, whereas if the defect is more generalized, causing hyperkalaemia as well as acidosis, it is known as generalized distal (type 4) RTA. These conditions are described in Chapter 5, but the underlying mechanisms are briefly summarized again here, and details of diagnostic tests are given in [Appendix 9.1](#). Type 3 RTA is a mixture of types 1 and 2 and is very rare. The term was originally used to describe a transient condition occurring in infants with immature tubules. However, it is now usually applied to a rare inherited deficiency of carbonic dehydratase type II, in which infants also have cerebral calcification, mental retardation and osteopetrosis (see Chapter 31).

Proximal (type 2) renal tubular acidosis. Isolated proximal RTA may be autosomal recessive or dominant. A mutation in the sodium–bicarbonate cotransporter gene (*SLC4A4*) is responsible for the recessive form; the molecular basis for the dominant form is yet to be elucidated. The net effect is that bicarbonate reabsorption is impaired, leading to metabolic acidosis and bicarbonaturia, with a decrease in the plasma bicarbonate concentration until the filtered load of bicarbonate falls to a point at which hydrogen ion secretion is sufficient to allow reabsorption of all filtered bicarbonate. Thus, a new steady state is established, in which there is a metabolic acidosis with a low plasma bicarbonate concentration (15–20 mmol/L) but no bicarbonaturia.

Administration of bicarbonate to such patients will establish a steady state closer to normal, but quite large doses of bicarbonate are required (e.g. 5–15 mmol/kg body weight/24h), since as the plasma bicarbonate rises, so does the magnitude of renal bicarbonate loss. Hydrogen ion secretion in the distal tubules is normal and the urine can be acidified in response to an acid load.

Proximal RTA may occur as an isolated defect, but is more usually part of a generalized defect of proximal tubular function, the Fanconi syndrome (see [p. 174](#)).

Distal (type 1) renal tubular acidosis. Decreased activity of the apical H^+ -ATPase (proton pump) is probably the commonest defect in distal RTA and may be the end result of a number of different pathological processes. The most common of these is Sjögren syndrome, which should be excluded in any patient presenting in adulthood. Other dysproteinaemic and autoimmune conditions may also cause acquired distal RTA, as may chronic hypercalciuria with nephrocalcinosis or treatment with drugs such as amphotericin, lithium and analgesics. Inherited forms (which may be autosomal dominant or recessive) include mutations in the genes encoding the H^+ -ATPase pump and the chloride–bicarbonate exchanger. There is a complex relationship between distal RTA, nephrocalcinosis and kidney stone formation. In some patients, hypercalciuria appears to be the primary abnormality, causing interstitial and tubular damage with calcium deposition and secondary

RTA. In others, RTA is the primary condition causing increased calcium phosphate resorption from bone in an attempt to buffer the retained acid; the subsequent hypercalciuria is proportional to the severity of the acidosis.

While other distal tubular functions remain unimpaired, hydrogen ion secretion is reduced so that urinary pH cannot be lowered below 5.5. A resultant increase in the exchange of potassium for sodium ions in the distal tubules causes significant renal potassium loss and the condition is usually accompanied by hypokalaemia.

Diagnosis depends on the demonstration of an inappropriately high urinary pH (>5.5) during either spontaneous acidosis or an acid loading test (see [Appendix 9.1](#)). Treatment involves potassium supplementation together with bicarbonate. Unlike proximal RTA, the dose of bicarbonate required is small (e.g. a little over 1 mmol/kg body weight/24h in adults), since there is only a minor degree of bicarbonaturia and this does not increase as the plasma bicarbonate concentration rises.

Patients with incomplete distal RTA have low urinary citrate excretion and urine pH persistently >5.5 but are able to maintain their plasma bicarbonate concentrations within the reference range, possibly by increasing proximal tubular ammonium production. They may also have hypercalciuria and are at risk of developing osteoporosis, nephrocalcinosis and calcium phosphate kidney stones. Hypercalciuria may be reversed and the risk of developing osteoporosis and kidney stones reduced by alkali therapy, which decreases calcium phosphate resorption from bone.

Distal renal tubular acidosis with hyperkalaemia (type 4). In type 4 RTA, there is a generalized impairment of distal tubular function associated with aldosterone deficiency or resistance, with decreased tubular secretion of both hydrogen and potassium ions. A relatively severe hyperkalaemia is usually the primary abnormality and the accompanying hyperchloraemic metabolic acidosis is often mild with a plasma bicarbonate concentration >16 mmol/L.

The condition may arise because of a lack of mineralocorticoid activity (e.g. in adrenal failure), disease of the kidney resulting in impaired production of renin (hyporeninaemic hypoaldosteronism, e.g. in diabetic nephropathy) or resistance to the action of mineralocorticoids on the distal tubules (e.g. in patients treated with spironolactone). Treatment of the condition depends on the underlying cause.

Hereditary renal hypouricaemia

This is a rare disorder of the renal tubular handling of urate, in which there is a net decrease in reabsorption of urate, resulting in hypouricaemia and an increased renal urate clearance. Plasma urate concentrations are <150 $\mu\text{mol/L}$ in men and <126 $\mu\text{mol/L}$ in women. The condition is generally harmless, although some patients also have hypercalciuria, and about 25% have a tendency to stone formation. It is transmitted in an autosomal recessive manner and heterozygotes tend to have intermediate plasma urate concentrations. Mutations have been demonstrated in the gene for a urate–anion exchanger, which is found on the luminal membrane of proximal

tubular cells and which accounts for the majority of urate reabsorption in normal kidneys.

Generalized tubular defects (Fanconi syndrome)

Generalized renal tubular defects tend to occur together in a distinct syndrome known as the renal Fanconi syndrome (which should not be confused with Fanconi anaemia, a form of congenital aplastic anaemia or Fanconi–Bickel syndrome, a rare disorder of carbohydrate metabolism). There is a failure in net proximal tubular reabsorption of glucose, amino acids, phosphate and bicarbonate, with consequent glycosuria, amino aciduria, phosphaturia and acidosis, together with the development of vitamin D-resistant metabolic bone disease. There may also be increased urinary losses of water and other substances, for example sodium, potassium, calcium, magnesium, urate and low molecular weight proteins. The exact mechanism by which the Fanconi syndrome occurs is not clear and there may be distal, as well as proximal, tubular dysfunction.

Causes of the renal Fanconi syndrome may broadly be divided into inherited and acquired and are listed in Box 9.2. The most common cause of inherited Fanconi syndrome in children is cystinosis, an autosomal recessive disorder of cystine transport across lysosomal membranes. The gene responsible (*CTNS*) is located on chromosome 17p13 and encodes a lysosomal membrane protein, cystinosin. There is accumulation of cystine in the lysosomes of most tissues, including the kidneys, and in the infantile form of the disease, the Fanconi syndrome progresses to cause glomerular damage and renal failure during childhood. Cystinosis is usually treated with cysteamine, which is concentrated inside the lysosomes and reacts with cystine to form both cysteine and a cysteine–cysteamine complex. These are able to cross the lysosomal membrane via different transporters. When administered regularly, cysteamine decreases the cystine

load in lysosomes, conserves renal function and improves growth. The adequacy of treatment can be assessed by measuring the cystine content of white blood cells. If renal function becomes significantly impaired, transplantation is particularly useful, since the transplanted kidney does not have the genetic defect.

There is also an adult onset form of cystinosis in which there is no Fanconi syndrome or glomerular impairment, and an intermediate form that presents during adolescence and does eventually lead to renal failure.

Other inherited metabolic diseases that are associated with the Fanconi syndrome are listed in Box 9.2. There is also an idiopathic inherited form, but this is a diagnosis of exclusion. It is interesting that in inherited metabolic diseases for which there is a specific treatment (e.g. avoidance of lactose and galactose in galactosaemia), the Fanconi syndrome resolves on treatment, presumably because of the fall in the concentration of a toxic metabolite.

While the inherited diseases associated with the Fanconi syndrome tend to present in childhood, the acquired forms tend to occur in adults. These may also be reversible if exposure to the causative agent can be stopped.

The clinical features of the Fanconi syndrome tend to be rather non-specific and include polyuria, polydipsia, dehydration, hypokalaemia and acidosis, with impaired growth and rickets in children and osteomalacia in adults.

Treatment is primarily directed at the underlying cause, but inappropriate renal losses need to be replaced (e.g. with fluids, bicarbonate and potassium) and the bone disease treated with phosphate replacement and vitamin D.

RENAL CALCULI

Introduction

Stone formation in the urinary tract (urolithiasis) has been described since ancient times, but in the past, lower urinary tract stones, particularly those arising in the bladder, appear to have been more frequent, engendering a surgical enthusiasm for ‘cutting for stone’. In industrialized, relatively affluent populations, renal stone formation (nephrolithiasis) has increased in frequency, while bladder stone formation has almost disappeared as the prevalence of malnutrition and infection have decreased.

However, while the frequency of nephrolithiasis is acknowledged to be increasing in the developed world, precise incidence and prevalence figures have not been well established. Nevertheless, it would appear that as many as 5% of the population (possibly even more) will have a clinical stone event at some time during their lives. In previous decades, stone formation was more frequent in men than in women, but in recent years the incidence has become almost equal. The ten-year risk of further stone recurrence can be as high as 70% after a first episode, so investigation and treatment, which can reduce this figure to 25%, is worthwhile.

The clinical effects of stone formation tend to be similar whatever the type, but it is apparent that there are a number of distinct metabolic derangements that can each

BOX 9.2 Some causes of renal Fanconi syndrome

Inherited

- Idiopathic
- Oculocerebrorenal (Lowe) syndrome
- Associated with inherited metabolic disease:
 - Cystinosis
 - Fructose intolerance
 - Galactosaemia
 - Glycogen storage disease type I
 - Tyrosinaemia
 - Wilson disease

Acquired

- Exogenous toxins
 - Heavy metals: lead, cadmium, mercury, copper
 - Drugs (e.g. tetracycline that has been stored for too long, gentamicin, ifosfamide, tenofovir)
- Paraproteinaemia
- Amyloidosis

TABLE 9.2 The main types of renal stone, in approximate order of frequency of occurrence

Type of stone	Frequency (%)
Predominantly calcium oxalate	60
Uric acid	17
Magnesium ammonium phosphate and calcium phosphate (struvite)	12
Predominantly calcium phosphate	10
Cystine	1

give rise to stones of a characteristic composition. The main types of renal stones are listed in Table 9.2 in approximate order of frequency of occurrence, and aetiological factors in the formation of each are described in detail below.

The classic clinical manifestation of nephrolithiasis is renal or ureteric colic. The pain is characteristically severe, requiring opiates for analgesia, and is usually accompanied by haematuria. Some stones may be discovered incidentally when abdominal X-rays are taken for an unrelated reason, and passage of tiny stones may cause only minimal discomfort. In general, permanent intrinsic renal damage rarely occurs after an acute event unless there is superadded infection in an obstructed kidney. However, there is an increased incidence of chronic kidney disease in patients with a history of kidney stones and current UK guidelines recommend screening such patients annually with measurement of plasma creatinine and calculation of eGFR (see Chapter 7).

Pathogenesis of renal stones

The role of the kidneys in water conservation means that it is often necessary to excrete concentrated urine. Since some constituents of urine are relatively insoluble in water, to the extent that supersaturated solutions form, it is not surprising that these constituents sometimes crystallize out to form renal calculi.

Certain factors predispose to this process: chronic dehydration, as may occur in hot climates, is one factor. Increased urinary excretion of certain constituents (e.g. calcium, urate or oxalate) increases the likelihood of supersaturation occurring, and alteration of urinary pH may adversely affect the solubility of some solutes. For example, urate stones are more likely to form in acidic urine, whereas alkaline conditions, as may occur with a urinary tract infection, make calcium phosphate precipitation more likely. There is evidence that specific microorganisms may precipitate early crystallization. Anatomical abnormalities of the kidneys, such as medullary sponge kidney or pelvi-ureteric junction obstruction, increase the risk of stone formation, at least in part because of urinary stasis. There is a 2–3 fold risk of stone formation in people with a family history of urolithiasis. Patients who are overweight, especially if they have insulin resistance, have an increased risk of developing both calcium oxalate and uric acid stones, partly because of excretion of excess dietary constituents in the urine and partly because of the production of persistently acidic urine.

These factors are opposed by the presence in urine of inhibitors of crystallization (e.g. magnesium, pyrophosphate, citrate and certain glycoproteins), so that crystal formation in urine is usually slower than in simple salt solutions.

Each of the types of stone listed in Table 9.2 will now be considered in more detail.

Calcium stones

Calcium-containing stones form the majority of renal calculi and may consist of calcium oxalate, calcium phosphate or a mixture of the two. Hyperoxaluria, with or without hypercalciuria, is likely to be involved in the formation of pure calcium oxalate stones, whereas pure calcium phosphate stones suggest either hypercalciuria or persistently alkaline urine.

Hypercalciuria. Hypercalciuria is present in around 30% of patients with calcium-containing stones, although the exact prevalence depends on the population studied and the upper limit accepted for the reference range (of the order of 7.5 mmol/24 h for men and 6.25 mmol/24 h for women or 0.1 mmol/kg body weight/24 h).

A minority of hypercalciuric stone formers also have hypercalcaemia, and it is then important to establish a cause for this; it is most likely to be due to primary hyperparathyroidism. The treatment is that of the underlying cause.

Normocalcaemic hypercalciuria may be divided broadly into four groups: skeletal resorption, dietary, absorptive and renal leak hypercalciuria. Skeletal resorption and hence urinary excretion of calcium may be seen in patients following prolonged immobilization, Paget disease of bone or excessive glucocorticoid activity including chronic steroid therapy. Pure dietary hypercalciuria is rare, but high consumption of dairy products, combined calcium and vitamin D supplements or salt all tend to increase urinary calcium excretion.

Increased intestinal absorption of calcium accounts for around 50% of subjects with normocalcaemic hypercalciuria. The mechanism is not well understood, but there is some evidence for increased end-organ sensitivity to vitamin D, resulting in absorption of a greater fraction of dietary calcium than in normal subjects. Plasma parathyroid hormone (PTH) concentrations may be decreased.

Renal leak hypercalciuria may be seen in renal tubular acidosis, medullary sponge kidney, chronic loop diuretic therapy and proximal tubular syndromes such as Dent disease, but is more often idiopathic, accounting for 25% of hypercalciuric subjects. Some patients may have an unrecognized bone resorption defect; indeed, it is not always possible to determine whether the primary disorder is of renal or bone origin. Patients may be differentiated from those with absorptive hypercalciuria by a calcium load test: calcium excretion is high after loading in both groups but remains >0.23 mmol/mmol creatinine after fasting in patients with a renal leak of calcium (see Appendix 6.1). Plasma PTH is often mildly raised in response to the chronic calcium loss, although any increase is more commonly due to vitamin D deficiency. Treatment with thiazide-like diuretics reduces both

calcium excretion and plasma PTH concentrations, and reduces the risk of osteoporosis.

Treatment of patients with hypercalciuria and/or calcium containing stones includes increasing fluid intake to achieve daily urine volumes of 2–3 L, correcting dietary factors such as excessive salt, protein, sugar and calorie intake, and avoiding combined calcium and vitamin D supplements. A low sodium diet enhances both sodium and calcium reabsorption in the proximal tubules and so decreases urinary excretion (calcium is reabsorbed passively along the concentration gradient produced by active sodium and water reabsorption). Restricting animal protein reduces the dietary acid load and therefore the loss of calcium from bone. Restricting sucrose and fructose consumption appears to reduce urinary calcium excretion and may help with weight loss, which reduces the risk of stone recurrence. Formal calcium restriction is no longer recommended owing to the risk of osteoporosis as well as to a paradoxical rise in stone risk from the increased absorption of free oxalate in the intestine (calcium oxalate is poorly absorbed). Subjects should be advised to consume a ‘normal’ amount of calcium per day of around 1000 mg. However, calcium supplements, especially if taken between meals, should be avoided as they are associated with an increased risk of stone formation. Thiazide-like diuretics, such as chlortalidone or indapamide, specifically reduce renal calcium excretion and are particularly successful in patients with renal leak hypercalciuria. Those with absorptive hypercalciuria may become refractory to treatment and require an occasional ‘thiazide holiday’. Response to treatment should be monitored by measuring urinary calcium excretion. Biochemical side-effects, including hypokalaemia, hyperuricaemia, hypercalcaemia and hyperglycaemia, are relatively common and should be sought routinely. Potassium citrate supplements should be added, especially if the urinary citrate excretion is below the mid range and the urine pH is regularly <6.5, or if there is hypokalaemia. Excessive treatment with potassium citrate, resulting in the production of alkaline urine, increases the risk of calcium phosphate stone formation and should be avoided. Patients with distal renal tubular acidosis may show a sufficient fall in urinary calcium excretion in response to potassium citrate alone to avoid treatment with thiazide diuretics. This group includes patients with a partial form of the disorder in which plasma pH is normal under basal conditions, but the urine cannot be acidified when tested formally.

Hyperoxaluria. Now that oxalate can be measured reliably in the urine, it has become apparent that hyperoxaluria contributes as much, if not more, to calcium oxalate stone formation as hypercalciuria. A relatively small increase in urinary oxalate excretion above normal can have a marked effect on the risk of stone recurrence. In most instances, hyperoxaluria results from excessive dietary intake or increased intestinal absorption of oxalate; the two rare primary hyperoxalurias are described below.

The upper reference limit for urinary oxalate excretion is of the order of 400–500 $\mu\text{mol}/24\text{h}$. A dietary excess of oxalate-containing foods can increase excretion to

700 $\mu\text{mol}/24\text{h}$ or even greater, particularly if the dietary calcium content is low.

Increased intestinal absorption of oxalate may occur in short bowel syndrome and malabsorption, whatever the cause (enteric hyperoxaluria). Unabsorbed fatty acids in the gut lumen combine with calcium, reducing the available calcium for calcium oxalate formation. This leaves larger than usual amounts of oxalate in the free form, which can be easily absorbed. In addition, exposure of the colonic mucosa to substances such as fatty acids and bile salts, which have detergent properties, may increase its permeability to oxalate and further increase the amount absorbed.

Primary hyperoxaluria is a rare inherited metabolic disease that must be considered if nephrolithiasis occurs during childhood (although a few affected individuals do not present until adult life). There is increased synthesis of oxalate, with a consequent increase in its urinary excretion, together with that of some other organic acids. The pattern of accompanying organic aciduria has allowed classification into two types. In type 1 primary hyperoxaluria, excessive amounts of glyoxylic and glycolic acids are excreted, whereas in the rarer type 2, excretion of these acids is normal but that of L-glyceric acid is increased. The biochemical defect in type 1 is a deficiency of the peroxisomal enzyme alanine:glyoxylate aminotransferase. In type 2, the defect is in a cytosolic enzyme, D-glycerate dehydrogenase/glyoxylate reductase. The inheritance of both types is autosomal recessive. In type 1, the 24 h excretion of oxalate is of the order of 1.5–3 mmol; it may be lower in type 2, which may have a less severe clinical course. Besides renal stone formation, there is also a tubulointerstitial nephropathy that progresses to chronic kidney disease. Plasma oxalate concentrations begin to rise as renal clearance decreases, eventually leading to widespread tissue deposition of oxalate (e.g. in myocardium, retinae and synovial membranes). However, the condition appears to exhibit marked clinical and biochemical heterogeneity.

Other causes of hyperoxaluria include ingestion of ethylene glycol, which is rapidly converted to glycolate and can lead to calcium oxalate crystals forming in the renal tubules, excessive ingestion of vitamin C, which may lead to increased oxalate formation in some individuals, and chronic *Aspergillus* infection. Pyridoxine is a cofactor for the alanine:glyoxylate aminotransferase enzyme, and deficiency results in mild hyperoxaluria that responds to physiological replacement doses. A syndrome of ‘mild metabolic hyperoxaluria’ has also been described in adults that responds to pharmacological doses of pyridoxine.

Treatment of calcium oxalate stone formers includes increased fluid intake, dietary restriction of oxalate (Box 9.3) and oral potassium citrate if urine citrate excretion is below mid range or the pH is consistently <6.5. If there is no hypercalciuria, oral calcium supplements can be taken at mealtimes to decrease intestinal oxalate absorption. The starting dose is 500 mg equivalent of calcium per day, which may be increased to 10 g/day in patients with severe malabsorption and should be titrated against urine calcium and oxalate excretion. Pyridoxine reduces urinary oxalate excretion in some individuals: the starting dose should be 10 mg/day, increasing to a

BOX 9.3 Foods rich in available oxalate

- Tea (especially black)
- Ovaltine
- Drinks rich in vitamin C (converted to oxalate)
- Spinach
- Rhubarb
- Nuts
- Strawberries
- Raspberries
- Chocolate
- Pulses
- Beetroot

maximum of 500mg. Cholestyramine can be used as a last resort to bind intestinal oxalate, but it is often poorly tolerated.

Other factors in calcium stone formation. Although uric acid can itself form renal stones (see below), hyperuricosuria may also contribute to calcium stone formation. This may be through heterogeneous nucleation following uric acid crystallization or through other mechanisms, and this remains a controversial area. Dietary restriction of proteins and purines and/or the use of allopurinol may correct hyperuricosuria and reduce the risk of recurrence.

Citrate is a recognized inhibitor of calcium stone formation, and some stone formers have low urinary citrate concentrations as the only biochemical abnormality. This is particularly so in patients with distal renal tubular acidosis, who are already at increased risk of calcium phosphate stone formation because of failure to acidify the urine adequately. Potassium citrate supplementation is effective but should be used cautiously in patients with renal impairment or hyperkalaemia. Sodium citrate should be avoided as it can increase urinary calcium excretion.

Magnesium is also a recognized stone inhibitor. Although magnesium supplementation has not been shown to reduce stone risk, it may be worth trying if definite hypomagnesaemia is present.

Normal urine also contains a variety of protein-based inhibitors of stone formation, and it may well be that deficiencies or defects in these will be found to be the cause of some types of stone in the future. For example, a genetic variant of uromodulin (Tamm–Horsfall glycoprotein) has been found that has stone-promoting properties, whereas the normal type is thought to inhibit stone formation.

Infection-related stones

Infection-related (triple phosphate) stones are composed predominantly of magnesium ammonium phosphate (struvite), with variable amounts of calcium phosphate as carbonate–apatite. They form in the presence of high urinary concentrations of ammonia, bicarbonate and carbonate, which essentially means that they only form when the urine is infected with urea-splitting bacteria (e.g. *Proteus*, *Klebsiella* and *Pseudomonas* spp.). For this reason, and in contrast to other types of stones, they occur more frequently in women and in other people with a predisposition to urinary tract infection, such as in those with an

indwelling catheter or a spinal injury. They may also occur occasionally in other stone formers. The clinical presentation is often insidious as they tend to form staghorn calculi that may cause silent deterioration of renal function. Treatment includes correcting any underlying cause if possible, and rapid access to antibiotics appropriate to the known sensitivity of previously cultured organisms. Patients can keep a supply of antibiotics at home or even take continuous prophylaxis. Complete sterilization of the urine is possible only if stones are eradicated.

Uric acid stones

Hyperuricaemia and gout are discussed in Chapter 32. In healthy people, the amount of uric acid excreted in the urine depends on, among other things, the purine content of the diet. This makes the definition of a reference range rather difficult, particularly since even at ‘normal’ excretion rates of 3.6–4.8 mmol/24h, the urine is supersaturated with uric acid and yet most people do not form uric acid stones. Stones may form in patients with hyperuricaemia from any cause, as well as in those with renal hypouricaemia due to an isolated genetic defect or as part of a Fanconi syndrome.

Most patients with uric acid stones have normal plasma urate concentrations and urinary urate excretion, but produce concentrated urine with consistently low pH (<5.5). Patients with an ileostomy are at particularly high risk owing to bicarbonate and water loss from the stoma. The solubility of urate decreases sharply below its isoelectric point (pI) of 5.75. This offers a useful therapeutic intervention, in that if alkali is used to maintain the urine pH at 6.5–7.0, stones can be redissolved and further formation prevented even if there is a degree of hyperuricosuria. More pronounced alkalinization of the urine should be avoided, as it increases the risk of calcium phosphate deposition. Well-motivated subjects may titrate their dose of alkali (usually potassium citrate) by testing their own urine with pH paper. Patients with severe hyperuricosuria may need allopurinol to prevent stone formation and should be advised to restrict dietary purine intake.

Cystine stones

These have already been discussed in the section on cystinuria, above.

Miscellaneous rarities

Renal stones submitted for analysis occasionally may not fall into one of the categories discussed above. Some may be entirely unrelated to the renal tract (factitious disorders), whereas others may be from the renal tract but not be true stones (e.g. blood clots, sloughed papillae, encrusted sutures). However, there are a few other inherited metabolic diseases that do result in the formation of stones of unusual composition.

In hereditary xanthinuria, there is a deficiency in xanthine oxidase, with the consequent replacement of uric acid in the urine by xanthine and hypoxanthine. In about two-thirds of affected people this remains an asymptomatic metabolic abnormality, usually detected because of

very low plasma urate concentrations, but in the remaining one-third xanthine stones form in the renal tract. There may also be associated myopathy or arthritis.

An even rarer subtype of xanthinuria has been described, in which there is deficiency of xanthine oxidase together with sulphite oxidase, but here the main clinical concern is the neurological involvement.

Xanthine stones have also been described in patients with normal plasma urate concentrations who clearly do not have xanthine oxidase deficiency. The cause of these is unknown.

Another rare inherited disorder of purine metabolism associated with renal stone formation is adenine phosphoribosyl transferase (APRT) deficiency. This enzyme is involved in the salvage pathway for the purine base adenine, and deficiency results in increased urinary excretion of 2,8-dihydroxyadenine. This leads to stone formation in most homozygotes, although up to 15% remain clinically stone free. It is worth noting that many of the chemical tests used for uric acid also give a positive reaction with 2,8-dihydroxyadenine. In children, the finding of uric acid stones using chemical testing should, therefore, be further investigated using a more specific technique.

Very rarely, stones may be composed entirely of glycoprotein matrix or extraneous compounds such as triamterene, silicate or indinavir, all of which are excreted by the kidney.

Investigation of stone formers

All stone formers should have at least a minimum basic screen including serum creatinine, potassium, bicarbonate, urate and calcium with a 24 h urine collection for measurement of volume, calcium and oxalate. Evaluation should be at least six weeks after surgery or lithotripsy to avoid contamination of urine. Patients who have recurrent stones, a strong family history or who present before the age of 25 should have more extensive investigation as outlined in **Box 9.4**. The use of acid-containing bottles for urine collection is controversial because of patient safety concerns, but there is a risk of calcium oxalate and phosphate precipitation before analysis if the sample is not adequately acidified. Crystals are very difficult to redissolve, even if the urine collection is acidified on receipt in the laboratory. Accurate urate estimation requires a non-acidified collection.

There is a marked biological variation in calcium and oxalate excretion, partly owing to diet, so at least two estimations separated by a week should be requested before any treatment is started. Testing a spot urine for albumin will detect most patients with proximal tubular disorders, and can be confirmed by low molecular weight protein estimation. Urinary albumin will also be raised if there is intrinsic kidney damage or if the patient has active stone disease.

Analysis of available stones can be highly informative, although not all practitioners in the field would agree. External quality assurance surveys in the UK demonstrate that stone analysis is not generally well done, especially if the method used is qualitative. Infrared spectroscopy is the gold standard, but if this is not available, quantitative chemical techniques are adequate. Knowledge of a stone's constituent(s) obviously directs

further biochemical investigation and monitoring. It is also important to continue to analyse the stones if there is recurrence – there may be changes in the constituents that necessitate a change in management.

Treatment

Treatment of specific stone types has been covered in the relevant sections. All patients will also benefit from general advice about diet, including those with no identifiable risk factors. Adequate fluid intake is the most important, aiming to achieve daily urine volumes of at least two but preferably three litres. Periods of dehydration, such as during sporting activities, should be avoided. Most patients can be taught to increase fluid intake to maintain a pale, straw-coloured urine. Reduction of salt, refined carbohydrate and animal protein intake has been shown to have a much greater effect on stone risk than calcium restriction. In fact, the population quartile with the lowest calcium intake has a higher risk of stone formation than the quartile with the highest intake, owing to reciprocal hyperoxaluria. Calcium restriction is therefore no longer recommended. Reducing the intake of oxalate (**Box 9.3**) will contribute to lowering of the calcium oxalate product in the urine. However, in otherwise healthy people, over 80% of urinary oxalate is produced endogenously. Tea is particularly rich in oxalate, especially if taken without milk (calcium precipitates the oxalate), and should be avoided. Citrate excretion by the kidney may be enhanced by oral potassium citrate supplements, orange juice or bicarbonate-rich mineral water. Urinary tract infections

should be treated promptly and adequately: laboratory confirmation of bacterial eradication is recommended. Long-term prophylaxis with antibiotics may be required.

CONCLUSION

Primary disorders of the renal tubules are not common, but biochemical investigations are important in both diagnosing and monitoring them.

The pathogenesis of renal stone formation is still not fully understood, but enough is known for a logical approach to be taken in the biochemical investigation of stone formers. This is something that probably has not been uniformly well done in the past.

ACKNOWLEDGEMENT

We would like to thank Stephen K. Bangert who co-authored this chapter for previous editions of the book.

An easy to understand review of the physiology, pathology, diagnosis and management of the renal tubular acidoses.

APPENDIX 9.1 DIAGNOSIS OF RENAL TUBULAR ACIDOSIS

A variety of provocative tests of urinary acidification have been used in the investigation of RTAs, but whether these can firmly diagnose the type of defect remains to be established.

In general, hyperchloraemic metabolic acidosis that is not explained by bicarbonate loss from the intestinal tract should raise the suspicion of a urinary acidification defect. The plasma potassium may give a clue as to the type (high in type 4, low in types 1 and 2). The presence of other features of the renal Fanconi syndrome suggests

type 2 RTA. The amount of bicarbonate required to correct the acidosis also gives an indication of the type of RTA (type 1 responding most readily and type 2 least readily). However, it may be necessary to confirm the diagnosis by using one of the following two tests:

Urinary acidification test

This can be used to confirm the diagnosis of distal RTA. The test is not necessary if the pH of a urine specimen collected after an overnight fast is <5.5 or if it is >5.5 in a patient confirmed to be acidotic in the resting state. If this is not the case, the patient is given ammonium chloride at a dose of 100 mg/kg body weight. Special formulations are available to minimize gastrointestinal side-effects. Urinary pH is then measured on fresh urine samples at hourly intervals for 8 h.

In normal subjects, urinary pH should fall to <5.5 in at least one sample. In distal renal tubular acidosis this does not occur and urinary pH usually remains >6.5.

Ammonium chloride should not be used in patients with liver disease, in whom calcium chloride may be used as an alternative acidifying agent (1 mmol/kg body weight). Ammonium chloride is unpleasant to take and alternative tests have been sought, for example the fludrocortisone–furosemide test. The principle of this latter test is to increase sodium delivery to the distal renal tubules at a time that sodium reabsorption and, therefore, hydrogen ion excretion is maximally stimulated by a mineralocorticoid. One mg of fludrocortisone is given orally an hour before furosemide 40 mg, also orally. Urine samples are collected every 30 min for up to 6 h or until a urine pH <5.5 is achieved. However, both false positives and false negatives can occur and ammonium chloride loading remains the definitive test.

Fractional excretion of bicarbonate

This test can be used to confirm the diagnosis of proximal RTA, as long as the patient's plasma bicarbonate is maintained above 20 mmol/L.

Plasma and urine samples are obtained and creatinine and bicarbonate concentrations measured in each. The fractional excretion of bicarbonate is then calculated:

$$\frac{\text{urine[bicarbonate]}/\text{plasma[bicarbonate]}}{\text{urine[creatinine]}/\text{plasma[creatinine]}} \times 100\%$$

In patients with proximal RTA, the fractional excretion is >10–15%, whereas in most patients with distal RTA it is <10%.

CONCLUSION 199

INTRODUCTION

Food is essential for human life. At the extremes, too little leads to starvation and too much leads to obesity, each with its associated effects on morbidity and mortality. Between these extremes, different people across the world follow apparently very different diets with no obvious resulting differences in their day-to-day health. It is apparent that in the long term the composition of the diet has an effect on the incidence of certain diseases, for example ischaemic heart disease and certain types of cancer, but often these associations are difficult to tease out because of the many confounding factors involved. However, this does not prevent very firm opinions being formulated and held about what is and what is not 'good nutrition', based on a variety of influences from basic science to religion.

Biochemistry clearly has a role in establishing the way in which the body uses various nutrients and has been important in defining certain deficiency states. Clinical biochemistry is still important in diagnosing deficiencies of certain specific nutrients, but whether there is a good biochemical marker of overall nutritional status is less clear. This chapter begins with a consideration of the various nutrients, including the effects of their deficiency or excess, and then discusses nutritional assessment. The following chapter discusses nutritional disorders and their management, both from the point of view of nutrition as an aetiological factor in disease, and disorders that are not primarily nutritional but where dietary modification or nutritional support may be important in treatment.

NUTRITIONAL REQUIREMENTS

The 'correct' intake

Part of the explanation of the fact that apparently very different diets can sustain life equally well is the concept that individual foodstuffs actually comprise different combinations of certain basic nutrients, and that it is the supply of these basic nutrients that is important rather than their origin. However, even when individual nutrients are considered, the definition of the 'correct' intake is problematical since this may be taken, for example, to be any of the following: the intake that avoids clinical signs of deficiency; the intake that maintains a given circulating concentration or tissue content of the nutrient; the intake that cures symptoms or signs of clinical deficiency; the intake that maintains a balance between intake and consumption or loss from the body over a defined period, or any one of a variety of other definitions. Even if a suitable measure can be determined for a specific nutrient, there are further problems in setting the absolute figure, since within a population, requirements will vary between individuals (owing, for example to differences in age, gender size and body composition) and even in an individual, requirements may vary in the short term (owing, for example to pregnancy, illness or environmental stress).

It is thus difficult to accurately estimate average requirements for a nutrient, and most attempts to make recommendations about intakes have depended on setting levels where most of the population will not be deficient, although it is also possible to define intakes below which most of a population will develop deficiency, and in some cases intakes that are high enough to be toxic.

TABLE 10.1 Definitions of terms used in describing nutrient requirements

Abbreviation	Term	Definition
DRV	Dietary reference value	General term that includes all those listed and some more pragmatic approaches
RDI RDA	Recommended daily intake Recommended daily amount	Average intakes that should meet the needs of almost all members of a population. In the UK, these are based on the Department of Health and Social Security publications: <i>Recommended intakes of nutrients for the UK and Recommended daily amounts of food energy and nutrients for groups of people in the UK</i>
EAR	Estimated average requirement	Mean requirement for a population: about half will need more and half less
RNI LRNI	Reference nutrient intake Lower reference nutrient intake	Intakes two standard deviations above (RNI) and below (LRNI) the EAR for a population. Assuming individual requirements are normally distributed, these limits should define requirements for 95% of the population

Adapted from Department of Health 1991.

These points are covered in more detail in some of the texts listed under Further reading, below, and no attempt will be made here to define ideal intakes in absolute terms. Some of the terms used to describe nutrient requirements are defined in Table 10.1.

Energy

The body uses energy in the maintenance of metabolic processes, in physical activity and in growth. In the resting individual, energy-requiring processes include the active pumping of ions across cell membranes, thermoregulation, cell division and basal function of all of the body's systems. Resting energy expenditure appears to alter with energy intake to some extent. Physical activity, particularly if vigorous, can increase energy expenditure markedly, although such activity is not usually sustained for long enough to make the increase substantial when measured over a 24 h period. The laying down of new tissues represents an investment of energy, so it is not surprising that energy requirements, expressed in terms of body weight, are highest in infants and young children, with a gradual decline from the third decade into old age.

Thus, the energy requirement of an individual varies with body size and composition, gender, age, nutritional status and climate. In women, energy expenditure is increased during pregnancy and lactation, and in any individual, illness or response to trauma (e.g. systemic infection, burns) may cause a considerable increase.

Energy expenditure and energy intake do not always rise and fall in parallel. A sustained deficiency in energy intake generally leads to consumption of body stores of energy, including protein as well as glycogen and fat. Excessive energy intake (if sustained) results in obesity. Both of these conditions are considered further in the next chapter.

Dietary energy is mainly obtained from a combination of fat and carbohydrate. In a Western diet, each may account for 40–50% of total energy intake, although in developing countries the proportion from carbohydrate tends to be higher and that from fat, lower. Although dietary protein is generally thought of as a source of

materials (amino acids) for endogenous protein production, it may also be used for energy production, for example if protein intake is adequate but non-protein energy intake is low. Ethanol also has to be considered as a significant energy source in certain populations; for example, in the UK, it forms 7% of average energy intake. (Interestingly, at higher ethanol intakes – 25–35% of dietary energy – ethanol appears not to be completely utilized as a source of energy, although the reason for this is not clear.)

Carbohydrate

Dietary carbohydrate provides 4.1 kcal/g and most is derived from sugars and starch. The sugars are mainly the monosaccharides glucose, fructose and galactose, and the disaccharides sucrose, lactose and maltose. Dietary sugars can be divided into those which are present in intact cells, such as in whole fruit (intrinsic sugars), and those which are free and readily absorbed as a result of having been added to food, usually as sucrose (extrinsic sugars). Milk sugars are usually considered as intrinsic. A high intake of extrinsic sugars is associated with an increased prevalence of dental caries. Sugar derivatives, such as the sugar alcohols sorbitol and xylitol, can be partially digested and can provide 2.4 kcal/g.

In the UK, it is recommended that in the adult, 40–50% of energy intake should be provided by carbohydrate, but non-milk extrinsic sugars should not exceed 11% of energy intake. There is considerable debate about whether a high intake of non-milk extrinsic sugars may have harmful effects in addition to the increased risk of dental caries. If such an intake results in an increased energy intake, then obesity is likely to be a problem, but in any case, ingestion of large amounts of extrinsic sugars can lead to raised plasma glucose, insulin and lipid concentrations, all of which are potentially harmful.

Large amounts of starch are not harmful: indeed, in developing countries, starch may form 75–80% of the total energy intake. Starches are α -glucan polysaccharides, of which there are two major forms, amylose and amylopectin (see Fig. 10.1). They are partially resistant to

FIGURE 10.1 ■ Molecular structure of starches. Amylose is a straight chain glucose polymer with a molecular weight of 100 000 Da or more and amylopectin is a branched chain glucose polymer with a molecular weight of over 1 million Da.

hydrolysis during digestion and are thus not totally available as an energy source. Certain other carbohydrates, that are not energy sources, but form part of 'dietary fibre', are considered later.

A deficiency in dietary carbohydrate will either lead to energy deficiency or result in potentially harmful amounts of other energy sources being required in the diet if energy intake is to be maintained. However, certain tissues have an obligatory requirement for glucose as an energy substrate (e.g. brain and nervous system (in the short term), red blood cells) and, while this need can be met by gluconeogenesis, some carbohydrate is necessary in the diet if ketosis is to be avoided.

Fat

The term 'fat' includes a range of substances, including triacylglycerols (triglycerides), phospholipids and sterols (e.g. cholesterol). Triacylglycerols are the most common storage fats and are thus the most important fatty energy source in foods. They are a relatively 'concentrated' energy source, with a higher energy content per unit weight (9.3 kcal/g) than carbohydrate (4.1 kcal/g). Although all triacylglycerols can act in this way, there may be important long-term health differences between them, dependent on the structure of the fatty acid residues they contain. The main differences are in the length of the

carbon chain, the presence (and number) of any unsaturated bonds and, if such bonds are present, the positional and geometric isomers present. Some examples of these differences are illustrated in Figure 10.2. The effects of excessive intake of triglycerides are discussed further in Chapter 11, and the differences in absorption and metabolism between long chain and medium chain triglycerides in Chapter 12.

Dietary fat deficiency does not generally seem to be a problem, as most fats necessary to the body can be endogenously synthesized when a high proportion of total energy intake is supplied by carbohydrate. However, there are certain fatty acids that appear to be essential, at least in small amounts. These are linoleic acid (C18:2, ω -6) (for nomenclature, see Fig. 10.2) and α -linolenic acid (C18:3, ω -3). They are important components of phospholipids, in which they help to maintain the function of cellular and subcellular membranes. They are also involved in the regulation of cholesterol transport, breakdown and excretion. They are the precursors of arachidonic (C20:4, ω -6), eicosapentaenoic (C20:5, ω -3) and docosahexaenoic (C22:6, ω -3) acids and are thus also important in the synthesis of prostaglandins, thromboxanes and leukotrienes. These three longer chain fatty acids are not strictly essential fatty acids (EFAs), but may become conditionally so in EFA deficiency. Adequate dietary supply of the longer chain fatty acids is probably also important during rapid

brain growth in infancy, particularly in fast-growing premature infants.

The clinical effects of EFA deficiency include dermatitis, alopecia and fatty liver, but these are only seen when EFAs provide less than 1–2% of total dietary energy intake. In patients receiving long-term fat-free parenteral nutrition, cutaneous application of small amounts of appropriate oils has alleviated biochemical EFA deficiency.

SATURATED FATTY ACIDS

$\text{CH}_3 (\text{CH}_2)_{14} \text{COOH}$
Palmitic (hexadecanoic) acid (C16:0)

$\text{CH}_3 (\text{CH}_2)_{16} \text{COOH}$
Stearic (octadecanoic) acid (C18:0)

MONOUNSATURATED FATTY ACIDS

$\text{CH}_3 (\text{CH}_2)_5 \text{CH}=\text{CH}(\text{CH}_2)_7 \text{COOH}$
Palmitoleic (Δ^9 hexadecenoic) acid (C16:1)

$\text{CH}_3 (\text{CH}_2)_7 \text{CH}=\text{CH}(\text{CH}_2)_7 \text{COOH}$
Oleic (Δ^9 octadecenoic) acid (C18:1)

POLYUNSATURATED FATTY ACIDS

ω -6
 $\text{CH}_3 (\text{CH}_2)_4 \text{CH}=\text{CHCH}_2 \text{CH}=\text{CH}(\text{CH}_2)_7 \text{COOH}$
Linoleic ($\Delta^{9,12}$ octadecadienoic) acid (C18:2)

ω -3
 $\text{CH}_3 \text{CH}_2 \text{CH}=\text{CHCH}_2 \text{CH}=\text{CHCH}_2 \text{CH}=\text{CH}(\text{CH}_2)_7 \text{COOH}$
 α linoleic ($\Delta^{9,12,15}$ octadecatrienoic) acid (C18:3)

ω -6
 $\text{CH}_3 (\text{CH}_2)_4 \text{CH}=\text{CHCH}_2 \text{CH}=\text{CHCH}_2 \text{CH}=\text{CHCH}_2 \text{CH}=\text{CH}(\text{CH}_2)_3 \text{COOH}$
Arachidonic ($\Delta^{5,8,11,14}$ eicosatetraenoic) acid (C20:4)

FIGURE 10.2 ■ Molecular structure of some fatty acids. The systematic name (in brackets) indicates the number of carbon atoms in the chain (e.g. octadeca- = 18) and the presence and number of any double bonds (e.g. -anoic = 0, -enoic = 1, -dienoic = 2, -trienoic = 3 etc.). This is sometimes abbreviated to (Cx:y), x and y indicating the numbers of carbon atoms and double bonds respectively. The numbers following the Δ symbol in the systematic names indicate the positions of the double bonds, for example, Δ^9 indicates a double bond between carbons 9 and 10, counting the carboxylic acid carbon as 1. An alternative system counts from the methyl carbon to the first double bond (e.g. ω -3). Most double bonds in naturally occurring unsaturated fatty acids are in the *cis* configuration, although industrial processing of vegetable oils to produce saturated fatty acids (hydrogenation) can also cause isomerization to the *trans* position.

Protein

Proteins have a key structural and functional role in virtually all bodily processes, and a supply of appropriate amino acids is necessary during normal turnover, with additional amounts if extra protein is being formed, for example during growth, pregnancy or lactation. This supply generally comes from dietary protein, of either animal or vegetable origin, but the actual amount of protein required depends on its amino acid content. Human protein contains 20 amino acids (Box 10.1), of which nine are recognized to be essential (or ‘indispensable’) in adults – the remaining 11 can be synthesized endogenously if the food protein is deficient in these but contains sufficient essential amino acids. Some amino acids, for example cysteine and glutamine, whilst not

BOX 10.1

Essential and non-essential α -amino acids found in human proteins

Designations can change under certain circumstances, for example phenylalanine and methionine are necessary for the synthesis of tyrosine and cysteine, respectively; if either phenylalanine or methionine is in short supply, then each of the other two can become ‘conditionally’ essential. Other amino acids (e.g. ornithine, citrulline, taurine) occur in the body, but are not found in proteins.

Essential amino acids

Histidine
Isoleucine
Leucine
Lysine
Methionine
Phenylalanine
Threonine
Tryptophan
Valine

Non-essential amino acids

Alanine
Arginine
Asparagine
Aspartic acid
Cysteine
Glutamic acid
Glutamine
Glycine
Proline^a
Serine
Tyrosine

^aProline is actually an imino acid but by convention, is included here.

normally essential, may become so in conditions such as severe illness, trauma or burns, when requirements exceed the body’s ability to synthesize them. In children, due to the increased demands of growth, the threshold for an amino acid to become conditionally essential is lower. Only L-amino acids are incorporated into human proteins.

Some proteins, particularly those derived from animal sources such as eggs, milk, fish and meat, contain all the essential amino acids in sufficient amounts for protein synthesis and are said to be complete, or of high quality. Foods lacking one or more amino acids are termed incomplete proteins; these are often from plant sources such as pulses. In diets in which plant foods are the main source of protein, combining different types of food in appropriate quantities is required in order to obtain all the essential amino acids. However, the amino acid profile of dietary proteins does not completely predict the amounts of these amino acids that will be available for protein synthesis after digestion and absorption: some of them may be biologically unavailable. Lysine is particularly important in this regard, as its supply in many dietary proteins is relatively low in comparison to nutritional requirements. It becomes unavailable if its ϵ -amino group reacts with another molecule, because ϵ -amino bonds are not cleaved by digestive enzymes. Such bonds may form with other amino acids (e.g. the carboxyl side chains of glutamic or aspartic acids) or with reducing sugars (during cooking or storage of foods).

Deficiency of protein generally occurs as part of more generalized malnutrition and is discussed later. Excessive protein intake in renal disease accelerates deterioration in renal function (see Chapter 7) and it is possible that it may have effects in healthy people, for example on renal function and on bone mineral density.

Micronutrients

Vitamins and certain trace elements are essential components of the diet required in very small amounts. Deficiency of individual micronutrients classically results in typical symptoms and signs according to the vitamin or trace element involved; recognition and treatment of deficiency of a single micronutrient deficiency is relatively easy. However, milder forms of deficiency, particularly of multiple micronutrients concurrently, may be difficult to recognize clinically.

Micronutrient status is likely to be affected by acute illness, owing to a combination of reduced intake and increased demand. Such increased demand may be due to catabolism resulting from the illness, subsequent anabolism and from disease-specific increased losses, for example loss from fistulae, diarrhoea and dialysis. As laboratory concentration of micronutrients may be perturbed in the acute phase, deficiencies in this group of patients can be particularly difficult to assess.

It is increasingly being recognized that subclinical deficiencies of micronutrients may have detrimental effects, some of which are described in the following pages. As the assessment of micronutrients can be important in patients receiving supplementation, consideration is also given to aspects of micronutrient toxicity.

Vitamin D is considered with bone metabolism in Chapter 31. Cobalt as a constituent of vitamin B₁₂ is discussed, together with this vitamin, folate and iron, in Chapter 27. Iodine is essential in the formation of thyroid hormones (see Chapter 19).

Vitamins

Fat-soluble vitamins

Vitamins are traditionally classified into those that are fat soluble (A, D, E and K) and the remainder, which are

water soluble. This is probably still a useful distinction, as it predicts when deficiency is likely (e.g. fat-soluble vitamins in steatorrhoea), and is retained here.

The fat-soluble vitamins A, E and K are structurally different, but are all non-polar, water-insoluble lipids. Absorption of each of them requires micelle formation in the gut lumen, for which bile salts are necessary.

Vitamin A. Dietary vitamin A occurs in a variety of forms which can be broadly divided into preformed vitamin A (retinol) and carotenoids, which are cleaved in the body to give vitamin A (see Fig. 10.3). In the UK, up to 75% of dietary vitamin A is preformed, derived from foods such as fortified cereals, margarine and dairy products, fish-liver oil and multivitamin preparations. Carotenoids are found in plants; the most important in the UK diet is β -carotene, which is found in carrots, dark green leafy vegetables, pumpkins and mangoes.

Retinol is transported in the bloodstream bound to retinol-binding protein (RBP), which in turn forms a complex with thyroid-binding pre-albumin. Protein-energy malnutrition can result in reduced synthesis of RBP and thus impaired retinol transport from the liver, producing a functional vitamin A deficiency, even in the presence of adequate liver reserves. β -Carotene undergoes oxidative fission in the intestine to give retinal (see Fig. 10.3), and hence retinol. The cleavage of provitamin A carotenoids appears to be inhibited when vitamin A stores are high, hence, toxicity from ingestion of plant sources is rare. Ingestion of excess preformed vitamin A leads to its absorption and hepatic storage.

The best understood of the actions of vitamin A is probably its role in vision. The 11-*cis* form of retinal is a component of the visual pigment rhodopsin, which is found in the rods of the retina. Light causes the retinal to change to the all-*trans* form (see Fig. 10.3) and this triggers a series of conformational and other changes, the

FIGURE 10.3 ■ Structure of vitamin A and some related compounds.

end result being that an electrical signal is transmitted to the cortex of the brain and is perceived as light. A similar mechanism operates in the cones of the retina.

Vitamin A is also necessary for growth and for normal development and differentiation of tissues. These actions are mediated by retinoic acid, which is present in foods in only small amounts but can be manufactured in the body from retinol. It modulates gene expression by activation of nuclear receptors, of which there are two groups: retinoic acid receptors (RAR) bind all-*trans*-retinoic acid (and some other retinoids); retinoid X receptors (RXR) bind 9-*cis*-retinoic acid. The latter interact with other receptors (e.g. those for vitamin D and thyroid hormones), and in the absence of retinoic acid can also act as repressors of gene expression. Other metabolic roles of vitamin A include carrying mannosyl units in the synthesis of hydrophobic glycoproteins and the retinoylation of proteins, for example the regulatory subunits of cAMP protein kinases.

Vitamin A deficiency is common in some developing countries, particularly in children, and is the single most common preventable cause of blindness in the world. An early symptom is night blindness, because of inadequate amounts of 11-*cis*-retinal in the retina. However, deficiency also has important effects in mucus-secreting epithelia and so there are other consequences for the eyes. Keratinizing squamous metaplasia in the conjunctiva causes conjunctival xerosis and this may be followed by the appearance of white plaques of desquamated thickened epithelium, known as Bitot's spots. Similar metaplasia in the cornea can lead to ulceration, which may progress to scarring and consequent blindness. Changes in other mucus-secreting epithelia, for example in the respiratory and gastrointestinal tracts, probably account in part for the lowered resistance to infections reported in vitamin A deficiency. In such areas of the world, public health programmes aimed at administering large doses of vitamin A have been successful in reducing morbidity and mortality associated with its deficiency, particularly in young children.

Acute ingestion of large amounts of preformed vitamin A can result in raised intracranial pressure, with headaches, nausea, vomiting and visual disturbances. Chronic overdosage is associated with bone damage including increased bone resorption, spontaneous fracture and sometimes raised plasma calcium concentration and alkaline phosphatase activity. Liver damage, hair loss and skin changes have also been reported.

Retinol is teratogenic (or, at least, the synthetic retinoids used in the treatment of certain dermatological conditions are) and so, in the UK, pregnant women are advised against self-medication with vitamin A and against

consumption of liver and products made from it. A high intake of β -carotene results in an orange-yellow appearance of the plasma, body fat and skin, but is not usually regarded as harmful in the short term. However, there may be an increased incidence of malignancy in people taking β -carotene supplements, particularly among heavy smokers.

Vitamin E. There are eight very similar compounds that have vitamin E activity, four tocopherols and four tocotrienols. The most active is the natural isomer of α -tocopherol, which accounts for about 90% of the vitamin E present in human tissues. Its structure is shown in Figure 10.4. It appears to be the major lipid-soluble antioxidant in cell membranes, acting to prevent the peroxidation of unsaturated fatty acids by free oxygen radicals. α -Tocopherol, but not its related tocopherols and tocotrienols, also has actions that are independent of its antioxidant properties. It modulates the transcription of certain genes, inhibits platelet aggregation and vascular smooth muscle proliferation and has an effect on cell signalling in the immune system.

The nutritional requirement for vitamin E is approximately proportional to the intake of polyunsaturated fatty acids. However, since foods rich in these (e.g. vegetable oils) also tend to contain large amounts of vitamin E, deficiency states are rare.

Vitamin E is not easily transported across the placenta and the first vitamin E deficiency state to be firmly established was in premature infants, who developed haemolytic anaemia, thrombocytosis and oedema. In children and adults who are unable to absorb or utilize vitamin E adequately (e.g. in cystic fibrosis or abetalipoproteinaemia), a progressive spinocerebellar degeneration may develop. The full syndrome consists of ataxia of the limbs, loss of position and vibration senses, absent deep tendon reflexes and pigmentary degeneration of the retina. Treatment with vitamin E supplements can prevent these neurological features or, if they are already present, arrest or even reverse them. For α -tocopherol to be made available to the tissues from very low density lipoprotein, it must first bind to hepatic α -tocopherol transfer protein. Individuals with a deficiency of this transfer protein develop a very similar clinical syndrome (ataxia with vitamin E deficiency,AVED).

There is some evidence that increased tissue concentrations of antioxidants, in particular vitamin E, may protect against conditions such as cancer and ischaemic heart disease, but this remains controversial.

Vitamin E supplements have also been taken to improve general well-being and sexual performance, but the only firm conclusion that can be drawn is that quite high

FIGURE 10.4 ■ Structure of α -tocopherol. It is an alcohol of empirical formula $C_{29}H_{50}O_2$, with a long alkyl tail, which confers fat solubility. The hydroxyl group gives it its characteristic antioxidant property.

FIGURE 10.5 ■ Structure of vitamin K₁ (phylomenadione) and vitamin K₂ (menaquinone), together with two vitamin K antagonists that have anticoagulant properties.

intakes of vitamin E are non-toxic, although very high intakes may antagonize vitamin K and potentiate anticoagulant therapy.

Vitamin K. The structures of the two forms of vitamin K and two vitamin K antagonists are shown in [Figure 10.5](#). Vitamin K is involved in the post-translational modification of the blood coagulation factors II (prothrombin), VII, IX and X. A vitamin K-dependent enzyme system catalyses the carboxylation of the first ten amino-terminal glutamate residues in prothrombin to γ -carboxyglutamate (Gla). This carboxylation facilitates the binding of calcium, which is necessary for prothrombin to bind to platelet phospholipid, which is in turn necessary for the conversion of prothrombin to thrombin in the final common pathway of the clotting cascade. A similar process of γ -carboxylation occurs in factors VII, IX and X to form sites with a high affinity for calcium, and this is also known to occur in some clotting inhibitors (protein C and protein S). It also occurs in some proteins outside the clotting system, for example in osteocalcin and the matrix Gla protein in bone, in nephrocalcin in the renal cortex and in the product of the growth arrest specific

gene (*GAS6*), which regulates differentiation and development in nervous tissue and apoptosis in other tissues.

The main dietary form of vitamin K is phylomenadione (K₁), with leafy green vegetables being the richest source, although other vegetable sources are important in most diets. Menaquinones (K₂) produced by the intestinal bacteria may also be important, since while circulating vitamin K is mainly phylomenadione, hepatic reserves are mainly menaquinones.

Vitamin K deficiency in its severest form leads to a bleeding syndrome, but dietary deficiency is rare after the first few months of life, unless there is an underlying disease affecting the absorption or utilization of the vitamin. However, vitamin K is undetectable in the blood of new-born babies, their hepatic reserves are low compared with adults and human breast milk contains barely adequate amounts. Thus, deficiency may present in infants as vitamin K deficiency bleeding (VKDB), within the first 24h from the time of birth (early), between two and seven days (classic) or after seven days (late). Intracranial haemorrhage is rare in the early form, but occurs in more than 50% of babies with the late form and is likely to lead to death or severe neurological

sequelae. The administration of vitamin K in the neonatal period abolishes the risk of deficiency. A single intramuscular injection of 1 mg of phytomenadione is highly effective for this purpose but suspicions, which now appear to be unfounded, were raised that its use led to an increased risk of childhood malignancy, particularly leukaemia. This adverse association has not been found for the administration of oral vitamin K, but the latter requires a multi-dose regimen. The current UK recommendation is that either intramuscular or oral vitamin K should be offered to all neonates after informed discussion with the parents.

Toxicity from naturally occurring K vitamins would appear to be rare, even in quite high doses. However, the use of synthetic preparations of menadione for nutritional purposes is best avoided, as serious unwanted effects have been recorded (e.g. haemolysis and liver damage in neonates).

Water-soluble vitamins

The water-soluble vitamins are polar compounds that, with the exception of vitamin B₁₂, tend to be absorbed rapidly from the upper small intestine, mainly through either sodium-dependent active transport or carrier-mediated diffusion. Vitamin B₁₂ and folate are discussed in Chapter 26.

Thiamin. The physiologically active form of thiamin (vitamin B₁) is thiamin pyrophosphate (TPP). This functions as a cofactor in the conversion of pyruvate to acetyl-CoA by the pyruvate dehydrogenase complex and in the conversion of 2-oxoglutarate to succinyl-CoA by the 2-oxoglutarate dehydrogenase complex. It acts as a cofactor to the enzyme transketolase in the pentose phosphate pathway and plays a part in the metabolism of branched chain amino acids. Thiamin also has non-cofactor roles: thiamin triphosphate is found in nerve and muscle cells, where it activates membrane ion channels, possibly by phosphorylating them.

Thiamin is found in most foodstuffs, but wheatgerm, oatmeal and yeast are particularly rich sources. However, the body store of about 30 mg is only 30 times the daily requirement and so an inadequate diet is likely to lead to deficiency of thiamin sooner than of any other vitamin. Thiamin deficiency used to be widespread in areas where rice formed a major part of the diet, resulting from the consumption of polished rice (from which the husk had been removed). In present times, thiamin deficiency is seen more typically in alcoholics (alcohol decreases the absorption of thiamin). Diets high in carbohydrate require more thiamin for their assimilation than diets high in fat, and subclinical deficiency may be unmasked by refeeding with a carbohydrate-rich diet. Patients on long-term renal replacement treatment may become deficient in thiamin (and other water-soluble vitamins) unless given supplements.

Most of the clinical features of the disease beriberi respond to treatment with thiamin, suggesting that it is mainly due to thiamin deficiency. Two forms are described, one in which there is peripheral neuropathy, muscle weakness, general fatigue and reduced

attention span ('dry' beriberi) and one in which there is also oedema and heart failure ('wet' beriberi). Some of these features may be the result of coexisting protein deficiency.

Patients with thiamin deficiency (commonly alcoholics) may present with a neuropathy and cardiomyopathy, but may also develop an encephalopathy, the Wernicke–Korsakoff syndrome. Wernicke encephalopathy and Korsakoff psychosis were originally described as two separate conditions, but now appear to be the acute and chronic manifestations, respectively, of a single condition. Wernicke encephalopathy has an acute onset, with ophthalmoplegia, nystagmus, ataxia and stupor or apathy. It is a medical emergency: the ophthalmoplegia, ataxia and lowered consciousness respond, in most cases within two days, to treatment with thiamin but, in up to 80% of cases, the mental changes fail to resolve completely and Korsakoff psychosis develops. Once established, this responds only slowly or not at all to thiamin treatment. The main features are retrograde amnesia, difficulty in assimilating new ideas and confabulation. Susceptibility to the development of this syndrome in thiamin deficiency may be greater in people who have a genetic variant of transketolase that binds thiamin less avidly than usual.

Thiamin is relatively non-toxic and can be given safely if deficiency is suspected. However, anaphylaxis has occurred after parenteral administration, and a wide variety of toxic effects has been described in adults with chronic intakes in excess of 50 mg/kg body weight or 3 g/24 h.

Riboflavin. Riboflavin (Vitamin B₂) is a constituent of the two flavins found in flavoproteins, flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), each of which acts as an electron carrier in many vital biological oxidoreduction systems. It is also a constituent of the cryptochromes, blue-light sensitive pigments in the eye that are important in the setting and maintenance of circadian rhythms. Clinical riboflavin deficiency is rare in countries where milk is a regular part of the diet; of-fal is another rich source. Even when dietary deficiency is present, clinical effects are rare because any riboflavin present in the body can be very efficiently conserved and reutilized.

The clinical features of riboflavin deficiency recorded in volunteers on a riboflavin-deficient diet include angular stomatitis, cheilosis, atrophic lingual papillae, glossitis, magenta tongue, seborrhoeic skin lesions, superficial lesions of the genitalia and vascularization of the cornea. The biochemical basis of these clinical manifestations is not immediately obvious and it may be that riboflavin deficiency has effects on the metabolism of other nutrients, for example pyridoxine, iron and folate.

Riboflavin absorption from the gastrointestinal tract is readily saturated, and any excess that does occur is rapidly excreted in the urine, so riboflavin does not accumulate in the body even when the oral intake is very high. This is probably just as well, since as well as reoxidation of reduced flavin coenzymes being a major source of oxygen radicals in the body, riboflavin is itself capable of non-enzymically generating reactive oxygen species.

Nicotinamide. Nicotinamide is a constituent of nicotinamide adenine dinucleotide (NAD⁺) and its phosphate (NADP⁺).

These are involved in a large number of oxidoreduction reactions in both cytosol and mitochondria, undergoing reversible reduction to NADH and NADPH, respectively. The major role of NADH is to transfer electrons from metabolic intermediates into the electron transfer chain, while NADPH acts as a reducing agent in a large number of biosynthetic processes. NAD⁺ and NADP⁺ are commonly referred to as coenzymes, but are probably better considered as true substrates.

Nicotinamide and its precursor nicotinic acid are both plentiful in animal and plant foods, although in some plant sources, for example maize, they are in a bound form and biologically unavailable. In man, a small amount is also formed in a minor pathway of tryptophan catabolism, via kynurenine to nicotinate, and it is usually accepted that 60 mg of tryptophan is equivalent to 1 mg of dietary nicotinamide or nicotinic acid. Both dietary and endogenous sources appear to be relatively important, since the deficiency state, pellagra, may occur when either is decreased. Simple dietary deficiency is now rare unless maize forms the main dietary constituent, but may be a complication of therapeutic low-protein diets. Decreased formation from tryptophan may occur where there is coexisting pyridoxine or riboflavin deficiency, since kynureninase and kynurenine hydroxylase are both dependent on these. Oestrogens also decrease the rate of tryptophan metabolism, so premenopausal women are more susceptible than men to borderline dietary deficiency. In Hartnup disease, there is decreased tryptophan absorption from the gut, and in carcinoid syndrome, there is increased usage of tryptophan in the synthesis of large amounts of 5-hydroxytryptamine – patients with either of these conditions are, therefore, particularly susceptible to decreases in nicotinamide and nicotinic acid intake.

The initial features of pellagra are non-specific (weakness, lassitude, anorexia and indigestion), but are followed by pigmented dermatitis in areas of skin exposed to sunlight, diarrhoea with widespread inflammation of epithelial surfaces and dementia, which may be preceded by irritability and depression.

Nicotinic acid is sometimes used in high doses for the treatment of combined hyperlipidaemia and the adverse effects are known to include flushing, hepatotoxicity, hyperuricaemia and impaired glucose tolerance.

'Niacin' is sometimes used to mean both nicotinic acid and nicotinamide and sometimes just one or other of them; because of this imprecision, the term has not been used here.

Vitamin B₆. Pyridoxal, pyridoxine, pyridoxamine and their 5'-phosphates (Fig. 10.6) are interconvertible in the body and all have vitamin B₆ activity. Pyridoxal phosphate is a cofactor for over 60 enzymes that catalyse reactions of amino acids, and so the absolute requirement is related to the rate of amino acid metabolism. It is also a cofactor for glycogen phosphorylase, and has roles in the modulation of steroid hormone action and the regulation of gene expression. Primary dietary deficiency of vitamin B₆ is rare, since it is widely distributed in foods (although in some vegetable sources, it may be present in a biologically unavailable glycoside form), body stores of the vitamin are reasonable and it is synthesized by intestinal flora. The first definite cases of deficiency described were in infants fed a milk preparation that had been overheated during manufacture, destroying much of the vitamin B₆. Some (but not all) of the infants developed neurological symptoms, including convulsions, which responded to vitamin B₆ supplements. Human volunteers and animals fed a B₆-deficient diet develop neurological symptoms together with changes in the mouth and skin. The changes in the nervous system are presumably due to the role of vitamin B₆ in the metabolism of neurotransmitters. Certain drugs are known to interfere with vitamin B₆ metabolism, for example isoniazid, which binds to pyridoxal-5-phosphate reducing its availability, and penicillamine; vitamin B₆ supplementation during drug treatment is advised.

Pharmacological doses of pyridoxine may be useful in certain rare inherited conditions, for example hypochromic sideroblastic anaemia, but in others (e.g. premenstrual tension), the evidence for benefit is less good, and in very high doses, pyridoxine may itself cause a severe peripheral sensory neuropathy.

FIGURE 10.6 ■ Structures of various forms of vitamin B₆.

Pantothenic acid. Pantothenic acid is a constituent of the coenzyme A molecule and is thus involved in many major metabolic pathways. It is also present (not as part of coenzyme A) in fatty acid synthase.

The name means 'available everywhere' and this reflects its distribution in foods. Particularly rich sources include liver, meat, cereals, milk, egg yolk and fresh vegetables. Spontaneous isolated deficiency in man has never been proven, but experimental deficiency in human volunteers leads to vomiting, malaise, abdominal distress and burning cramps, and later on, tenderness in the heels, fatigue and insomnia.

Biotin. Biotin acts as a coenzyme in a number of one-carbon transfer reactions. ATP hydrolysis is coupled to the carboxylation of the biotin to form N-1'-carboxybiotin, which then carboxylates the substrate of the enzyme. Examples include pyruvate carboxylase and acetyl-CoA carboxylase, so biotin is important in gluconeogenesis and lipogenesis and also plays a part in the catabolism of branched chain amino acids.

Biotin is widely distributed in foods, with offal, milk and eggs being particularly rich sources. Intestinal bacteria synthesize biotin, but it is not clear how much of this is available for absorption. Deficiency has been described in patients on parenteral nutrition deficient in biotin and also in people who consume large amounts of raw eggs: egg white contains a glycoprotein called avidin that binds biotin and prevents absorption. Such patients develop a fine scaly dermatitis and hair loss, but isolated biotin deficiency in man is otherwise unknown, apart from a suggestion that subclinical deficiency in pregnant women may be an aetiological factor in some birth defects. Even large doses of biotin appear to be non-toxic.

Vitamin C. Vitamin C comprises L-ascorbic acid and the oxidized derivative, L-dehydroascorbic acid. In animal tissues, 90% is in the form of ascorbic acid, but the two are interconvertible and both are biologically active. Man is unusual in that most other mammals can synthesize ascorbate from D-glucose or D-galactose. Guinea pigs cannot and so form a useful experimental model.

Vitamin C is an important aqueous antioxidant in the body, although its relationships with other antioxidants remain to be fully elucidated. Its best characterized role is in the post-translational reduction of proline to form hydroxyproline. This imino acid is relatively uncommon in the body apart from in collagen, where it is essential, and one of the effects of vitamin C deficiency is impaired collagen formation. Vitamin C also assists in the intestinal absorption of non-haem iron, by keeping it in the ferrous (Fe^{2+}) form.

The main dietary sources of vitamin C are citrus and soft fruits, together with the growing points of certain vegetables, although, in the UK, potatoes also make a significant contribution. It is one of the most labile of nutrients, being destroyed by oxygen, metal ions, alkaline conditions, heat and light: cooking reduces the amount of dietary ascorbic acid available for absorption.

Deficiency of vitamin C causes scurvy, with perifollicular (or more extensive) haemorrhages, bleeding gums, poor wound healing, failure of hair follicle eruption and

anaemia. Factors assumed to contribute to the anaemia include blood loss, impaired iron absorption and a reduction in the capacity of ascorbic acid to protect folate from irreversible oxidation. Patients with scurvy may also experience changes in personality and psychomotor performance: it is thought that these are due to impaired synthesis of catecholamines by dopamine β -hydroxylase, a vitamin C-dependent enzyme. Dietary deficiency can occur, particularly if food is overcooked, and requirements are increased in certain patients, for example following trauma or surgery or in the presence of certain drugs, for example sulfasalazine, aspirin. Smokers also seem to have an increased turnover of vitamin C.

There have been many attempts to demonstrate benefits from an excess intake of vitamin C (i.e. higher than that required to prevent scurvy) in a diverse range of conditions. None of these has yet been proven, although as one of the proponents, Linus Pauling, was a double Nobel laureate, they remain widely held beliefs. Potential risks of very high doses include diarrhoea and increased formation of urinary oxalate, although the latter may be an *in vitro* effect in stored urine, and thus not a risk factor for renal stones.

Other organic substances. Food contains many other organic substances besides those described thus far. There is, however, no convincing evidence that any of these are essential nutrients in man, although some (e.g. choline, pangamic acid, laetrile) have been proposed as such, and choline is now regarded as an essential nutrient in the USA. Carnitine, which is involved in the transport of acyl-CoA across the mitochondrial membrane in fatty acid oxidation, is synthesized in the liver in adults, but there may be a dietary requirement in premature infants.

Some organic (and inorganic) substances are deliberately added to foods. They include preservatives, flavourings, colourings, sweeteners and processing aids. In the UK, there are strict legislative controls over the use of such additives.

There has been much interest in recent years in foods that contain nutrients that have benefits beyond their purely nutritional properties (sometimes known as functional foods), and some of these are considered further in Chapter 11.

Other organic compounds found in foods (e.g. alcohol, caffeine, solanine) have potentially toxic pharmacological effects. Solanine is a plant glycoalkaloid that occurs in small amounts in all potatoes, but at much higher concentrations in green potatoes. It acts as a cholinesterase inhibitor, and ingestion of large amounts causes abdominal pain followed by nausea, vomiting and respiratory problems that can be fatal. Cholinesterase activity returns to normal within a few hours of consumption of small amounts of solanine, so there is not usually any cumulative ill effect from repeat ingestion of small doses. Other toxins are formed in food as a result of processing or cooking it: for example 3-monochloropropane 1,3-diol (from industrial processing of vegetable protein), acrylamide 2-propenamide (from frying or baking foods) and polycyclic aromatic hydrocarbons (in foods exposed to wood smoke) are all carcinogenic, at least in animals.

Trans fatty acids are formed during the hydrogenation of vegetable and fish oils, although they are also present naturally in meat and dairy products: an increased intake is associated with increased cardiovascular risk.

Contaminants in food have the potential to cause harm. Examples include bacteria, for example *Campylobacter jejuni*, which causes gastroenteritis; moulds, for example patulin, which can grow on apples, and aflatoxins from moulds found in foods, including peanuts and corn, which are carcinogens particularly associated with hepatic cell carcinoma.

Trace elements

Minerals are important nutrients, some being major body constituents while others (the trace elements) are required in much smaller amounts. The trace elements that are known to be essential (zinc, copper, selenium, molybdenum, manganese and chromium) are considered here, although there are a number of others (e.g. arsenic, cadmium, fluorine, lead, lithium, nickel, silicon, tin, vanadium) that have been suggested as having physiological roles, but which have yet to be proven to be essential.

Zinc. Zinc is an essential component of over 200 enzymes, having both catalytic and structural roles. Some enzymes appear to be more sensitive to zinc deficiency than others, and it is of relevance to the clinical biochemist that plasma alkaline phosphatase activity tends to decrease when zinc is deficient. Zinc is also incorporated into proteins that do not have enzyme activity; for example, it has a role in maintaining the aggregation of presecretory insulin granules and has direct and indirect roles in reducing free radical activity. Thus, zinc is important in most of the major metabolic processes in the body, including protein synthesis, cellular replication and collagen synthesis.

The best dietary sources of zinc are red meat, shellfish, nuts and cereals, although processing food tends to remove zinc (e.g. white flour is a poor source). Only about 30% of dietary zinc is absorbed and there is a significant enterohepatic circulation. Absorption occurs through both active and passive processes. Some zinc remains in enterocytes bound to a metallothionein, the proportion depending on the amount of metallothionein present. When the body content of zinc is high, metallothionein synthesis is stimulated, reducing the amount of zinc entering the circulation.

Although zinc is present in all body tissues, 60% is in skeletal muscle, 30% in bone and 4–6% in the skin. In the circulation, 80% is contained within red cells, while in the plasma, up to one-third is firmly bound to α_2 -macroglobulin and most of the remainder is loosely bound to albumin. The main route of excretion is in the faeces.

As might be expected from the diversity of its functions, deficiency of zinc tends to have a wide range of effects. Dermatitis and hair loss are frequent, together with growth retardation and poor wound healing. Anorexia, lethargy and impaired sensations of taste and smell may also occur. Immune function may be depressed, and since zinc has a role both in the hepatic synthesis of

retinol-binding protein and in the conversion of retinol to retinal in the retina, night vision may be impaired.

Zinc deficiency can arise from inadequate intake (e.g. during parenteral feeding), impaired absorption or increased losses (e.g. through a gastrointestinal fistula). Zinc deficiency is an important part of protein–energy malnutrition and may limit weight gain during refeeding unless adequate amounts are provided. Requirements for zinc are increased in premature infants, during pregnancy and lactation and following trauma. The autosomal recessive disease acrodermatitis enteropathica is due to severely impaired intestinal absorption of zinc. Affected children have a scaly dermatitis (often secondarily infected), diarrhoea and impaired growth, all of which respond to oral zinc supplements in relatively high doses.

Chronic ingestion of high zinc intakes in otherwise healthy people may lead to features of copper deficiency (e.g. microcytic anaemia, neutropenia). This is because the induction of metallothionein synthesis in enterocytes by zinc results in increased binding of copper to metallothionein, which prevents its transfer to the circulation. (This effect is utilized in the treatment of some patients with Wilson disease; see Chapter 14.) Acute toxicity has been recorded following ingestion of water with a high zinc content, or the use of such water in renal dialysis.

Copper. The main role of copper is as a component of copper metalloenzymes, of which there are many. In the synthesis of collagen and elastin, the cross-linking reactions require various copper-containing amine oxidases, and copper is also involved in the oxidation of Fe^{2+} to Fe^{3+} during haemoglobin formation and the binding of iron to transferrin. Examples of other copper-containing enzymes include superoxide dismutase, tyrosinase and cytochrome *c* oxidase.

Copper is widely distributed in the diet, occurring, for example in shellfish, liver and kidney, with lesser amounts in milk, meat and cereals and very little in processed foods. Not all dietary copper is absorbed, the proportion varying from 35% to 70% for reasons that are still not fully understood, although an increased intake of zinc reduces absorption (see above). From the gut, copper is carried to the liver bound to albumin and there is incorporated into caeruloplasmin. Caeruloplasmin is then secreted into the blood and accounts for 80–90% of the circulating copper. The main route for excretion of copper is in the bile, with very little in the urine unless renal damage is present or copper-binding substances (e.g. penicillamine) have been given. Normal copper homeostasis, therefore, depends on the balance between intestinal absorption and biliary excretion.

Overt copper deficiency is rare, since the liver contains substantial stores, but has been seen in malnourished children and in adults on long-term total parenteral nutrition (TPN). Features include neutropenia and skeletal fragility, with a microcytic hypochromic (iron-resistant) anaemia if the deficiency is prolonged. In adults, subclinical deficiency may be a risk factor for cardiovascular disease – in animals, copper deficiency can cause vascular and myocardial disease, together with hypercholesterolaemia. There is also a rare X-linked recessive disorder known as Menkes disease, in which there is impaired copper

absorption and renal copper wasting. Affected boys show progressive developmental and mental retardation, their hair becomes depigmented and sparse and their bones are abnormal. Parenteral copper can restore both circulating and tissue concentrations, but is otherwise ineffective and death typically occurs by the age of three.

Excess copper in the body is toxic, as demonstrated by Wilson disease, which is discussed in Chapters 13 and 14. However, copper overload purely from chronic dietary excess is rare, although it has been described in association with contaminated water supplies. Although a problem of toxicology rather than nutrition, acute ingestion of copper salts can cause nausea, vomiting and diarrhoea, with intravascular haemolysis in severe cases.

Selenium. Selenium is essential to the activity of the enzyme glutathione peroxidase, which is an important component of cellular antioxidant capacity. Selenium deficiency results in both reduced enzyme activity and reduced amounts of the enzyme protein, although when the intake of selenium is increased, there is an increase in glutathione peroxidase activity only up to a plateau level. Other selenoproteins are known, including iodothyronine deiodinase, which catalyses the conversion of thyroxine to tri-iodothyronine, and thioredoxin reductase, which reduces nucleotides in DNA synthesis.

Cereals, meat and fish contribute most of the dietary selenium, mainly in the form of the amino acids selenomethionine and selenocysteine. About half of dietary selenium is absorbed, the main route of excretion being in the urine. Selenium deficiency, when it occurs, is generally the result of a low intake and has been described in patients on long-term parenteral nutrition and children with certain inherited metabolic diseases treated with very restrictive therapeutic diets, although such occurrences are rare. In certain areas of China, where the soil selenium is low, there is endemic deficiency of selenium and a selenium responsive cardiomyopathy (Keshan disease) has been described. However, a low average selenium intake has also been reported in other countries, with no specific selenium responsive diseases being described. Nonetheless, more recent epidemiological evidence has suggested an increased incidence of cancer in low selenium areas, and some countries (e.g. Finland) now add selenium to the fertilizers used for arable crops.

Excess dietary selenium causes toxicity in livestock, but it is only in selenium-rich areas of China that convincing endemic dietary selenosis has been described in man. Features include 'garlic breath' (due to dimethyl selenide), deformity and loss of hair and nails, skin and gastrointestinal symptoms and, in severe cases, neurological problems. Similar features have been seen in people taking selenium supplements that accidentally contained vastly more selenium than they were supposed to. In general, selenium toxicity seems to begin at intakes only ten times the normal intake, although the threshold may be even lower in the presence of certain diseases, for example cystic fibrosis.

Molybdenum. Molybdenum combines with molybdopterin to form molybdenum cofactor, essential for the activity of the enzymes xanthine oxidase, aldehyde oxidase and sulphite oxidase.

The dietary requirement for molybdenum is very small and it is present in most human diets in meats, legumes and grains, so that dietary deficiency is exceptionally rare. Molybdenum deficiency has been reported in a patient with Crohn disease on TPN, who developed fatigue, somnolence and amino acid intolerance that responded to molybdenum supplements. There is a rare, autosomal recessive, inherited deficiency of molybdenum cofactor, which results in severe neurological abnormalities, mental retardation, lens dislocation and xanthinuria (see Chapter 9) in affected children, but no clinical improvement results from dietary supplementation.

High dietary intakes of molybdenum may be associated with altered purine metabolism (an increased incidence of gout has been noted in some populations) and with poorly understood changes in copper metabolism.

Manganese. Manganese is a component of certain enzymes (e.g. pyruvate carboxylase, mitochondrial superoxide dismutase, arginase) and is also an activator of many others (e.g. hydrolases, glycosyl transferases, kinases, decarboxylases), so deficiency could potentially affect the metabolism of carbohydrates, glycosaminoglycans and cholesterol.

Good dietary sources of manganese include leafy vegetables, unrefined cereals and tea, although only a small proportion (3–4%) is actually absorbed. The body content of manganese is low, with about a quarter of this relatively fixed in bone and the highest tissue concentrations in the pancreas and liver. The usual route of excretion is in the bile.

Deficiency of manganese in animals causes poor growth, defective collagen formation, depressed reproductive function, impaired glucose tolerance and neurological deficits, but the effects of dietary deficiency in man are less well established. A case of probable manganese deficiency occurred in a man on long-term TPN (who had a decrease in vitamin K-dependent clotting factors, hypocholesterolaemia, mild dermatitis and a slight change in hair colour). Dietary toxicity of manganese is unlikely since absorption is low and excretion in the bile and urine efficient. Toxicity has been recorded in manganese miners, who develop a condition clinically similar to Parkinson's disease, but this appears to be due to absorption from manganese ore dust in the lungs rather than from the intestine. High signals on T1-weighted magnetic resonance imaging (MRI) scans of the brain, consistent with manganese deposition, have been well documented in patients on long-term TPN in association with evidence of Parkinson disease and neuropsychiatric abnormalities.

Chromium. The main biological role of chromium in man appears to be to potentiate the action of insulin, as part of a low molecular weight chromium binding substance (chromodulin). Chromium may also be important in gene expression, lipoprotein metabolism and in maintaining nucleic acid structure.

Dietary sources of chromium include yeast, meat, whole grains, mushrooms and nuts. Absorption is very low and urinary excretion increases with intake. Human deficiency was first observed in long-term parenteral nutrition patients who developed insulin-resistant glucose intolerance

and neuropathy. In animals, deficiency also causes impaired growth and fertility and hypercholesterolaemia, but these have not been seen in humans. In general, there is no conclusive evidence that diabetes and hypercholesterolaemia are usually associated with chromium deficiency, nor that supplementation ameliorates these conditions.

As a normal dietary constituent, chromium toxicity seems unlikely to occur. However, the absorption of chromium picolinate, which is marketed as a dietary substitute, is higher than from other dietary sources and there have been reports of adverse effects, including renal failure. Industrial toxicity of chromium salts is well established and, recently, local and systemic effects of chromium and cobalt from metallic joint prostheses have been recognized.

Fibre

Dietary fibre is a term used to describe carbohydrate polymers that are not hydrolysed by the endogenous enzymes of the gastrointestinal tract. These include edible carbohydrate polymers naturally occurring in the food, carbohydrate polymers that have been obtained from food raw materials by artificial means and certain synthetic polymers. Lignin (a complex carbohydrate polymer containing aromatic residues) is also included in the definition. Dietary fibre is, therefore, a mixture of substances, including non-starch polysaccharides (NSPs), and starch and oligosaccharides that are resistant to digestion. Most dietary fibre consists of NSPs, and consideration of the NSP content of foods is probably the most useful approach to fibre, particularly since NSPs can be measured with more specificity than total dietary fibre.

Non-starch polysaccharides are a complex group of polymers that can be classified in a number of ways, for example according to the constituent monomers or whether the resulting polymer is soluble or not. Cellulose is a polymer of glucose but, unlike starches, is an unbranched β -1,4 glucan. It constitutes about a quarter of the NSP intake of an average UK diet and about half of the insoluble NSP. Other, non-cellulosic, polysaccharides tend to be made up of hexoses (e.g. glucose in the soluble glucans), pentoses (e.g. arabinose and xylose in the partly soluble arabinoxylans) or uronic acids (e.g. galacturonic acid in the soluble pectins).

The exact composition of dietary NSPs depends on their source. The richest sources are whole grain cereals, with wheat, maize and rice containing mainly insoluble forms, and oats, barley and rye a significant proportion of soluble NSPs. Fruit and vegetables have a higher water content than cereals and so the proportional NSP content tends to be lower, with pulses and nuts probably being the next best sources after cereals. Vegetables tend to contain roughly equal proportions of the soluble and insoluble fractions, but in fruits, this varies widely, with uronic acid-derived NSPs being the main soluble form.

A low dietary fibre intake has been associated with an increased incidence of constipation, diverticular disease, appendicitis, gallbladder disease and carcinoma of the large bowel, although the precise basis of these associations is difficult to work out.

Analysing the benefits of dietary fibre is complicated by the fact that its exact quantification in food

is technically difficult and that studies have tended to examine different types and combinations of fibre in different populations. A recent meta-analysis found an inverse association between the intake of dietary fibre, cereal fibre and whole grains and the risk of colorectal cancer, but no association with intake of fibre from fruit, vegetables or legumes. Possible mechanisms for this protective effect include an increase in stool bulk with dilution of faecal carcinogens and decrease in transit time with reduction in contact of carcinogens with the colorectal epithelium. Bacterial fermentation of fibre leads to the production of short chain fatty acids, which may have an additional protective effect by reducing intra-luminal pH. A similar inverse association between the intake of dietary fibre and breast cancer risk has been shown and inhibition of intestinal reabsorption of oestrogens with increased faecal excretion has been postulated as the basis of this.

Certain of the soluble NSPs have also been associated with short-term decreases in plasma glucose, insulin and cholesterol concentrations, but as yet there is no firm evidence either for a dietary lack of NSPs being implicated in the pathogenesis of type 2 diabetes or hyperlipidaemia, or for a role for dietary NSPs in the management of these conditions, other than the fact that a high dietary NSP intake tends to be a marker for a diet more in line with current 'healthy eating' concepts. Higher intake of dietary fibre is often associated with other lifestyle factors such as increased physical activity, lower alcohol and dietary fat consumption and lower prevalence of obesity, which may act as confounding factors in evaluating its role.

High dietary fibre intakes in infants and young children may displace energy-rich foods and restrict growth. In adults, high dietary intakes of NSP-rich foods are probably not harmful, although they may cause flatulence, and there is a possible increase in the risk of mechanical bowel problems such as colonic volvulus. Divalent cations can bind to certain constituents of NSPs, for example to uronic acid residues, or to associated phytates, but this does not seem to cause mineral deficiency on a mixed diet. However, caution should be exercised in recommending dietary fibre supplements, particularly those high in phytates, to populations with borderline mineral balance, for example unprocessed bran for the elderly.

ASSESSMENT OF NUTRITIONAL STATUS

General

It is important to be able to assess nutritional status, not only in large surveys attempting to define dietary reference values, but also to determine whether individual patients' nutritional needs are being met, to identify patients likely to have increased morbidity and mortality without nutritional support, and to monitor progress with time.

However, the wide range of individual nutrients, and the fact that nutritional status is reflected in all body compartments, not all of which are easily accessible to

measurement, means that precise assessments are difficult to make. The various techniques that are used include:

- clinical assessment
- dietary assessment
- measurement of anthropometric indices
- functional assessment
- laboratory-based techniques.

Clinical assessment

Evidence of nutritional disorders may become apparent during the normal clinical processes of history taking and physical examination. The history should ascertain normal food intake and dietary preferences, the patient's usual weight and any unexplained weight changes. Any difficulties in chewing or swallowing are important, together with gastrointestinal symptoms such as anorexia, nausea, vomiting or altered bowel habit. In the past medical history, any chronic disease may have effects on nutritional status, and surgery involving the gastrointestinal tract or associated organs may also be of importance. Chronic use of alcohol or drugs (therapeutic or otherwise) may have nutritional implications, and socio-economic factors are important in terms of availability of foodstuffs, adequacy of preparation and general support.

Physical examination may reveal clinical signs suggestive of generalized nutritional depletion (e.g. muscle wasting, oedema); evidence of deficiency of specific nutrients as described above may also be present.

Dietary assessment

Dietary assessment involves reviewing the intake of food, and its individual dietary components, and comparing the amount consumed with reference values to see whether deficiency or excess is likely. To be maximally accurate, this would involve weighing all food eaten and analysing its chemical composition, which is clearly impractical for clinical purposes. Hence, an approximation of food intake must be arrived at and reference then made to standard food tables to calculate nutrient content (see Ashwell, in Further reading, below).

Methods of dietary assessment can be divided into those that record current intake, recall past intake or estimate typical intake. Recording current intake can be achieved in a quantitative way in which all food is weighed or measured prior to being eaten. However, this is intrusive even for a short period and an alternative technique is for the patient to describe the amount of food eaten; photographic atlases are available to improve accuracy. Dietary recall methods involve asking the patient to recount everything consumed, usually in the previous 24h. Whilst these methods lack accuracy and tend to underestimate food intake they can reveal major areas of deficiency, or excess, requiring further evaluation. Food frequency questionnaires evaluate typical food consumption over a longer period. They can be particularly useful for population studies, for example assessing vitamin D consumption in the elderly.

TABLE 10.2 Body mass index (BMI)

BMI	Description	Grade of obesity or chronic energy deficiency	BMI is calculated from the formula
			$\frac{\text{weight in kg}}{(\text{height in metres})^2}$
<16	Chronic energy deficiency	III	
16–16.9	Chronic energy deficiency	II	
17–18.4	Chronic energy deficiency	I	
18.5–24.9	Desirable		
25.0–29.9	Overweight (or pre-obese)		
30.0–34.9	Obese	I	
35.0–39.9	Obese	II	
>40.0	Obese	III	

The 'desirable' and other ranges shown are for adult white individuals – the ranges are probably different for other racial groups, for example in Asians, the risks associated with being overweight begin to increase above 23 kg/m².

Anthropometric measurements

Clinical assessment can often indicate under- or overnutrition. However, a previously well nourished patient may be in a negative nutritional state for a long time before appearing clinically undernourished. Anthropometry comprises measurements of the human body and there are several anthropometric indices that are useful nutritional indicators as a baseline for initial assessment and as tools for ongoing monitoring.

Height and weight. In adults, body weight can be used as a measure of nutrition in various ways. An individual's weight can be compared against 'ideal' or desirable weight using formulae or tables, although it is now usual to calculate the body mass index (BMI) (see Table 10.2) in this context. The BMI can be used to grade the severity of obesity or of chronic energy deficiency but as it cannot distinguish between fat mass and lean mass it can be unrepresentative in patients with a large muscle mass, for example athletes, or in patients with an increased weight due to fluid retention. Variations in BMI between ethnic groups are also documented. In situations when measurement of height is not possible (e.g. immobility, spinal disorder), alternative indices such as the demispan – the distance between the index/middle finger web and the sternal notch – can be used to calculate BMI.

In ill patients, calculation of weight lost as percentage of usual weight can be useful, weight loss of more than 10% being an indicator of poor clinical outcome. However, determination of weight loss by history has been proven to be inaccurate.

In the UK, it is recommended that all patients are screened for nutritional risk at presentation to a doctor or other healthcare professional, and, in in-patient settings (both in hospitals and in nursing homes), at regular intervals thereafter. A suitable tool for this purpose is the Malnutrition Universal Screening Tool (MUST), which considers weight and unintentional weight loss, the time over which nutrient intake has been reduced and/or the

likelihood for impaired nutrient intake in the future (see Further reading, below, for more details).

In hospitalized patients, serial weight measurements are valuable in monitoring nutritional status, particularly where nutritional support is being provided. Acute changes are invariably due to changes in fluid balance (unless poor technique is responsible), but longer-term trends reflect tissue changes. As long as the patient is ambulant, weight measurements should be simple to obtain and record, although this may be surprisingly difficult to achieve on a busy hospital ward.

Nutrition is an important factor in growth and, in children, measurement of height and estimation of rate of growth is an important part of the assessment of nutritional status, in addition to measurement of weight.

Circumference measurements. In patients who are confined to bed, either because of debility or because movement is restricted by multiple fluid lines or splints, weight measurements are difficult to obtain unless the patient is in a special (and expensive) weighing bed. In these circumstances, some idea of tissue bulk may be obtained by a mid-arm circumference (MAC) measurement made with a tape measure. The measure should be placed round the non-dominant arm, at a point midway between the acromion (shoulder tip) and the olecranon process (point of the elbow). Age- and sex-related reference standards are available for the raw measurements, which include muscle, fat and bone or attempts can be made to refine the measurement to reflect muscle mass alone. The first stage is to correct for fat by including the triceps skinfold (TSF, see below) measurement and using the formula $(MAC - (\pi \times TSF))$ to derive the mid-arm muscle circumference. This can be further manipulated to give uncorrected muscle area, and finally an adjustment made for the contribution of the humerus, to give corrected muscle area. The latter can then be used to estimate total body muscle mass, although given the difficulties in making the two original measurements accurately, the margin of error by this stage is quite high. In the research environment, dual-energy X-ray absorptiometry (DEXA) is being used to make similar measurements of body composition.

While these calculated values may be useful in epidemiological surveys, in nutritional support the initial MAC measurement alone may help to indicate whether support is required, and serial measurements help to assess the success of treatment, although short-term changes are more likely to be due to imprecision in measurement than changes in tissue bulk. Measurements of calf circumference can be used in a similar way.

Another 'circumference' parameter that may be useful in assessing the health risks of moderate obesity is to measure waist and hip circumferences and calculate the waist:hip ratio. This reflects the distribution of fat rather than the degree of obesity; the risk of ischaemic heart disease and stroke rises sharply with waist:hip ratios of more than 1.0 for men and 0.8 for women. Even more simply, measurement of waist circumference alone can be used in this context, with a significant increase in cardiovascular risk being associated with waist measurements of over 102 cm in men and 88 cm in women (in Caucasian populations).

Skinfold thickness. Measurement of skinfold thickness, obtained using calipers, is useful in assessing and monitoring nutritional status in patients who cannot be weighed, and also has a place in epidemiological surveys. However, the technique is prone to large variations, both within and between observers. The imprecision arises in identification of the exact location for measurement; the way the skinfold is picked up; the way the calipers are placed on the fold; the compression of the fold by the calipers and the exact timing of the reading. Some improvement in performance may be achieved by taking the mean of three readings, usually on the left (or non-dominant) side. As with circumference measurements, the presence of oedema at the measurement site may be a further confounding factor.

A variety of sites have been used for skinfold measurement, but the most common are triceps, biceps, subscapular and suprailiac. Equations are available for calculation of total body fat from these measurements (usually for research purposes), but this assumes that subcutaneous fat reflects total body fat, which is not always the case: obese men tend to lay down more intra-abdominal fat than women, and visceral fat and subcutaneous fat have been shown to be biologically distinct. In clinical practice, body weight is more useful than skinfold thickness in the management of obesity, but in undernourished patients the latter may be useful. Age- and sex-related reference standards are published (e.g. for triceps skinfold thickness) and so measurement at presentation may identify severe malnourishment: a triceps skinfold of <5 mm almost always reflects low body fat stores. Serial measurements can help in monitoring nutritional support but, again, short-term changes are more likely to reflect imprecision in measurement than sudden changes in fat stores.

Functional assessment

The effects of nutritional status on certain aspects of bodily function can be used in the assessment of undernutrition, although with variable degrees of success. The best example is probably the effect of haematinic deficiency on red blood cell morphology where, for example a hypochromic, microcytic picture may be the first indication of iron deficiency and macrocytosis of vitamin B₁₂ or folate deficiency (see Chapter 26).

Functional tests of muscle mass have also been used, for example grip strength, isometric knee extension and response to electrical stimulation. However, while muscle strength correlates with muscle mass in normal subjects, there are many non-nutritional factors that can cause weakness in sick patients, and malnutrition alone has to be quite severe before strength diminishes. There is also the possibility that repeated measurements may have a training effect on the muscles involved.

Visceral protein is sometimes disproportionately decreased in protein deficiency and various measures of visceral function have been used in nutritional assessment. Two of these are discussed below.

Hepatic secretory proteins. The liver synthesizes most of the circulating plasma proteins (apart from immunoglobulins) and, in epidemiological studies, there

is a clear correlation between plasma concentrations of these proteins and other markers of malnutrition. For example, in adults who are otherwise well, a plasma albumin <35 g/L and a plasma transferrin <1.5 g/L usually indicate protein malnutrition. Since most of these proteins can be measured quite easily, there is a temptation to use them as nutritional markers in individual patients, but there are many pitfalls for the unwary.

Albumin is probably the most frequently measured plasma protein and low concentrations may reflect a deficiency in dietary protein intake. However, it must be remembered that decreased synthesis may be due to other factors, for example liver disease, and that the plasma concentration is also affected by fluid balance, loss of protein from the body, tissue catabolism and distribution of albumin across the various body compartments. It should also be remembered that, while the intravascular concentration of albumin is relatively high, more than half of the total mass of albumin is actually extravascular. It is noteworthy that in uncomplicated starvation, plasma albumin concentrations may remain normal for a relatively long period (the fractional catabolic rate decreases), whereas in sepsis, the concentration can fall significantly over a much shorter period.

Even in circumstances where the plasma albumin concentration does reflect nutritional status, the relatively long half-life (20 days) means that it does not respond to rapid changes and so measurements of other plasma proteins with shorter half-lives have been used. These include transferrin (9 days), prealbumin (1–2 days) and retinol-binding protein (10 h), but unfortunately, these all have similar drawbacks to albumin and are also affected by factors such as the acute phase response, oestrogen concentrations and factors relating to their own specific function (e.g. iron deficiency in the case of transferrin). Serial determinations may be of more use than single measurements, and measurement of a marker of the acute phase reaction (e.g. C-reactive protein) at the same time may help in interpretation. In clinical practice, measurement of these proteins rarely contributes to the management of individual patients, and failure to appreciate their limitations may lead to inappropriate decisions being made.

The immune response. Malnourished people are more susceptible to infections. Plasma immunoglobulin concentrations are generally maintained, but cell-mediated immunity may be impaired. The circulating absolute lymphocyte count is often low (<2.0 × 10⁹/L) in malnutrition, although this is a very non-specific finding.

Delayed cutaneous hypersensitivity testing against common allergens has been used to assess malnutrition, but many non-nutritional factors (e.g. infection, malignancy, radiation, surgery, drugs) affect the response and, in any case, the results may not be reproducible. In vitro tests of T cell function may be an alternative, but in clinical practice neither of these approaches is in common use.

Laboratory-based assessment of individual nutrients

Energy

Laboratory-based techniques are not in general use for the assessment of energy stores, whether of fat or

carbohydrate. However, there are techniques for the measurement of energy expenditure that may be of use in assessing how much energy to provide as part of nutritional support.

Direct calorimetry measures heat loss from the body, which can be used to derive the metabolic rate assuming that body temperature remains constant and no external work is performed. The technique involves the subject remaining in a special, insulated room equipped for heat exchange, so is not applicable in general clinical practice. Indirect calorimetry measures oxygen consumption and carbon dioxide production, and from these the respiratory quotient can be calculated, together with the energy expenditure (Fig. 10.7). This is the technique used by the ‘metabolic measurement carts’ that have been popular in some intensive care units.

The use of doubly-labelled water (containing the stable isotopes ²H and ¹⁸O) has produced new data on total energy expenditure in free-living individuals, but the technique is not suitable for the assessment of patients.

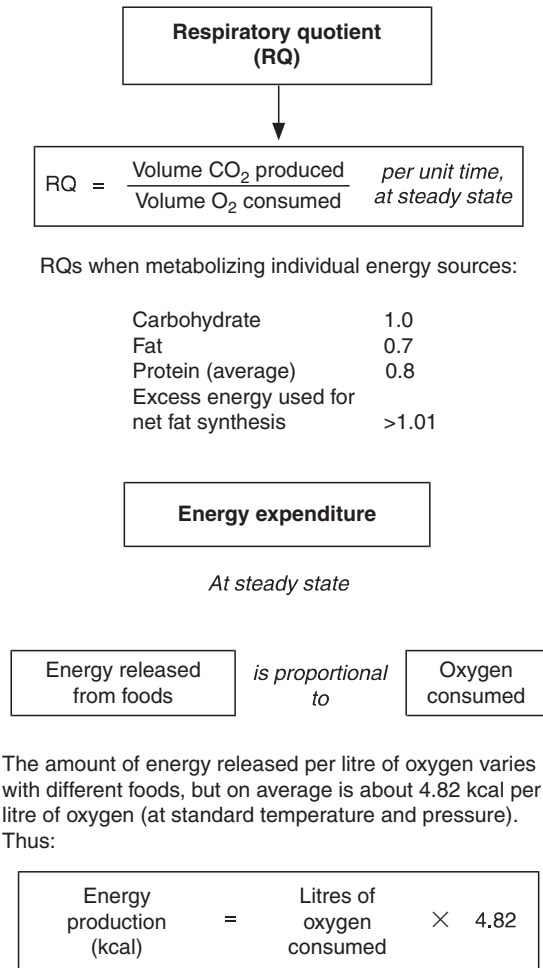

FIGURE 10.7 ■ Calculation of respiratory quotient and energy expenditure.

Heart rate can also be used as an index of energy metabolism, but although the measurement is obviously very much easier, the relationship between heart rate and energy expenditure is not linear and there are many confounding factors, so it can be useful in studies of groups of people but not in individuals.

Basal metabolic rate (BMR) can be estimated for healthy individuals from knowledge of age, sex, height and weight using the Harris–Benedict (Fig. 10.8), Schofield (Fig. 10.9) or similar equations and, for sick patients, suitable adjustment can then be made for disease state, pyrexia, mobility etc. However, the more severely ill the patient, the less likely it is that the calculated figure truly reflects total energy expenditure.

In disease-free individuals, the following formulae give an estimate of BMR in kcal/24h:

FIGURE 10.8 ■ Harris–Benedict equations for the calculation of basal metabolic rate (BMR).

As a simpler alternative to the Harris–Benedict equations, the following equations can be used to calculate BMR in kcal/24 h:

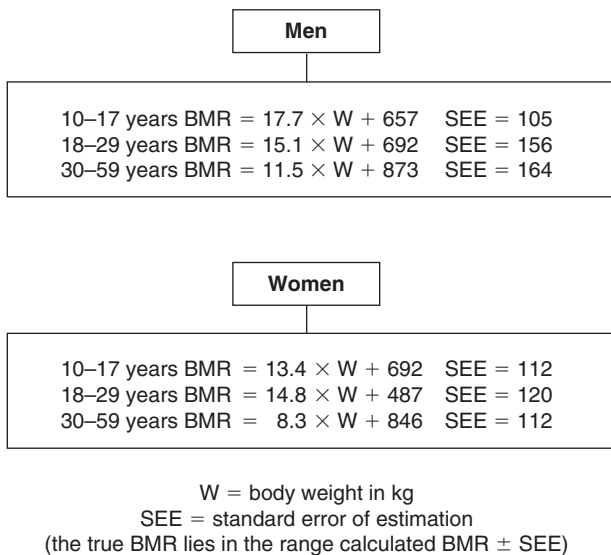

FIGURE 10.9 ■ Schofield equations for the calculation of basal metabolic rate (BMR) in kcal/24 h.

Protein

Laboratory-based tests for visceral protein have already been discussed under functional tests of nutritional status. However, there are a number of other tests that assess total body protein (predominantly muscle).

Total body nitrogen can be measured by neutron activation (an estimate of total body protein is simply obtained by multiplying this figure by 6.25) and this can demonstrate changes over a period of only a few weeks. However, the technique is expensive and involves a significant dose of radiation, so it is only used as a research tool. Almost all body potassium is intracellular; there is virtually none in adipocytes and potassium in the skeleton and red blood cells is not readily exchangeable, so exchangeable potassium measured using dilution of ⁴²K is a measure of fat-free mass. By monitoring both total body nitrogen and potassium, it can be shown that nitrogen losses in malnutrition are relatively higher from lean tissue (high potassium content) than from fibrous tissue (low potassium content).

Measurements of bioelectrical impedance have also been used to predict lean body mass. However, the technique actually measures total body water and the extension to lean body mass assumes a constant level of hydration in such tissue, which may not always be the case, particularly in sick individuals.

Outside the research environment, a direct measure of muscle mass may be obtained from the 24h excretion of creatinine, a metabolite of muscle creatine. This is sometimes corrected for height (the creatinine:height ratio) and standard values are available. However, urinary creatinine excretion does fluctuate (e.g. with exercise, pyrexia, meat intake) and the technique depends on complete urine collections and normal renal function, so that in practice, it is not widely used.

It may sometimes be useful to assess nitrogen balance. Nitrogen intake may require dietary analysis or, for patients on enteral or parenteral formulations, it will already be known. Nitrogen output for research purposes involves analysing stool and urine for total nitrogen content, but in the past, for clinical purposes, urinary urea nitrogen has been measured and standard adjustments made for urinary non-urea nitrogen and faecal nitrogen. This approach was valid for reasonably well patients (assuming the urine was not infected with a urea-splitting organism), but diverges further from the true nitrogen output of the more severely ill the patient, so its use cannot be recommended.

Vitamins

It is sometimes useful to assess body stores of fat-soluble vitamins, as outlined below, but only rarely necessary to measure the water-soluble vitamins (with the exception of vitamin B₁₂ and folate, see Chapter 26). This is because they are relatively non-toxic and, if deficiency is suspected, a trial of therapy is safe and simpler than trying to measure them. The interpretation of laboratory data is not without difficulty – some vitamins are affected by the acute phase response, for example vitamin D concentration may fall by up to 40% – so differentiation of true deficiency may be difficult. Measurement of concentrations of some vitamins in erythrocytes rather than plasma,

during the acute phase, has been shown to be more representative of body stores.

Vitamin A. The standardized definition of vitamin A deficiency is in terms of liver stores of retinol, but this is not a practical indicator. By convention, a plasma retinol concentration $<0.7 \mu\text{mol/L}$, is used to define deficiency. However, plasma retinol concentration tends to be maintained over a wide range of liver reserves, making it an insensitive detector of deficiency and as retinol is carried bound to retinol-binding protein (RBP) in the plasma, conditions reducing RBP concentration (e.g. liver disease) may lower plasma retinol concentration without reflecting decreased stores. The diagnosis of vitamin A deficiency is often made on clinical grounds. The response to a test dose of vitamin A may help to distinguish true deficiency from functional deficiency due to a lack of RBP. In the former, the plasma vitamin A concentration rises markedly within a few hours; in the latter it does not. Very high retinol intakes may increase the plasma concentration.

Plasma carotenes can also be measured and, in general, reflect dietary intake. Dietary assessment is usually all that is necessary for this, but measurement is occasionally helpful to establish whether an odd skin colouration is due to hypercarotenaemia or not.

Vitamin D. Patients with a nutritional deficiency of vitamin D may present with clinical symptoms and signs; suspicion may also be raised by the finding of an increase in plasma alkaline phosphatase activity. Plasma calcium may be low but is frequently within the reference range as a result of secondary hyperparathyroidism, which may result in a low plasma phosphate concentration.

The main storage form of vitamin D in the body is 25-hydroxycholecalciferol and this is also the main form in plasma, where it is bound to a specific binding protein. Measurement of plasma 25-hydroxycholecalciferol provides a useful indicator of vitamin D stores: the reference range for total 25-hydroxycholecalciferol is of the order of 50–140 nmol/L, although the result should be interpreted with regard to the time of year, as there can be a two-fold seasonal variation in temperate regions. Concentrations $<50 \text{ nmol/L}$ indicate vitamin D insufficiency that may benefit from supplementation, and values $<25 \text{ nmol/L}$ suggest deficiency.

It is also possible to measure the active metabolite of vitamin D (1,25-dihydroxycholecalciferol, calcitriol), although this is more difficult as the plasma concentrations are approximately 1000-fold lower than those of 25-hydroxycholecalciferol. Its synthesis is normally closely regulated and concentrations do not reflect vitamin D status. Such measurements tend only to be necessary in the investigation of rare, inherited disorders of vitamin D metabolism or action (see Chapter 30).

Vitamin D toxicity can occur if supplements are given, as the difference between appropriate and toxic intakes is fairly small. This is generally detected in the laboratory as hypercalcaemia that gets better when the supplements are reduced or stopped, but it is occasionally necessary to confirm the diagnosis with plasma vitamin D measurement.

Vitamin E. Vitamin E status is assessed by measurement of plasma tocopherol concentration, most commonly by high performance liquid chromatography. Increases in plasma lipoprotein concentrations tend to result in increases in plasma tocopherol, so it may be appropriate, in some circumstances (e.g. in patients with cholestasis or if the plasma tocopherol is found to be low in order to confirm deficiency) to express the result as a plasma tocopherol:cholesterol ratio.

Vitamin K. Although it is possible to measure vitamin K in plasma, the usual laboratory approach is to measure the plasma concentrations of the vitamin K-dependent clotting factors. In vitamin K deficiency, these are present in normal quantities, but in a non-functional state (proteins formed in vitamin K absence – PIVKA), and so a functional assay, conventionally the prothrombin time or international normalized ratio (INR), is used (although the activated partial thromboplastin time is also abnormal in vitamin K deficiency).

There is no generally available test of vitamin K excess, largely because its lack of toxicity makes it unnecessary.

Thiamin. The single most important factor in detecting thiamin deficiency is a high index of clinical suspicion, and the safest confirmatory test is a trial of thiamin supplements, since delay can be harmful in a deficient patient. However, assuming appropriate samples can be obtained without delaying treatment, there are laboratory tests that can be used to assess thiamin status.

Methods are now available for measurement of thiamine and its phosphate esters in whole blood, but because of the low concentration and consequent analytical problems, some laboratories still use functional tests of thiamin deficiency, the most common of which is probably measurement of red cell transketolase with and without the addition of thiamin pyrophosphate (TPP). In normal subjects, TPP enhancement of transketolase is up to 15%, but may be increased to as much as 25% in severe deficiency. Urinary thiamin measurement has been used, with low outputs being found in clinical deficiency states. Discrimination is said to be improved if the percentage excretion of a test dose is measured; a higher proportion is retained in deficiency.

Riboflavin. The laboratory approach to the assessment of riboflavin (vitamin B₂) status is similar to that taken with thiamin. Urinary excretion can be measured and an output of 0.5–0.8 mg/24 h probably indicates an adequate intake, but does not necessarily reflect total body content. Factors such as age, physical activity and illness can also influence urinary excretion. Discrimination may be improved by measuring the percentage excretion of a loading dose of riboflavin, an increased proportion being retained in deficiency states.

In the blood, about 90% of riboflavin is present in the red cells. This can be measured directly, but measurement of red cell glutathione reductase activity is probably more useful. The enzyme is flavin adenine dinucleotide (FAD) dependent, so that activity falls in riboflavin deficiency, but is restored on addition of FAD. An increase in activity of 30% or more confirms riboflavin deficiency. The test assesses long-term tissue riboflavin status and is

very sensitive. It cannot be used if there is coexistent red cell glucose 6-phosphatase deficiency.

Nicotinamide. Laboratory tests of nicotinamide status tend not to be entirely satisfactory, possibly because no specific functional test has yet been developed. Approaches used to date include measurement of whole blood NAD concentration and of urinary excretion of nicotinamide metabolites, in particular 1-methyl nicotinamide.

Vitamin B₆. A variety of biochemical techniques have been described for the assessment of vitamin B₆ status. Urinary excretion of 4-pyridoxic acid reflects immediate dietary intake and pyridoxal 5-phosphate in blood can also be measured, but indirect approaches are less technically demanding and have been more widely adopted.

In vitamin B₆-deficient subjects, the urinary excretion of xanthurenic acid shows a marked increase following an L-tryptophan load, and this is the basis of the tryptophan load test. This is relatively easy to perform and has been widely used, but interpretation of the results requires caution as there are a number of other factors that can affect tryptophan metabolism. The most useful test currently available is probably the measurement of red cell aminotransferase (e.g. aspartate aminotransferase) activity, with and without the addition of pyridoxal 5-phosphate, in a technique analogous to that used for the functional assessment of thiamin (red cell transketolase) and riboflavin (red cell glutathione reductase). Serum aminotransferase activities are also affected by vitamin B₆ deficiency, but the very wide fluctuations seen in disease states make them less useful than erythrocyte activities in this context.

Pantothenic acid. Tests of pantothenic acid status are rarely necessary and no biochemical test has become generally accepted. Pantothenic acid itself can be measured in urine and serum, the urinary excretion being more immediately affected by dietary intake. Assessment of the red cell content of coenzyme A may be a functional test of pantothenic acid status.

Biotin. Techniques have been described for the measurement of biotin in both urine and blood. However, these are not straightforward and, in practice, biotin status is rarely assessed biochemically.

Vitamin C. Vitamin C can be measured in plasma, white blood cells and urine. Unfortunately, none of these is entirely satisfactory in assessing vitamin C status. Plasma concentration tends to reflect recent intake and so will fall with decreased intake before body stores are depleted. Leukocyte (or buffy coat) vitamin C content probably reflects body stores better than the plasma concentration, but the measurement is technically difficult, requires large quantities of blood and, if the buffy coat content is measured, any abnormality in the relative proportions of white cells and platelets will introduce further error.

Urinary ascorbate can be measured relatively easily in a fresh sample, and output decreases quite markedly in deficiency. However, the technique is not very

specific and various ascorbic acid saturation tests have been devised to improve on this. These all assume that if body stores are depleted, most of a standard daily dose of ascorbic acid will be retained until stores are repleted, after which relatively large amounts of ascorbate appear in the urine. These tests are not perfect, but are simple to carry out and appear to be satisfactory if a clinical suspicion of vitamin C deficiency needs to be confirmed. An added advantage is that any deficiency is actually treated by the test.

Trace elements

There is a general problem in assessing body stores of trace elements, in that plasma concentrations are not necessarily related to tissue content, as is apparent in the following discussion.

Zinc. Assessment of body zinc status is not easy. Measurement of serum zinc concentration is probably the simplest approach, but the result is influenced by many things other than total body zinc. There is a diurnal variation with a peak at about 10.00 h, fluctuation with recent dietary intake and a fall with hypoalbuminaemia. It also tends to fall in disease: for example, in acute inflammation, interleukin-1 stimulates zinc uptake by the liver, although in tissue destruction, the zinc may be maintained as zinc is released from the tissues, even though net balance is actually negative as losses in urine increase.

Urinary zinc excretion is also difficult to interpret. Low values may reflect deficiency, but, even if environmental contamination can be avoided, normal or raised excretion does not exclude deficiency; urinary losses may even be the cause of the deficiency.

Since serum and urine zinc measurements are generally unsatisfactory, a variety of other approaches have been tried. Hair zinc is liable to environmental contamination (e.g. from certain shampoos), turns over relatively slowly and depends on the rate of hair growth. Erythrocyte zinc content responds only slowly to changes in zinc status, which can be rapid. (However, the high zinc content of red cells, in the enzyme carbonate dehydratase, is important, since it means that *in vitro* haemolysis increases the measured serum zinc concentration.) Changes in the plasma and tissue activities of zinc-dependent enzymes like carbonate dehydratase and alkaline phosphatase have given varying results. Leukocyte zinc content correlates well with muscle content, but its measurement is not easy and requires large quantities of blood.

Serum zinc remains a common, albeit unsatisfactory, measure of zinc status, although some authorities state that a serum zinc concentration <7 µmol/L is a clear indication of deficiency. When true deficiency is suspected, a therapeutic trial of zinc supplementation with careful clinical monitoring is probably the best approach.

Copper. The diagnosis of copper overload is discussed in Chapters 13 and 14. In the detection of copper deficiency, plasma copper concentration may be low, but deficiency may be masked because caeruloplasmin synthesis is increased in the acute phase response. Caeruloplasmin

is also increased in pregnancy and by exogenous oestrogens. Measurement of caeruloplasmin before and after moderate copper supplementation may be a useful technique; an increase confirming deficiency. Interpretation of copper concentrations in other body fluids and tissues is difficult when looking for deficiency, although changes in the activities of copper-containing enzymes like superoxide dismutase may prove to be useful functional tests of copper deficiency in the future.

Selenium. Plasma selenium concentration is an indicator of recent selenium intake, rather than body stores. Measurement of whole blood selenium concentration has been used but may give a false picture if there has been recent blood transfusion. Selenium in plasma is bound to lipoproteins, which may decrease in concentration in malnutrition, causing a secondary decrease in plasma selenium not necessarily related to body content. The activity of the selenium-containing enzyme glutathione peroxidase tends to decrease in selenium deficiency and may be a better functional indicator, but it is not clear whether the measurement is best made in erythrocytes, platelets or even plasma. Excess selenium is excreted in the urine, so urinary measurements are useful in suspected toxicity, but are not helpful in deficiency.

Molybdenum. Plasma and urine concentrations of molybdenum are normally very low and measurements in these fluids are not useful in detecting deficiency. Increased urinary excretion of xanthine and sulphite, which decrease with molybdate supplementation, may be a useful approach in confirming suspected deficiency.

Manganese. Measurement of plasma and urine manganese is useful when investigating suspected toxicity, but since most manganese is intracellular, whole blood measurements are used in the detection of deficiency.

Chromium. Plasma and urine chromium can be measured by inductively coupled plasma mass spectrometry, but the limit of detection is such that they are more useful in detecting toxicity.

CONCLUSION

Clinical nutrition is a huge topic, with many different professions and specialties involved. Biochemical tests have their limitations in measuring nutritional status, and it is important for the clinical biochemist to be aware of these, in order that the tests are not used inappropriately.

CONCLUSION 213

INTRODUCTION

The term ‘nutritional disorders’ covers a wide range of conditions. Some of these disorders are primarily nutritional and some are not, albeit that nutrition is still an important factor. This makes their classification somewhat arbitrary, but the following broad categories can be recognized:

- specific deficiency caused by inadequate supply of individual nutrients and occasionally, oversupply of an individual nutrient leading to toxicity, which has been discussed in Chapter 10
- generalized undernutrition, which is an important cause of morbidity and mortality across the world
- generalized overnutrition, in the form of obesity, which has become an important public health problem
- eating disorders are not primarily nutritional disorders, but have important nutritional effects and significant metabolic consequences
- specific diseases in which dietary factors may be important in their aetiology. In some cases there may be scope for dietary modification to alter the course of the disease (e.g. hyperlipidaemia). In others, this is not so (e.g. where carcinogenesis has already been stimulated by a dietary component)
- conditions in which diet has no role in aetiology, but for which specific dietary intervention

is an essential part of management (e.g. phenylketonuria)

- primarily non-nutritional diseases in which general nutritional support may improve outcome, especially if patients are, or are likely to become, malnourished during the course of their illness.

MALNUTRITION

‘Malnutrition’ is often taken to mean inadequate nutrition, but this definition also includes dietary excess, so the term ‘undernutrition’ is to be preferred. Undernutrition is a major public health problem in the developing world. Diets of affected populations tend to be deficient in both macronutrients and micronutrients. A high prevalence of bacterial and parasitic disease tends to contribute to undernutrition; in addition, an effect of undernutrition is to increase susceptibility to infection. In children, severe undernutrition is predominantly a state of protein energy malnutrition (PEM). In adults, in whom protein requirements are relatively lower (since growth has ceased), the term chronic energy deficiency (CED) is used. In the UK, severe undernutrition is most commonly seen in adults, usually in association with intercurrent illness and is discussed later in the chapter under nutrition support.

Protein–energy malnutrition in children

Worldwide, PEM remains the most common disorder of infancy and childhood: as many as 200 million children may be significantly affected at any one time and it accounts for over half the deaths in the under-five age group in developing countries. One way of assessing and categorizing undernutrition is by using a weight for height z score, which compares a child's height to that of a healthy reference population of children of the same height or length. The z score is expressed in terms of standard deviations (SD) from the mean of the reference population. When height or length cannot be measured easily, upper arm circumference, which changes little in healthy children between the ages of six months and five years, can be used as a measure of lean body mass to identify undernutrition. Using these methods, acute undernutrition can be divided into moderate and severe. Moderate undernutrition is defined as a weight for height or length z score between -2 and $-3SD$. Severe undernutrition is defined by a z score of $<-3SD$, an arm circumference <110 mm or the presence of nutritional oedema. Moderate or severe undernutrition without nutritional oedema is termed marasmus. Undernutrition with oedema is termed kwashiorkor.

Marasmus tends to occur in younger children who have the greatest energy requirements and susceptibility to infection. Affected children appear emaciated with loss of subcutaneous fat, muscle wasting and triangular facies due to loss of buccal fat pads. In addition to oedema, children with kwashiorkor have enlarged and fatty livers. They may also have dermatoses and depigmentation of hair, the latter being attributed to reduced availability of tyrosine, a precursor of melanin.

The classic explanation for the two different syndromes suggests that marasmus occurs on a diet poor in protein and energy and kwashiorkor on a diet poor in protein but with relatively more carbohydrate. In marasmus, insulin secretion would, therefore, be expected to be low, prompting breakdown of muscle protein and mobilization of amino acids for hepatic synthesis of protein, particularly albumin. In kwashiorkor, relatively higher carbohydrate intake would lead to maintenance of insulin secretion with relative sparing of muscle protein, therefore limiting amino acids available for synthesis of liver proteins. Reduced synthesis of albumin and apolipoproteins would lead to hypoalbuminaemia and oedema, and accumulation of lipids in the liver, respectively. However, recent studies have found marasmus and kwashiorkor to exist in populations where children are eating similar diets. It has been suggested that the clinical syndromes may in fact reflect differences in the metabolic response to starvation, for example varying rates of fatty acid oxidation, rather than the content of the diet.

The treatment of PEM is the provision of appropriate nutrition and treatment of associated infection. Treatment of moderate undernutrition involves the addition to the diet of suitable nutrient rich supplements containing significant energy and the recommended daily allowance of micronutrients; examples include cereal and legume blended flours and lipid rich fortified spreads.

Severe PEM is associated with atrophy of the small bowel mucosa, reducing its capacity for digestion and absorption, hence liquid, milk-based products, supplemented with potassium and phosphate, are favoured for treatment, initially administered as small boluses. Intravenous fluids should be avoided, except in children with profuse diarrhoea. Children with kwashiorkor have increased total body water with sodium retention. Those with marasmus have chronic hypovolaemia with secondary hyperaldosteronism, although tissue breakdown and urinary potassium loss tend to result in hypokalaemia. However, children with marasmus are particularly likely to have a degree of cardiac atrophy and reduced stroke volume, predisposing to cardiac failure if fluid overloaded. In addition, the reduction in subcutaneous fat renders these children susceptible to hypothermia and hypoglycaemia during the recovery process.

Chronic energy deficiency in Western adults

Studies of both medical and surgical inpatients in developed countries indicate that a significant proportion of patients have CED, although variation in the criteria used to define this means that the exact prevalence is uncertain. Caution is required in applying the marasmus/kwashiorkor distinction to such patients, since the presence of hypoalbuminaemia or oedema is more likely to be due to the underlying illness than malnutrition. Nonetheless, severe CED in such patients has important effects. Wasting of respiratory muscles increases the risk of chest infection and may delay weaning from a ventilator. Myocardial function may be impaired and skeletal muscle wasting delays mobilization, with a consequent increased risk of thromboembolism and bed sores. Chronic energy deficiency also results in impaired resistance to infection, and gut permeability may be increased, allowing entry of bacteria and toxins through the gut wall. Apathy and depression impair active efforts at recovery and may also impair appetite, worsening the situation further.

The recognition of undernutrition in adults and its treatment are considered later in this chapter in the section on nutritional support.

OBESITY

Obesity is an excess of body fat. For epidemiological studies and population surveys, as well as clinical assessment of individual patients, body mass index (BMI) is frequently used to define overweight (BMI ≥ 25 kg/m²) and obesity (BMI ≥ 30 kg/m²). Whilst it is a useful index, BMI is not without problems, but alternative methods are expensive and not readily available. In children, there are marked changes in BMI with age. It is recommended that obesity in children is defined with reference to BMI centiles, and charts are available for this purpose, but there is no universally accepted BMI classification system. In the UK, it is suggested that the 91st and 95th centiles should be used in children as indicators of overweight and obesity, respectively. Estimates of the prevalence of obesity

are likely to be subject to variation because of differences in the definition, cut-offs and reference standards used.

It is estimated that at least one billion people worldwide are overweight or obese and at least 300 million are obese. In the UK, from 1993 to 2010, the proportion of men and women who were overweight remained stable at 40% for men and 30% for women. However, there was a gradual increase in the proportion classified as obese from 13.2% of men (16.4% of women) in 1993 to 26.2% of men (26.1% of women) in 2010. Obesity is associated with significant health risks and the economic cost has been estimated as 3–8% of total healthcare expenditure. There is a relationship between mortality risk and increased BMI which, although strongest in those below 50 years of age, persists into the ninth decade of life. In addition, various complications are associated with obesity (see [Table 11.1](#)).

Aetiology of obesity

The aetiology of obesity is complex and influences on body fat content include genetic, perinatal, behavioural

and environmental factors. Epidemiological data indicate that the consumption of a diet that is high in fat and the frequent consumption of 'fast food' increase the risk of obesity. This is well demonstrated by the recent rise in obesity in developing countries, whose populations have replaced their indigenous diet with a more energy-dense Westernized alternative. There is also a close relationship between low levels of physical activity and weight gain and the duration of television viewing is a predictor of obesity risk in both adults and children.

Family studies have established that hereditary influences are important in determining body weight, although, to-date, genetic studies have concentrated on severe, early-onset forms of obesity, which are rare. Mutations resulting in leptin (see below) and leptin-receptor deficiencies have been described. Affected children are of normal birth weight, but exhibit extreme hyperphagia and gain weight rapidly. Children with congenital absence of pro-opiomelanocortin (POMC) gene products also become obese, despite glucocorticoid deficiency, an endocrine state normally associated with weight loss. These patients characteristically have pale skin and red hair, resulting from an absence of the action of POMC-derived peptides on melanocytes. A number of heterozygous point mutations in POMC have been found, which increase the risk of obesity, although are not invariably associated with it. Heterozygous mutations in the melanocortin receptor MC4R have been associated with dominantly inherited obesity and have been found in 1–2.5% of those with a BMI of $>30\text{ kg/m}^2$.

There are a number of conditions which have obesity as a feature of their clinical phenotype. The majority of these are associated with short stature; this contrasts with simple obesity where children tend to be tall. Examples of pleiotropic obesity syndromes are shown in [Table 11.2](#).

TABLE 11.1 Complications associated with obesity

System	Complication
Cardiovascular	Coronary heart disease, cardiac failure, hypertension
Respiratory	Sleep apnoea, dyspnoea
Gastrointestinal	Fatty liver, reflux oesophagitis, gallstones
Musculoskeletal	Arthritis, back pain
Endocrine and metabolic	Type 2 diabetes mellitus, insulin resistance, polycystic ovary syndrome, amenorrhoea, dyslipidaemia
Skin	Acanthosis nigricans, intertrigo

TABLE 11.2 Pleiotropic obesity syndromes

Syndrome	Genetic basis	Clinical features
Alstrom	Autosomal recessive <i>ALMS</i> gene located at 2p13	Obesity and type 2 diabetes mellitus Blindness Dilated cardiomyopathy Sensorineural hearing loss Other: hepatic, pulmonary, renal and urological dysfunction
Bardet–Biedl	Autosomal recessive 14 genes code for BB proteins involved in ciliary action	Obesity Hypogonadism Intellectual impairment Polydactyly Retinitis pigmentosa
Carpenter	Autosomal recessive <i>RAB23</i> gene located at 6p11	Obesity Cardiac defects Craniosynostosis Polysyndactyly
Prader–Willi	15q 11–13 Imprinted sequence	Obesity and hyperphagia Hypogonadotrophic hypogonadism Hypotonia Intellectual impairment Short stature Small hands and feet

Secondary causes of obesity

Investigation of patients to exclude secondary causes of obesity is usually unrewarding, but remains important. Clinical features suggesting endocrine pathology should be pursued, but in-depth dynamic function testing to exclude rare disorders is not usually necessary. Hypothyroidism should be excluded by measuring serum thyroid stimulating hormone and free thyroxine concentrations. The investigation of possible Cushing syndrome may be more difficult, as false positive results have been described in pseudo-Cushing syndrome due to obesity. Growth hormone deficiency may also lead to weight gain, although morbid obesity is not usually present. Associations are also recognized between obesity and polycystic ovary syndrome, hypogonadism and insulinoma.

Some drugs are associated with weight gain. The effect is assumed to be due either to central effects on appetite (e.g. certain anticonvulsants and antipsychotics) or to peripheral metabolic effects (e.g. oral hypoglycaemic agents, protease inhibitors).

Appetite

Energy homeostasis is the result of a complex, integrated process involving neural, humoral and psychological factors that are integrated by the brain to ensure that nutrient supply remains at appropriate levels for different environmental conditions. In the past, there has not tended to be an evolutionary advantage in weight loss, hence the mechanisms underlying energy homeostasis are tailored to ensure a powerful drive to eat, especially after weight loss.

Central appetite control

The hypothalamus. The body's appetite control centres are located in the hypothalamus. The ventromedial hypothalamus is thought to act as the satiety centre and the lateral hypothalamus as the feeding centre. Histochemical and molecular imaging techniques have shown that the hypothalamic nuclei involved in feeding regulation form interconnected circuits, utilizing neuropeptides as well as the classic amine neurotransmitters

The hypothalamus receives both neural and humoral input. At the base of the third ventricle, the arcuate nucleus (Arc; also known as the infundibular nucleus in humans) is able to receive signals from the circulation. The blood-brain barrier (BBB) surrounding the Arc is not complete and this allows hormones such as leptin, secreted by adipocytes, and insulin, from the pancreas, to gain access to the afferent signalling pathway that regulates appetite.

From the Arc, monosynaptic projections are made to many other brain regions, with the projections to the paraventricular nucleus (PVN) being of importance in the regulation of food intake. Integration of peripheral and central signals relating to energy homeostasis takes place in the Arc. Two neuron populations play a role. The orexigenic (appetite-stimulating) peptides neuropeptide Y (NPY) and Agouti-related peptide (AgRP) are co-localized, while in another population of neurons, the anorectic (appetite-inhibiting) peptide cocaine- and amphetamine-regulated

transcript (CART) and pro-opiomelanocortin (POMC, the precursor of α -melanocyte stimulating hormone (α MSH)) are also co-localized. The orexigenic NPY/AgRP neurons inhibit the anorexigenic POMC neurons through γ -aminobutyric acid (GABA)-ergic interneuronal connections. Fasting increases NPY and AgRP, while CART and POMC expression is reduced.

The brain stem. The vagus nerve and sympathetic fibres transmit satiety signals from the gut and liver to the nucleus of the tractus solitarius (NTS) in the brain stem. In areas such as the area postrema, which is in the brain stem adjacent to the NTS at the base of the fourth ventricle, the BBB is incomplete, also allowing circulating hormones access to the brain. The brain stem and hypothalamus are linked by projections from the NTS to the PVN and lateral hypothalamus, and from the raphe nuclei to the arcuate nucleus. Neurons such as those expressing glucagon-like peptide-1 (GLP-1) receive afferents from the vagal and glossopharyngeal nerves, integrating and relaying sensory information to hypothalamic and brain stem centres. Whilst the brain stem plays a role in regulating the size of individual meals, it is thought that the hypothalamus is necessary for long-term energy balance and appetite regulation.

Hypothalamic messengers

Neuropeptide Y. Neuropeptide Y is a 36-amino acid peptide member of the family of peptides comprising NPY, pancreatic polypeptide (PP) and peptide YY (PYY). Neuropeptide Y is one of the most potent stimulators of feeding. At least five distinct G-protein coupled receptors (Y1, Y2, Y4, Y5 and Y6) mediate the actions of NPY, PYY and PP. In rodents, repeated administration of NPY leads to hyperphagia and obesity associated with decreased thermogenesis in brown adipose tissue, hyperinsulinaemia, hypercortisosteronaemia, reduced plasma testosterone concentrations, and insulin resistance in skeletal muscle.

Agouti-related protein. Agouti-related protein increases food intake by acting as an antagonist at central melanocortin-3 and melanocortin-4 receptors (see below). In contrast to the fairly short-lived effects of NPY, central administration of a single dose of AgRP to rodents leads to an increase in food intake for up to one week. Repeated administration leads to hyperphagia and obesity.

Melanocortins. Melanocortins are peptides that are cleaved from the POMC precursor molecule by tissue-specific post-translational cleavage (e.g. in the anterior pituitary, POMC gives rise to adrenocorticotrophic hormone, ACTH). They bind to a family of melanocortin receptors (MC1-R to MC5-R). In the arcuate nucleus, α MSH is released from POMC-expressing neurons that project to the PVN, where it acts through MC3-R and MC4-R to inhibit food intake. The endogenous antagonist AgRP (see above) is released from the terminals of arcuate NPY/AgRP neurons at the PVN: AgRP stimulates food intake by blocking the anorectic effect of α MSH. The MC4 receptor, in particular, seems to be critical to regulation of body weight; thus far, the most common cause of monogenic obesity in humans is mutation in MC4-R.

Cocaine- and amphetamine-regulated transcript. Cocaine- and amphetamine-regulated transcript is co-expressed with POMC in arcuate neurons, and these neurons are directly stimulated by leptin (see later). Central administration of CART to rats inhibits feeding and completely blocks the feeding response stimulated by NPY. Food-deprived animals show decreased expression of CART mRNA in the arcuate nucleus. CART may thus be another endogenous inhibitor of food intake.

5-Hydroxytryptamine. 5-Hydroxytryptamine (5-HT) is a monoamine neurotransmitter that is synthesized in both the central nervous system and in the chromaffin cells of the gastrointestinal tract. There are numerous 5-HT receptor subtypes: in the brain these receptors occur mainly in the limbic system and the hypothalamus. 5-Hydroxytryptamine modifies mood and behaviour, and a number of different types of drug that increase the effects of 5-HT are used as antidepressants. Drugs that either mimic 5-HT at its receptors or inhibit its reuptake at synapses generally also reduce feeding. The mechanism for this is not clear.

Peripheral signals of appetite

Peripheral signals influencing food intake can be broadly divided into those that cause satiety and those that are secreted in proportion to the amount of fat in the body. The gut and the brain seem to have a close evolutionary relationship. Peptides discovered in the hypothalamus have also been identified in the gut, and gut peptides have been found to be produced by the brain.

Gastric emptying and stretching. Slow gastric emptying increases stomach distension, which activates stretch receptors. The vagus nerve carries afferent signals related to stomach distension to the NTS, facilitating satiety by projections to the appetite-regulating nuclei of the hypothalamus, for example the PVN. Cholecystokinin (CCK) is a potent inhibitor of gastric emptying by vagal afferent-mediated central mechanisms, and this may explain its anorectic actions. Peptide YY and GLP-1 (see below) may also cause anorexia by reducing gastric emptying in this way.

The main neural connection from the gastrointestinal tract to the brain is through the vagal afferent fibres, via the nodose ganglion. Sympathetic afferent fibres in the spinal nerves also carry satiety signals to the brain stem, as previously described.

Hormones. The endocrinological capacity of the gut is diverse, as diffuse populations of endocrine cells are scattered throughout the mucosa. Primary gastrointestinal functions such as motility, secretion and absorption are regulated by gut hormones, which simultaneously provide feedback to the CNS on the availability of nutrients, thereby regulating food intake.

Insulin. Insulin was the first hormonal candidate, related to adipose tissue, to be postulated as the circulating factor that regulates the hypothalamic control of food intake. Insulin was also thought to be important in achieving the usual long-term stability of body weight

and fat mass. The rise in circulating insulin in response to a glucose load is proportional to fat mass. Insulin reaches the CNS via receptor-mediated transport across the BBB and through areas of relative permeability. Central nervous system administration of insulin to rodents causes a reduction in food intake, while brain-specific insulin receptor knockout mice and insulin receptor substrate-2 knockout mice develop obesity. However, when insulin is commenced in patients with type 2 diabetes, weight gain rather than weight loss is observed, possibly as a result of a loss of the anorexigenic effect of hyperglycaemia and the lipogenic actions of insulin.

Cholecystokinin. Cholecystokinin was the first gut hormone described to relay the signal of nutrient intake to the brain, thus leading to the inhibition of further food intake. Cholecystokinin is produced by endocrine cells (I cells) present within the jejunum and duodenum and it is also found in enteric nerves in the ileum and colon. Plasma concentrations of CCK increase in response to the intraluminal presence of the digestion products of protein and fats. Gastric emptying is potently inhibited by CCK through a vagal afferent-mediated central mechanism. In addition to causing satiety via vagally mediated pathways, CCK can cross the BBB and bind directly to specific receptors in the area postrema.

Peptide YY. Peptide YY is secreted from the endocrine L cells of the small and large bowel. It is a 36-amino acid peptide related to NPY. The highest PYY tissue concentrations are in the distal gastrointestinal tract. Postprandial PYY concentrations are proportional to meal energy content. Two isoforms exist, and both PYY_{1-36}} and PYY_{3-36}} may have local effects on gut motility, inhibit secretion of gastric acid and pancreatic enzymes, and inhibit gallbladder emptying. Obese individuals have lower circulating concentrations of PYY.

It is proposed that PYY_{3-36}}, released into the circulation after a meal, inhibits appetite by acting directly on the arcuate nucleus via the Y2R, a presynaptic inhibitory autoreceptor, leading to an inhibition of the NPY neurons and a possible reciprocal stimulation of the POMC neurons. There is a tonic GABA-mediated inhibition of POMC neurons by NPY neurons, and thus decreased GABA-mediated tone as produced by leptin may lead to disinhibition of POMC neurons. Thus, peripheral PYY_{3-36}} reduces the expression of NPY mRNA and increases that of POMC. Exogenous PYY_{3-36}} reduces food intake in rodents, rhesus monkeys and in normal weight and obese humans.

Pancreatic polypeptide (PP). Pancreatic polypeptide (PP) is thought to have arisen by gene duplication of the PYY gene, as PP and PYY are closely related structurally. The PP cells of the pancreatic islets produce PP in response to ingestion of food. This release is in proportion to the energy ingested, and postprandial concentrations remain elevated for up to 6h. Obese subjects have low PP concentrations, while high concentrations of PP have been demonstrated in patients with anorexia nervosa. Peripheral administration of PP to rodents and humans has been shown to reduce food intake.

Leptin. Leptin is a 167 kDa peptide, the product of the *ob* gene, and is produced predominantly by adipose tissue.

Circulating leptin concentrations are directly proportional to adiposity and correlate better with total fat mass than with body weight. Central or peripheral administration of leptin in rodents causes a profound decrease in food intake and weight loss. The *ob/ob* mouse, completely deficient in leptin, is hyperphagic, hyperinsulinaemic and very obese, and the leptin receptor-defective *db/db* mouse has a similar phenotype. Chronic administration of leptin to the *ob/ob* mouse results in sustained reduction in body weight and reduced food intake, but has no effect on the *db/db* mouse.

Leptin deficiency in humans is rare, although it has been suggested that some obese humans have lower leptin concentrations than would be expected. Most obese people have normal leptin genes and have elevated leptin concentrations, reflecting their high adiposity.

Ghrelin. Ghrelin is a 28-amino acid peptide identified in 1999 as the endogenous agonist at the growth hormone secretagogue receptor, and is present in the circulation of healthy individuals. Ghrelin is synthesized in the endocrine cells of the stomach and (in much smaller amounts) in the hypothalamus. Ghrelin has been shown to increase NPY and AgRP in the hypothalamic arcuate nucleus, thus being postulated to increase appetite and act as an initiator of feeding. Plasma concentrations of ghrelin peak before a meal and fall rapidly after nutrient ingestion, supporting the hypothesis that it has a role as a stimulus to eating by signalling pre-meal hunger. A state of negative energy balance increases fasting plasma ghrelin concentrations, while concentrations are reduced by positive energy balance. This suggests that ghrelin is also important in long-term regulation of body weight in normal individuals. Exogenous administration of ghrelin increases appetite and *ad libitum* caloric intake, as well as growth hormone secretion.

Insulin resistance has been postulated to play a role in determining low fasting ghrelin concentrations. Attenuated postprandial reduction of ghrelin concentrations has been shown in the obese, while in normal weight individuals, postprandial suppression of ghrelin secretion is proportional to the calories consumed.

Glucagon-like peptide-1. Processing of proglucagon in the pancreas results in the formation of glucagon, glicentin-related pancreatic polypeptide (GRPP) and major proglucagon fragments. In intestinal L-cells, proglucagon processing results in glicentin, oxyntomodulin (OXM), GLP-1, spacer peptide-2 (SP-2) and glucagon-like peptide-2 (GLP-2). Glucagon-like peptide-1 is co-secreted with PYY in response to the presence of nutrients in the gut.

Glucagon-like peptide-1 is an incretin, stimulating the release of insulin, while also inhibiting the release of glucagon; GLP-1 receptor agonists are used in the treatment of type 2 diabetes. Glucagon-like peptide-1 reduces gastric emptying and inhibits gastric acid secretion, while also regulating food intake. Central administration of GLP-1 in rodents strongly inhibits feeding, and GLP-1 also seems to produce a small, dose-dependent reduction in food intake in humans.

Management of obesity

The objectives of the management of obesity are to reduce body weight and then to maintain a lower body

weight in the longer term. A criterion for success of a reduction of 5–15% in body weight has been proposed. Various approaches can be used to achieve this, alone, or in combination.

Non-surgical options

Dietary approaches offer the obese patient education in the principles of healthy eating and a regimen intended to achieve a deficit in energy balance. Very low calorie diets (400–500 kcal/24h) have been shown to produce greater initial weight loss than low calorie diets (1000–1500 kcal/24h), but results after one year are not significantly different.

It is difficult to achieve weight loss merely through physical exercise. For example, a man of average build who completes a marathon in 4.5 h will only burn about 2000 kcal, approximately the same amount of energy that he would be expected to consume during an entire less active day. He would have to run a marathon every ten days, without an increase in energy intake, to lose a kilogram a month. However, physical activity can contribute towards an energy deficit and is important in increasing cardiorespiratory fitness.

For some obese patients, learned patterns of eating behaviour may be amenable to behaviour modification. Establishment of new patterns of eating and physical activity makes other strategies for weight loss more likely to be successful.

Various drugs have been used for the treatment of obesity. Many have been discontinued due to unacceptable side-effects, including recently, sibutramine, a centrally acting agent affecting reuptake of serotonin, norepinephrine and dopamine; and rimonabant, an inhibitor of cannabinoid receptor-1. Orlistat is a potent inhibitor of pancreatic lipase and, therefore, increases faecal fat loss when taken orally with food. Adverse effects include abdominal distension, flatulence, liquid stools and occasional faecal incontinence. Some of the weight loss in those taking the drug may be a consequence of a conscious decrease in fat intake to avoid these side-effects. Less than 1% of an oral dose is absorbed, so it has minimal interaction with most drugs. However, absorption of fat soluble vitamins may be affected and supplementation may be required. Methylcellulose is available for use as a bulking agent, with the idea that it produces a feeling of satiety, but there is little evidence to support its use. Thyroid hormones have no role in the treatment of obesity, except in patients with biochemically proven hypothyroidism.

Bariatric surgery

The limited long-term success of behavioural and drug therapy for obesity has led to increased use of surgical treatments, with considerable success. Bariatric surgery is considered an option for selected patients with a BMI ≥ 40 kg/m², or those with a BMI > 35 kg/m² with significant comorbidities (e.g. diabetes mellitus), when less invasive methods of weight loss have been unsuccessful and the patient is at high risk of obesity-associated complications.

Possible contraindications to surgery include significant mental health problems, an intercurrent medical

FIGURE 11.1 ■ Bariatric surgery procedures. (A) Adjustable gastric band (AGB). (B) Vertical sleeve gastrectomy (VSG). (C) Roux-en-Y gastric bypass (RYGB). (D) Biliopancreatic diversion with a duodenal switch (BPD-DS).

condition likely to influence surgical risk, a history of poor compliance with medical treatment and pregnancy. Patients should be managed by a multidisciplinary team, including the surgeon, a metabolic physician, dietitian and psychiatrist. Bariatric procedures tend to be described as either restrictive or malabsorptive according to the nature of the surgery involved (see [Figure 11.1](#)). However, these descriptions do not define the mechanism of weight loss.

Restrictive procedures. Laparoscopic gastric banding involves insertion of an inflatable silicon gastric band horizontally around the proximal part of the stomach. The gastric band is connected to a subcutaneous injection port which, when inflated with saline, leads to constriction and the formation of a gastric pouch.

In a laparoscopic sleeve gastrectomy, over three-quarters of the stomach is removed. The gastric remnant is used to fashion a sleeve of stomach, rather than a pouch, which extends from the oesophagus to the duodenum.

Combined restrictive and malabsorptive procedures. Roux-en-Y gastric bypass requires the formation of a small proximal gastric pouch, which empties into a segment of jejunum brought up to the pouch as a Roux-en-Y loop. It results in a degree of malabsorption as a result of bypass of the upper small intestine.

Biliopancreatic diversion with or without duodenal switch involves removal of part of the stomach, together with an alteration in the path of the small intestine.

Most patients report a reduction in appetite after bariatric surgery, an effect more marked after biliopancreatic procedures. Weight loss after bariatric surgery is often reported as the percentage of excess weight loss (%EWL), where excess weight is the total amount above ideal weight. In some series, the %EWL has been reported to be up to 46% after gastric banding, 60% after Roux-en-Y bypass and 64% after biliopancreatic diversion. In addition to weight loss, there is resolution of type 2 diabetes mellitus in many patients and improvement in dyslipidaemia, hypertension and obstructive sleep apnoea. The percentage of patients with resolution of diabetes varies according to the procedure performed, being highest after biliopancreatic

diversion, but it is not directly related to %EWL. This resolution can be very rapid. This suggests that changes in glucose homeostasis are operation-specific and may be determined by intestinal factors. The stomach is the major producer of the orexigenic hormone ghrelin and the functional area of the stomach is reduced in the majority of these procedures. However, postoperative changes in ghrelin are variable and its role in weight loss is unclear. The concentration of the anorectic hormone PYY increases early after malabsorptive procedures, probably due to the re-routing of gut contents, and is thought to be an important contributor to the subsequent weight loss. Incretins, for example GLP-1 and oxyntomodulin, are thought to play a synergistic role in postoperative weight loss.

The mortality rate after bariatric surgery is <1% for younger patients with a BMI <50 kg/m² and average complication rates are <10%. Early complications are related to the surgery itself, for example postoperative bleeding and anastomotic leak. Longer-term problems include erosion from, or displacement of, a gastric band, anastomotic stricture and dumping syndrome owing to the rapid passage of food into the intestine, as well as various metabolic problems, for example metabolic bone disease and kidney stones.

Following bariatric surgery, long-term follow-up is essential. After surgery, patients should be advised to follow a well balanced, calorie-controlled diet. They are usually advised to avoid carbonated drinks, high sugar foods and foods with textures that are difficult to chew such as tough meat and bread. It is also recommended that solid food be chosen for meals, with drinks taken in between. Vitamin and mineral supplementation is recommended after bariatric surgery. After combined restrictive and malabsorptive procedures, but not laparoscopic banding, biochemical assessment of vitamin and trace elements should form part of ongoing review. One suggested scheme for such monitoring is shown in [Table 11.3](#). It is now recognized that a significant proportion of obese patients are deficient in vitamins and trace elements preoperatively. The aetiology includes nutritional deficiency from a diet that, whilst excessive in energy, is likely to have been of poor quality.

TABLE 11.3 Suggested monitoring scheme after bariatric surgery

Roux-en-Y gastric bypass	Biliopancreatic bypass
First year: 3–6-monthly Thereafter: annually	First year: 3-monthly Thereafter: 3–6-monthly depending on results and clinical status
Full blood count	Full blood count
Renal profile	Renal profile
Liver profile	Liver profile
Plasma glucose	Plasma glucose
Lipid profile	Lipid profile
Iron, ferritin, vitamin B ₁₂	Iron, ferritin, vitamin B ₁₂
Vitamin D ₁₂	Fat soluble vitamins (6–12-monthly)
Also consider: PTH, thiamin, folate	A, E, D and prothrombin time Trace elements (annually) Zinc, selenium Metabolic bone evaluation (6–12-monthly) PTH, 24 h urinary calcium Metabolic stone evaluation (12-monthly) 24 h urine calcium, citrate, urate and oxalate

EATING DISORDERS

Eating disorders, which include anorexia nervosa, bulimia nervosa and atypical eating disorders, are a range of syndromes involving physical, psychological and social features. About 1 in 250 females and 1 in 2000 males suffer from anorexia nervosa and about five times as many from bulimia. Atypical eating disorders may be more common, with many patients going untreated.

Anorexia nervosa

Anorexia nervosa is characterized by weight loss (or in children lack of weight gain), leading to a body weight of at least 15% below the normal or expected weight for age and height. The weight loss is the result of patients perceiving themselves to be too fat and so setting a low target body weight that is achieved by food avoidance and, sometimes, obsessive exercise. Secondary to weight loss, patients with anorexia nervosa show evidence of endocrine disturbance involving the hypothalamo–gonadal axis with amenorrhoea in females and decreased libido or impotence in males.

Patients with anorexia nervosa may become severely emaciated and treatment includes nutrition support and psychological therapies. Such patients are at risk of refeeding syndrome (see p. 211), but may also exhibit other biochemical abnormalities prior to reintroduction of appropriate nutrition. Hypokalaemia is frequent in patients with eating disorders; causes include vomiting and loss resulting from misuse of laxatives and diuretics. Hypomagnesaemia is also common and may result from reduced intake and be secondary to laxative and diuretic abuse. Patients who vomit and abuse diuretics are also at risk of hypochlorhaemic metabolic alkalosis. Prolonged use of diuretics may lead to hyponatraemia. Patients who

‘water load’ prior to being weighed at clinic appointments may exhibit a dilutional hyponatraemia. Elevation of liver enzyme activities may be seen in anorexia. This is usually transient and relatively mild, although rarely, severe liver damage occurs; the abnormalities may occur before or during refeeding and suggested mechanisms include liver ischaemia, glutathione depletion and fatty change occurring on refeeding.

At low body weight, there are changes in the hypothalamo–pituitary–gonadal axis. Menstruation ceases and the endocrine changes are of hypogonadotrophic hypogonadism with low concentrations of follicle stimulating hormone, luteinizing hormone and oestradiol. These changes are thought to be related to low concentrations of leptin, which has a role in gonadotrophin releasing hormone secretion. In males, comparable changes occur with low concentrations of testosterone. Plasma concentrations of free thyroxine and free triiodothyronine tend to be low in anorexia, with increased concentrations of reverse triiodothyronine. The thyroid stimulating hormone response to thyroid releasing hormone is abnormal in some patients and it has been suggested that this also is secondary to reduced leptin secretion. In contrast, plasma cortisol concentrations tend to be increased. These and other endocrine changes in patients with anorexia nervosa are summarized in [Box 11.1](#).

BOX 11.1 Endocrine abnormalities found in anorexia nervosa

The hypothalamo–pituitary–adrenal axis

- Increased plasma concentrations of cortisol
- Increased cortisol production rate
- Decreased metabolic clearance of cortisol
- Abnormal dexamethasone suppression test (either failure of suppression or ‘early escape’)
- Increased 24 h urinary excretion of free cortisol

The hypothalamo–pituitary–gonadal axis

- Secondary amenorrhoea
- Low plasma oestradiol concentrations
- Low plasma luteinizing hormone (LH) and follicle stimulating hormone (FSH) concentrations
- Normal LH/FSH response to gonadotrophin releasing hormone (GnRH) following priming

Other hormonal abnormalities

- Exaggerated growth hormone (GH) response to growth hormone releasing hormone (GHRH)
- Reduced GH response to apomorphine; abnormal release of GH in response to thyrotrophin releasing hormone (TRH)
- GH response to a glucose load may show a paradoxical rise
- GH response to insulin hypoglycaemia may be blunted
- Low plasma free T₄ and free T₃ concentrations
- High plasma reverse tri-iodothyronine (rT₃) concentrations
- Delayed thyroid stimulating hormone (TSH) response to TRH
- Subnormal arginine vasopressin (AVP) response to increased plasma sodium concentrations

Bulimia nervosa

Bulimia nervosa is also characterized by a self-perception of being too fat. However, in contrast to anorexia, there are recurrent episodes of overeating. To attempt to counteract the fattening effects of the food consumed, the patient may alternate overeating with periods of starvation, or may induce vomiting and use drugs such as diuretics, laxatives and appetite suppressants to attempt weight reduction.

The endocrine disturbances in bulimia are milder than those in anorexia nervosa. Patients have mild hypercortisolism and basal thyroid hormone concentrations are normal. The secretion of cholecystokinin in response to a meal is impaired in bulimia. About 50% of patients have menstrual abnormalities, which may be one of two types. Patients with low body weight have low plasma oestradiol concentrations and failure of follicular development, while those with normal body weight have normal plasma oestradiol concentrations, but a failure of progesterone secretion in the luteal phase.

Again, the diagnosis is a clinical one, but biochemical tests are important in looking for deficiencies, for example of potassium. Interestingly, in view of the putative role of serotonin in feeding, monoamine oxidase inhibitors, tricyclic antidepressants and fluoxetine have been shown to have beneficial effects in bulimia. However, the effects are smaller than those produced by non-pharmacological therapies and are not maintained.

DIET IN THE AETIOLOGY OF DISEASE

Diet is known to modulate factors that are important in the aetiology of cardiovascular disease (CVD), and dietary change is an important element of CVD risk management. This topic is discussed in detail in Chapter 38. Diet is also important in the aetiology of some gastrointestinal diseases (e.g. coeliac disease), and this is discussed in Chapter 12. Other conditions in which diet plays a causative role include dental caries and some cancers.

Dental caries

The most common reasons for the loss of teeth are dental caries in children and periodontal disease in adults. Periodontal disease has only a minor association with nutrition, but there is a strong relationship between the formation of dental caries and diet.

The first stage of cariogenesis is the formation of plaque. Plaque begins to develop on the surface of a clean tooth by the adsorption of salivary proteins and glycoproteins to form the pellicle. Bacteria (e.g. *Streptococcus mutans*) then become attached to the pellicle and begin to reproduce, eventually forming a continuous layer. A polysaccharide coating then develops over them, formed from the action of bacterial enzymes on dietary sugars. This coating helps to maintain plaque integrity, but also acts as a source of energy for the bacteria during the gaps between the host's meals. Dietary sugars diffuse into the plaque and are fermented by the plaque bacteria into mainly lactic acid, which then dissolves the mineral phase of tooth enamel, causing caries. Both the amount and frequency of sugars

in the diet are positively correlated with caries formation. Some foods (e.g. milk, cheese and the sugar substitute xylitol) protect against dental caries, as does increasing salivary flow with sugar-free chewing gum.

Dietary fluoride, for example in fluoridated drinking water, is important in preventing the development of dental caries. A concentration of 1 mg/L increases the resistance of the enamel, particularly if the exposure occurs while it is being laid down prior to the tooth erupting, and reduces tooth decay in children by about 50%.

TABLE 11.4 Some examples of associations between dietary factors and cancer

Site of cancer	Associated dietary factors
Mouth, pharynx and larynx	Alcohol, very hot drinks, Chinese-style salted fish
Oesophagus	Alcohol, very hot drinks, nitrosamines (in preserved foods)
Stomach	Smoked fish, pickled foods, cured meats, salt; nitrosamines formed in the stomach from nitrites in the diet
Large intestine	High fat, high protein diet, low fibre intake
Liver	Aflatoxin-contaminated foods (aflatoxins are a product of the fungus <i>Aspergillus flavus</i>), alcohol
Breast	High fat diet, alcohol

Cancer

Many associations have been noted between specific dietary components and various cancers (see Table 11.4). The overall risk of cancer appears to be highest in populations that consume diets high in fat and energy, in which there is a high prevalence of obesity and in which alcohol intake is high. Diets that are high in 'fibre', particularly those with a high fruit and vegetable content, appear to offer some protection from certain cancers. However, research in this area is difficult because, although dietary factors may predispose to or protect against cancer, the effect may be small compared with other known carcinogens (e.g. cigarette smoke), there may be interactions between different dietary constituents and methods for the measurement of dietary intakes are inherently inaccurate. Furthermore, altering the amount of any one component of the diet necessarily alters the relative amounts of the others.

THERAPEUTIC DIETS, DIETARY SUPPLEMENTS AND NUTRACEUTICALS

Details of therapeutic diets can be found in textbooks of dietetics, but the main features of some of the more common ones are summarized in Table 11.5.

Apart from the well-established benefits of therapeutic diets, claims are also made that some dietary constituents have health benefits beyond their purely nutritional role. Functional foods are defined as foods that provide a health benefit beyond basic nutrition, when consumed in normal amounts as part of a varied diet. Nutraceuticals are dietary supplements that provide a concentrated form of an agent from a food, in a dose exceeding that obtainable from a

TABLE 11.5 The main features of some therapeutic diets

Disease	Main features of dietetic management
Diabetes mellitus	Reduce risk of microvascular disease by achieving near normal glycaemia, while avoiding risk of hypoglycaemia Reduce risk of macrovascular disease, including management of body weight, dyslipidaemia and hypertension 45–60% dietary energy from carbohydrate, especially from complex carbohydrates or those with low glycaemic index May have up to 10% energy from sucrose, provided it is eaten in the context of a healthy diet and spread throughout the day <10% energy from saturated and <i>trans</i> fatty acids <10% energy from polyunsaturated fatty acids, including ω 3-polyunsaturated fatty acids from oily fish 10–20% energy from monounsaturated fatty acids Protein not more than 1 g/kg/day, i.e. not a high intake
Obesity	Aim for 10% weight loss. Further targets can be set if appropriate Reduce dietary energy by reducing fat and sugar intake Encourage a regular meal pattern, including complex carbohydrates at each meal Encourage physical activity
Undernutrition, e.g. caused by dysphagia, cancer, loss of appetite	Increase protein and energy intake by food fortification measures, energy and nutrient-dense foods, and nourishing drinks Prescribe nutritional supplements if measures above fail
Hyperlipidaemia	Reduce saturated fat intake to 10% dietary energy Partially replace saturated fats with monounsaturated fats and complex carbohydrates Increase ω 3-polyunsaturated fatty acid intake At least five portions of fruit and vegetables per day Reduce salt intake Avoid excess alcohol Lose weight if obese
Celiac disease	Eliminate all gluten-containing foods (wheat, barley, rye and possibly oats) from the diet
Allergy	Exclusion diets, e.g. exclusion of wheat, milk, eggs or additives
Renal disease	Normal protein intake, 0.8–1.0 g/kg/day (low protein diets are now rarely used) Maintain energy intake Adjust sodium, potassium and fluid intake depending on whether predominant retention or loss
Inherited metabolic diseases, e.g. phenylketonuria, galactosaemia	Specialist dietary advice required

normal diet. All such products are sold as foods, or food supplements, rather than drugs, and so are not subject to pharmaceutical licensing regulations. There is, therefore, little evidence and there are few clinical trials to enable assessment of their efficacy and formal documentation of side-effects. It has been noted that kava (*Piper methysticum*), which is said to help in anxiety, is probably hepatotoxic and preparations of St John's wort (*Hypericum perforatum*) are known to decrease the efficacy of antiretroviral drugs, ciclosporin, tacrolimus and some antiepilepsy drugs.

A probiotic is a preparation containing defined microorganisms in sufficient numbers to alter the microflora of the host and exert a beneficial health effect. Such preparations are commonly manufactured as a dairy product supplemented with species such as *Bifidobacteria* or *Lactobacilli*. They have been shown to be effective in reducing the duration of antibiotic-associated diarrhoea and alleviating symptoms and promoting digestion in lactose malabsorption.

Other dietary supplements for which there is less good evidence of benefit include coenzyme Q10 (for mitochondrial disorders, heart failure and ischaemia–reperfusion injury), saw palmetto (for benign prostatic hypertrophy) and taurine, carnitine, creatine, chondroitin and glucosamine (for osteoarthritis). The American Association of Clinical Endocrinologists has produced a useful summary of the available evidence (see Further reading, below).

PROVISION OF NUTRITION SUPPORT

Deficiencies of specific vitamins or minerals are treated by appropriate supplementation of individual nutrients, and this could be thought of as a form of nutritional support. However, the term is usually used to mean the provision of balanced mixtures of nutrients to replace all, or a major part, of normal food intake. It is recommended that nutrition support is provided by a multidisciplinary team (e.g. gastroenterologist, pharmacist, clinical biochemist, dietician, nutrition nurse) that assesses patients on an individual basis and makes adjustments to their nutritional therapy as required. Such an approach has been shown to improve clinical outcomes and reduce morbidity and mortality.

Indications for nutrition support

The basic indications for nutrition support are intestinal failure (e.g. after massive bowel resection) or inability to eat (e.g. in neurological diseases that affect swallowing). However, it should be considered in any patient who is malnourished or likely to become so (see Box 11.2).

Simple measures to support nutritional intake include food enrichment, for example by the addition of cream to soup, or cheese to potato. Various proprietary preparations exist: modular supplements, typically in powder

BOX 11.2 Indications for nutrition support

Nutrition support should be considered in people who are malnourished, as defined by any of the following:

- a BMI of $<18.5 \text{ kg/m}^2$
- unintentional weight loss $>10\%$ within the last 3–6 months
- a BMI of $<20 \text{ kg/m}^2$ and unintentional weight loss $>5\%$ within the last 3–6 months.

Nutrition support should be considered in people at risk of malnutrition, as defined by any of the following:

- have eaten little or nothing for more than five days and/or are likely to eat little or nothing for the next five days or longer
- have a poor absorptive capacity, and/or have high nutrient losses and/or have increased nutritional needs from causes such as catabolism.

form, contain just one macronutrient, and a range of fortified puddings provide both protein and energy. Fortified juice-based products and nutritionally complete, milky-type drinks are also available.

For patients whose intake remains poor, despite use of such measures, or in whom their use is inappropriate, nutritional support via the enteral (gut) or parenteral (intravenous) route is required. Whenever possible, the gut, rather than the intravenous route, should be used to deliver nutritional support. There are several reasons for this. There appears to be no metabolic advantage in intravenous feeding and there are some positive advantages to enteral feeding. Nutrients are needed in the gut lumen to maintain the structural and functional integrity of the gastrointestinal tract. Enteral feeding also stimulates gallbladder motility and reduces the risk of cholelithiasis. Only a limited proportion of certain nutrients is actually absorbed from the gut and, in general, the enteral requirements for specific nutrients are better understood than parenteral requirements. Enteral feeding can supply the gut-specific substrates glutamine and short chain fatty acids, which are not usually present in commercial parenteral feeding solutions. Enteral feeding is also less hazardous than use of the intravenous route and, in financial terms, is much the cheaper of the two options.

In some situations, it may be difficult to decide which route is more appropriate. Particularly in postoperative patients, gut function tends to be assessed by clinical indicators of gut motility, for example the presence of bowel sounds and the passage of flatus or faeces. It is well-established that in such patients, intestinal function tends to return before motility. It may be safe, therefore, to commence enteral feeding cautiously before bowel sounds are heard.

Estimates can be made of the basal metabolic rate in order to tailor feeds to individual nutritional needs. However, guidelines produced by the UK National Institute for Health and Care Excellence (NICE) suggest that, for patients who are not severely ill or injured, or at increased risk of refeeding syndrome (see later), feeds should supply the following:

- 25–35 kcal/kg body weight/day total energy (including that derived from protein)
- 0.8–1.5 g protein (or equivalent as amino acids) (0.13–0.24 g nitrogen)/kg per day
- 30–35 mL fluid/kg (with allowance for extra losses, e.g. from drains or fistulae, and extra input, e.g. from intravenous drugs)
- adequate electrolytes, minerals and micronutrients and fibre if appropriate.

Enteral feeding

The route of administration of enteral feeding tends to be determined by the likely duration of feeding, although physical constraints, for example oral surgery, may need to be taken into consideration. For the majority of patients requiring short-term enteral feeding, the most appropriate method of delivery is via a fine-bore nasogastric feeding tube. Placement of the tube is relatively simple, although its correct positioning in the stomach should always be checked before use by ensuring aspiration of acidic gastric contents (using pH paper), lest inadvertent pulmonary (or, rarely, intracranial) misplacement has occurred.

There is a risk of gastric regurgitation and subsequent pulmonary aspiration during nasogastric feeding and, to minimize this, patients should be nursed at 45° wherever possible. For patients at increased risk of aspiration (e.g. those on ventilators or being nursed flat after certain neurosurgical procedures, diabetic patients with neuropathy) insertion of a feeding tube into the duodenum or jejunum may lessen the risk.

For long-term enteral feeding the preferred route is often a tube placed through the abdominal wall directly into the stomach – a gastrostomy. This avoids local problems such as rhinitis and nasal erosions, which can be associated with prolonged use of a nasogastric tube, and is more secure. This type of gastrostomy is usually inserted percutaneously under endoscopic control (PEG).

The exact nature of the enteral feed given is dependent upon the patient's nutritional requirements, the indication for feeding and any comorbidity, for example renal failure. Whilst a normal diet could be liquefied and used for enteral feeding, this is not generally recommended owing to the risk of infection. Instead, proprietary feeds are preferred. These tend to be of three types: polymeric, pre-digested or disease-specific; they are typically nutritionally complete, may contain fibre and generally contain 1–1.5 kcal/mL.

In polymeric feeds, the nitrogen is in the form of whole protein, the carbohydrate source is partially hydrolysed starch and the fat contains long chain triglycerides. In patients with significant malabsorption, a pre-digested feed may be appropriate. In this, the nitrogen is supplied in the form of short peptides and the fat component contains both long and medium chain triglycerides. In severe malabsorption, elemental feeds providing nitrogen as amino acids and carbohydrate as glucose, with very little fat, can be used. Feeds can also be manufactured with their components adjusted to be suitable for the patient's underlying condition, for example low sodium and volume in patients with liver failure.

Parenteral nutrition

In a patient whose gut is not functioning (or is not functioning sufficiently well to sustain adequate nutrition), parenteral feeding has to be used. Parenteral nutrition (PN) solutions are hyperosmolar and tend to be irritant when infused via peripheral cannulae. For short-term feeding, such administration is possible (particularly if hyperosmolarity is reduced by having fat as a major energy source), but infusion into a large vein is preferred. This is usually achieved via a midline, peripherally inserted central line (PICC) or a central venous line. For longer-term feeding, a tunneled line, such as a Hickman, is preferred, to reduce the possibility of infection. Ideally, lines should be used solely for PN. However, if vascular access is compromised, a line with multiple lumens may be provided, but one lumen should be specified and reserved for feeding.

Composition of parenteral nutrition fluids

The carbohydrate component of parenteral nutrition solutions is provided as glucose. Protein is given as a mixture of L-amino acids. There are relatively few data to enable characterization of the optimal quantity of total or individual amino acids. Parenteral glutamine has been shown to be of benefit in certain groups of patients, although the exact situations in which its use is appropriate, and the most appropriate dose, are not yet fully defined. There are, as yet, no definite clinical recommendations regarding supplementation of arginine, branched chain amino acids, cysteine or taurine in parenteral nutrition solutions. Lipid preparations for parenteral use consist of oil stabilized in an emulsion with egg yolk lecithin. The most widely available preparations worldwide are based on soybean oil, but newer products now exist including olive oil-soybean mixtures, fish oil emulsions and multiple lipids (e.g. 'SMOF' a mixture of soy, medium chain triglycerides, olive and fish oil). Fatty acids have a role in the immune response, for example via their incorporation into cell membranes and effects on membrane fluidity and receptor expression. Particularly in patients in whom a robust inflammatory response is required, or in whom there is a particular risk of exacerbation of oxidative stress, evidence is accumulating that the choice of lipid preparation may have an effect on outcome.

Parenteral nutrition should contain appropriate amounts of micronutrients. In the past, trace elements were added based on knowledge of the requirements of well patients eating a normal diet and instances of deficiency and toxicity occurred. Since then, the recommendations for the micronutrient component of commercial preparations used in PN have been regularly reviewed, the most recent modifications suggesting a decrease in the content of copper, manganese and chromium.

Premixed bags of PN solutions, with a variety of amino acid (or nitrogen), energy and electrolyte content, are readily available from commercial suppliers. The bag with contents most suitable for an individual patient's requirements is chosen and variation in the rate of infusion allows some adjustment to the amount of nutrition administered. For patients whose requirements cannot be

accommodated by such premixed bags, individually prescribed nutrition solutions can be prepared under sterile conditions in many hospital pharmacies.

Complications of parenteral nutritional support

Malnutrition is known to be associated with adverse effects that lead to complications and prolonged hospital stay. Nutrition support has been shown to improve quality of life and to reduce complication rates, infection, mortality and length of hospital stay. However, nutrition support, particularly when provided by the parenteral route, is itself associated with complications.

The main non-metabolic complications are related to the placement and presence of the feeding line. Complications associated with central venous catheterization include arterial puncture, air embolism and pneumothorax. Once inserted, good care of the line is essential, using sterile technique to minimize the major risk of catheter-related sepsis. Other possible complications include line blockage, line displacement and thromboembolism.

The aim of monitoring in patients receiving nutrition support is to ensure efficacy and to prevent or identify associated complications. It is important to keep careful records of the amount of nutrition that the patient has actually received and to chart any additional fluid input and losses. Regular weighing and measurement of skin fold thickness may provide an objective way of charting the effectiveness of nutrition support. A protocol for laboratory monitoring of nutritional support has been proposed by NICE (see [Table 11.6](#)). Other aspects to be monitored, particularly in patients on long-term feeding, include the course of the primary disease and the patients' quality of life.

Electrolyte abnormalities are common in patients receiving PN and are most likely to occur soon after initiation of treatment. Abnormalities of sodium, potassium and magnesium are common and factors such as gut losses through vomiting, faecal or stomal loss, renal failure and body water excess, for example from ascites, may be contributory.

Hyperglycaemia is frequent in parenteral feeding, particularly in patients with coexisting sepsis and, if detected, should be controlled with a continuous peripheral insulin infusion: careful control of blood glucose has been shown to improve outcome in critically ill patients. Hypoglycaemia has been documented on abrupt cessation of total parenteral nutrition, but is not commonly encountered with modern feeding regimens.

Hypercalcaemia can occasionally occur in patients receiving parenteral nutrition that includes a vitamin D supplement, and hypocalcaemia can occur if insufficient supplements are given. Hypocalcaemia of unexplained origin should prompt measurement of the plasma magnesium concentration, as hypomagnesaemia may itself cause hypocalcaemia.

The refeeding syndrome comprises a group of abnormalities that may occur when nutrition is provided to those who are severely malnourished. The most well recognized feature of the syndrome is hypophosphataemia, but other electrolyte abnormalities can also occur together with cardiac, pulmonary, neuromuscular and

TABLE 11.6 Protocol for laboratory monitoring of nutrition support

Parameter	Frequency
Full blood count	Baseline 1–2 times a week until stable Then weekly
Renal profile	Baseline Daily until stable Then 1–2 times a week
Liver profile (including prothrombin time)	Baseline Twice weekly until stable Then weekly
Glucose	Baseline 1–2 times a day (more if needed) until stable Then weekly
Calcium, albumin	Baseline Then weekly
Magnesium, phosphate	Baseline Daily if at risk of refeeding syndrome Three times a week until stable Then weekly
Iron, ferritin folate, vitamin B ₁₂	Baseline Every 3–6 months
CRP ²	Baseline As required to assess presence of an acute phase response and assist interpretation of protein, trace element and vitamin results
Zinc, copper	Baseline Then every 2–4 weeks depending on result
Selenium ^a	Baseline if risk of depletion Further testing dependent on baseline
Manganese ^b Vitamin D ^b	Every 3–6 months if on home PN 6 monthly if on long-term support
Bone densitometry ^b	On starting home PN Then every two years

^aNeeded primarily for patients having PN in the community.

^bRarely needed for patients having enteral feeding. PN, parenteral nutrition.

haematological complications. It most commonly occurs in association with parenteral nutrition, although it has been documented as a complication of enteral nutrition. It should be anticipated in those patients at increased risk (see Box 11.3) in whom feeding should be commenced at a low rate and increased gradually.

The aetiology of the hypophosphataemia is probably multifactorial. One important factor is that, during prolonged starvation, energy production is derived principally from fatty acid oxidation rather than from glucose; however, on refeeding and reintroduction of carbohydrate, there is a rapid return to the use of glucose as the predominate substrate with a high requirement for phosphate to synthesize the phosphorylated intermediates and products of glycolysis (e.g. ATP and 2,3-DPG). This leads to hypophosphataemia. There is an intracellular shift of potassium and magnesium as a result of increased insulin release, which leads to hypokalaemia and hypomagnesaemia. Sodium and water retention may occur: an anti-natriuretic action of insulin has been suggested as a possible mechanism.

BOX 11.3**Criteria for identifying people at high risk of developing refeeding problems**

The patient has one or more of the following:

- BMI <16 kg/m²
- unintentional weight loss >15% within the last 3–6 months
- little or no nutritional intake for more than ten days
- low plasma concentrations of potassium, phosphate or magnesium prior to feeding.

or

The patient has two or more of the following:

- BMI <18.5 kg/m²
- unintentional weight loss >10% within the last 3–6 months
- little or no nutritional intake for more than five days
- a history of alcohol abuse or treatment with drugs including insulin, chemotherapy, antacids or diuretics.

Thiamin deficiency is common in severely malnourished individuals. Thiamin is a cofactor in glycolysis and, when carbohydrate intake is restored after caloric deprivation, demands are increased. In thiamin deficiency, pyruvate is converted to lactate, which may lead to lactic acidosis. Precipitation of the complications of thiamin deficiency should be prevented in those at risk of refeeding syndrome by administration of thiamin (initially in amounts in excess of normal requirements) before commencing, and during, nutrition support.

The clinical features of refeeding syndrome are related to the electrolyte abnormalities and vitamin deficiency.

Mild elevation of plasma liver enzyme activities is common after several weeks of parenteral feeding. Liver histology reveals hepatic steatosis with accumulation of macro- and microvesicular fat. However, the histological abnormalities are more closely correlated with the presence of intra-abdominal sepsis, renal failure and pre-existing liver disease than with the duration of PN.

Liver disease is a significant complication of long-term PN, estimated to occur in 15–60% of patients. In adults, steatosis occurs, progressing to intrahepatic cholestasis and then cirrhosis. The incidence of liver disease is higher in children, in whom cholestasis occurs earlier and can be rapidly progressive. Aetiological factors include the nature of the primary disease and residual intestinal anatomy, the presence of sepsis, lack of enteral nutrition and possible nutrient deficiencies or toxicity. Management of PN-induced liver disease includes detection and treatment of sepsis and optimization of the feeding regimen, perhaps with consideration of reduction in energy content. Ursodeoxycholic acid has been used with some benefit, particularly in neonates; rarely, liver and small intestinal transplantation may be required.

The prevalence of metabolic bone disease, characterized by reduced bone mineral density (BMD), is high in patients on long-term PN. Possible contributing factors include abnormalities (insufficiency or excess) of vitamin D, calcium, vitamin K, copper and aluminium. In addition, inflammatory bowel disease, which is an aetiological

factor in a number of the patients, is, itself associated with reduced BMD through the action of bone resorbing cytokines and corticosteroid use. The use of bisphosphonates may be associated with an increase in BMD (as assessed by dual-energy X-ray absorptiometry, DEXA) in patients on PN, but their effect on fracture prevention is unclear.

Short bowel syndrome

For the majority of patients, parenteral nutrition is required for a short period during intercurrent illness. For others, it is a long-term treatment and they incorporate its administration into their daily routine at home and are otherwise well. The majority of these patients will have a short bowel. A short bowel is defined as one that is of insufficient length to enable adequate absorption, so that supplementation of macronutrients, and/or water, and/or electrolytes is essential. This is likely to occur in patients left with <200 cm of small bowel. The most common causes of short bowel syndrome are mesenteric artery thrombosis, Crohn disease and radiation damage. The majority of patients with a short bowel can be divided into two groups: those with a short bowel and a jejunocolic anastomosis, and those with a short bowel and a high output stoma. To facilitate management, the latter group can be divided into net 'absorbers' and net 'secretors'. The absorbers generally have more than ~100 cm of jejunum remaining. They are able to absorb more sodium and water from the diet than they take orally and have low stomal output. Net secretors have very little residual jejunum; stomal output is high (4–8 L/24h) and losses of sodium and water exceed oral input.

Management of a patient with a high output jejunostomy includes oral fluid restriction to reduce stomal output. Any fluid given should contain sodium in a concentration of at least 100 mmol/L, together with glucose, to minimize passive sodium loss and facilitate glucose-coupled absorption of sodium. Antimotility agents (e.g. loperamide and codeine) and antisecretory drugs (e.g. H₂ antagonists, proton-pump inhibitors and somatostatin) may be prescribed to further reduce stomal output.

For some patients with short bowel syndrome, small bowel transplantation is an alternative to long-term parenteral nutrition. Indications for intestinal transplantation include PN-related liver disease, central venous catheter related thrombosis and frequent central line sepsis. Patients who experience frequent episodes of dehydration, despite intravenous fluids may also be eligible. Survival rates after transplantation have shown steady improvement and are currently about 80% at one year and 43% at ten years.

CONCLUSION

Nutritional disorders include a wide spectrum of conditions, including generalized undernutrition, overnutrition leading to obesity, the eating disorders and diseases where nutrition has a role in the aetiology. Globally, both undernutrition and obesity are important public health problems. The treatment of undernutrition is often complicated by factors such as war, famine and infectious diseases. Obesity remains difficult to treat once present, although the advances in the understanding of the physiology of feeding discussed in this chapter are leading to new pharmacological and surgical interventions.

Nutritional interventions in the treatment of diseases may involve the use of therapeutic diets, the administration of dietary supplements or the provision of nutritional support, either enteral or parenteral. Nutritional support is best delivered by a multidisciplinary team. Further research is required to establish the efficacy (or otherwise) of most dietary supplements.

ACKNOWLEDGEMENT

We would like to thank Stephen K. Bangert and Carel W. Le Roux who wrote the chapter in the previous edition of this book.

INTRODUCTION

Gastrointestinal complaints continue to account for a sizeable proportion of medical consultations. This is best illustrated by the fact that irritable bowel syndrome (IBS), the most commonly encountered gastrointestinal disorder, is estimated to have a prevalence of 20% in the UK. About 30% of these people seek medical attention, which in turn accounts for as many as 20–50% of patients attending general gastroenterology outpatient clinics in the UK. Furthermore, the prevalence of reflux oesophagitis and non-specific dyspepsia is increasing, and with the advent of safe and effective drugs to inhibit gastric acid secretion, it is estimated that the cost of treatment for these disorders may grow to account for as much as 20% of drug expenditure in primary care.

The development of endoscopic techniques has revolutionized the investigation of gastrointestinal disorders. The combination of upper gastrointestinal endoscopy, colonoscopy and optic and/or wireless capsule enteroscopy now allows visualization of the whole of the gastrointestinal tract and biopsies can be obtained from all parts of the bowel. This has resulted in loss of demand

for many of the classic biochemical investigations (such as gastric acid secretion) and, as some of these methods are now obsolete, we have omitted them from this chapter. Endoscopy and biochemical investigations, however, provide different kinds of information that are, in many respects, complementary. Endoscopy provides a static morphological picture that by itself, or with biopsy, has the potential to provide a diagnosis that automatically translates to treatment. Biochemical methods, on the other hand, provide a wider range of information. These include the following.

- **Providing a diagnosis.** This is a frequently desired purpose of clinical biochemistry, but is rarely achieved. Nevertheless, the indirect documentation of the presence of *Helicobacter pylori* is often the only test required before treatment, and non-invasive tests for small bowel bacterial overgrowth may be the only tests required in order to treat diabetic patients with diarrhoea.
- **Clinical screening tests prior to invasive investigation.** Examples of these kinds of investigations are serum transglutaminase antibody measurements and tests of intestinal permeability, which, if normal, may

avoid the need for more invasive tests and, if positive, are an indication for jejunal or duodenal biopsy.

- **The detection and assessment of the severity of intestinal dysfunction.** These tests are called upon in order to provide an explanation for clinical signs (such as weight loss), for monitoring response to therapy and for confirmation of diagnosis (e.g. measurement of intestinal permeability following gluten withdrawal and challenge in coeliac disease, although this is rarely necessary in practice).
- **Providing prognostic information.** Biochemical tests are uniquely suited to assess functional changes that may herald a drastic change in the activity of the disease. This is best exemplified by increased concentrations of inflammatory markers in the faeces of patients with clinically quiescent inflammatory bowel disease (IBD, i.e. ulcerative colitis and Crohn disease), as these predict imminent clinical relapse.
- **Investigating the impact of non-intestinal factors on intestinal function, whether biochemical or physiological.** These may be exogenous, for example related to radiotherapy, drugs, alcohol, dietary or environmental factors, or endogenous, for example due to malnutrition, reduced blood flow, anaemia etc. Non-steroidal anti-inflammatory drug (NSAID)-induced enteropathy is an example of gastrointestinal disease caused by an exogenous factor.

Our intention in this chapter is to review new and established laboratory-based investigations of the gastrointestinal tract that are useful clinically or for research purposes. We will not always provide the reference ranges for test results, as these may differ depending on environmental, geographical and racial factors, as well as differences in methodology.

MOUTH AND OESOPHAGUS

Clinical biochemistry has not had a major impact in the investigation of oral or oesophageal diseases. The reason is obvious in that the main functions of these organs are physical, namely grinding of food and transport to the stomach. Nevertheless, the buccal mucosa is a common site for obtaining material for genetic analysis and saliva can be assayed for a number of antibodies (although this is rarely done in clinical practice). Although the salivary glands and parotid secretions contain amylase (and initiate digestion of complex carbohydrates), peptides and growth factors (that may confer a degree of protection to the stomach and accelerate healing of gastric lesions), measurements of these are not helpful clinically and are used only in research.

The common oesophageal disturbances such as reflux and dysmotility (oesophageal spasms, neuromuscular incoordination, achalasia etc.) are investigated and diagnosed by imaging techniques (endoscopy, radiology), high-resolution manometry and pH recording, rather than by biochemical methods. Oesophageal cancer, infections (cytomegalovirus, *Candida albicans* and herpes simplex) and drug- and radiation-induced diseases are similarly diagnosed largely from the clinical history and by endoscopy and biopsy.

STOMACH

The stomach acts as a reservoir for ingested food, where it is mixed with acid, mucus and pepsin and then released at a controlled rate into the duodenum. The mucosal surface of the stomach is lined with mucus-secreting columnar epithelial cells, interrupted by gastric pits containing acid-secreting parietal (or oxyntic) cells and pepsinogen-secreting chief cells. The secreted hydrochloric acid kills many ingested bacteria, provides the acid pH necessary for pepsin (from pepsinogen) to begin digesting proteins and stimulates bile secretion. Mucus secretion is necessary to protect the mucosal surface of the stomach wall from its acidic contents. The stomach also secretes intrinsic factor, which binds vitamin B₁₂ and allows it to be absorbed in the terminal ileum. The muscular contractions of the stomach wall have the mechanical effect of macerating food.

Helicobacter pylori

Helicobacter pylori is now accepted to be the main cause of gastric and duodenal ulcers; other causes include NSAIDs and, very rarely, the Zollinger–Ellison syndrome. *Helicobacter pylori* may play an important role in gastric cancers (adenocarcinomas and mucosal-associated lymphoid tissue lymphomas) and is undoubtedly the main cause of chronic gastritis, though in most patients this is asymptomatic. Many experts also believe *H. pylori* to be a major cause of non ulcer-related dyspepsia, and recent recommendations suggest that anyone who so wishes should be tested for *H. pylori* and treated if found to be positive.

The mode of transmission of *H. pylori* is uncertain. It is thought to be an infection acquired in childhood, presumably by the faeco–oral route, which would explain the higher prevalence in developing countries and the progressive decline in prevalence in developed countries, with better hygiene, preservation of food and smaller family sizes. Whatever the mode of transmission, *H. pylori* elicits an inflammatory response that is usually asymptomatic. This takes the form of chronic gastritis, with an acute inflammatory cell infiltrate of variable severity. Nine out of ten people infected by *H. pylori* do not develop ulcers. The variable development of clinically significant disease relates to the site of infection, virulence factors (e.g. phospholipases, vacuolating cytotoxins (VAC), CagA protein) and poorly defined host factors that include blood flow, mucus secretion and pepsinogen stimulation. There are three recognized patterns of infection by *H. pylori* in the stomach. The most common type is that of low-grade inflammation of the mid-body of the stomach. This occurs in people with a high threshold for immune response and *H. pylori* that has a low expression of CagA and VAC. Gastric acid secretion is reduced and there are usually no significant clinical consequences. If the microbe is predominantly in the antrum, the inflammation leads to dysfunction of the antral G-cells that become hyper-reactive and secrete disproportionate amounts of gastrin in response to food and gastric distension. Gastrin has a trophic effect on the gastric parietal cells, increasing their number and stimulating them directly, via cell surface receptors, to produce more acid, resulting in the hyper-acidic state characteristic of patients with duodenal ulceration.

The third pattern, a pangastric infection with *H. pylori*, is characteristic of those who develop gastric ulcers and those at risk of developing gastric cancer. These individuals tend to have normal or reduced gastric acid secretion. In theory, it would be possible to perform an endoscopy on every patient with indigestion and document the pattern of infection. However, this would be prohibitively expensive owing to the large number of symptomatic patients. A less expensive option would be to assess a panel of hormones that are secreted from defined anatomical locations in the stomach (for instance pepsinogen 1 and 2 and gastrin-17), but further work is required before this approach becomes widely accepted. A more pragmatic approach has, therefore, been adopted in adult patients under 50–55 years of age, namely to test and treat for *H. pylori* infection, irrespective of the precise diagnosis (ulcer, gastritis etc.), unless 'red flag' indicators suggestive of malignancy (e.g. weight loss, dysphagia) are present.

Having established the presence of *H. pylori* (see below), there are a number of eradication regimens available, and the eradication failure rate, after trying at least three different regimens, should be <5–10%. If *H. pylori* is successfully eradicated, reinfection rates are extremely low (<1%).

Diagnosis of *H. pylori* infection

There are various methods for the diagnosis of *H. pylori* infection. At endoscopy, it is possible to take biopsies from which the organism can be visualized histologically or cultured, the latter being performed only if there are repeated treatment failures. Alternatively, the biopsy can be tested directly using commercially available kits incorporating a gel containing urea and an indicator that changes colour at an alkaline pH. In the presence of *H. pylori* (which contains urease), the urea is broken down to carbon dioxide and ammonia. The latter increases the pH of the gel and a colour change takes place. Less invasive methods involve measurement of *H. pylori*-specific antibodies (IgG or IgA). These are eminently suitable for screening (sensitivity 92%, specificity 83%), but cannot be used to document the success of treatment as high antibody titres can persist despite successful eradication.

The *H. pylori* breath test is currently the most widely used method for non-invasive diagnosis. It uses the same principle as the biopsy-based test and comes at a fraction of the cost of endoscopy and biopsy. Patients are given isotopically labelled urea (¹³C or ¹⁴C) to drink. If there is no urease present, the urea is absorbed intact and excreted in the urine. If *H. pylori* is present, labelled carbon dioxide is absorbed into the circulation and exhaled in the breath. Breath samples are obtained before, and 45–60 min after, drinking the labelled urea. The detection of labelled carbon is most commonly performed by mass spectrophotometry. The breath test is widely used and can also be used to assess the success of the treatment (sensitivity 95%, specificity 96%). Lastly, there are commercial kits that use the polymerase chain reaction to amplify nuclear sequences specific for *H. pylori* from saliva or faeces (sensitivity 95%, specificity 94%). The stool tests are increasingly being used for the detection

and confirmation of successful eradication of *H. pylori* rather than the breath test.

Gastric acid secretion

Before the discovery of the role of *H. pylori* in peptic ulcer disease, it was common practice to investigate gastric acid secretion in patients with duodenal ulcers, who tend to be hyper-secretors, and those with gastric ulcers, who tend to have normal or low secretion rates. Gastric cancers are often associated with hypochlorhydria, and achlorhydria is common in pernicious anaemia and in gastric cancer.

Acid secretion tests are now only rarely used in the research setting and are no longer available in the vast majority of clinical biochemistry departments: they have become obsolete as the test results do not alter clinical practice or management.

Gastrin

In <0.5% of patients with gastroduodenal ulcers, the cause is unregulated gastrin release from an endocrine tumour termed a gastrinoma, which can lead to the Zollinger–Ellison syndrome characterized by multiple gastroduodenal ulcers. The persistently high plasma gastrin concentrations not only lead to marked hypersecretion of gastric acid, but also, because the hormone is trophic for parietal cells, to increased parietal cell mass. Patients may present with symptoms that are indistinguishable from *H. pylori*-associated peptic ulcer disease. However, co-existing diarrhoea (due to acidic inactivation of pancreatic enzymes), multiple ulcers involving the second part of the duodenum, recurrent ulceration and ulcers refractory to conventional treatment should always arouse suspicion. Gastrinomas are either sporadic (the more common form) or associated with multiple endocrine neoplasia type 1 (MEN 1, Wermer syndrome), a syndrome characterized by the presence of two or more of pituitary, pancreatic islet and parathyroid tumours. Multiple endocrine neoplasia type 1 is also associated with an increased prevalence of carcinoid, adrenocortical and thyroid tumours.

Gastrinomas are commonly situated in the pancreas, but are increasingly recorded arising from the duodenum, stomach and bones. Some 60% are clearly malignant, with multiple metastases at diagnosis. Given a suspicion of the Zollinger–Ellison syndrome, the first step is to measure fasting serum gastrin, as virtually all cases are associated with high concentrations. The differential diagnosis of a mildly elevated gastrin concentration includes hypochlorhydria, long-term proton pump inhibitor drug therapy, pernicious anaemia and antral G-cell hyperplasia. Given a strong suggestion of a gastrinoma, the next step is to localize the tumour, which is best done at a specialist centre. Techniques for localization of the tumour include endoscopic ultrasound, octreotide scanning, magnetic resonance imaging (MRI), positron emission tomography (PET) and computerized tomography (CT) (the latter being particularly useful to detect metastases). Definitive diagnosis is histological. The treatment of gastrinomas usually involves a combination of surgery, chemotherapy and acid suppression for symptomatic relief.

Intrinsic factor

Intrinsic factor is a glycoprotein principally secreted by the parietal cells of the stomach. Its secretion is governed by the same biochemical processes that regulate acid secretion and its action is to assist in the absorption of vitamin B₁₂. Vitamin B₁₂ is released from dietary proteins by the action of pepsin and then combines with R-binders (haptocorrins), glycoproteins secreted by the stomach, that assist in its protection against acid degradation. It is subsequently cleaved from R-binder complexes by pancreatic proteolysis in the duodenum and then binds to intrinsic factor to form a resistant complex that is taken up by ileal cell receptors (cubulin).

The commonest cause of intrinsic factor deficiency is autoimmunity; the reason for requesting intrinsic factor antibody measurement is usually the discovery of a low plasma vitamin B₁₂ concentration – a cause of macrocytic anaemia and various neurological disorders. The diagnosis of pernicious anaemia is based on the finding of a low plasma B₁₂ concentration together with the presence of antiparietal cell antibodies and/or intrinsic factor antibodies (see Chapter 27). Current automated vitamin B₁₂ assays suffer, in differing amounts, from interference from intrinsic factor antibodies; alternative strategies for assessment of B₁₂ status include measurement of serum homocysteine, methylmalonic acid and holotranscobalamin concentrations. Other causes of intrinsic factor deficiency leading to low plasma B₁₂ include gastrectomy, achlorhydria and congenital absence of intrinsic factor, which is rare. Vitamin B₁₂ deficiency can also occur because of deficient intake (e.g. in vegans, starvation or reduced food intake of any cause) or in small bowel disease involving the terminal ileum. Gastric biopsies showing histopathological features of atrophic gastritis may be helpful and there are some indications that patients should undergo surveillance endoscopies once a diagnosis is made because of an increased incidence of gastric cancer. In patients in whom small bowel disease is suspected, the choice is that of wireless capsule enteroscopy or CT/MRI enteroclysis (specialized techniques in which a contrast medium is infused into the small intestine) for diagnosis. Previously, on finding a low vitamin B₁₂ concentration, it was customary to request a Schilling test, which had the potential to help in the differential diagnosis, but this test has become obsolete as imaging techniques have improved. Although proton pump inhibitors induce a state of gastric acid hyposecretion and are widely used, it is exceptionally rare to see vitamin B₁₂ deficiency in these patients.

PANCREAS

The exocrine function of the pancreas includes the production of bicarbonate and enzymes, including amylase, lipase, trypsin, chymotrypsin, esterases and carboxypeptidases. The differential diagnosis of exocrine pancreatic disease in neonates and children is predominantly between cystic fibrosis and pancreatic acinar cell aplasia (Shwachman–Diamond syndrome). The major diseases affecting the pancreas in adults are acute pancreatitis,

chronic pancreatitis leading to pancreatic insufficiency and carcinoma of the pancreas. Chronic pancreatitis results in progressive loss of both islet cells and acinar tissue. Presentation is typically with recurrent upper abdominal pain radiating to the back, although malabsorption, for example steatorrhoea, may be the presenting feature. Approximately 90% of the pancreatic acinar tissue must be lost before features of malabsorption become apparent and clinically significant reduction in endocrine function generally occurs late in the disease process.

Pancreatic function tests

Tests of pancreatic function are usually divided into the direct (invasive) tests and indirect tests on blood, urine or faecal samples.

Direct or invasive function tests

The ‘gold standard’ test of pancreatic function is the secretin–pancreozymin test. This test assesses exocrine function by measuring bicarbonate and pancreatic enzyme secretion (amylase and trypsin) in aspirates from a tube sited in the duodenum, usually under fluoroscopic control. Secretin is given to induce fluid secretion, while pancreozymin or its analogue caerulein (secretin–caerulein test), is given to induce enzyme production. This test requires meticulous attention to technique in positioning the tube correctly and maintaining its patency, and is uncomfortable for the patient. This test is now rarely used in routine practice. However, it remains the test that has the highest sensitivity and specificity for the differential diagnosis of pancreatic insufficiency.

Non-invasive pancreatic function testing

Serum enzymes. The measurement of pancreatic enzymes in serum is standard practice in acute pancreatitis, but is seldom useful in the investigation of chronic pancreatitis.

Amylase is the most commonly measured enzyme owing to the availability of cheap, easily automated methods. A disadvantage is the lack of specificity for the pancreas, as amylase in the circulation is derived from both pancreatic and non-pancreatic (mostly salivary) sources in approximately equal amounts. Measurement of the specific pancreatic amylase can be achieved using immunosubtraction techniques. Consideration of the ethnicity of the patient is important when interpreting amylase results, as subjects of African origin have a higher reference range for non-pancreatic amylase. The mechanism for this difference is unknown. An increase in both the pancreatic and non-pancreatic fractions may indicate the presence of macroamylasaemia – immunoglobulin–amylase complexes that have a prolonged half-life in the circulation owing to a reduction in clearance. Non-pancreatic causes of an increased serum amylase are given in Table 12.1. Lipase has greater specificity for pancreatic disease than amylase, but methods available tend to be more complex and expensive. The majority of the lipase in blood is the pancreatic form, although a sublingual lipase is also present. Lipase is not affected by ethnicity. Trypsin is 100% specific to

TABLE 12.1 Non-pancreatic causes of an elevated plasma amylase activity

Condition	Reason for hyperamylasaemia
Perforated peptic ulcer	Increased entry of pancreatic enzymes into the circulation
Small bowel obstruction or perforation	Increased entry of pancreatic enzymes into the circulation
Ruptured ectopic (tubal) pregnancy and salpingitis	Release of Fallopian tube amylase
Salivary gland inflammation, e.g. with calculi or mumps	Release of salivary gland amylase
Opiate administration	Contraction of the sphincter of Oddi
Renal failure	Impaired renal clearance of amylase
Macroamylasaemia	Amylase becomes combined with a plasma protein (in some cases, an immunoglobulin), and the increased size of the complex results in impaired renal clearance. Thus, hyperamylasaemia may be detected in the absence of disease
Certain tumours of the lung and ovary	Production of amylase by the tumour
Diabetic ketoacidosis	Impaired renal clearance
Subjects of African origin	Higher circulating amylase of unknown cause

the pancreas and would therefore, theoretically, be the best of the three enzymes to measure. However, there are physiological obstacles that mean that trypsin itself is seldom measured in blood samples. Trypsin is produced and stored in the pancreas as its inactive zymogen form (trypsinogen), and is activated after secretion into the intestinal tract. Active trypsin entering the circulation is bound immediately to the protease inhibitors α_2 -macroglobulin and α_1 -antitrypsin. Once bound, trypsin is not measurable using standard techniques, but any trypsinogen entering the circulation can be measured as 'immunoreactive trypsinogen' (IRT). Immunoreactive trypsinogen can be used as a first-line test for screening for cystic fibrosis using the blood spots taken on Guthrie cards at 7–10 days of age. A national programme of cystic fibrosis screening started in 2006–2007 in the UK; IRT is used for initial screening with subsequent genetic testing for confirmation.

Faecal tests. The measurement of faecal fat excretion as a test of fat malabsorption (and thus indirectly of pancreatic exocrine function), is now regarded as obsolete by most clinical biochemists and gastroenterologists.

Pancreatic enzymes that have been measured in faeces include chymotrypsin and elastase. Stool chymotrypsin measurements have suffered from a lack of standardization in the techniques used, making it difficult to compare results obtained from the various groups who have used the test. Measurement of faecal pancreatic elastase-1 is now recommended as the marker of choice for detecting pancreatic insufficiency. Elastase is an endopeptidase and sterol binding protein. As with chymotrypsin, elastase is not degraded during transit through the intestinal tract and is stable in faecal samples *in vitro*. Two commercially available enzyme linked immunosorbent assays (ELISAs) using antibodies specific for pancreatic elastase have been studied in patients with pancreatic insufficiency. Sensitivities of 60–100% for moderate to severe pancreatic disease, using a cut-off of 200 $\mu\text{g/g}$ wet weight, have been reported for faecal elastase. Discrimination between diarrhoea of pancreatic and non-pancreatic origins has been reported to be good, with better specificity than chymotrypsin. Faecal elastase measurements may also be useful in determining the amount of pancreatic enzyme

replacement therapy required in patients with cystic fibrosis or chronic pancreatic insufficiency (chymotrypsin cannot be used for this purpose). While biochemical tests attempt to give a functional diagnosis in chronic pancreatitis, imaging techniques provide further information that may disclose the cause. Plain abdominal radiography, endoscopic ultrasound, CT and magnetic resonance cholangiopancreatography (MRCP) are all useful. Endoscopic retrograde cholangiopancreatography (ERCP) with, or more commonly without, secretin stimulation is widely used, but carries a 10% risk of significant complications.

SMALL BOWEL BACTERIAL OVERGROWTH

With the discovery of microbes in the 19th century, theories were formulated linking the intestine with the development of systemic disease as a result of an unfavourable interaction between intestinal luminal microbes and the body. These ideas are equally evident today in the mass media, whereby producers of live yoghurts (containing viable bacteria) seek to equate ingestion of their products (probiotics) with health, vitality and happiness.

The normal intestinal microflora

Despite the perceived importance of intestinal bacteria, the reality is that we are still at the descriptive stages of assessing the normal intestinal flora and do not fully understand its function and impact on our well-being. Though the bulk of intestinal microbes inhabit the lower bowel, even the stomach is not usually sterile with bacterial population counts (predominantly Gram-positive aerobes) of up to 10^3 per gram of luminal content. The jejunum has a similarly Gram-positive flora, with a higher population of up to 10^4 per gram of luminal contents. The ileum contains a more varied flora that includes both aerobes and anaerobes, with populations in the region of 10^5 – 10^8 per gram. In the large intestine, Gram-negative anaerobes become the predominant species, overall bacterial populations rising significantly to 10^{10} – 10^{12} per gram of caecal content. Similar counts are present in the distal colon where the bacterial flora corresponds to that seen on faecal analyses.

The above data have been obtained using invasive techniques not commonly used in clinical practice. However, intestinal bacterial populations and species differ between individuals and relate in a complex way to age, diet, geographical and racial factors, antimicrobial treatment and intrinsic gut diseases.

Definition, causes and symptoms of small bowel bacterial overgrowth

The relatively small numbers of bacteria normally present in the small intestine are probably of little significance. However, problems can arise when the bacterial population of the small intestine is increased – bacterial overgrowth. An essential consideration of this definition is that bacterial overgrowth is based on quantitative and qualitative estimates of coliform bacteria in small bowel aspirates, something which is not possible in routine clinical practice. There are a number of diseases and conditions associated with small bowel bacterial overgrowth, a combination of factors predisposing to overgrowth in any given condition. Gastric hypochlorhydria of any cause may contribute to small bowel bacterial overgrowth. Other factors include: alterations in systemic immunology (e.g. isolated immunoglobulin A deficiency, hypogammaglobulinaemia, combined immune deficiency, infection with human immunodeficiency virus); impaired motility (e.g. advanced age, autonomic neuropathy in diabetes, fibrosis in scleroderma); pancreatic insufficiency; oral antibiotics; intrinsic small bowel disease (e.g. jejunal diverticulosis, coeliac disease, small bowel Crohn disease), and surgery (removal of the ileocaecal junction, surgically induced blind loops and, increasingly, bariatric surgery).

Small bowel bacterial overgrowth can be asymptomatic or be associated with non-specific symptoms, such as abdominal distension (bloating), eructation, flatulence, borborygmi and diarrhoea. The classic clinical presentation includes vitamin B₁₂ deficiency (intestinal bacteria compete with enterocytes for this vitamin), high blood folate concentrations (bacteria are a source of this vitamin) and fat malabsorption, and is rarely seen today. Rather, the condition is thought of when patients who are predisposed to overgrowth present with intestinal symptoms, for example diabetic patients with diarrhoea, weight loss and anaemia. An interesting suggestion is that small bowel bacterial overgrowth (intestinal dysbiosis) may be responsible for the symptoms in a proportion of patients diagnosed with IBS.

Diagnosis of small bowel bacterial overgrowth

Because of geographical and/or racial differences in small bowel bacterial flora, it is advisable that each laboratory independently establishes its own reference ranges for investigatory tests. The gold standard diagnostic procedure is microbiological examination (quantitative and qualitative bacteriological cultures) of small bowel contents, but this is impractical for routine clinical practice. More convenient, non-invasive biochemical procedures, based on oral administration of substances that are metabolized by bacteria to yield products that can be detected in breath,

have now been introduced, but their reliability remains controversial. The substances employed are either not absorbed from the small intestine (e.g. lactulose), therefore becoming available for metabolism by bacteria, or normally absorbed from the small bowel (e.g. glucose and D-xylose) and, therefore, only subject to metabolism by bacteria when these are present in the small bowel. Lactulose and similar test substances have the theoretical advantage of assessing the whole of the small bowel while the readily absorbed ones may be more selective for the proximal small bowel. The test results are also dependent upon the rate of intestinal transit. When transit is very rapid, the ingested load may be delivered to the caecum and give a false positive result. Furthermore, the tests vary in their sensitivity, presumably due to the influence of other ill-defined factors.

The ¹⁴C-glycocholate breath test was one of the first to be used for the non-invasive diagnosis of small bowel bacterial overgrowth, but it is obsolete because false negative results are common. Small bowel bacterial breath tests now in routine use include those involving test substances labelled with ¹³C (less commonly ¹⁴C), labelled CO₂ and breath hydrogen tests. Hydrogen breath tests depend on the fact that mammalian cells do not produce hydrogen. A breath hydrogen >20 ppm in expired gas after administration of the test substance (50g glucose or 10g lactulose) indicates bacterial overgrowth. Breath hydrogen is relatively simple to measure as a near-patient test. However, there are inherent limitations in the detection of breath hydrogen, for example with smoking and because of hydrogen production by oral flora. Carbohydrate may also be retained within the gut from an earlier meal. Abnormalities in gut transit and concomitant antibiotic therapy can also influence the result. Curiously, some individuals fail to produce breath hydrogen when challenged with a non-absorbed carbohydrate such as lactulose. There are a number of different protocols available for the performance of such breath tests and their value continues to be debated.

MALDIGESTION AND MALABSORPTION

It is conventional to distinguish between impaired uptake of nutrients due to maldigestion on the one hand and malabsorption on the other. The symptoms produced by the two conditions share many clinical features and there is a very broad spectrum of underlying causes. However, as the two processes are integrated and so inextricably linked, they are often lumped together as ‘malabsorption’. A very clear understanding of both the normal processes of digestion and absorption and the ways in which they can be disturbed is crucial to identifying the role that clinical biochemistry plays, both in making the clinical diagnosis and assessing prognosis.

Clinical features

Malabsorption can involve single or multiple nutrients. Accordingly, some patients may present with a single clinical feature; others may have several. Clinical features can relate to nutrient deficiency (or deficiencies), the

retention of nutrients in the gut (leading, e.g. to increased bacterial fermentation) or both.

Genetically determined intestinal lactase deficiency (see below) is a paradigm for maldigestion. The symptoms range from none, to those of abdominal bloating, excessive flatulence and watery diarrhoea (reminiscent of IBS), largely depending on the degree of the lactase deficiency, intake of lactose and intestinal transit time. Coeliac disease is an example of a condition causing malabsorption. Early recognition of the disease is now common but, in the past, the classic presenting features included: frequent loose stools, steatorrhoea, anaemia (iron or folic acid deficiency), wasting or impaired growth, osteomalacia (malabsorption of vitamin D and calcium), tetany (hypocalcaemia) and, occasionally, easy bruising (vitamin K deficiency). Exposure to gluten fractions present in wheat and several other cereals is an essential predisposing factor for coeliac disease. These fractions are thought to undergo an enzymatic reaction by transglutaminase (which catalyses the deamidation of specific residues of glutamine to glutamate). In patients with the disease (and mostly in those with the characteristic human leukocyte antigen (HLA) alleles DQ2 and DQ8), the peptide produced has an affinity for a groove in the encoded HLA molecules. This in turn evokes an abnormal intestinal mucosal T cell response, resulting in an inflammatory response that causes the characteristic changes of coeliac disease. The antibody response evoked can be useful in diagnosis. Anti-tissue transglutaminase antibodies are not a substitute for the definitive diagnostic test (the demonstration of total villous atrophy in a small bowel biopsy), but are useful as a screening procedure prior to endoscopy and in follow-up, as they usually become normal with successful treatment. Examples of ways in which malabsorption can present are shown in Table 12.2. Some of the basic laboratory investigations that should be carried out in patients in whom a diagnosis of malabsorption is suspected, are shown in Table 12.3. If all of these tests are normal, the diagnosis is unlikely; if they are abnormal, the next step is to look for a specific cause, guided by the history, clinical findings and laboratory results. Anaemia is

TABLE 12.2 Examples of the way in which malabsorption can present

Presentation	Cause
Passage of pale, bulky, offensive stools	Fat malabsorption or maldigestion
Abdominal distension, borborygmi, watery diarrhoea and excessive flatus	Malabsorption of carbohydrate
Vague malaise and tiredness, sometimes with weight loss (adults); growth retardation (children)	Generalized deficiency of nutrients
Anaemia	Deficiency of iron, folate or vitamin B ₁₂
Easy bruising or bleeding	Deficiency of vitamin K
Failure to thrive (infants)	Generalized deficiency of nutrients

TABLE 12.3 Some basic laboratory investigations in patients with suspected malabsorption

Investigation	To look for
Tests for evidence of malabsorption	
Full blood count	Anaemia, evidence of haematinic deficiency
Ferritin	Iron deficiency
Vitamin B ₁₂	B ₁₂ deficiency
Folate	Folate deficiency
Prothrombin time/ International normalized ratio	Vitamin K deficiency
Albumin	Malnutrition
Vitamin D	Vitamin D deficiency
Tests for causes of malabsorption	
C-reactive protein	Inflammatory conditions
Immunoglobulins	Hypogammaglobulinaemia
Antigliadin and anti-tissue transglutaminase antibodies	Coeliac disease
Faecal elastase	Pancreatic insufficiency

a particularly common feature of gastric and small bowel disease. The physiology and biochemistry of the vitamins and minerals involved in blood formation is discussed in detail in Chapter 27. Metabolic bone disease is discussed in detail in Chapter 31. In patients with malabsorption, much emphasis has hitherto been placed on malabsorption of calcium and vitamin D leading to osteomalacia. The advent of dual energy X-ray absorptiometry (DEXA) scans with reliable, sensitive and reproducible quantitation of bone mineral density has made it clear that there is a high prevalence of reduced bone mineral density in patients with coeliac disease and Crohn disease, even with successful treatment. Bone mineral density is frequently reduced in both disorders and osteoporosis may be seen in up to 25% of patients. Bone disease in these conditions predominantly affects the hips, with vertebrae and the forearm bones somewhat less severely affected. An important point is that reduced bone mineral density is often present in IBD at diagnosis and is independent of corticosteroid treatment (which is itself a cause of osteoporosis). Reduced bone mineral density in patients with IBD is associated with cytokine spillover from the gut into the circulation, leading to impairment of osteoblastic activity with no concomitant decrease in osteoclastic activity.

Carbohydrate absorption

Dietary carbohydrates

In most human diets, carbohydrates are the principal source of energy. The major form in the diet is starch, which accounts for about two-thirds of digestible dietary carbohydrate, the remaining third being made up of sucrose, lactose and their constituent monosaccharides. Starch is a polymer of glucose consisting of two forms: amylose and amylopectin. Amylose consists of long, unbranched chains of glucose molecules joined by α -1,4

links. Amylopectin consists of chains of glucose molecules with branching points for side chains every 12–25 glucose units. At each branching point, there is an α -1,6 link. Sucrose and lactose are disaccharides, sucrose consisting of a dimer of glucose and fructose, while lactose is a dimer of glucose and galactose.

Digestion of carbohydrates

Luminal events in carbohydrate digestion. The initial step in starch absorption is enzymatic digestion of α -1,4 links by salivary amylase to release maltose (dimer of two glucose molecules) and maltotriose (trimer of three glucose molecules). The salivary enzyme is rapidly inactivated by gastric acid, but hydrolysis is continued by pancreatic amylase, the end-products being maltose, maltotriose, short-branched oligosaccharides and α -limit dextrins, the latter two being residual branched segments resulting from incomplete digestion of amylopectin. No free glucose is produced.

Enterocyte events in carbohydrate digestion. The final step of carbohydrate digestion, the conversion of oligosaccharides to monosaccharides, is performed by

the disaccharidases of the small intestinal enterocytes. The main disaccharidases are maltase, sucrase-isomaltase and lactase (see Fig. 12.1). These enzymes are synthesized on the endoplasmic reticulum, transported to the Golgi apparatus and then to the brush border. They are distributed throughout the length of the small intestine, but sucrase and lactase are in highest concentrations in the jejunum. They are normally present in considerable excess, so that some reduction in activity does not normally result in symptoms.

The three main monosaccharides derived from the diet (glucose, galactose and fructose) are absorbed by saturable carrier-mediated transport systems in the enterocyte brush border. Secondary active transport of glucose and galactose occurs through a sodium co-transport system, driven by a sodium gradient dependent on Na^+, K^+ -ATPase on the basolateral surface of the cell. Fructose absorption is not active, but occurs through carrier-mediated (facilitated) diffusion.

Both the digestion and absorption of carbohydrates are highly efficient, but the process is incomplete, particularly for starch, with up to one-fifth of dietary starch failing to be absorbed. The efficiency of starch absorption varies, depending on the foodstuff from which it is

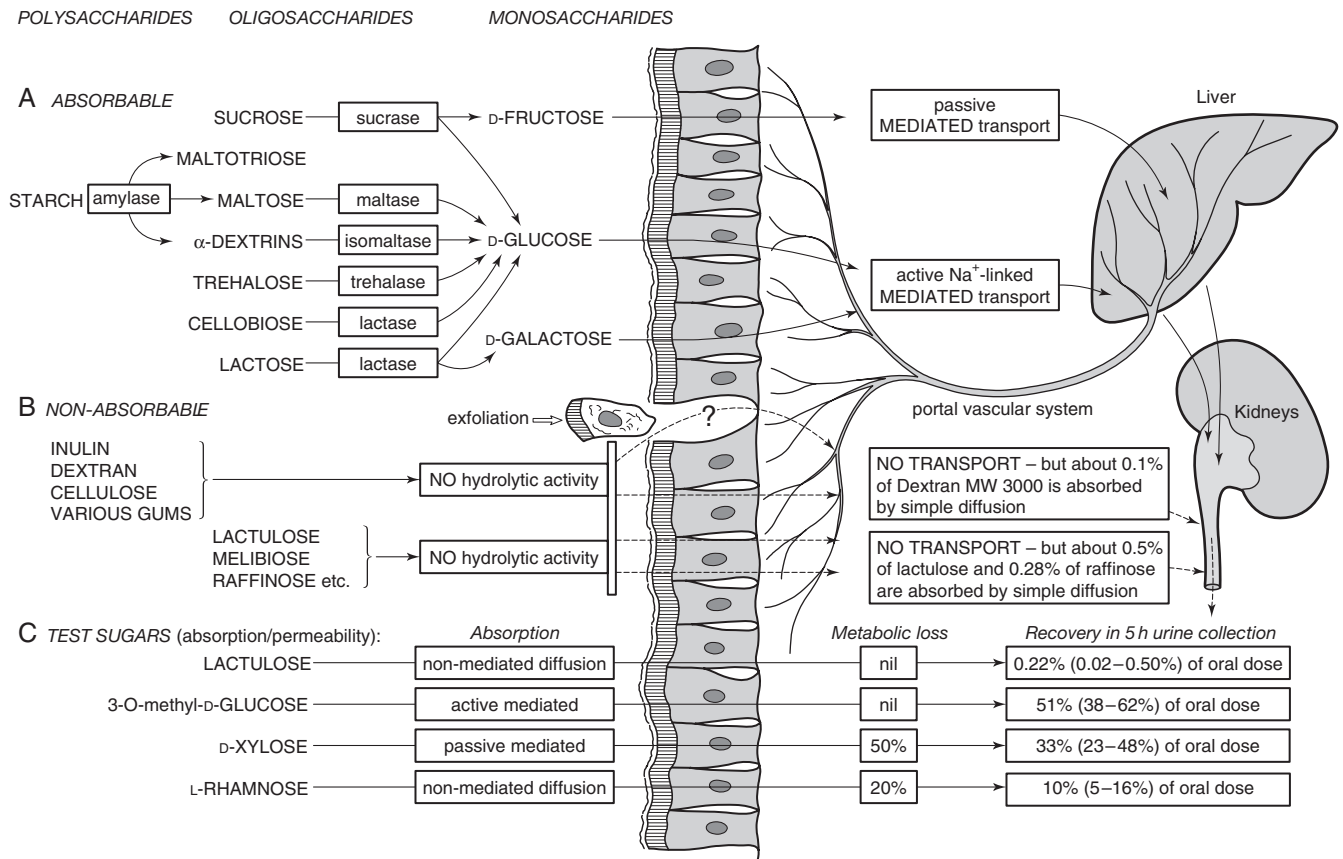

FIGURE 12.1 ■ Digestion and absorption of saccharides. (A) Ingested starch is broken down to the various disaccharides by salivary and pancreatic amylase. The disaccharides are cleaved by the various brush border disaccharidases to yield D-fructose, D-glucose and D-galactose. These in turn are transported across the brush border and enterocytes, and into the circulation by specific transport systems. (B) Non-hydrolysable polysaccharides, disaccharides and trisaccharides are thought to be excluded from permeation across the brush border. The small quantities that do permeate the intestine appear to pass by a paracellular route or through areas of cell extrusion (apoptosis). (C) Four commonly used sugars, used in a combined test of intestinal absorptive capacity and intestinal permeability, use different transport routes across the intestine, which allows assessment of the various intestinal functions. This increases the discriminatory value of the tests when assessing intestinal disease.

derived. For example, rice starch is highly absorbed, but between 10 and 20% of starch in wheat and certain beans enters the colon, where bacteria produce short chain fatty acids (which may be an important energy source for colonocytes), methane and hydrogen.

Clinical aspects of carbohydrate absorption

Although inherited disorders of sucrase-isomaltase and of transport proteins causing glucose-galactose malabsorption and fructose malabsorption are recognized, they are very uncommon. Adult lactase deficiency, however, is common in humans and may be regarded as a normal finding in many ethnic groups. Malabsorption of carbohydrates predisposes to osmotic diarrhoea with excessive flatus, abdominal distension and discomfort ('gripping' pains).

Lactase deficiency. Lactase activity is highest in the earliest months of life, but levels of the enzyme usually decline in all races after weaning. The prevalence of adult lactase deficiency is highly variable between races; so, for example, 5–15% of northern Europeans have demonstrable hypolactasia or alactasia, but >70% of Africans, Asians and especially Inuits have deficiency of the enzyme. However, the vast majority of affected individuals are asymptomatic, because overall completeness of disaccharide hydrolysis depends on the amount ingested, intestinal dilution and transit times, as well as the state of the enzyme (reduced or absent enzyme activity).

In practice, the diagnosis is often made by a therapeutic trial of a diet low in lactose, but metabolic tests are available (see below) and the diagnosis can be confirmed by assaying lactase activity in small bowel biopsy samples (though this is rarely required). Congenital lactase deficiency (i.e. lactase deficiency that is present at birth) has been described, but is extremely rare. The form of enzyme deficiency discussed above is usually known as primary or 'genetic' lactase deficiency. However, lactase deficiency may also complicate mucosal diseases of the small intestine and is then referred to as 'secondary'. This secondary lactase deficiency is a regular feature of coeliac disease, and is also seen in tropical sprue, IBD, radiation enteritis, chronic alcoholism with malnutrition and the enteropathy associated with acquired immune deficiency syndrome (AIDS). It may also accompany infections such as acute gastroenteritis and giardiasis, but usually resolves following resolution or successful treatment of the illness.

Investigation of carbohydrate absorption

The glucose tolerance test is of no value in the detection of malabsorption. The small intestinal reserve capacity for absorption of D-glucose is so great that absorption is usually well maintained, even when mucosal disease is severe. Furthermore, the rise in blood glucose concentration following oral administration is influenced by additional factors such as gastric emptying and endocrine status, which complicate interpretation.

Xylose absorption test. D-Xylose, a pentose sugar of plant origin, has been the basis of an absorption test

in routine clinical use since the 1930s. In the human, D-xylose is absorbed mainly from the jejunum, by a passive carrier-mediated system distinct from that utilized by D-glucose. Unlike D-glucose, there is no reserve capacity for the intestinal uptake of D-xylose, which made this sugar a potentially good indicator, responsive to minor changes in jejunal absorption. However, the concentration of xylose measured after an oral dose is affected by other factors including renal, hepatic and cardiac disease and the test is no longer widely available.

Lactose tolerance test. This test may be used in suspected lactase deficiency. In essence, serial blood samples for glucose estimation are taken after oral ingestion of 50 g of lactose. A rise in venous plasma glucose of <1.1 mmol/L is indicative of impaired lactose hydrolysis. The occurrence of typical symptoms following ingestion of lactose provides further evidence for the diagnosis.

Differential tests of intestinal disaccharide hydrolysis. Small amounts of non-hydrolysable disaccharides are absorbed by passive diffusion and appear in the urine: when hydrolysable disaccharides are not hydrolysed for some reason, the same thing happens. The intestinal uptake and urinary excretion of intact disaccharides in urine are, therefore, influenced by the extent of small intestinal disaccharidase activity: the greater the rate of hydrolysis, the less the excretion of intact disaccharide in urine. Excretion ratios of hydrolysable:non-hydrolysable disaccharides following ingestion of a mixture are, therefore inversely proportional to the efficacy of intestinal hydrolysis. Accurate, non-invasive assessment of intestinal lactase, sucrase or isomaltase can be made, using measurements of lactose/lactulose, sucrose/lactulose or palatinose/lactulose excretion ratios respectively, either separately or in combination. Ratios of lactose, sucrose or palatinose divided by lactulose (% molar dose excreted) may indicate isolated (genetically determined or primary) deficiency of lactase, sucrase (rare, a cause for severe diarrhoea in children) or palatinase (for isomaltase, not clinically relevant). However, if the absorption of two or more disaccharides is impaired, this suggests a secondary deficiency, for example mucosal diseases such as coeliac disease, infection or immune deficiency. Representative results using this test in patients with human immunodeficiency virus (HIV) infection are shown in [Figure 12.2](#).

This is undoubtedly the test of choice for the accurate and reliable assessment of whole bowel disaccharidase activity. It is, however, also more labour intensive and demanding on the patient than the other procedures mentioned above.

Protein absorption

The average Western diet contains some 80–100 g of protein per day, which provides not only the amino acids necessary for protein synthesis, but also some (10–15%) of the energy content of the diet. In addition, the gut digests and absorbs substantial amounts (perhaps 60 g) of endogenous protein derived from intestinal secretions, mucus and the shedding of mucosal cells.

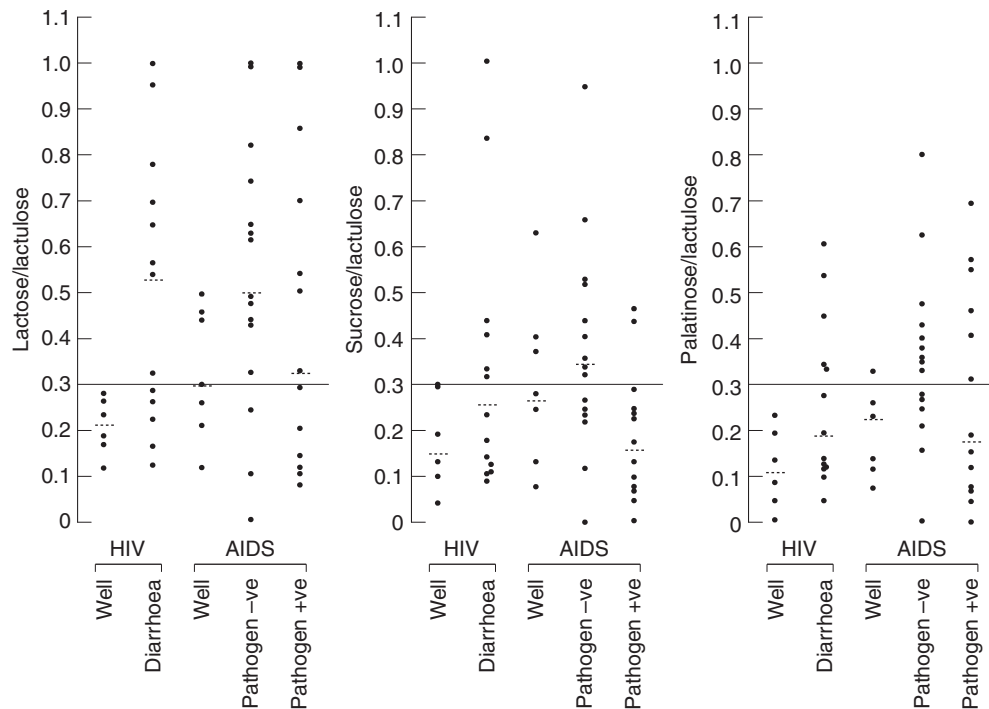

FIGURE 12.2 ■ Quantitative estimation of the rate of intestinal hydrolysis of ingested disaccharides in patients with HIV and AIDS. The test is carried out after an overnight fast and a preceding 12–18 h dietary exclusion of lactose- and sucrose-containing foods. Subjects ingest a solution containing lactulose 5 g, lactose 10 g, sucrose 10 g and palatinose 10 g (with or without L-rhamnose, which allows the integrity of intestinal permeability to be assessed at the same time), followed by a 10 h urinary collection with measurement of the disaccharides (% dose excreted) and calculation of the ratios. Well subjects have molar lactose/lactulose, sucrose/lactulose and palatinose/lactulose urine excretion ratios <0.3, indicative of normal intestinal lactase, sucrase and palatinase activities. Increased ratios in patients with the various stages of HIV are indicative of impaired hydrolysis of each of these sugars. The fact that the hydrolysis of all three sugars is impaired shows that this is secondary disaccharidase deficiency.

Digestion of proteins

Protein digestion takes place throughout the length of the small intestine and is efficient, with only 5% of the protein entering the gut lumen being lost in the stools each day.

Protein digestion begins in the stomach with the grinding and mixing action of gastric peristalsis and the food being exposed to gastric acid and pepsin. Pepsin is a protease that cleaves internal peptide bonds adjacent to hydrophobic amino acids. Pepsin is inactivated at a pH >4.0 and its action is, therefore, confined to the stomach. Digestion of proteins proceeds further through the action of the pancreatic proteases trypsin, chymotrypsin, elastase and carboxypeptidases A and B in the proximal jejunum. These are secreted as inactive proenzymes. Trypsin is released from trypsinogen by the brush border-derived enterokinase and activates the other proenzymes. Trypsin, chymotrypsin and elastase are endopeptidases, hydrolysing peptide bonds adjacent to certain specific amino acids, while carboxypeptidases A and B are exopeptidases, removing amino acids one at a time from the C-terminal ends of the peptides. The proteases reduce chyme to a mixture of free amino acids and oligopeptides (of between two and six amino acid residues). These are then further digested by brush border peptidases. There are at least eight mucosal peptidases that are synthesized and transported in a similar manner to the disaccharidases. However, unlike carbohydrates, the peptides are not completely digested to their constituent units, brush

border enzyme action leaving a mixture of amino acids, di- and tripeptides. There are specific transport systems that effectively absorb di- and tripeptides and, indeed, do so at a faster rate than for free amino acids; this discovery has had implications for the development of enteral feeding regimens. Peptide uptake is by sodium-linked active transport. Once inside the mucosa, peptidases within the enterocyte cleave small peptides to their constituent amino acids. A number of transport systems exist for the uptake of luminal amino acids and there are some rare inherited defects of amino acid absorption, including Hartnup disease (p. 171) and cystinuria (p. 170).

Clinical aspects of protein absorption

The most common cause of protein malnutrition worldwide is inadequate intake, often combined with poor absorption due to tropical enteropathy and frequent episodes of infective enteritis. The clinical syndrome is best illustrated by children from famine areas of the third world with their pot bellies (ascites because of hypoalbuminaemia). There are no specific syndromes of protein malabsorption, although protein deficiency can contribute to the wasting and nutritional disturbance of severe malabsorption syndrome. In several diseases, for example Crohn disease, ulcerative colitis and Whipple disease, excessive protein loss into the gut produces the syndrome of protein-losing enteropathy. This process is not one of malabsorption, although there may be associated malabsorption.

Investigation of protein absorption

There is no clinically useful non-invasive method of assessing protein digestion and absorption. Furthermore, there is little clinical need for such tests as mucosal diseases causing amino acid malabsorption are so rare. Protein-losing enteropathy can, however, be detected easily, most accurately by measuring the faecal excretion of intravenously administered albumin labelled with ^{51}Cr and somewhat less reliably by measurement of faecal α_1 -antitrypsin and α_1 -antichymotrypsin.

Fat absorption

Although the average fat content of the diet has been falling in the Western world over the last 20 years in response to medical advice, the average fat intake is still of the order of 90–100 g/day. There has also been a relative decline in the proportion of saturated fat in the diet with a concomitant increase in polyunsaturated fatty acids. The principal long chain polyunsaturated fatty acids are linoleic (C18:2) and linolenic (C18:3) acids. The other dominant fatty acids are oleic (C18:1) and palmitic (C16:0) acids. In food, these are mainly present as esters with glycerol (triacylglycerols or triglycerides). Additional dietary fat consists of phospholipid, cholesterol and fat-soluble vitamins. Because fats are insoluble in water, the mechanisms for their digestion and absorption are complex, but an understanding of the mechanism of fat digestion and absorption is crucial to an understanding of the wide variety of diseases that cause malabsorption of fat and are consequently associated with steatorrhoea.

Digestion of triacylglycerols

Luminal digestion. The first stage in the digestion of triacylglycerols is the process of peristaltic emulsification. Physical grinding of food, first by chewing and then in the stomach, produces an initial, relatively unstable emulsion that enters the duodenum. The emulsion is stabilized as the fat droplets are coated with phospholipid, provided exogenously in the diet and endogenously from bile. Further stabilization is achieved by a coating of bile salts and with small amounts of monoacylglycerols and fatty acid ions.

The main digestion of the emulsion occurs through the action of pancreatic lipase, but a minor initial component of digestion may be provided through the actions of lingual and gastric lipases, which have pH optima in the acid range. This component is important, however, in providing partial digestion of triglycerides to enhance and contribute to the stability of the emulsion. Pancreatic lipase acts in conjunction with a cofactor, pancreatic colipase, which is secreted in an inactive form (procolipase) and subsequently activated by tryptic digestion. Pancreatic lipase activity is greatest at near neutral pH and is therefore dependent on adequate bicarbonate secretion from the pancreas, under the influence of secretin. The combined action of lipase and colipase hydrolyses triacylglycerols to release fatty acids from the 1 and 3 positions, so that each triacylglycerol molecule is hydrolysed to a monoacylglycerol (with a fatty acid attached at the 2 position) and two

free fatty acids. Bile salts are amphipathic, that is, they contain both water-soluble and lipid-soluble components. This property allows them to aggregate in micelles such that the hydrophobic components line up adjacent to one another on the inside of the micelle with the hydrophilic aspects facing outwards into the aqueous phase. The water-insoluble fatty acids, monoglycerides and cholesterol are, therefore, held 'inside' the micelle to form a highly stable particulate emulsion. While triacylglycerol absorption is fairly efficient in the absence of bile salts, by contrast the absorption of cholesterol and fat-soluble vitamins is severely compromised unless the bile salt concentration in the duodenum is above a critical micellar concentration.

Absorption of triacylglycerols. The transport of lipids across the surface of enterocytes is by passive diffusion, that is, the lipids partition across lipid components in the brush border membrane. The microclimate at the enterocyte surface is slightly more acidic than in the jejunal lumen, which encourages the liberation of fatty acids from micelles. There is some suggestion, however, that a component of fat absorption for certain fatty acids, particularly linoleic and oleic acids, may occur by facilitated diffusion. Triacylglycerols are resynthesized from monoacylglycerols and fatty acids in enterocytes and incorporated into chylomicrons. The carrier protein apolipoprotein B48 is essential for chylomicron synthesis, and absence of this protein, as in congenital abetalipoproteinaemia, produces severe fat malabsorption. While longer chain triacylglycerols (above C10) pass into the lymphatics, medium chain triacylglycerols (C6–10) are at least partly absorbed intact, probably by passive diffusion, to reach the liver by the portal circulation.

Digestion and absorption of other fats

Phospholipids are hydrolysed to fatty acids and lysophosphatidylcholine by pancreatic phospholipase A₂, while cholesteryl esters are hydrolysed by a pancreatic esterase. The fatty acids form micelles with bile acids, and thus both lipids are ultimately transported to enterocytes in a similar way to the digestion products of triacylglycerols. Phospholipids are resynthesized in the endoplasmic reticulum of mucosal cells and cholesterol is esterified by acyl-CoA cholesterol acyltransferase before being incorporated into chylomicrons. The efficiency of fat absorption is considerable so that, in health, the process is virtually complete. Most fat absorption occurs within the proximal jejunum.

Clinical aspects of fat malabsorption

Fat absorption is a complex, multistage process. Therefore, disease at several levels in the alimentary system can result in fat malabsorption, which, when severe, is characterized by the presence of steatorrhoea. Interference with delivery of bile salts into the duodenum, pancreatic exocrine deficiency, failure to achieve near-neutral duodenal pH either from hypersecretion of gastric acid or hyposecretion of pancreatic bicarbonate, and mucosal disease due to villous atrophy, lymphangiectasia, abetalipoproteinaemia etc, can all result in steatorrhoea. Tests of fat absorption have been used in the past as screening methods to detect malabsorption. In modern clinical practice, it

is increasingly evident that confirmation of steatorrhoea (rather than quantification) by microscopy of faeces for fat after suitable staining is sufficient to initiate appropriate investigation of the relevant organs that may play a role in fat digestion and absorption.

Investigation of fat absorption

Faecal fat excretion. Quantitative measurement of faecal fat excretion is the most sensitive method of detecting fat malabsorption. However, this investigation is unpleasant both for patients and laboratory staff, and few laboratories now include it in their repertoires. There have been a number of efforts to find alternative measures of fat absorption. The ^{14}C -triolein (or ^{13}C) breath test is probably the best of these, but, nevertheless, is not widely used.

$^{13/14}\text{C}$ -triolein breath test. Following an overnight fast and collection of a basal sample of expired air, the patient is given ^{13}C - or ^{14}C -triolein in a 60 g fat meal. Hourly breath samples are then collected for 7 h for measurement of labelled carbon expiration. If triolein is effectively absorbed, large amounts of labelled CO_2 will appear in the expired breath, fat malabsorption being indicated by smaller amounts being exhaled. However, when steatorrhoea is macroscopically obvious, confirmation by measurement is not required, and investigation should be directed towards diagnosing the cause.

INTESTINAL PERMEABILITY

An alternative approach to the measurement of absorptive function in the assessment of small bowel disease is to assess barrier function – that is the ability of the intestine to exclude compounds from being absorbed. Increased intestinal permeability is not characteristic of any single disease, but is seen in a variety of gastrointestinal pathologies.

Previously, tests using the differential permeability of combinations of sugars were used to assess intestinal permeability, but these are now largely obsolete, because of capsule enteroscopy. For those interested in these tests, details are provided in Further reading.

FAECAL TESTS OF INTESTINAL INFLAMMATION

The intestinal tract is a most hospitable environment for bacteria. The intestine has developed a very effective and complicated way of accommodating them and protecting the host, but it is clear that the defence system is somewhat less than 100% efficient. If there is a breach in mucosal integrity of any sort, the microbes gain an advantage and elicit a significant inflammatory reaction. Hence, almost all colonic and most small bowel disorders are associated with inflammation.

The first reliable quantitative non-invasive test for assessing intestinal inflammation was the ^{111}In white cell technique, which involved abdominal scintigraphy (for localization of disease) and a four-day faecal collection (for quantitative estimation of the inflammatory activity).

The test is uniquely sensitive for the detection of inflammation, but is not disease-specific. Disadvantages are its cost, the requirement for special labelling facilities, a high dose of radiation and the inconvenience of a complete four-day faecal collection. Simpler methods were needed and subsequently developed. The qualities of a marker for assessing intestinal inflammation are that it should be stable, resistant to degradation by intestinal bacteria, easily extractable from faeces, easily assayed and, preferably, specific for a particular type of inflammatory cell. Two such markers have undergone rigorous testing, namely calprotectin and lactoferrin with other proteins, including M2PK and S100A12, entering the field more recently. Calprotectin acts as a representative for this group of proteins and its use will, therefore, be described in detail.

Calprotectin

Calprotectin accounts for about 60% of total soluble proteins in the cytosolic fraction of neutrophil granulocytes. It is a member of the S100 family of calcium and zinc binding proteins (a heterodimer of S100A8/A9) and is found in neutrophils, monocytes and some squamous epithelial cells. It is released by activation of leukocytes as a consequence of inflammatory disease. Calprotectin has antimicrobial properties and, in addition, it can inhibit the proliferation of both normal and malignant cells, probably by sequestration of zinc, which is a critical element for many enzymes. In particular, the metalloproteinases MMP-2, MMP-3, MMP-7, MMP-8, MMP-9 and MMP-13 are inhibited *in vitro* by calprotectin at biologically relevant concentrations, suggesting that it may have important regulatory functions.

In the presence of calcium, calprotectin is remarkably resistant to proteolytic degradation and it is this fact that underlies its stability in faeces. Commercially available kits can be obtained for the extraction of calprotectin from faeces and quantitation by ELISA and require no more than a 200 mg sample. Reference ranges should be established by individual laboratories, as there are almost certainly racial and geographical variations. In the UK, the upper limit of the reference range for faecal calprotectin is 50–60 $\mu\text{g/g}$. African Caribbeans resident in the UK may have values up to 200 $\mu\text{g/g}$ without disease. In general, when used as a screening procedure for intestinal disease, increased values between 50 and 200 $\mu\text{g/g}$ rarely disclose significant disease. In these cases, we recommend repeating the test before further investigation. Calprotectin concentrations between 200 and 500 $\mu\text{g/g}$ are commonly seen in patients with diverticulitis, colon malignancies and polyps, and those on NSAIDs, whilst those with values >500 $\mu\text{g/g}$ almost invariably have IBD or intestinal infections.

Calprotectin in disease

Inflammatory bowel disease

Studies from different groups have shown that faecal calprotectin concentrations are almost invariably increased above healthy controls in patients with active ulcerative colitis and Crohn disease. The clinical implication is that faecal calprotectin clearly has potential as a screening test to distinguish patients with IBS, who will have normal

concentrations, from those with IBD, whose concentrations are characteristically increased by at least ten-fold in active disease.

Patients with clinically inactive IBD may have a normal faecal calprotectin (depending on treatment), but often have an increased concentration. The considerable overlap between the values in clinically active and inactive disease is such that it is inadvisable to make predictions of a patient's clinical status based solely on faecal calprotectin concentrations.

Faecal calprotectin is particularly useful in patients with inactive ulcerative colitis and Crohn disease, as values five times above the upper limit of normal have 90% sensitivity and 83% specificity in predicting clinical relapse within six months, allowing the opportunity for early treatment.

Colorectal cancer

Colorectal cancer (adenocarcinoma) is the second most common cause of death from malignancy in the Western world. Survival rates are closely related to the stage of cancer at the time of diagnosis, and the most promising approach to reducing mortality rates is the early detection of precancerous or cancerous lesions. The most widely accepted non-invasive method for detecting colorectal cancer is faecal occult blood (FOB) testing. Screening in asymptomatic populations has, at best, reduced mortality rates by 15–33%; a national bowel cancer screening programme using faecal occult blood testing was initiated in the UK in 2006.

Various studies have consistently demonstrated that faecal calprotectin concentrations are increased in patients with colorectal cancer. Sensitivity is of the order of 80–90%, whereas that for FOB is only 40–58%. Furthermore, faecal calprotectin is increased in 50% of patients with colorectal polyps (some of which may be precancerous). However, the test is not recommended for cancer screening purposes because of its lack of specificity. Numerous faecal molecular marker probes, usually polymerase chain reaction (PCR) based, are currently being tested for the detection of colorectal cancer. To-date, they lack sensitivity, but are very specific.

Irritable bowel syndrome

Given that faecal calprotectin has a sensitivity of almost 100% in detecting patients with active IBD, this raises the possibility of using it as a screening test to distinguish between these patients attending outpatient clinics and the more common patients with IBS who do not warrant invasive investigation. The main value of the test in patients with IBS is that a normal test result practically rules out chronic inflammatory bowel disease and thereby reduces the need for invasive investigation. Of patients with IBS, 15–20% have raised faecal calprotectin, typically to 2–3 times normal.

Neuroendocrine tumours of the gastrointestinal tract and pancreas (NETs)

Neuroendocrine tumours of the gastrointestinal tract are relatively rare, but easily diagnosed when they produce clinically distinct and specific syndromes. However, many

of the tumours do not secrete substances that lead to the specific syndromes, and are only detected because of the physical effects of local or metastatic lesions. A proportion of these tumours have a genetic predisposition due to a loss of tumour suppressor genes, namely multiple endocrine neoplasia (MEN) type 1 and 2 (see Chapter 41).

As a group, the neuroendocrine tumours are characterized histologically by sheets of small round cells that are derived from intestinal neuroendocrine cells in the submucosa, with very infrequent mitosis. It is, therefore, not usually possible to distinguish between a benign and malignant tumour histologically, unless there is evidence of metastasis. This contrasts very sharply with the common gastrointestinal cancers (oesophageal, gastric and colonic) that originate from the epithelial cells (squamous cell cancer and adenocarcinomas), where histopathological diagnosis is usually straightforward. From the clinical biochemistry viewpoint, it is most logical to discuss the different tumours according to the clinical syndromes that they cause.

Intestinal carcinoid tumours and the carcinoid syndrome

The carcinoid syndrome. The cardinal presenting symptoms of the carcinoid syndrome are persistent diarrhoea (40–80%), flushing (30–70%) and nondescript abdominal pain (10%). The diarrhoea is watery and the need to defecate often coincides with the flushing periods. The flushing is intermittent, of sudden onset, brief (lasting for <15 min), associated with a feeling of warmth and can be precipitated by alcohol ingestion, exercise or by certain foods, especially cheese. The flushing is mainly on the neck and face and is otherwise not distinctively different from menopausal flushing or drug-induced flushing (chlorpropamide and calcium channel blockers). Moreover, there are other well-recognized, albeit less common, manifestations of the carcinoid syndrome. Cardiac valvular involvement (10% of patients) present as right sided heart failure. A further 10% of patients develop asthma-like symptoms, and those with metabolically active tumours that utilize much of the ingested tryptophan may have pellagra-like skin lesions due to nicotinic acid (niacin) deficiency.

The carcinoid syndrome is a manifestation of a carcinoid tumour, a tumour of argentaffin cells that can occur anywhere in tissue derived from the embryonic gut, but most frequently is found in the ileum. Its pathophysiology, diagnosis and management are discussed in detail in Chapter 41. Measurement of urine 5-HIAA and/or serum chromogranin A is used in the diagnosis and monitoring of carcinoid syndrome patients.

Pancreatic endocrine tumours

Pancreatic endocrine tumours have been variously called 'islet cell tumours' or APUDomas (amine precursor uptake and decarboxylation) and are of similar origin to carcinoids. They share certain features, consisting of homogeneous sheets of small cells with very few mitoses. Malignant potential may be indicated by local invasion or metastasis, and each tumour is usually associated with

symptoms attributable to a single hormone/peptide, although the tumour may release a number of hormones. Unlike carcinoids, pancreatic endocrine tumours are mostly functional, that is, they are associated with symptoms that are attributable to the hormone that they release. Their prominence in textbooks is disproportionate to their clinical importance, and the vast majority of patients are managed and treated within specialist units. As a group of tumours, they are exceptionally rare with an annual incidence of 1–2/million population. Insulinomas and gastrinomas are the most common, with vasoactive intestinal peptide (VIPomas), glucagonomas and somatostatinomas being ten times rarer, while others are confined to single case reports. Pancreatic endocrine tumours are not infrequently discovered because of their association with MEN-1 and 2 (see Chapter 41) or the phacomatoses (tuberous sclerosis, von Hippel–Lindau and von Recklinghausen disease).

Insulinomas. Tumours of the β cells of the pancreas secrete insulin without the normal physiological feedback action of circulating blood glucose. Fifty per cent of insulinomas are <1 cm in diameter at diagnosis, most are solitary (except when associated with MEN) and 90% are benign. Insulinomas typically present with symptoms of hypoglycaemia, especially after fasting or exercise. The most common symptoms are loss of consciousness (sometimes presenting as coma), dizziness, diplopia, blurred vision, confusion, abnormal behaviour, excessive sweating, palpitations and weight gain (because of the increased food intake that relieves some of the symptoms). The diagnosis is based on the presence of ‘Whipple’s triad’, namely symptoms of hypoglycaemia, documented hypoglycaemia and relief of symptoms when glucose is administered to restore normal blood glucose concentrations.

The first step in the diagnosis of insulinoma is the documentation of fasting hypoglycaemia, which can best be differentiated from postprandial hypoglycaemia from the clinical history. A low plasma glucose concentration in the presence of inappropriately high insulin and C-peptide concentrations is strongly suggestive of an insulinoma. Insulin and C-peptide are formed in equimolar amounts from the enzymatic cleavage of proinsulin. A high insulin concentration in the presence of a low C-peptide concentration is indicative of the administration of exogenous insulin. Hypoglycaemia associated with misuse of sulfonylureas may need to be excluded from the differential diagnosis by measurement of serum sulfonylurea concentrations. Other causes of hypoglycaemia, including alcohol misuse, Addison disease and liver failure, should also be excluded. Hypoglycaemia can be life-threatening and only surgery can offer curative treatment. Techniques such as CT and MRI may localize tumours larger than 1 cm, but at least 50% of tumours are smaller than this. Angiography has a high detection rate for smaller insulinomas, as these are highly vascular, and endoscopic ultrasound is increasingly used for their detection. In the most difficult cases, it may be necessary to sample venous blood selectively from the pancreas in order to detect a differential increase in C-peptide concentrations following arterial injection of calcium.

Glucagonoma. The clinical hallmark of a glucagonoma is the symptom complex of migratory necrolytic erythema, weight loss and anaemia. Glucose concentrations may be high due to the antagonist action of glucagon to insulin. The skin lesions are the most distinct component of glucagonoma, and the difficulty recognizing them may account for the fact that they have often been a feature of the disease for an average of six years prior to diagnosis.

Unlike insulinomas, glucagonomas are usually large (>5 cm) at the time of diagnosis and >50% are malignant. Localization by conventional imaging techniques is, therefore, not a problem. The diagnosis can be confirmed by finding raised plasma glucagon concentrations: these are usually elevated five-fold or more. Minor elevations of glucagon can be found in chronic renal failure, acute pancreatitis and severe trauma, especially with burns and sepsis, but these conditions are easily identified clinically. Surgery should always be considered despite the malignant nature of many of the tumours. The medical treatment is largely directed at control of diabetes; octreotide is sometimes useful.

VIPoma. VIPomas are rare tumours, characterized by copious watery diarrhoea with dehydration and hypokalaemia. The severity of the diarrhoea is comparable to that seen in cholera with excretions in excess of 2 L/24 h. The diagnostic feature of the diarrhoea is that it continues despite prolonged fasting. Plasma VIP concentrations are elevated 4–5-fold; the same imaging techniques are used to localize the tumour as in glucagonomas. VIPomas have the same propensity as glucagonomas for malignancy. While surgery is usually considered, their medical management remains important with rehydration and correction of electrolyte disturbances in severe cases, and use of antidiarrhoeals (e.g. loperamide, codeine phosphate and somatostatin analogues).

Somatostatinoma. Excessive secretion of somatostatin (the somatostatin syndrome) is characterized by diabetes (somatostatin inhibits release of insulin); diarrhoea (because of inhibition of exocrine pancreatic function); weight loss and gallstones (a result of impaired gallbladder contraction). However, as pancreatic surgery for tumours becomes more common, it is evident that only 10% of somatostatinomas are functional, that is, associated with the somatostatin syndrome. Somatostatinomas tend to be large (2–10 cm at diagnosis), and the majority are malignant with evidence of metastasis being present at the time of diagnosis. A significant number are detected during cholecystectomy or following pancreatic tumour work-up. Occasionally, symptomatic patients with the somatostatin syndrome are diagnosed on the basis of increased plasma somatostatin concentrations. Treatment options include surgery and chemotherapy.

THE ACUTE ABDOMEN

Introduction

The term acute abdomen is used to indicate the rapid onset of severe symptoms that may indicate potentially life-threatening intra-abdominal pathology requiring urgent

surgical intervention. Its clinical importance is not in doubt. Many of the diseases that present in this way have a high mortality if not treated surgically; conversely, others are associated with high mortality and morbidity if surgery is performed. The vast majority of patients with an acute abdomen present initially to an accident and emergency department (at least in the UK) and are then transferred to the care of surgeons.

The clinical diagnosis is based principally on the nature of the pain. Common causes of the acute abdomen are shown in [Box 12.1](#). Additionally, there are diseases such as measles causing ileitis and perforation that have a higher incidence in the developing world. Non-abdominal pathologies may simulate an acute abdomen.

History and examination often yield a likely diagnosis, but investigations are helpful in providing confirmation, e.g. testing for pregnancy in women with lower abdominal pain, measurement of amylase when acute pancreatitis is suspected. In addition, a full blood count may reveal an increase in neutrophil count suggestive of infection or anaemia secondary to blood loss, and it is important to have knowledge of renal function and electrolytes prior to undertaking surgery.

BOX 12.1 Causes of an acute abdomen

Common causes

- Non-specific abdominal pain
- Acute appendicitis
- Acute cholecystitis, ascending cholangitis
- Small and large bowel obstruction
- Intussusception, volvulus and strangulated hernias
- Renal/ureteric colic
- Perforated peptic ulcer
- Acute pancreatitis
- Acute diverticulitis
- Gynaecological conditions (salpingitis, ectopic pregnancy)
- Ruptured aortic aneurysm
- Bleeding (haematoma) associated with anticoagulation

Less common causes

- Gastroenteritis including infection with *Salmonella*, *Shigella*, *Yersinia*, measles virus etc.
- Crohn disease
- Mesenteric lymphadenitis
- Pyelonephritis
- Meckel diverticulitis

Conditions that may simulate an acute abdomen

- Acute intermittent porphyria
- Myocardial infarction
- Myocarditis
- Pulmonary embolism
- Pneumothorax
- Pneumonia
- Oesophagitis (reflux, infectious)
- Oesophageal rupture
- Sick-cell crisis
- Acute leukaemia
- Herpes zoster
- Familial Mediterranean fever

There follows a brief account of the disorders where clinical biochemistry may play an important role in confirming the diagnosis of diseases that present as an acute abdomen, namely acute pancreatitis, ectopic pregnancy and porphyria. It should, however, be appreciated that other diagnostic modalities can also provide important information, for example, ultrasound or CT examination in suspected acute pancreatitis.

Acute pancreatitis

Acute pancreatitis is an acute inflammation of the pancreas. Some cases may be self-limiting, but others may be severe and associated with organ failure including pulmonary insufficiency and acute kidney injury and with local complications such as pancreatic necrosis, abscess or pseudocyst formation.

[Table 12.4](#) shows the factors that are recognized to be important in its aetiology, of which gallstones and alcohol account for >80% of cases. The precise pathogenesis is often uncertain, but the most widely accepted hypotheses suggest that insults to the pancreas cause activation of zymogens (inactive pro-enzymes) within the gland and consequent autolytic destruction and production of inflammatory cytokines and chemokines. How the initial insult brings about these changes is disputed, although ischaemia may promote both.

Almost all patients with acute pancreatitis have abdominal pain. This is severe epigastric pain, usually of sudden onset, often with radiation to the back. In more severe cases, there is nausea and vomiting, fever, hypotension, shock and multiorgan failure that may lead to death. Biochemical features of acute pancreatitis include: uraemia (compromised renal function); hypoalbuminaemia (extravasation); hypocalcaemia (partly related to hypoalbuminaemia and partly because fatty acids released in and around the inflamed pancreas by pancreatic lipase form insoluble calcium salts); hyperglycaemia (increased sympathetic activity and destruction of the islets of Langerhans); metabolic acidosis; hypoxaemia, and raised plasma activities of liver enzymes. None of these is invariably present and none is diagnostic for pancreatitis. In acute necrotizing pancreatitis, methaemalbuminaemia may be detectable. The main use of these tests is to provide information about the prognosis, and they may also influence management. Biochemical tests that are used for their diagnostic potential in acute pancreatitis include amylase and lipase.

Amylase

In acute pancreatitis, amylase activity rises within 2–12 h of the onset of symptoms, usually returning to normal within 3–5 days. Serum amylase above five times the upper reference limit is very suggestive of acute pancreatitis. Smaller increases may have other explanations (see [Table 12.1](#)).

In exceptionally rare cases, pancreatitis severe enough to cause death may occur without a rise in serum amylase. A persistently high amylase following an attack of acute pancreatitis suggests the formation of a pancreatic

TABLE 12.4 Causes of acute pancreatitis

Factors	Comment
Gallstones	The most frequent, and best established, aetiological factor. Migrating small gallstones may block the pancreatic duct (some people believe that reflux of bile into the pancreas is also important) and thereby initiate the damage
Alcohol misuse	The acute effects of ethanol on the pancreas are complex. Alcohol alters pancreatic blood flow and, coupled with the generation of free radicals from ethanol metabolism, this may cause free radical damage. Alcoholic stimulation of pancreatic secretion coupled with spasm of the sphincter of Oddi could lead to obstructive injury. Ethanol may also sensitize the pancreas to the effects of other agents that lead to zymogen activation and the generation of harmful cytokines. The overall contribution of these factors to the development of alcoholic pancreatitis is unclear
Drugs	Thiazide diuretics, oral contraceptives, corticosteroids, 5-aminosalicylic acids (used in the treatment of inflammatory bowel disease), azathioprine, 6-mercaptopurine, asparaginase, didanosine, valproate, statins and other drugs have all been implicated as aetiological agents, but only rarely. The mechanisms are unknown
Hypercalcaemia	Often quoted, but the majority of patients with hypercalcaemia do not develop pancreatitis
Hypertriglyceridaemia	Severe hypertriglyceridaemia is important in its own right, but excessive alcohol ingestion is a confounding factor in many cases
Trauma	Blunt trauma to the abdomen may occasionally cause acute pancreatitis; the trauma may also be iatrogenic, e.g. following endoscopic retrograde cholangiopancreatography (ERCP)
Infectious causes	Coxsackievirus, <i>Ascaris lumbricoides</i> , <i>Candida</i> , <i>Salmonella</i> , HIV
Rare causes	Pancreatic tumours, hereditary pancreatitis, autoimmune pancreatitis, scorpion toxins, idiopathic

pseudocyst, a cyst containing pancreatic enzymes, which needs to be differentiated from an abscess, which is infective in nature. Since amylase is excreted in urine, the diagnostic efficacy of urinary amylase measurement in acute pancreatitis has also been investigated. Diagnostic performance can be improved by the simultaneous measurement of amylase and creatinine in paired serum and urine samples. The normal ratio of amylase clearance to creatinine clearance is 2.2–4.2%, rising to 6.3–13.3% in acute pancreatitis. This approach is less convenient than simply measuring serum amylase. In general, the main use of urinary amylase is in establishing a diagnosis of macroamylasaemia. This is a condition where serum amylase is consistently raised (characteristically 2–3-fold) owing to the formation of complexes of amylase from non-pancreatic and pancreatic origin with immunoglobulins, usually IgG. When this is the case, a raised serum activity is not accompanied by a correspondingly increased urinary amylase. The isoenzyme raised in the plasma in illness depends on the source of the amylase, for example in pancreatitis, the P enzyme is raised, whereas in ruptured tubal pregnancy, the S isoenzyme is increased, and in renal failure, both S and P are raised. An increase in both isoenzyme fractions of amylase with a normal lipase is also suggestive of macroamylasaemia.

Lipase

The rise in plasma lipase activity approximately parallels that of amylase. Measurement of both enzymes may improve diagnostic accuracy, at least in part because the fall in lipase is slower, so that it remains raised for longer following an acute attack. Lipase activity increases in any condition where hyperamylasaemia is due to pancreatic pathology, but not when the amylase is of non-pancreatic origin. In particular, serum lipase activity is normal in macroamylasaemia. While lipase measurements overcome some of the non-specificity of amylase estimation in acute pancreatitis, lipase may still be raised

in non-pancreatic disease. This, together with the fact that analytical methods for lipase are more complex and expensive than those for amylase means that lipase measurements are not widely used in the UK. Nevertheless, national guidelines recommend the measurement of lipase for diagnosis.

Choice of test for pancreatitis

Of the approaches discussed above, the measurement of serum amylase activity is the most frequently used biochemical test for pancreatitis, mainly because it is easy to perform. In areas where there is a large population of African Caribbeans (who have a higher reference range), the measurement of lipase may occasionally be useful to establish whether a raised amylase is of pancreatic origin. A number of other markers of acute pancreatitis have been investigated (e.g. elastase and phospholipase A₂), but as yet these have not become established in routine use.

Ectopic pregnancy

A fertilized ovum occasionally may implant outside the uterus, where it gives rise to an ectopic pregnancy. The most common site is in one of the Fallopian tubes. Although this is not a common cause of an acute abdomen, even in young women, it is important because if a tubal pregnancy ruptures, the resulting massive intra-abdominal haemorrhage is life-threatening.

Serum progesterone is lower in absolute concentration and human chorionic gonadotrophin (hCG), which normally doubles in concentration every two days after implantation, tends to increase somewhat less rapidly in ectopic than in normal pregnancy. However, while such measures can be useful, they are not applicable in an acute situation. Rapid, sensitive urinary hCG assays are now available as near patient tests and will usually indicate whether or not the patient is pregnant (although occasionally hCG is undetectable in both maternal urine and

serum in ectopic pregnancy). Quantitation of serum hCG is valuable, since, in a normal pregnancy, a gestational sac should be detectable in the uterus on transabdominal ultrasonography once the hCG is >1000 IU/L. The clinical diagnosis of ectopic pregnancy can be difficult, and the results of biochemical tests have to be considered in light of the clinical assessment and the results of other techniques, such as transabdominal and transvaginal ultrasonography.

Acute porphyria

Acute porphyria is an exceptionally rare cause of an acute abdomen. The diagnosis may be suggested by the history (e.g. the association of the abdominal pain with the ingestion of a drug known to provoke acute attacks in susceptible subjects), or occasionally by someone noticing that the patient's urine is dark red, or that it darkens on standing.

The porphyrias are discussed in detail in Chapter 28, but in a patient with acute abdominal pain, a negative screening test for urinary porphobilinogen (PBG) effectively excludes porphyria as the cause of the pain. (δ -Aminolaevulinic acid dehydratase deficiency remains a theoretical possibility, but only isolated cases of this condition have been reported.) If the test for urinary PBG is positive, then one of the acute porphyrias is likely.

CONCLUSION 249

INTRODUCTION

It is widely accepted that the term 'liver function tests', as currently used in clinical practice, is a misnomer. Certainly this is true as compared with pulmonary or renal function tests. These describe the measurement of distinct physiological and biochemical organ functions that have meaning in the absence of any organ pathology. In marked contrast, most of the parameters that comprise the standard liver 'function' tests, such as the plasma activities of certain aminotransferases, which have major and well-defined roles within the cell, have no *functional* significance at all in plasma, where they are simply markers of hepatocyte disruption. Their measurement is only of any significance when applied to liver pathology. To this extent, understanding of the conventional liver function tests relies on a broad grasp of the principles of liver disease, and the present chapter should, therefore, be read in conjunction with Chapter 14.

This is not to say that the function of the liver is not well understood. But, while it is conventional to list the functions that the liver can perform, this detracts from gaining a broad conceptual picture of what the liver 'does'. Essentially, the liver is a regulatory barrier between the systemic circulation and the organism's environment experienced via the gut. The job of the acinus, the functional unit of the liver, is to regulate the concentrations of solutes entering the systemic circulation via the terminal hepatic venules or being excreted in the bile. It is the principal organ of metabolic homeostasis, that is, maintenance of blood composition within physiologically acceptable limits by the conversion, synthesis and release of components required by other organs and by removal of toxic substances that may be injurious to tissues.

This chapter reviews briefly the anatomy, physiology and biochemistry of the normal liver as a basis for understanding the tests currently applied in clinical practice and those that may be developed in the future.

ANATOMY OF THE LIVER

The macroscopic and microscopic anatomy of the liver is difficult to understand, partly because of its inherently complicated three-dimensional structure and partly because of the recent trend to replace simple (but misleading) morphological descriptions with more accurate, but less obvious, functional descriptions.

The hepatic circulation

The liver has a dual blood supply. Arterial blood, direct from the aorta, is supplied via the hepatic artery from the coeliac axis. The second source is the portal vein, which is formed by the joining of the superior mesenteric and splenic veins and which collects blood from the gut. After passage through the sinusoids (see below), blood drains from the liver via the hepatic veins at the posterior aspect of the liver into the inferior vena cava and thence to the right side of the heart. The portal venous system delivers about 80% of the blood and 20% of the oxygen supplied to the liver. A major cause of abnormal function in chronic liver disease is disturbance of blood flow through the liver, consequent on the fibrosis that follows chronic liver cell damage, but if the portal vein is blocked, relatively normal liver function can be maintained for many years. Arterial occlusion occurring suddenly, for example as a result of trauma, leads to acute liver failure, but more gradual occlusion by a tumour mass is compatible with normal liver function for quite long periods.

Macroscopic structure

The liver is a wedge-shaped organ located in the right upper quadrant of the abdomen. Its mass varies with that of the individual, being in the order of 22 g/kg body weight. In a typical 70 kg subject, the liver weighs about 1.5 kg. It has a large right lobe, a smaller left lobe anteriorly and two further small lobes, the quadrate and the caudate lobes. These lobes relate to the venous drainage, not to the portal distribution (see below). Thus, the left hepatic vein drains the left hepatic lobe and the right and middle hepatic veins drain the right hepatic lobe. In terms of the portal structures, there are two *functional* lobes defined by the right and left portal veins. The division is marked by a line joining the inferior vena cava and the gallbladder bed (Fig. 13.1).

Microscopic structure

Hepatocytes, the hepatic parenchymal cells, comprise about 80% of the total cell mass of the liver. As viewed under the microscope, the functional unit of the liver appears to be the acinus, often termed the lobule, and it is in terms of this structure that pathological changes are described. Since liver biopsy has, under many circumstances, become the *de facto* 'gold standard' of liver disease diagnosis, it is important to understand this terminology. It is also important to understand that this unit does not comprise a homogeneous collection of hepatocytes and

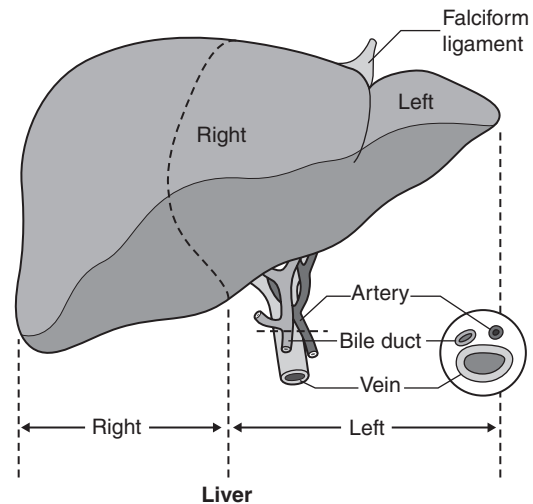

FIGURE 13.1 ■ The anterior surface of the liver. The labelling in the upper part of the figure represents the conventional description into a right and left lobe separated by the falciform ligament. The lower part of the labelling refers to the right and left lobes defined by distribution of the portal structures. The right and left portal structures (portal vein, hepatic artery and bile ducts) enter the functional right and left lobes, respectively.

that there is marked functional heterogeneity across the acinus, with different zones having different physiological and biochemical functions (see below).

The acinus

The acinar/lobular concept of the structure of the liver is based on a central efferent terminal hepatic venule surrounded by radially oriented plates of hepatocytes and sinusoidal channels. Three to five portal tracts (or 'triads'), containing branches of the portal vein, hepatic artery and bile duct, are situated around the periphery of each acinus (Fig. 13.2A).

The acini represent microcirculatory units comprising groups of liver cells, each fed by a single terminal portal venule and hepatic arteriole, the blood from which passes via the sinusoids into a terminal hepatic vein (Fig. 13.2B). Flow is unidirectional, from portal tract to hepatic vein. The 20 or so hepatocytes that separate the portal tracts from the terminal hepatic vein in an acinus have been arbitrarily separated into three zones, through which the portal blood passes sequentially. Zone 1 is conventionally used to describe hepatocytes nearest the afferent arteriole in the portal tract (the periportal area), and those surrounding the terminal hepatic vein, in the 'centrilobular' or 'perivenular' area, are described as zone 3. Between these two zones is an ill-defined area (zone 2), which is intermediate in terms of the composition of the perfusing blood. It must be emphasized that there are no anatomical boundaries between these three zones but, clearly, as blood perfuses each zone sequentially, its composition is altered and this leads to the functional heterogeneity of hepatocytes across the acini in response to the changes in their microenvironment. Zone 1 hepatocytes receive blood rich in oxygen and have a high level of metabolic activity. It is not surprising, therefore, that oxidative functions of the liver tend

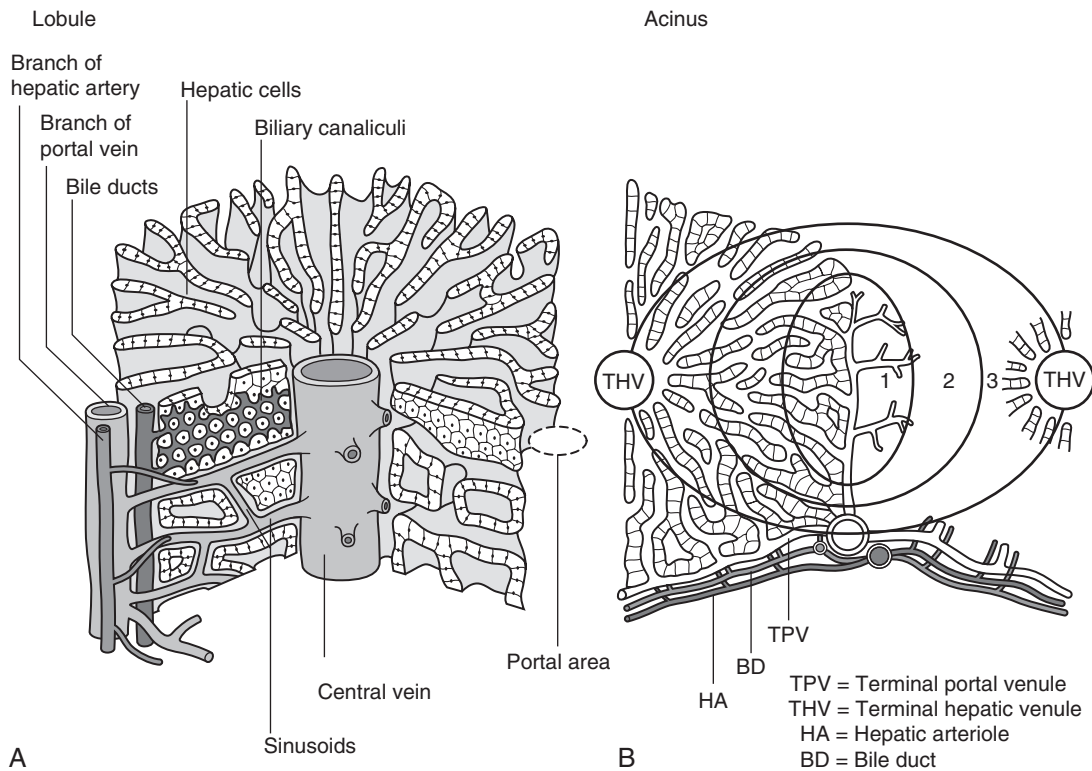

FIGURE 13.2 ■ (A) The conventional hepatic acinus (lobule) based on the central vein with surrounding portal tracts. (B) The hepatic acinus and its three functional zones. The axis is formed by the terminal portal venule, hepatic arteriole and bile duct. Blood flows from the periphery of the acinus to the terminal hepatic venule.

to be performed mainly by hepatocytes in zone 1, with metabolic processes that can operate at lower oxygen tensions occurring mainly in zone 3.

A detailed discussion of the functional heterogeneity of the three zones is not undertaken here, but we mention some examples that could be important if damage to the liver is not uniform. Thus, oxidative metabolism (the respiratory chain, citric acid cycle and fatty acid oxidation), gluconeogenesis, urea synthesis and the production and excretion of bile all occur mainly in zone 1, while glycolysis, glutamine synthesis from ammonia, and xenobiotic metabolism occur predominantly in zone 3. It is not difficult to appreciate that different pathological insults may differentially damage the various zones. Perhaps blood tests may eventually be developed to investigate the integrity of the different zones and thereby reduce the need for histological examination in the diagnosis of different liver disorders.

Ultrastructure

Hepatocytes are arranged in single-cell sheets or 'plates', supported by a fine mesh of a collagenous material (reticulin) and separated from overlying fenestrated endothelial lining cells by the space of Disse (Fig. 13.3). The hepatocytes are exposed to blood flowing through the sinusoids on each side of the plates. Their sinusoidal surfaces have a microvillar structure that greatly increases the surface area of the cell membrane, thereby facilitating efficient exchange of solutes between the blood and the cells. Bile produced by the hepatocytes is excreted via specific transporters located in the membrane of the biliary canaliculi (see below). The latter are formed by

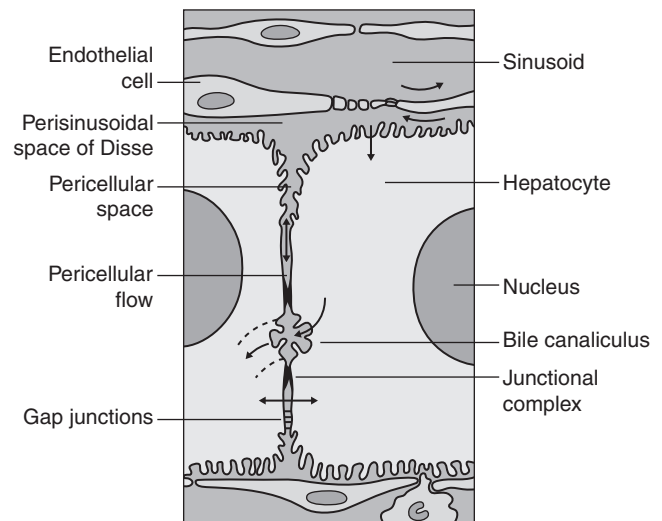

FIGURE 13.3 ■ Ultrastructure of the liver. Solute transport is shown across the sinusoid, which does not have a conventional basement membrane, and across the space of Disse. Here they may be taken up across the hepatocyte membrane and subsequently across the canalicular membrane, or enter the canaliculus through the 'paracellular pathway' via the intercellular junctions.

invaginations of the smooth basolateral membranes between adjacent hepatocytes, and also have a microvillar structure. Direct communication between the blood and bile is prevented by tight junctions in the basolateral membranes on either side of the biliary canaliculi. In addition to the endothelial cells that filter fluid exchanged between the sinusoidal lumen and

the space of Disse, the sinusoids also contain Kupffer cells (a major part of the reticuloendothelial system), hepatic stellate cells (vitamin A-storing, fat-storing cells, also known as Ito cells, that produce several connective tissue components) and liver-resident natural killer cells with antitumour activity. These non-parenchymal cells are an area of intensive research; current evidence suggests that they play a major role in synthesis of growth factors responsible for control of liver regeneration and development of fibrosis in liver disorders (see below).

Bile, bile ducts and biliary drainage

The biliary canaliculi formed between adjacent hepatocytes are continuous with canaliculi between other hepatocytes within the plane of the liver cell plates, and eventually drain into ductules lined by specific biliary epithelial cells and ultimately into the major bile ducts, thence to the common bile duct and the gut. Interruption of the flow of bile, the exocrine secretion of the liver, is responsible for many of the signs of hepatobiliary disease. Bile pigment and bile acid metabolism are described below, and the pathological anatomy of the liver and biliary tract is described in Chapter 14.

HEPATIC REGENERATION

The fact that the liver has a great capacity for regeneration is the rationale for much of the practice of clinical hepatology, particularly for undertaking prolonged periods of liver-intensive care during acute liver failure and for the feasibility of extensive resection, particularly for the management of primary and, less commonly, secondary malignant liver tumours.

Hepatic regeneration has been studied mainly in animals, most extensively the rodent model, after partial hepatic resection. Twenty-four hours after liver resection, there is extensive division of the remaining cells accompanied by a surge in DNA synthesis; this is followed 24 h later by increased replication of the non-parenchymal cells. The initiation of these events is by growth factors that are now being identified. Epidermal growth factor (EGF), transforming growth factor α (TGF α) and hepatocyte growth factor (HGF) are all involved in switching on regeneration, and transforming growth factor β (TGF β) is involved in switching it off. Normally quiescent differentiated hepatocytes replicate rapidly after resection, while intrahepatic precursor cells, termed oval cells, proliferate and generate lineage only in situations where hepatocyte proliferation is blocked or delayed. Bone marrow cells can generate oval cells, but such transdifferentiation is now known to be inefficient and occurs only rarely.

PHYSIOLOGICAL FUNCTIONS

Because the various functions of the liver may fail at different times, creating differing clinical pictures, it is necessary to consider each function separately. The physiology and

biochemistry of the liver subsume most of intermediary metabolism and, as such, are clearly beyond the scope of this chapter. Other than giving a brief outline, emphasis is placed on those functions whose measurement or disturbance is important in liver tests or pathology, respectively.

Carbohydrate metabolism

As has been known for many years, removal of the liver in an animal leads to death from hypoglycaemia. A major metabolic function of the liver is to store sugar and reduce the variations in blood glucose consequent upon the human habit of eating intermittently. Thus, during a meal, the liver stores glucose as glycogen and then releases it (glycogenolysis) slowly when food is not being eaten. This is particularly important for those organs such as the brain and red blood cells that have an obligatory requirement for glucose. Specific glucose transporter molecules located in the sinusoidal membrane that mediate facilitated diffusion are involved in both processes. Between meals, as the supply of glycogen decreases (only about 75 g can be stored), the liver starts to make glucose (gluconeogenesis) from other sources, particularly lactate, but also pyruvate, glycerol and alanine, although only from alanine is there a significant *net* production of glucose. During more prolonged periods of starvation, the total body requirement for glucose falls and energy demand is increasingly met by production of ketone bodies, derived mainly from fatty acids via acetyl-CoA. Apart from being stored, glucose is used by the liver as an energy substrate via glycolysis and the citric acid cycle, or for the synthesis of fatty acids and triglycerides.

Insulin is secreted in response to the rise in blood glucose concentration after a meal and promotes an increase in peripheral glucose uptake and a decrease in gluconeogenesis. In acute liver failure, the liver may not be able to maintain an adequate concentration of blood glucose and hypoglycaemia may become a life-threatening complication; in *chronic* liver disease, hyperglycaemia is more common, most likely because of a failure of the liver to store glycogen and failure of peripheral tissues to take up glucose adequately. The liver also metabolizes other dietary sugars including fructose and galactose, converting them to glucose phosphates (see Chapter 14).

Lipid metabolism

After a meal, dietary triglycerides are hydrolysed to free fatty acids and monoglycerides by pancreatic lipases and dissolved in an aqueous medium, facilitated by the detergent action of bile salts excreted by the liver into the gut. The liver meets its own metabolic energy requirements, and those of the body as a whole, by mitochondrial β -oxidation of short chain fatty acids. The resultant acetyl-CoA either enters the citric acid cycle or reacts with another molecule of acetyl-CoA to form ketone bodies. Although the role of the liver is central to the oxidation of fatty acids, most tissues contain the enzymes required to undertake complete oxidation. The liver also synthesizes fatty acids, triglycerides, cholesterol, phospholipids and lipoproteins. Disturbances of fatty acid metabolism, including decreased oxidation (as in excessive alcohol

consumption), increased hepatic fatty acid synthesis and decreased breakdown of triglycerides to fatty acids and glycerol, may all be involved in the development of fatty liver ('steatosis'), an increasingly prevalent problem found in obesity and as an additional or incidental histological finding in many liver disorders.

Protein metabolism

Hepatic protein metabolism is central to the assessment of liver function, and its disturbance underlies many of the clinical complications that occur in severe liver cell dysfunction.

Synthesis

Other than the immunoglobulins, most circulating proteins are synthesized wholly or largely by the liver, and the concentrations of several are used as a measure of hepatic synthetic function. Apart from albumin, transcobalamin II and C-reactive protein, all are glycoproteins. Glycosylation (often with terminal sialic acid residues on the carbohydrate moieties) has several functions. In some instances (e.g. fibronectin), it serves to make the protein resistant to proteolysis; in others it affects function. In yet others (e.g. caeruloplasmin), it affects the half-life of the protein in the blood, because hepatocytes possess receptors that can bind galactose and some other carbohydrate residues exposed after removal of sialic acid and remove the desialylated glycoproteins from the circulation. Disturbance in glycosylation produces some specific defects in protein structure that may be useful clinically in the diagnosis of alcoholic (see p. 242) and malignant liver disease (see Chapter 14).

Metabolism of amino acids and disposal of urea

A 70 kg man on a normal diet needs to excrete between 10 and 20 g of nitrogen per 24 h. This derives, in the form of ammonia, from amino acids that are surplus to requirements (and cannot be stored) and those that are not reutilized after normal turnover. The ammonia is converted into urea in the liver and excreted by the kidneys. The liver processes dietary amino acids arriving via the portal vein and from breakdown of muscle proteins, both for its own requirements and for export to peripheral tissues. Aromatic amino acids (AAA: phenylalanine, tyrosine and tryptophan) are metabolized by the liver, but hepatic extraction of branched chain amino acids (BCAA: leucine, isoleucine and valine) is small and these are taken up largely by muscle. The ratio of BCAA/AAA is decreased in acute liver failure and this alteration forms the basis of one theory of the pathogenesis of hepatic encephalopathy, namely that it is due to the toxic effects of increased concentrations of ammonia on the brain.

The major pathways of ammonia production and clearance are shown in Figure 13.4. Amino acids first undergo transamination to glutamate, followed by oxidative deamination with the formation of ammonia. The resultant ammonia is fed into the Krebs–Henseleit (urea) cycle and excreted as urea or stored transiently as glutamine

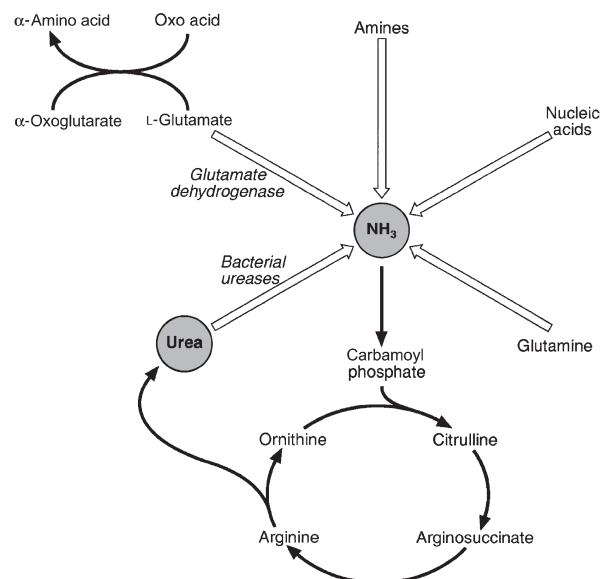

FIGURE 13.4 ■ Production and disposal of ammonia.

(through the action of glutamine synthase). Additional ammonia is produced by the action of bacteria on dietary protein and urea present in gut contents. Plasma ammonia concentration is measured in many laboratories and a raised concentration is taken as evidence that an encephalopathic state is due to hepatic pathology. Measurement of the various enzymes involved in the urea cycle is increasingly undertaken for diagnosis of inherited abnormalities of urea synthesis.

Biotransformation and excretion

The lungs and kidneys are effective in excreting volatile and water-soluble substances, respectively, but many compounds, both exogenous (such as drugs) and endogenous, including end products of metabolism, are lipid soluble and non-volatile. Many of these compounds are toxic, and a vital function of the liver is to render such substances more water soluble so that they can be excreted in urine or bile.

Two phases of biotransformation of metabolites by the liver are recognized. In phase I, a suitable polar group is made available, which is conjugated in phase II. Phase I reactions occur in the smooth endoplasmic reticulum and are mediated mainly by the mixed function oxidase system (cytochrome P450 isoenzymes) that utilize atmospheric oxygen, typically generating hydroxylated or carboxylated compounds. Phase II reactions involve their subsequent conjugation by the action of glucuronyl transferases with glucuronic acid, acetyl or methyl radicals or, in the case of bile acids, with glycine, taurine or sulphate (see below). There is considerable functional heterogeneity of the glucuronyl transferases, of which there are several isoenzymes that have varied substrate specificities, particularly for exogenous compounds. An alternative, non-oxidative pathway for biotransformation of both endogenous and exogenous substances is by conjugation with reduced glutathione by glutathione S-transferases.

Bile secretion

The constituents of bile, the exocrine secretion of the liver, are conjugated bile salts, cholesterol, phospholipids (mainly lecithin), bilirubin mono- and diglucuronides, electrolytes and small amounts of protein. The liver is the major site of cholesterol biosynthesis and the sole site of conversion of cholesterol into bile acids, which are the major organic anions excreted by the liver. The primary bile acids, cholic and chenodeoxycholic acid, are conjugated with either glycine or taurine to form bile salts, which enhances their solubility at the pH of body fluids (Fig. 13.5). This facilitates their main function of solubilizing both biliary cholesterol and the products of dietary fat digestion resulting from lipid hydrolysis. Secondary bile acids, deoxycholic and lithocholic acids, are derived from primary bile acids by the action of intestinal bacterial 7α -dehydroxylase, either as bile salts or deconjugated bile acids. Most of the bile acids reaching the gut are reabsorbed in the terminal ileum and return via the portal vein to the liver (enterohepatic circulation) where, as free acids, they are again conjugated and excreted. A third metabolite, ursodeoxycholate (a stereoisomer of chenodeoxycholic acid), is found in trace amounts and has been classified as a tertiary bile acid. This enterohepatic circulation is regulated by the activities of distinct bile salt transport proteins, including the canalicular bile salt export pump, the ileal sodium-dependent bile salt transporter and the hepatic sinusoidal sodium-taurocholate co-transporting polypeptide. Several other bile salt transporters and organic anion-transporting polypeptides have been characterized (see below). During bile secretory

failure (cholestasis), bile salt transport proteins undergo adaptive responses that serve to protect the liver from retention of toxic bile salts and facilitate non-hepatic routes of bile salt excretion. The measurement of serum bile acids has been extensively investigated as a test of liver function (see p. 243).

LIVER FUNCTION TESTS

Liver function tests have four potential applications.

1. *As an aid to establishing whether an individual has liver disease.* In effect, they are being used to answer the question, 'Is there any evidence of liver damage or dysfunction?'
2. *As an aid to making a specific diagnosis.* While functional tests are clearly distinct from diagnostic tests, it is still reasonable to assume that certain patterns of dysfunction may be characteristic of particular diseases.
3. *To establish the severity of liver dysfunction or damage once a specific diagnosis has been established.* This is important from a prognostic point of view, although the standard biochemical 'liver function tests' do not always reflect accurately the severity of tissue damage.
4. *To monitor the progression of the disease and any response to therapeutic intervention.*

Within this framework, two classes of tests will be considered. The first are the standard liver function tests – a group of tests often applied irrespectively of the suspected

FIGURE 13.5 ■ Synthesis and enterohepatic circulation of bile acids.

diagnosis and to which all the caveats about lack of true functional assessment apply. The second group includes those biochemical assays used for assessment of liver disease in specific situations, for example α_1 -antitrypsin in suspected deficiency of this protein and α -fetoprotein in suspected primary hepatic cancer (hepatocellular cancer). The latter are described briefly here, for the sake of completeness, and in more detail in the next chapter in the context of their diagnostic application. The standard liver function tests are usually considered to include the plasma total bilirubin concentration, the activities in plasma of certain enzymes (particularly alanine and/or aspartate aminotransferases, alkaline phosphatase and γ -glutamyltransferase), and the total plasma protein, albumin and globulin concentrations. The prothrombin time (discussed later) also provides useful information about the synthetic capacity of the liver in the short term, as it is a functional measure of factor VII (among others) concentration and this clotting factor has a short half-life in plasma (see below). It has been estimated that this group of tests will correctly allocate patients to a liver disease/non-liver disease category in about 75% of cases.

Bilirubin and bile pigment metabolism

Although bilirubin has been characterized as a non-toxic metabolic product of a relatively minor metabolic pathway, marked elevation in its plasma concentration leads to the alarming sign of jaundice and usually suggests the presence of underlying liver or biliary tract disease that may range from trivial to life-threatening, especially in neonates (see below). Accurate interpretation of the laboratory tests associated with bile pigment metabolism in the jaundiced individual requires a clear understanding of the physiology and biochemistry of the bile pigments. Most bilirubin is derived from the breakdown of haem, itself derived from senescent red blood cells (Fig. 13.6). A much smaller proportion comes from other haemoproteins such as catalase, myoglobin and the cytochromes. An even smaller fraction comes from 'ineffective erythropoiesis', although this may represent a significant source of bilirubin in haematological conditions such as thalassaemia and pernicious anaemia. The initial and rate-limiting step is the oxidation of haem to biliverdin by haem oxygenase; this is followed by reduction (catalysed by biliverdin reductase) to bilirubin, with the production of an equimolar amount of carbon monoxide and ferric (Fe^{3+}) iron. These reactions take place in the macrophages of the reticuloendothelial system, predominantly in the liver, spleen and bone marrow. The resultant 'unconjugated' bilirubin is tightly bound to albumin in a 1:1 molar ratio, but additional binding sites of lower affinity are recruited in hyperbilirubinaemic states. This binding limits extrahepatic uptake of the potentially toxic unconjugated bilirubin and facilitates transport to the liver. Other molecules, such as thyroxine and certain drugs, can compete for albumin binding sites and thereby displace bilirubin, although the clinical relevance of this displacement is limited, except possibly in neonates.

FIGURE 13.6 ■ Formation of bilirubin.

Bilirubin, tightly bound to albumin, is actively transported across the hepatocyte sinusoidal membrane and binds to ligandin (glutathione transferase B). It is then conjugated with glucuronic acid by the action of uridine diphosphate (UDP)-glucuronosyltransferase (glucuronyl transferase) to form mono- and diglucuronides and thereby rendered water soluble (Fig. 13.7). Glucuronidated bilirubin is secreted via an active transport mechanism into the biliary canaliculi and thence reaches the gut. The components of this transport pathway have been identified as products of genes encoding multidrug resistance (MDR) proteins (MRPs) and MDR-associated proteins. The protein MDR3 is known to transport phosphatidylcholine to chaperone bile salts, while MRP2 pumps glucuronidated compounds, that is, conjugated bilirubin as well as organic anions. Secretion is probably rate limiting in the overall transport of bilirubin from plasma to bile. In the gut, some bilirubin is deconjugated by bacterial glucuronidases and (being fat soluble again) is reabsorbed, but most is oxidized to urobilinogen; this is further metabolized to other pigments, particularly stercobilin, and excreted (Fig. 13.8). A small amount of urobilinogen is reabsorbed and undergoes an enterohepatic circulation. Conjugated bilirubin also circulates bound to albumin, but with low affinity, such that the unbound fraction can

FIGURE 13.7 ■ (A) The unfolded structure of bilirubin showing the site of glucuronic acid conjugation (arrows), which breaks the hydrogen bonding and results in the molecule becoming soluble. (B) The folded structure showing the extensive hydrogen bonding.

be filtered by the glomeruli and excreted by the kidneys, giving rise to pigmented urine. A small fraction is reabsorbed by the renal tubules.

The significance of hyperbilirubinaemia

Less than 500 mg of bilirubin is produced each day, but the normal liver can conjugate up to 1500 mg/day. This large functional reserve is one reason why the plasma bilirubin concentration is an insensitive test for liver disease, since it begins to rise only after significant liver damage has occurred. In more than 95% of the apparently healthy adult population, the plasma bilirubin concentration is <25 μmol/L and this can be considered the upper limit of the reference range (Fig. 13.9). It is virtually all unconjugated. Jaundice can be detected by experienced observers when the plasma concentration exceeds 50 μmol/L and, when it rises above 100 μmol/L, it will be apparent to lay observers.

The absolute concentration of plasma bilirubin is of little help in establishing a diagnosis. Its measurement is, however, important in monitoring the progress of diseases such as primary biliary cirrhosis, where changes are of prognostic significance (see p. 248), neonatal jaundice (with respect to the need for exchange transfusion), for assessing response to treatment (such as surgical relief of bile duct obstruction) and to detect hyperbilirubinaemia that is suspected, but not clinically apparent. In addition, the absolute concentration of bilirubin is important in prescribing the correct dose of certain cytotoxic agents, especially if they are normally excreted in bile.

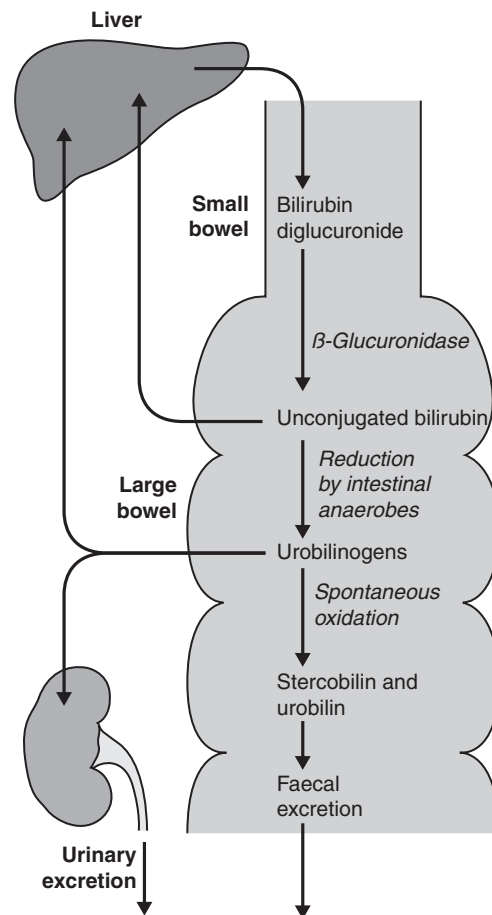

FIGURE 13.8 ■ Enterohepatic circulation of bilirubin and urobilinogen.

FIGURE 13.9 ■ Distribution of serum bilirubin concentrations in 18454 apparently healthy men. (From Bailey A, Robinson D, Dawson M 1977 Does Gilbert's disease exist? Lancet i:931-933, with permission).

For example, in patients treated with doxorubicin for malignant liver disease, the dose must be decreased in the presence of hyperbilirubinaemia to avoid drug-induced myelosuppression. The highest concentrations of bilirubin (sometimes approaching 1000 $\mu\text{mol/L}$) are seen when conjugated hyperbilirubinaemia of any cause is complicated by renal failure.

Tests for quantitation of bilirubin and its conjugated and unconjugated fractions

Current methods for the determination of plasma bilirubin are based on the diazo coupling of the pigments first described by Ehrlich in 1883. Two molecules of azodipyrrrole, which can be measured spectrophotometrically, are formed per molecule of bilirubin. In 1916, van den Berg and Muller noted that bilirubin from patients with obstructive jaundice reacted 'directly', whereas bilirubin from patients with haemolytic jaundice reacted 'indirectly', that is, an accelerator such as alcohol was required. The direct reacting pigment was later identified as conjugated bilirubin (CB) and the indirect reacting pigment as unconjugated bilirubin (UCB).

Although the distinction was found to be useful clinically, it soon became apparent that there is not, in fact, a precise relationship between indirectly reacting bilirubin and UCB, and directly reacting bilirubin and CB, respectively. In particular, direct measurements overestimate CB at low concentrations and underestimate it at high concentrations. To overcome these limitations, the alkaline methanolysis method was developed. The bilirubin mono- and diglucuronide conjugates are converted to the corresponding mono- and dimethyl esters by treatment with alkaline methanol. Unconjugated bilirubin is not affected by the reaction and is extracted into chloroform with the methyl ester derivatives. The pigments can then be separated and quantified by high performance liquid chromatography (HPLC). This approach shows that CB is virtually undetectable in plasma from healthy subjects or from patients with Gilbert syndrome. Techniques permitting accurate estimation of the two fractions at low bilirubin concentrations may become available routinely, and the detection of CB might then become the most specific and sensitive test of hepatobiliary function. Bilirubin bound to albumin (bili-albumin, delta bilirubin), probably covalently, is a third form of bilirubin. It may account for up to 90% of total bilirubin in both hepatocellular and cholestatic jaundice, although both impaired excretion and an intact conjugation mechanism are required for its formation. It is not detectable in healthy subjects or patients with unconjugated hyperbilirubinaemias, including Gilbert syndrome. It is this form of bilirubin that persists in the plasma of patients recovering from jaundice after bilirubin has ceased to be detectable in the urine. The precise mechanism by which jaundice occurs in patients with severe, long-term liver dysfunction has still not been firmly established. Both conjugated and unconjugated bilirubin are present, but the former predominates. Clinically, most patients retain the ability to conjugate bilirubin but have pigmented, bilirubin-containing urine. It is likely that conjugated bilirubin refluxes

retrogradely across the sinusoidal poles of hepatocytes because excretion via the biliary canalicular membrane becomes rate-limiting in the severely damaged liver. Leakage from damaged canaliculi via the paracellular pathway may also occur.

Plasma enzyme activities

As noted above, the enzymes used as liver tests, have little or no physiological function in the plasma: rather, they are empirical markers of some type of liver damage.

Alkaline phosphatase

The term alkaline phosphatase (ALP) describes a group of enzymes that hydrolyse phosphate esters at alkaline pH, although the physiological substrate within the body is not known. Alkaline phosphatase is present in several tissues, but the plasma component comprises mainly contributions from liver, bone, intestine and (during pregnancy) the placenta. There are two liver-derived isoenzymes. One derives from the hepatocyte and the other from the exterior surface of the biliary canalicular membrane. The latter probably enters the bloodstream via the paracellular pathway (see Fig. 13.3), although, in the presence of obstruction, it becomes distributed throughout the cytoplasm and may enter the plasma directly from across the plasma membrane. The function of hepatic ALP is unknown, but it may be involved in the transport of bile acids into bile.

The activity of plasma ALP rises when there is any form of obstruction to the biliary tract, whether mechanical or otherwise. The original assumption that this was due to failure of clearance by the obstructed liver was shown in the 1960s to be false. It was found that the clearance of ALP is not dependent on a patent biliary system and that during cholestasis only the liver ALP increases in activity, not the bone and intestinal isoenzymes. Subsequent studies have shown that this increase is from *de novo* synthesis of alkaline phosphatase, and it is possible in rat models to show that this is due to increased translation of the ALP mRNA rather than to increased transcription. The activity is definitely of biliary origin and the rise can be inhibited by blocking RNA synthesis. Biliary tract obstruction on its own is not sufficient to give rise to increased plasma activity of liver ALP; it appears that a high concentration of bile acids is also required, perhaps to solubilize the ALP bound to the canalicular membrane.

In cholestatic diseases due to biliary tract obstruction, the site of the obstruction may be at any level, from high in the small intrahepatic bile ducts (e.g. in primary biliary cirrhosis) down to the common bile duct (e.g. with gallstones). A rise in ALP activity usually predates the onset of clinical jaundice and, in those situations where surgical relief is possible, the return of plasma bilirubin to within the reference range usually precedes that of ALP. In a patient with symptoms of pain over the liver, an elevated ALP activity in the presence of a normal plasma bilirubin concentration is strongly suggestive of a hepatic space-occupying lesion, such as an intrahepatic tumour or an infiltrative disorder.

Overcoming the lack of tissue specificity. Increases in the activity of plasma ALP are not specific for liver disease. Modest increases occur in pregnancy, during periods of rapid bone growth in childhood and adolescence, and because of disease at other sites, particularly bone disease in which there is increased osteoblastic activity. While bone disease (hepatic osteodystrophy) may be a complication of longstanding cholestatic liver disease, the predominant form is osteoporosis, not osteomalacia, and the increased ALP activity is not due to the coexistent bone disease.

The specificity of the test can be enhanced by measuring specific ALP isoenzymes. Early studies used starch or polyacrylamide gel electrophoresis on the serum sample followed by specific staining of the gels for ALP; agarose gel electrophoresis is now more commonly used. In normal serum, two or three distinct bands can usually be identified, corresponding to the liver, bone and intestinal ALP isoenzymes. The liver band moves most rapidly towards the anode, with a more diffuse bone band closely behind. When present, the intestinal band lies behind the bone band. Additional bands are seen during pregnancy (the same isoenzyme is also detected occasionally in patients with malignancy, and is known as the Regan isoenzyme). In subjects with hepatocellular carcinoma, occasionally there is an additional, fast-running, band. The technique is semiquantitative, but it is usually visually obvious which of the isoenzymes is responsible for the increase in total activity.

An alternative approach is to repeat the standard ALP assay after first heating the serum at 56°C for 15 min. The liver and bone isoenzymes are sensitive to this treatment, and if the increased total activity is owing to either one of these, it will be reduced to about 40% or 15% of the original value, respectively. The placental isoenzyme activity remains unaffected by heating. This method is not as discriminatory as electrophoretic separation of the isoenzymes, but is easier to perform and can be used as a rough guide.

In practice, however, when there is doubt about the origin of an increased plasma ALP activity, it is customary to examine the results in relation to other enzymes, elevations in the activities of which are more liver specific. Thus, if the γ -glutamyltransferase (γ GT, see below) is also elevated, it may be inferred that the increase in ALP activity is probably of hepatic origin. In a few situations, elevation of ALP activity, apparently with hepatic specificity, may be seen in patients without overt liver disease, particularly those with Hodgkin lymphoma and some infections.

One specific situation in which isoenzyme analysis is of particular benefit is in patients with benign transient hyperphosphatasaemia (see Fig 13.10). First identified in children, it is now recognized also in adults. Serum ALP activity is typically >1000 U/L, with normal plasma activities of the aminotransferases and γ GT. It is usually associated with recent or intercurrent infection, often of the gastrointestinal tract. The mechanism is thought to be removal of sialic acid residues from circulating ALP by bacterial endotoxin or other substances released by the infecting organism. This alters the recognition of ALP by

FIGURE 13.10 ■ Alkaline phosphatase isoenzymes in benign transient hyperphosphatasaemia. Separation of plasma ALP isoenzymes on cellulose acetate membrane. The positions of bone (B), liver (L) and biliary (α_1) isoenzymes are indicated. The electrophoretic pattern and heat stability of transient hyperphosphatasaemia are illustrated in lanes 2 and 3. (Courtesy of Dr S. B. Rosalki).

clearance receptors, prolonging its half-life in the circulation. The isoenzyme pattern is characteristic, showing the presence of two bands for each of the liver and bone isoforms. Treatment of the sample with neuraminidase, which removes terminal sialic acids from the carbohydrate side-chains of ALP, results in a pattern identical to that seen in a normal sample treated with neuraminidase. The importance of recognizing benign transient hyperphosphatasaemia is that invasive investigations such as endoscopic retrograde cholangiopancreatography are unnecessary.

The aminotransferases

These enzymes, previously designated (and still frequently referred to) as 'transaminases', catalyse the transfer of an amino group from an α -amino acid to an α -oxo acid. This is their intracellular function. An increase in their activity in the plasma is simply a marker of hepatocyte disruption and, presumably, has no useful function. The two most widely measured for clinical purposes are aspartate aminotransferase (AST) and alanine aminotransferase (ALT) both of which have a wide tissue distribution. Aspartate aminotransferase is found in liver, heart, skeletal muscle, kidney, brain, erythrocytes and lung. Alanine aminotransferase has a similar tissue distribution, but activities are much lower in extrahepatic tissue so that an increase in plasma ALT is more specific for liver disease. In view of this wide tissue distribution, it is not surprising that increased activities are seen in extrahepatic disease such as rhabdomyolysis, where the enzymes are released from damaged muscle cells. However, distinction between increased aminotransferase activities due to liver disease and those due to skeletal or cardiac muscle damage can usually be made by measurement of creatine kinase or the cardiac-specific troponins, respectively.

The increased plasma activities of these enzymes seen in patients with liver disease are presumed to originate from necrotic or damaged hepatocytes, although actual necrosis is not a prerequisite. It should not be assumed that the enzyme content of hepatocytes in patients with liver disease is necessarily the same as in normal hepatocytes; in patients with metastatic liver disease, hepatocyte enzyme concentrations may be several times higher than normal.

The aminotransferases are sensitive tests of hepatocellular dysfunction. This is particularly well demonstrated by the observation that during epidemics of viral hepatitis, aminotransferase activities may be markedly elevated in asymptomatic individuals with subclinical hepatitis. Generally speaking, the specificity of the test increases with enzyme activity. Activities above ten times the upper limit of the reference range are most frequently due to primary hepatocyte damage, so that the hepatic pathology will be some form of acute (viral or drug-induced) or chronic (such as autoimmune) hepatitis. Occasionally, acute cardiac failure or hypovolaemic shock may cause AST activities within this range, presumably from a combination of increased hepatic venous pressure, low cardiac output and arterial hypoxia. Exceptionally, such elevated activities may also be found in obstructive jaundice, particularly when there is acute biliary tract obstruction or where cholangitis supervenes on biliary tract obstruction.

Values below ten times the upper limit of the reference range are non-specific and no aetiological inference can be drawn. Importantly, a plasma ALT or AST activity within the reference range does not necessarily exclude significant hepatocellular damage, as assessed histologically in some forms of chronic liver disease (e.g. autoimmune hepatitis). In several liver disorders, more discrimination can be gained by considering the aminotransferase activities in relation to the ALP or to each other. In general, the higher the AST/ALP ratio, the more likely the underlying condition is to be some form of hepatitis. Conversely, the lower this ratio, the more it is indicative of a cholestatic disorder. Plasma ALT activity tends to be only modestly raised in patients with alcoholic hepatitis compared with other forms of hepatitis, whereas the AST activity is often more markedly elevated. Thus, an AST/ALT ratio of >2 , in a patient who appears on clinical grounds to have a hepatic illness, strongly suggests that alcohol is involved.

The mitochondrial isoenzyme of AST (mAST). There are two forms of AST, one cytosolic and the other mitochondrial (mAST). The latter is synthesized under control of nuclear DNA as a precursor (pre-mAST), which is rapidly transferred across the mitochondrial membrane and then converted into mature mAST. The mitochondrial isoenzyme of AST accounts for about 80% of total AST activity within the liver cells. With the development of immunochemical methods for measurement of this enzyme in serum, there has been considerable interest in the use of the mAST/total AST ratio as a marker of chronic alcohol consumption. While preliminary studies suggested that this test adequately distinguishes between those who consume excess alcohol and healthy subjects, irrespective of the presence or absence of liver disease, and is only elevated in association with chronic abuse, this test has not been adopted into routine laboratory practice.

γ -Glutamyltransferase

This is a microsomal enzyme responsible for transfer of glutamyl groups from γ -glutamyl peptides to other peptides or amino acids. It may be involved in the transport of peptides across cell membranes as γ -glutamyl peptides.

Although widely distributed throughout most body organs except muscle, the plasma activity is mainly attributable to the liver isoenzyme. γ -Glutamyltransferase has poor specificity for liver disease and, especially in a patient with jaundice, it adds little to the information gained from measurement of AST and ALP. However, its measurement can be useful in two particular circumstances. First, when the origin of an elevated serum ALP is uncertain, a concomitant elevation in γ GT suggests that the ALP is of hepatic origin. The second relates to the controversial area of the relationship of γ GT to chronic alcohol consumption.

The laboratory tests for chronic alcoholism are discussed in the next chapter. Here, we attempt to summarize what is accepted about γ GT and excessive alcohol consumption. In those who consume excess alcohol and who have chronic liver disease, the absolute plasma activity of γ GT is higher than in those without significant liver disease, and there is a tendency for activities to remain high after abstinence. This suggests that the elevated plasma γ GT activities in such individuals may be due to induction of the enzyme by the alcohol and/or because of the liver damage. In contrast, among alcoholic patients without liver disease, only about half will have a raised γ GT and this will usually fall to normal after eight weeks of abstinence. The extent of the increase in γ GT activity above normal is not directly related to either the amount of alcohol consumed or the duration of its consumption. It is evident from the above that the efficiency of using γ GT for screening populations for excessive alcohol consumption will be poor. False positive results occur in those taking enzyme-inducing drugs (including some herbal remedies) and false negative results occur in those who do not have liver disease. Nonetheless, the finding of a markedly raised γ GT (greater than five times the upper limit of the reference range) provides good reason to enquire diligently about possible alcohol abuse. γ -Glutamyltransferase remains the best of the simple laboratory screening tests and, depending on the population studied, the sensitivity is in the order of 50% and the specificity is about 85%.

Glutathione S-transferase (GST)

Isoenzymes of GST are involved in the detoxification and conjugation of several electrophilic compounds with glutathione. As noted above, bilirubin and bile acids bind strongly to GST, which is also involved in the metabolism of endogenous compounds such as some of the prostaglandins. Various isoenzymes exist; virtually all the plasma GST- α activity is of hepatic origin and its measurement seems to be a sensitive test of acute hepatocellular damage. It has a half-life in blood of only about 90 min and is, therefore, a rapidly responding marker of liver injury. However, the currently available immunoassay does not lend itself to large-scale routine screening and is therefore not widely used in clinical practice.

Plasma proteins

The concentrations of proteins in plasma reflect the balance between availability of their precursors and their

rates of synthesis, release and clearance, as well as their volumes of distribution. It is, therefore, not surprising that in patients with liver disease, the concentrations are very variable. Measurements of some plasma proteins (e.g. albumin, coagulation proteins) can provide useful information about general hepatic function; measurements of others (e.g. α_1 -antitrypsin, caeruloplasmin) are used in the diagnosis of specific conditions affecting the liver.

Albumin

This is the major protein in plasma and it is synthesized exclusively by the liver. The liver produces about 12 g of albumin each day; of the total body pool of 300 g, about 60% is in the extravascular pool and 40% in the intravascular pool. The plasma half-life is about 21 days. Albumin is responsible for maintaining plasma oncotic pressure and binds several hormones, anions, drugs and fatty acids. There is no doubt that as chronic liver disease progresses, the plasma albumin concentration tends to fall and, in this context, it is a major prognostic factor (see p. 248). Nonetheless, it must not be assumed that plasma albumin concentration is simply an indicator of hepatic synthetic function.

The rate of hepatic albumin synthesis falls in the face of inadequate protein intake. This is a frequent occurrence in patients with advanced liver disease, and particularly those in whom excessive alcohol consumption is implicated. However, even when the rate of synthesis falls, plasma concentrations may remain within the reference range because of a compensatory reduction in the rate of degradation. Furthermore, hypoalbuminaemia may occur in the face of normal, or even increased, rates of synthesis when protein 'leaks' into lymph, ascites or otherwise into the extravascular compartment. Hypoalbuminaemia may also be the result of renal loss of albumin in the nephrotic syndrome, gastrointestinal tract loss in protein losing enteropathy or loss through the skin in burns patients.

Prothrombin time and coagulation factors

The prothrombin time (PT) is a test that has become widely used in hepatology. Quick's one-step prothrombin time measures the rate at which prothrombin is converted to thrombin in the presence of thromboplastin, calcium, fibrinogen and other coagulation factors (V, VII and X). In turn, the thrombin leads to the conversion of fibrinogen to fibrin. Prothrombin and factors VII, IX and X all require vitamin K to become active. In the UK, the use of the PT has been widely replaced by the use of the international normalized ratio (INR). This is derived by dividing the PT of the patient by that of the control. Thus, healthy individuals will have an INR of 1 (<1.2 is the accepted normal value), while a patient with a PT of 120s where the control is 12s would have an INR of 10 (see Chapter 26).

There are two reasons why patients with liver disease may have a prolonged PT, each with different diagnostic implications. First, the liver may be so damaged that it cannot adequately synthesize the clotting factors that require vitamin K for their activation. The half-life of

factor VII is about 6h, so that a prolonged INR is a reliable indicator of the presence of acute liver failure caused by a recent, overwhelming insult to the liver. Second, since vitamin K is a fat-soluble vitamin, it may be deficient because of impaired fat absorption when there is obstructive jaundice. The latter situation is remediable by parenteral administration of vitamin K. Thus, return of the INR to the normal range within 18h may be taken as evidence of obstructive jaundice, whereas failure to respond implies severe parenchymal disease.

The concentration of factor V is becoming a widely-used test in assessing the severity of acute liver failure, particularly in continental Europe; low factor V concentration is associated with a poor prognosis.

α -Fetoprotein

Under normal circumstances, the synthesis of this protein, the fetal equivalent of albumin, virtually ceases shortly after birth. However, the protein is synthesized in large amounts (and becomes detectable in plasma) in about 70% of patients with hepatocellular carcinoma, and to lesser degrees in certain other tumours and benign liver diseases (see Chapter 42).

α_1 -Antitrypsin

This protein is the major α_1 -globulin and responsible for 90% of plasma tryptic inhibitory capacity. α_1 -Antitrypsin deficiency is a major cause of chronic liver disease in children (see Chapter 14) and, less commonly, of chronic liver disease presenting in adulthood.

Transferrin

Transferrin is the major circulating iron-binding protein, and its concentration correlates with the total iron-binding capacity of plasma. In states of iron overload, such as hereditary haemochromatosis (see Chapter 14), the concentration is modestly reduced, but the saturation is 55–100% compared with the reference range of 30–40%. Plasma transferrin has also been suggested to be a more appropriate overall indicator of protein synthesis by the liver in view of its shorter half-life, as compared with albumin.

Transferrin is a glycoprotein that exists in the circulation in various forms, containing up to six terminal sialic acid residues on its carbohydrate side chains. In healthy individuals, the trisialo-, tetrasialo- and pentasialo- forms predominate. Alcohol appears to inhibit the glycosylation of several glycoproteins, including transferrin, and in subjects consuming excessive amounts of alcohol, plasma transferrin often lacks up to four of these sialic acid residues, resulting in asialo- and disialotransferrins, which are now collectively termed carbohydrate-deficient transferrin (CDT). Consumption of more than 80g of alcohol/day leads to an increase in the plasma CDT concentration, irrespective of any underlying liver disease. This returns to normal concentrations within two weeks of abstinence. Carbohydrate-deficient transferrin measurement has been proposed as a marker of excessive alcohol consumption, although it is not in widespread use; sensitivity is

approximately 80% and specificity somewhat higher, but results do not reflect the nature or severity of any liver disease (see Chapter 14).

Caeruloplasmin

This protein, the principal copper-containing protein in the plasma, has oxidase activity including the ferroxidase activity essential for the oxidation of Fe(II) to Fe(III). It consists of a single polypeptide chain containing six copper atoms, but there is minimal turnover of the copper, suggesting that it does not act as a copper transporter in the manner that transferrin is the circulating iron carrier. In the context of liver disease, it plays an important role in the diagnosis of Wilson disease since it is virtually absent from plasma in this condition.

Acute phase reactants

In response to tissue damage, there is an increase in hepatic synthesis of several plasma proteins, notably C-reactive protein, α_1 -antitrypsin, antichymotrypsin, fibrinogen and caeruloplasmin. These are an integral part of the inflammatory response, which is described in greater detail in Chapter 30.

Immunoglobulins

Measurement of immunoglobulins is useful in the diagnosis of several liver disorders and for monitoring response to therapy in some. Elevated plasma concentrations often indicate an underlying inflammatory process. An indication of elevation in the immunoglobulins can be obtained by subtracting the plasma albumin concentration from the total protein concentration. This gives a rough measure of the total globulin fraction, of which the immunoglobulins are the major component. Concentrations of the individual immunoglobulin types (IgG, IgA, IgM) can then be determined by various techniques. This can provide helpful information, because different liver disorders are associated with selective elevations in the concentrations of the three immunoglobulin types. Thus, the IgG fraction is usually markedly elevated in autoimmune hepatitis, IgM in primary biliary cirrhosis, and IgA in alcoholic liver disease. Repeated measurement of IgG concentration is also useful in monitoring response to therapy in autoimmune hepatitis. This topic is discussed in more detail in Chapter 30.

Bile acids

In healthy individuals, the concentrations of plasma bile acids (PBAs) are determined by the difference between the amount absorbed from the gut and that taken up by the liver. The latter is fairly constant and, normally, it is the amount absorbed from the gut that determines plasma concentrations. Under pathological conditions, hepatic blood flow and clearance become the determining factors. In this situation, measurement of PBA may be considered as an endogenous clearance test. Accumulation of bile acids in the skin is thought to be associated with the development of the pruritis that is a relatively common feature of cholestatic liver disease.

Measurement of total plasma bile acids using simple automated enzymatic assays has proved to be of value in the diagnosis and monitoring of intrahepatic cholestasis of pregnancy. Total PBA measurement has also been used in the investigation of pruritis in children and adults with cholestatic liver disease, although interference in the assay from ursodeoxycholic acid, which may be used in treating these conditions, has limited its application. Fractionated bile acid analysis using high performance liquid chromatography and mass spectrometry is needed for the diagnosis of the rare inborn errors of bile acid metabolism (e.g. oxosteroid 5 β -reductase deficiency and amidation defects). The role of bile acids in carbohydrate and lipid metabolism is currently a subject of considerable interest.

Quantitative evaluation of liver function

The very limited extent to which standard liver tests give any quantitative measurement of hepatic function has already been discussed. To overcome these deficiencies, several tests that measure the efficacy of hepatic clearance of certain compounds, exogenous or endogenous, have been investigated over the past 20–30 years. To date, none has entered routine clinical practice. The main reason is that they require administration of the test substance and then subsequent collection of blood or other body fluids, sometimes over a protracted period. Despite some simplification of these tests, the information gained is seldom seen as justifying the necessary expenditure of time and effort.

However, with the advent of liver transplantation as a realistic therapeutic option in many forms of liver disease, it is becoming increasingly important to obtain more precise prognoses based on an accurate assessment of liver function. Also, many liver diseases are of such chronicity that a test that could reliably assess the efficacy of new drugs, in terms of their ability to improve liver function, would provide a real advance in clinical management of these conditions.

Pharmacological basis and practical requirements of clearance tests

The concept of ‘clearance’ as a test of hepatic function is analogous to the more familiar use of clearance as an index of renal function. The substance chosen should be non-toxic, exclusively eliminated by the liver and easily measurable. The principle of these tests is as follows:

$$\begin{aligned} \text{clearance} &= \text{hepatic removal} / \text{arterial plasma concentration} \\ \text{hepatic removal} &= \text{plasma flow} \times (\text{arterial concentration} \\ &\quad - \text{hepatic venous plasma concentration}) \end{aligned}$$

Thus:

$$\text{clearance} = \frac{\text{plasma flow} \times (\text{arterial concentration} - \text{hepatic venous plasma concentration})}{\text{arterial plasma concentration}}$$

Clearance is thus a function of plasma (and hence blood) flow and the second term in the above equation,

known as the hepatic extraction ratio (E). When the extraction ratio approaches 1, the clearance equates to liver plasma flow. In healthy subjects, the value of E for indocyanine green is about 0.9 and the clearance of this substance is, indeed, a good indicator of blood flow. In liver disease, however, E may fall to as low as 0.2 and the clearance is no longer dependent on blood flow but more on the ability of the liver to clear the compound. Compounds such as aminopyrine, antipyrine and caffeine have extraction ratios of <0.25 in healthy subjects and, providing that saturating doses are given, clearance is largely independent of blood flow.

Indocyanine green is not conjugated in the liver, although its removal from the plasma depends on hepatic function. Ten milligrams per kilogram body weight is administered intravenously and samples taken at 3 min intervals between 3 and 15 min. The percentage disappearance rate (PDR) is calculated as:

$$\text{PDR} = \left(0.693 / t_{1/2}\right) \times 100$$

where $t_{1/2}$ is the half-life of indocyanine green. The reference range is 17–22%; values below this range are considered abnormal.

Other tests of liver function

Serum tests for hepatic fibrosis

Fibrosis, leading ultimately to cirrhosis, is a characteristic feature of progressive chronic liver disease and is responsible for much of the associated functional disturbance and portal hypertension. In chronic liver disease, collagen is laid down in the perisinusoidal space (see Fig. 13.3) and the space of Disse, to the extent that the fenestrations are lost and the sinusoids become capillarized with a true basement membrane. Hepatic stellate cells are likely to play a determining role in the fibrotic process and, increasingly, therapy is aimed at reversing, or at least inhibiting, this process. Until recently, the only method of assessing the extent of fibrosis or response to therapy was by histological examination of liver tissue but, because the fibrosis is often not uniformly distributed throughout the liver, there is a risk of sampling error. Transient elastography (Fibroscan[®]), a technique that measures liver stiffness, correlates with histological staging of fibrosis. A low amplitude shear wave is generated from a probe applied to the thoracic wall at the level of the right lobe of the liver. The velocity of propagation is directly proportional to liver stiffness. This estimates existing fibrosis but cannot provide any information on whether the fibrotic process is historical or ongoing. For this reason, biochemical markers of fibrogenesis have been sought for many years.

Several biochemical candidates have been proposed as markers of fibrosis either in isolation or combined together in a scoring system. Some of these incorporate standard biochemical tests whilst others involve measurement of compounds involved in the fibrogenic process (Table 13.1). The increasing prevalence of liver disease due to infection with the hepatitis C virus has provided focus to the search for non-invasive markers of clinically significant fibrosis.

TABLE 13.1 Scoring systems for assessing fibrogenesis

Score	Components
PGA index	Prothrombin time, γ GT, apolipoprotein A1 ($\pm \alpha_2$ -macroglobulin)
Fibro Test [®]	Haptoglobin, α_2 -macroglobulin, apolipoprotein A1, γ GT, bilirubin, (\pm ALT)
Fibrometer [™] test	Platelets, prothrombin time, AST, α_2 -macroglobulin, hyaluronate, urea, age
Hepa Score [®]	Bilirubin, γ GT, α_2 -macroglobulin, hyaluronate, age, sex
ELF score	PIIINP, hyaluronate, TIMP-1

ALT, alanine aminotransferase; AST, aspartate aminotransferase; PIIINP, amino-terminal procollagen type III; TIMP-1, Tissue inhibitor of metalloproteinase 1.

Collagen metabolites. Quantitatively, types I and III collagen are involved in hepatic fibrosis but type IV is also important in basement membranes. Measurement of the concentration of the amino-terminal procollagen type III (PIIINP) in plasma is a non-invasive marker of collagen type III metabolism. The PIIINP concentration reflects fibrinogenesis (i.e. the rate of ongoing fibrosis) rather than the absolute amount of fibrosis present in the liver. Nonetheless, PIIINP measurements are of value for indicating the development of fibrosis in patients receiving potentially hepatic fibrogenic drugs such as methotrexate. Other approaches, such as measurement of the carboxy-terminal cross-linking domain of type IV collagen, are being actively investigated.

Hyaluronate. Hyaluronate is a high molecular weight glycosaminoglycan with a structural role in the extracellular matrix. It is synthesized by hepatic stellate cells and cleared by specific uptake by endothelial cells. Increased plasma concentrations may be linked to endothelial dysfunction that occurs as fibrosis progresses.

Tissue inhibitor of metalloproteinase 1. Tissue inhibitor of metalloproteinase 1 (TIMP-1) is a member of the tissue inhibitors of metalloproteinases (MMP) family. These MMPs are secreted by fibroblasts and Kupffer cells and MMP-2 in particular is upregulated by type 1 collagen: MMP-2 is probably involved in the breakdown of normal extracellular matrix. Tissue inhibitor of metalloproteinase 1, which inhibits MMP-2, may also promote cell proliferation and have apoptotic properties. It is used in the calculation of the European liver fibrosis score (see below).

European liver fibrosis score (ELF). A combination of PIIINP, hyaluronate and TIMP-1 has been proposed as a better marker of fibrogenesis than the component parts on their own. The ELF score is produced from the equation below:

$$\text{ELF} = -7.412 + (\ln[\text{HA}] \times 0.681) + (\ln[\text{PIIINP}] \times 0.775) + (\ln[\text{TIMP}-1] \times 0.494)$$

All measurements are expressed as $\mu\text{g/L}$. Normal scores fall between -1.3 and $+0.3$.

The first major study of 1021 subjects with chronic liver disease of various causes showed a sensitivity of 90% and specificity of 92% for the presence of hepatic fibrosis. Further investigations into potential applications of the ELF score are ongoing.

USES OF LIVER FUNCTION TESTS

Differential diagnosis of jaundice

The differential diagnosis of jaundice is an exercise in applied physiology and anatomy. Provided the reader accepts that there is seldom a single mechanism, the traditional classification into pre-hepatic, hepatic and post-hepatic remains useful. In each case, bilirubin is being produced faster than it can be cleared.

Pre-hepatic jaundice

In pre-hepatic jaundice, an increased bilirubin load is presented to the liver and the plasma bilirubin concentration reaches a steady state at a higher concentration, typically in the range $50\text{--}75\ \mu\text{mol/L}$. A haemolytic process due either to fragile red cells (e.g. sickle cell disease, congenital spherocytosis) or an autoimmune attack on the red cells is usually implicated. The bilirubin is unconjugated and bound to albumin and thus does not appear in the urine, hence the term 'acholuric jaundice' is used to describe the jaundice accompanying haemolysis. Since there is no liver disease, the liver can conjugate and excrete the increased bilirubin load, but the amounts of urinary and faecal urobilinogen will be increased. As the haemoglobin concentration starts to fall as a result of the haemolytic process, the bone marrow will attempt to compensate by increasing the output of red cells. The maximum increase that the marrow can achieve (about eight times the normal rate) corresponds to a plasma bilirubin concentration of $\sim 75\ \mu\text{mol/L}$.

If, however, haemolysis occurs at such a rate that compensatory marrow hyperactivity cannot keep pace, then the haemoglobin concentration will fall and higher plasma bilirubin concentrations may be seen. On the other side of the equation, if the liver is damaged, then its ability to take up the bilirubin will be limited and concentrations of bilirubin $>75\ \mu\text{mol/L}$ may occur. Thus, when a patient is found to have mild jaundice and there is no bilirubin in the urine, examination of the haematological indices will usually be sufficient to make the diagnosis of some form of haemolytic anaemia, especially as other liver tests will, by contrast, be normal. If there is no evidence of haemolysis, the cause will usually be Gilbert syndrome (see below). Estimation of the conjugated and unconjugated fractions becomes of particular importance in determining if, in a patient already known to have chronic liver disease, haemolysis is contributing to deepening jaundice.

Urinary bilirubin and urobilinogen. The presence of bilirubin in urine (usually detected by commercially available dip-sticks) is always pathological and indicative

of hepatic or biliary tract disease. Bilirubinuria may precede hyperbilirubinaemia and, therefore, be a very sensitive test of impending liver damage, for example in the early, presymptomatic stage of viral hepatitis.

If bile pigments reach the gut in reduced amounts (as in obstructive jaundice), the amount of urobilinogen in the urine will decrease accordingly. If no urobilinogen can be detected on repeated testing over several days, complete biliary tract obstruction, the most common cause of which is pancreatic carcinoma, may be assumed. Although urine urobilinogen can be assessed qualitatively using dipsticks, testing is now rarely performed as there are much more reliable and accurate ways of diagnosing biliary obstruction.

Hepatic (hepatocellular) jaundice

This type of jaundice occurs in conditions characterized by primary damage to the hepatocytes, that is, acute and chronic hepatitis of any cause. The excess bilirubin is mainly conjugated.

Post-hepatic (cholestatic) jaundice

Cholestasis means failure of biliary secretion. As originally defined, the term referred to failure at the level of the hepatocytes, but in clinical practice it is more broadly defined to include obstruction to bile flow occurring anywhere between the biliary canalicular membrane of the hepatocyte and the gut. In cholestatic jaundice, the hyperbilirubinaemia is due to conjugated bilirubin.

Further investigation. The crucial decision for the clinician to make in a patient with conjugated hyperbilirubinaemia is whether or not a surgical approach is appropriate, as misdiagnoses can have grave consequences. The role of the liver function tests is clear: it is to suggest the most appropriate second-line investigation. In general, if the plasma aminotransferases are elevated and there is only slight increase in ALP activity, the picture is regarded as 'hepatic'. The approach is primarily medical management, possibly guided by the result of a liver biopsy and other investigations. On the other hand, if the predominant rise is in ALP, the picture is regarded as 'cholestatic' and it is important to determine the level at which there is failure of bile flow. This is achieved using imaging techniques, for example ultrasound examination, endoscopic retrograde cholangiography or magnetic resonance cholangiography. Obstruction to bile flow outside the liver is usually an indication for surgical intervention.

Imaging techniques have become so widely available and reliable that the great majority of patients with jaundice of unknown origin will have at least an ultrasound or radiological examination irrespective of the liver function tests. Perhaps only in the primary care setting, if the clinical picture and 'hepatic' liver function tests suggest acute hepatitis, will imaging not be undertaken.

The inherited hyperbilirubinaemias

The inherited hyperbilirubinaemias, manifested mainly in childhood, are considered here because

they illustrate specific disturbances of the pathways of bile pigment metabolism. Other than the specific defect, the liver functions normally and, apart from the plasma bilirubin, the results of most of the standard biochemical liver tests are within their reference ranges. Conventionally, these disorders are classified as conjugated and unconjugated types. Unconjugated hyperbilirubinaemia is said to be present when $<25 \mu\text{mol/L}$ or $<20\%$ of an increased bilirubin concentration is in the conjugated form.

Unconjugated types

Crigler–Najjar syndrome. This is an extremely rare condition, caused by a complete absence (type 1) or considerable reduction (type 2) of UDP-glucuronosyl transferase activity with respect to bilirubin glucuronidation. It is inherited in an autosomal recessive manner. The condition shows considerable heterogeneity. There is a failure to conjugate bilirubin and the child becomes very deeply jaundiced within the first few days of life, most of the plasma bilirubin being in the unconjugated state. The unconjugated bilirubin can cross the blood–brain barrier and be deposited in the basal ganglia, leading to characteristic neurological abnormalities termed kernicterus, which can include extrapyramidal-type movement disorders, visual defects and hearing problems. In the most severe form (type 1), death usually ensues within the first year of life, although repeated phototherapy has been used successfully to reduce bilirubin concentrations and liver transplantation is now a viable option. In Crigler–Najjar syndrome type 2, the activity of UDP-glucuronosyl transferase can be increased by giving phenobarbital (which induces synthesis of the enzyme) in addition to phototherapy. Survival into adulthood is now well described.

Gilbert syndrome. This, in contrast to Crigler–Najjar syndrome, is a common (occurring in approximately 7% of the population) and entirely benign condition, characterized by recurrent episodes of mild jaundice, the plasma bilirubin concentration being $<100 \mu\text{mol/L}$ and the only abnormality in the standard liver tests. Jaundice tends to be more pronounced when the affected individual is tired, has an intercurrent illness (e.g. influenza) or has been fasting. It should be remembered that caloric deprivation often occurs during hospital admission for any reason, and the resultant jaundice in an individual with Gilbert syndrome may be regarded as indicating a significant hepatic complication if the diagnosis is not made.

Gilbert syndrome is caused by a reduction in the concentration of the isoform of UDP-glucuronosyltransferase, UGT-1A, responsible for bilirubin conjugation, owing to polymorphisms in the promoter region of the *UGT-1A* gene that reduces its expression. A two base-pair addition (TA) in the TA₍₆₎ TAA element of the *UGT-1A* promoter sequence, when present in the homozygous state (TA₍₇₎/TA₍₇₎), results in an inability to produce sufficient UGT-1A to respond to increases in demand for bilirubin conjugation. Genotyping for the defect is now available as a routine test for the syndrome, and has superseded other tests.

Conjugated types

Dubin–Johnson syndrome. This is an uncommon, benign condition inherited in an autosomal recessive manner and characterized by decreased biliary canalicular transport of conjugated bilirubin and organic anions. Dubin–Johnson syndrome is caused by mutations in *MRP2*, the gene encoding multidrug resistance-associated protein 2, and presents with mild fluctuating jaundice at any age from the neonatal period to adult life, usually with normal aminotransferase and ALP activities. It is often precipitated by use of the contraceptive pill or during pregnancy and, with the increasing availability of mutational analysis, is now frequently revealed during screening of family members with the condition. The liver biopsy shows black coarse inclusions of an as yet unidentified pigment.

A second characteristic finding in this syndrome is that most of the urinary coproporphyrin is type I, whereas in unaffected subjects it is mainly type III. The total amount of urinary coproporphyrin is normal and the abnormality is probably related to a differential excretory capacity for the two isomers.

Rotor syndrome. Like Dubin–Johnson syndrome, this is an autosomal recessive condition characterized by a moderate fluctuating jaundice, few symptoms and having a good prognosis. However, several differences from Dubin–Johnson syndrome are evident: in particular there is no pigment in the liver. The total urine coproporphyrin content is high but with a normal ratio of isomers. The gene mutation causing this syndrome has not yet been identified.

Monitoring response to therapy

Liver biopsy, sophisticated imaging tests and specific biochemical tests, outlined in Chapter 14, are helpful in establishing a precise diagnosis in liver disease, but they have limited utility in repeated appraisal of disease progression or monitoring response to treatment over short periods. This reflects both their cost (in the case of imaging) and safety aspects (in the case of liver biopsy). Herein lies the major role of the standard liver function tests.

There are three broad situations in which frequent monitoring is useful.

1. **Documenting the return of ‘normality’ in acute conditions and early detection of progression to chronicity.** For example, following an acute attack of viral hepatitis B or C, a variable proportion of patients will progress to a chronic carrier state, sometimes with progressive liver disease ending in cirrhosis and perhaps liver cell cancer. The chronic state is defined as the presence of signs of liver disease and/or abnormal liver tests six months after the onset of the acute illness, and heralds the need for therapeutic intervention. Monitoring of patients with hepatitis A is usually not necessary unless the attack is particularly severe. Under such circumstances, progressive deterioration in liver tests and prolongation of the prothrombin time may herald the onset of acute liver failure and necessitate referral to a specialist unit.

2. **Monitoring response to treatment of chronic conditions.** Good examples here are in the immunosuppressive treatment of autoimmune hepatitis and antiviral therapy in chronic viral hepatitis; other examples are described in Chapter 14. Specifically, monitoring of changes in aminotransferase activities is a useful (and cheap) means of assessing response in autoimmune hepatitis (along with measurement of plasma IgG concentration), and as an adjunct to detection of the reduction in (or clearance of) viral genomic material from the blood in chronic viral hepatitis.
3. **Detecting hepatotoxicity caused by drugs.** Monitoring of liver function tests is undertaken for all drugs during clinical trials prior to licensing; any abnormalities are taken as evidence of hepatotoxicity (see Chapter 14). In some instances, where a drug is licensed, but an acceptable risk of toxicity (mild and reversible) has been identified, monitoring may be recommended as a part of continuing surveillance.

Neonatal jaundice

Healthy full-term babies may be jaundiced from the 2nd to the 8th day of life, and premature babies from the 2nd to the 10th, or even the 14th day. This so-called 'physiological' jaundice seldom exceeds 100 $\mu\text{mol/L}$ and is predominantly unconjugated, reflecting a combination of increased red cell destruction, decreased hepatic uptake and reabsorption from the gut. Jaundice detectable on the first day of life, or outside the range described above, is pathological, as is the finding of conjugated hyperbilirubinaemia at any time.

When the concentration of bilirubin is very high (>300 $\mu\text{mol/L}$ in full-term infants, but lower in premature babies), the fat-soluble unconjugated bilirubin may cross the blood-brain barrier and cause brain damage (kernicterus). While measurement of plasma bilirubin is not indicated as routine in jaundiced babies, it does become important when the jaundice is deepening so that treatment by phototherapy and/or exchange transfusion can be instituted and kernicterus prevented.

The neonatal hepatitis syndrome

This syndrome, of which there are several causes, describes a neonate usually less than one month old with pale stools, dark urine and hepatomegaly, who is failing to thrive. In common with adult practice, the major problem is to identify those patients that are amenable to effective surgical intervention, particularly those having congenital biliary atresia (see Chapter 25). It is crucial to confirm that the biliary tract is atretic before embarking on surgery.

Tests of bile duct patency. The Rose Bengal dye test has proved useful in the past for identifying patients with extrahepatic neonatal obstruction. If <10% of an intravenously administered dose is excreted in the stools over a 72 h period, this is strong evidence for biliary obstruction. Currently, technetium-labelled hepatobiliary imaging agents such as hydroxyindolediacetic acid (HIDA) are more often used than Rose Bengal. In combination with liver biopsy, accurate results are achieved in the great majority of cases.

ABNORMAL LIVER FUNCTION TESTS IN ASYMPTOMATIC PATIENTS

With the use of large automated analysers, health screening programmes and medical examinations for insurance purposes, clinical biochemists are increasingly consulted about the significance of abnormal liver tests in patients who are entirely asymptomatic. While the potential for generating needless anxiety is great and not all conditions diagnosed are treatable, much evidence suggests that such abnormalities should be taken seriously, and that referral for a specialist opinion for further investigation is often indicated and justifiable.

Bilirubin

Isolated increases in plasma bilirubin usually indicate Gilbert syndrome. The concentration is <100 $\mu\text{mol/L}$ and usually in the range 20–50 $\mu\text{mol/L}$. This hyperbilirubinaemia is unconjugated and other standard liver function tests are normal (see p. 246). Measurement of haemoglobin, reticulocyte count and, if necessary, haptoglobin will eliminate haemolysis as a cause. Genetic testing is available.

Alkaline phosphatase

In young people, an isolated increase in the activity of this enzyme is often physiological. Increased activity occurs during periods of rapid bone growth and during pregnancy. In older females, the finding of isolated raised ALP activity of hepatic origin may be the first manifestation of primary biliary cirrhosis and estimation of antimitochondrial antibody (see Chapter 14) will speed the diagnostic process. Alternatively (more commonly in males), it may be suggestive of primary sclerosing cholangitis. Subclinical malignant liver disease (primary or secondary), usually found to be a space-occupying mass within the liver, may also produce an isolated rise in plasma alkaline phosphatase activity. Benign transient hyperphosphataemia (see p. 240) is an important condition to recognize, as ALP will return to normal over a 6–8-week period after any infection has cleared and invasive investigations can be avoided.

Aminotransferases

In about 60% of patients, isolated increases in the activities of these enzymes will be attributable to fatty infiltration of the liver associated with obesity, diabetes mellitus or excessive alcohol consumption. However, they may also be due to certain drugs and herbal remedies. Once coexistent drug administration has been excluded, most remaining individuals who have persistently elevated enzyme activities will prove to have some form of chronic hepatitis. Many of these, particularly subjects born outside the UK or those with a history of drug abuse, may have occult chronic viral hepatitis (B or C) – although subclinical hepatitis A is also a possibility. Others will have elevated plasma immunoglobulin concentrations and high plasma titres of autoantibodies (see Chapter 14); on histological examination, cirrhosis will often be present. A small proportion will have other

conditions such as haemochromatosis, Wilson disease or α_1 -antitrypsin deficiency.

γ -Glutamyltransferase

Marked and persistent elevation in γ GT activity may be an indicator of unrecognized excessive alcohol consumption, but it is by no means specific and may also be found in most subclinical liver diseases, or be a result of induction of the enzyme by a number of drugs, components of herbal remedies or environmental agents. Some non-hepatic conditions, including pancreatic disease, hypothyroidism and certain neurological disorders, may also give rise to isolated increases in γ GT activity. The increasing prevalence of obesity, type 2 diabetes mellitus and non-alcoholic fatty liver disease (NAFLD) has meant that an isolated increase in γ GT is most commonly a consequence of fat deposition in the liver.

NORMAL LIVER FUNCTION TESTS IN THE PRESENCE OF OVERT LIVER DISEASE

Standard liver function tests within the reference range do not exclude chronic liver disease. Entirely normal test results may be present in patients with 'inactive' cirrhosis, that is, where there is little or no ongoing liver damage or inflammation. Common examples include alcoholic cirrhosis after abstinence from drinking and autoimmune hepatitis that is well controlled on immunosuppressive therapy. In the presence of normal standard liver function tests, signs of portal hypertension (such as oesophageal varices, which are usually indicators of chronic liver disease) should also raise the possibility of portal vein thrombosis. In this situation, the INR is often modestly prolonged.

ROLE OF LIVER FUNCTION TESTS IN ASSESSING PROGNOSIS

Orthotopic liver transplantation for liver failure is now a well-established form of management in severe acute and chronic liver disease. Nonetheless, the operation is not without risk and precise timing of the procedure is still difficult. Ideally, it should be undertaken only when the patient's life expectancy is less than what might be expected after the operation. Several models that aim to permit calculation of likely survival without transplantation

have been developed. Some 'standard' liver function tests figure prominently among the variables considered in these models.

Chronic liver disease

An early system, still widely applied, is the Child–Turcotte classification, which was later modified by Pugh et al. (Table 13.2). This was an entirely empirical formula designed primarily to assess the degree of risk of liver failure in patients undergoing surgical operations, but has since been used as a general measure of severity of liver disease and hence likely survival. The Child–Turcotte–Pugh (CTP) classification has been criticized on the grounds that two of the measures (ascites and encephalopathy) are subjective, and that the patient is assigned one of three scores that do not reflect a spectrum of overall impairment of liver function and hence the need for transplantation. In addition, a 'ceiling effect' occurs when patients with laboratory values greater than the defined upper limits are not scored as being more ill than those falling within these limits. Furthermore, the CTP classification does not take into account the terminal stages of liver impairment when renal failure supervenes, a complication that indicates a very poor outcome.

The need for more robust and objective criteria on which to base selection for liver transplantation has prompted the recent development of a Model for End Stage Liver Disease (MELD) scoring system. This prognostic model for cirrhosis draws on the analysis of prospective datasets using logistic regression analysis and receiver operating characteristics, and uses serum total bilirubin and creatinine concentrations and INR.

The equation used to calculate the MELD score is:

$$R = 9.6 \times \ln(88.4 \times \text{creatinine in } \mu\text{mol/L}) + 3.8 \\ \times \ln(17.1 \times \text{total bilirubin in } \mu\text{mol/L}) + 11.2 \\ \times \ln(\text{INR}) + 6.43$$

MELD scores derived from many patients in a wide range of institutions dealing with the selection of patients for liver transplantation, fall within a range of values that vary from 6 (less ill) to 40 (gravely ill). The scores are used to decide whether an individual needs an urgent liver transplant within the next three months, with patients that have a MELD score of >16 being prioritized for transplantation.

TABLE 13.2 Pugh's modification of Child's classification for assessing the severity of liver disease

Clinical and biochemical measurements	1	2	3
Ascites	Absent	Slight	Moderate
Encephalopathy (grade)	None	1 and 2	3 and 4
Bilirubin ($\mu\text{mol/L}$)	<25	25–40	>40
Albumin (g/L)	>35	28–35	<28
International normalized ratio (INR)	<1.7	1.71–2.3	>2.3

The disease is considered mild in patients scoring 5 or 6 points (Grade A), moderate in those with 7–9 points (Grade B) and severe in those with 10–15 points (Grade C).

(From Pugh R N H, Murray-Lyon I M, Dawson J L et al. 1973 Transection of the oesophagus for bleeding oesophageal varices. *British Journal of Surgery* 60:646–50, with permission).

Acute liver failure

Liver transplantation for acute liver failure is now routinely performed but, again, laboratory investigations are important in assessing the likelihood of survival without transplantation. For example, in patients with paracetamol-induced acute liver failure, an arterial hydrogen ion concentration of $>50\text{nmol/L}$ ($\text{pH} <7.3$) or, if this feature is absent, the combination of grade 3 encephalopathy, an INR >6.5 and serum creatinine of $>300\mu\text{mol/L}$, indicate a very slight chance of spontaneous recovery and represent a strong indication to proceed to transplantation.

CONCLUSION

There are three categories of liver function tests. These are: the standard tests, for example plasma bilirubin and albumin concentrations and the activities of various enzymes; clearance tests, and tests used in the management of specific liver diseases.

In general, the standard liver function tests are poor indicators of hepatic function and seldom provide a specific diagnosis; it is important not to over-interpret their results. They may, however, provide a guide to further investigations that may give a specific diagnosis, for example imaging by isotopes, ultrasound or radiography or histological examination of liver biopsy material. The standard liver function tests can be of value prognostically and in screening for liver disease, and are vital in the monitoring of liver disease and its response to treatment.

Tests for specific liver disease, for example plasma α -fetoprotein, copper and caeruloplasmin, can be diagnostic and are also used in management.

CLASSIFICATION OF LIVER DISEASE

Liver disease is best classified according to its presumed aetiology (Box 14.1). This is then qualified by the pathological state of the liver where known or inferred: usually cirrhosis, inflammation (i.e. hepatitis) or cholestasis. Thus, terms such as alcoholic cirrhosis, viral hepatitis or cholestasis of pregnancy all conform to this classification. Some idea of the severity of the disease is given by the terms 'compensated' and 'decompensated'. The term 'compensated' implies that, although the liver has been damaged it can, because of its large functional reserve, still function adequately. On the other hand, the term 'decompensated' implies that the liver is failing in some vital function. The terms are not precisely defined, but the development of ascites with or without peripheral

oedema, jaundice or hepatic encephalopathy, in a patient known to have liver disease, would all be regarded as signs of decompensation. Finally, the presumed evolution of the disease in time is given by the terms fulminant, acute, subacute or chronic. In chronic liver disease, additional terminology often employed to provide an indication of severity, especially when assessing histological changes in the liver, includes the terms active or inactive and mild, moderate or severe.

ACUTE HEPATITIS AND ITS SEQUELAE

The term 'hepatitis' indicates that there is hepatic inflammation, for which there are many causes: viral infections, drugs and toxins (including alcohol) are common, while

autoimmune causes are infrequently encountered in the primary care setting, but in a tertiary centre make up a substantial proportion of patients. The standard ‘liver function tests’ (LFTs) are useful to determine that hepatitis is present, how severe it is, to document the progression of the disease and to assess the response to therapy. However, their role in identifying the aetiology of the inflammation is limited.

When the patient presents with an acute hepatitis, the liver function tests characteristically show the so-called ‘hepatic’ picture:

- a pronounced rise in plasma aspartate or alanine aminotransferase (AST, ALT) activity, often to >1000 U/L
- a modest (less than twice the upper limit of the reference range) increase in plasma alkaline phosphatase (ALP) activity
- bilirubinuria and, in more severe cases, hyperbilirubinaemia, which is clinically detectable as jaundice when the total plasma bilirubin rises to >40 – 50 $\mu\text{mol/L}$.

As a broad generalization, plasma activities of the aminotransferases reflect the severity of the disease. Certainly, patients who progress to fulminant hepatitis usually have exceptionally high plasma activities, with elevations of 20–40 times the upper reference limit. However, the relationship is not strictly quantitative, for lower activities (2–3 times the upper reference limit) can be found in

individuals with severe hepatic necroinflammatory activity on histological examination of liver biopsy material.

Differential diagnosis

There are two aspects to this part of the diagnostic process. The first is to distinguish between viral hepatitis and other, non-viral, causes of a hepatic illness and then, within each group, to identify the causative agent. Generally speaking, the standard LFTs are not helpful in separating viral from non-viral causes, and further serological testing, radiological imaging or histological examination will be required.

Plasma aminotransferase activities are not usually grossly raised in alcoholic hepatitis; in this condition, a ratio of AST:ALT of >2 is characteristic, while in hepatitis due to other agents the ratio is usually <2 . In fulminant hepatitis, aminotransferase activities may be close to the reference ranges by the time the patient reaches hospital, emphasizing that results of LFTs can change rapidly with time and depend on the particular clinical course that ensues. Generally speaking, acute infection with hepatitis B virus is more severe than that caused by hepatitis A, and biochemical abnormalities are more protracted. Raised plasma IgM concentration and atypical lymphocytes are more characteristic of type A, but the standard LFTs do not permit distinction between the different types of viral hepatitis.

Acute viral hepatitis

The specific diagnosis is established by serological tests for the hepatitis viruses (Table 14.1). The extent to which individual patients require biochemical and serological investigation depends on the clinical situation. For example, in children, a clinical diagnosis can be established with reasonable certainty if the clinical features are compatible with hepatitis A (infectious hepatitis), particularly if the physician knows of local occurrence. In adults, particularly where there has been no contact with infectious hepatitis, LFTs should be performed together with appropriate serology.

After a variable incubation period (the duration of which depends on the type of virus and the viral load), there is usually a rise in plasma aminotransferase activities, although some infants can be infected without any disturbance of LFTs. In many cases, particularly among young children, an elevated AST or ALT is the only indication of the hepatic process and the patient remains asymptomatic. When symptoms do develop, they are coincident with the maximal aminotransferase activities. Taking infection with the hepatitis A virus as an example, the patient begins to feel unwell and lethargic and may become anorexic, with transient diarrhoea being frequent. Pyrexia can develop and the liver is found to be enlarged and tender. The urine may become dark (owing to bilirubinuria), the stools pale, and in more severe cases, jaundice becomes evident a few days later. Symptoms tend to resolve with the onset of jaundice, which usually subsides over a few days. Following infection with this virus, the patient may, despite being asymptomatic, enter a cholestatic phase. This is heralded by rising plasma activities of ALP and γ -glutamyltransferase (γ GT) that can persist for many weeks and may cause considerable diagnostic confusion. Particularly in the older patient, it is an indication for ultrasound examination to rule out obstruction of the biliary tract. The jaundice usually begins to resolve before aminotransferase activities return

to the reference range, but it has been a frequent observation that bilirubin may disappear from the urine while the patient remains clinically jaundiced. The explanation for this situation lies in the development of 'bili-albumin' (see p. 239).

Outcome of acute viral hepatitis

There are three main possible outcomes of acute viral hepatitis, each with its own characteristic progression of clinical features and pattern of LFTs.

Complete resolution. As noted above, the plasma aminotransferase activities start to rise before the onset of jaundice and often before hepatomegaly is clinically detectable. Activities begin to fall coincidentally with the onset of jaundice and symptoms, and return to normal (AST before ALT) at the same time as, or shortly before, the plasma bilirubin concentration. This is the natural history in the great majority of patients and, unless jaundice develops, many patients will be unaware that they have had an acute hepatitis.

Progression to chronic liver disease. This mode of progression is limited to viral hepatitis types B and C, but a relapsing course for hepatitis A is well described and there are occasional reports of type A triggering autoimmune hepatitis in susceptible individuals. Persistence of symptoms, signs and/or abnormal liver tests (particularly aminotransferase activity in the range of 2–10 times the upper reference limit) for more than six months constitutes, by definition, chronic hepatitis (see below). The accompanying changes in viral serology are complex and will not be considered in the present discussion.

Progression to acute liver failure. Very rarely (in <1% of patients), any type of viral hepatitis may pursue a fulminant course. This course of events is characterized by grossly elevated plasma aminotransferase activities,

TABLE 14.1 Summary of differential diagnosis of acute viral hepatitis caused by true hepatotropic viruses

Nomenclature	Type of virus	Incubation period	Spread	Progression to chronic liver disease	Other features	Serological diagnosis
HAV	Picornavirus (RNA)	1–6 weeks	Faeco-oral	No	Raised IgM, atypical lymphocytes	IgM class anti-HAV
HBV	Hepadnavirus (DNA)	6 weeks–6 months	Parenteral	Yes		HBsAg and IgM class anti-HBc
HCV	Flavivirus (RNA)	2–26 weeks	Parenteral	Yes	Raised IgG and γ GT; polyphasic AST/ALT changes	Anti-HCV antibodies; detection of HCV-RNA by PCR
HDV (Delta)	RNA, HBV-dependent viroid	Uncertain	Mainly parenteral	Yes		IgM class anti-HDV
HEV	Calicivirus (RNA)	5–10 weeks	Faeco-oral	No	The major cause of enteric NANB	Anti-HEV (not yet routinely available)

HAV, hepatitis A virus; HBV, hepatitis B virus; HDV, hepatitis D virus; HEV, hepatitis E virus; NANB, non-A, non-B; PCR, polymerase chain reaction; for other abbreviations, refer to text.

an increasingly prolonged prothrombin time (PT) or international normalized ratio (INR) and the development of hepatic encephalopathy, which may occasionally develop before jaundice becomes a prominent feature. The prognosis is poor. The syndrome of acute liver failure (ALF), one cause of which is acute viral hepatitis, is described in more detail below.

ACUTE LIVER FAILURE

Acute liver failure implies the development of severe hepatic dysfunction within six months of the first onset of liver disease and in the absence of any pre-existing liver disease. Hepatic encephalopathy and a prolonged and persistent increase in PT are the characteristic features, and where these occur within eight weeks of the first symptom, the condition is known as fulminant hepatic failure (FHF). In those who survive, there are no long-term hepatic sequelae. The commonest cause in the UK is paracetamol overdose (Chapter 40) followed by viral hepatitis types B and E; ALF due to hepatitis C virus is extremely rare. Rarer causes include adverse drug reactions, other viruses, *Amanita* mushroom poisoning, Wilson disease, secondary hepatic malignancy, lymphoma and recreational drugs.

Laboratory features

Laboratory investigation is aimed at determining the cause of the ALF as well as assessing its consequences and complications (which are very similar irrespective of the aetiology). Measurement of the blood concentration of paracetamol is important, particularly in view of the beneficial effect of treatment by N-acetylcysteine infusion. The serology of viral causes is complicated because the hepatitis B surface antigen (HBsAg) may become undetectable before the patient reaches hospital. In general, with ALF due to causes other than paracetamol overdose, it is usually too late for specific treatment for the condition (e.g. D-penicillamine for Wilson disease) to be effective and management is by general supportive measures and, if feasible, liver transplantation.

The standard LFTs show a grossly hepatic picture at the time of onset of the encephalopathy. Jaundice is deep and progressive and plasma aminotransferase activities of several thousand U/L are usually found, although these may have fallen considerably by the time the patient is sent to a referral centre. A rare cause of FHF is massive metastatic tumour infiltration. This is characterized by hepatomegaly (in contrast to the reduced-size liver found with most other causes of FHF) and a much more cholestatic picture – such that the AST:ALP ratio is <4 rather than the converse, as in most other cases.

Coagulation defects are a consistent finding. Plasma concentrations of fibrinogen are decreased as are those of factors II, V, VII, IX and X. These are reflected in a prolonged PT or INR which, in the UK, is used as the main measure of severity of disease and is the most widely used parameter for following progress. Hypoglycaemia, owing to a combination of impaired gluconeogenesis and

glycogen breakdown and synthesis, is such a consistent finding that glucose infusion is a routine part of management, particularly during transfer to a referral centre. Where paracetamol is involved, it may interfere with blood glucose estimation, resulting in erroneously high values. Acute kidney injury is a frequent and ominous complication that occurs in at least 50% of patients with FHF, particularly with paracetamol poisoning. In about one-half of patients, the renal lesion is acute tubular necrosis, and in the remainder it is 'functional' renal injury (see p. 261).

Laboratory criteria for liver transplantation

Currently, with the best supportive care, 30–50% of patients with fulminant hepatic failure will survive; the figures are rather better for those with paracetamol overdose and rather poorer for those with viral hepatitis, particularly those classified as non-A–E, or drug reactions. This poor prognosis has led to the introduction of liver transplantation as a therapeutic option. It is clearly important to reserve this option for those with the worst prognosis and who are most unlikely to recover with supportive treatment. With this in mind, a number of laboratory-based criteria have been identified to ascertain the likelihood of death. The major adverse factors are an arterial hydrogen ion concentration >50 nmol/L (pH <7.3), and progression to grade III coma (see p. 259) with an INR of >10 and plasma creatinine concentration >300 µmol/L. Recently, there has been considerable interest in the measurement of plasma factor V concentration. If the ratio of factor V to factor VIII is very low, the chance of survival without transplantation is very small.

CHRONIC HEPATITIS

Chronic hepatitis is usually defined as a condition in which clinical or biochemical features of liver disease persist for more than six months. However, it has become clear that many patients can have the condition for much longer periods before it manifests itself in this way. Indeed, occasionally, such individuals may present with what at first appears to be an acute hepatitis that, on further investigation, proves to be an acute exacerbation of a previously asymptomatic chronic process (see below). On histological grounds, the condition was previously classified into two categories: chronic persistent hepatitis (CPH), defined as inflammation confined to the portal tracts with no necrosis of hepatocytes, and chronic active hepatitis (CAH) characterized by inflammatory cells spilling out into the hepatic parenchyma and damaging periportal hepatocytes in a hallmark pattern described as 'piecemeal necrosis'. Chronic persistent hepatitis was believed to be a benign condition of little clinical significance, with a good prognosis. Chronic active hepatitis, in contrast, was envisaged as a disorder with a more serious prognosis, which frequently progressed to cirrhosis, with the inflammatory activity often continuing even after cirrhosis developed (so-called 'active cirrhosis').

Although CPH and CAH were purely histological descriptions of the morphological changes seen in patients with chronic liver disease, they were embraced by hepatologists and gastroenterologists as clinical entities. However, during the 1970s and 1980s, it was increasingly recognized that the associated changes could be found in patients with several quite distinct causes of chronic hepatitis (Table 14.2). Somewhat surprisingly, rather than questioning the validity of CPH and CAH as distinct syndromes, this led to expansion of the list of diseases considered to be capable of causing them. By the 1990s, the previously accepted view that CPH was associated with a good prognosis was being challenged, because it became apparent that CPH and CAH are changes at either end of a spectrum of morphological changes seen in chronic hepatitis, and that transitions between them can and do occur during flares of disease activity and periods of remission, regardless of the aetiology of the process.

Other criteria for CPH and CAH were also found to be untenable. A requirement for markedly elevated plasma aminotransferase activities for diagnosis of CAH could not be upheld because it was recognized that these enzymes are poor correlates of histologically assessed activity in chronic liver disease, and that mild elevations of aminotransferases do not exclude severe disease. The temporal criterion for duration of disease of at least six months (to distinguish chronic from acute liver disease) also proved difficult to apply because it is often not possible to define the time of onset and, as noted above,

patients presenting with acute hepatitis who had clear evidence of chronic liver disease were being identified.

Current recommendations for defining and describing chronic hepatitis are that the terms CAH and CPH should be abandoned in favour of precise morphological descriptions, graded for necroinflammatory activity and staged for degree of fibrosis. While the term 'piecemeal necrosis' may be retained, the terms 'periportal hepatitis' or (preferably) 'interface hepatitis' should be used to describe the changes previously associated with CAH. Description of the changes previously associated with CPH should employ terms such as mild or moderate portal or periportal hepatitis (as appropriate) *without significant necrosis*. All of these terms should be qualified by aetiological designations (e.g. autoimmune hepatitis, chronic hepatitis B, C, D etc.), wherever possible and practicable.

Laboratory investigation plays a crucial role in the differential diagnosis and management of chronic hepatitis (see Table 14.2), although histological examination of liver biopsy material is usually required to assist in assessing severity and providing additional aetiological information. Typically, chronicity is defined as persistence of a hepatic pattern of abnormal LFTs over several months. The plasma aminotransferase activities are usually elevated to 2–10 times the upper reference limits. Plasma alkaline phosphatase is often normal or only slightly raised, although higher values may be seen in patients where cirrhosis has developed with associated distortion of the hepatic architecture. Plasma bilirubin concentration is often also normal or mildly elevated but, in severe cases, there can be a profound hyperbilirubinaemia with jaundice. The PT/INR and other markers of coagulation are often mildly abnormal, and the plasma albumin concentration may be at the lower end of the normal range, reflecting decreased hepatic synthetic function. Marked hypoalbuminaemia is, however, a late feature associated with advanced cirrhosis. Depending on the aetiology of the chronic hepatitis, plasma immunoglobulin concentrations may also be elevated, sometimes quite markedly (see below).

The above abnormalities may be a sequel to an acute hepatitis, in which case the aminotransferase activities may have risen to 10–20 times the upper reference limits before falling back to the somewhat lower values more characteristic of chronic progression. However, a clinically evident acute phase may not have been apparent especially if the patient did not develop jaundice. Indeed, chronic hepatitis is not infrequently diagnosed incidentally during routine health screening or investigation of some other condition. Notably, profound fatigue is a common feature of all forms of chronic hepatitis, and the latter should, therefore, be considered in the differential diagnosis of chronic fatigue syndromes.

TABLE 14.2 Differential diagnosis of chronic hepatitis

Type	Laboratory tests	Comments
Viral type B type C	HBsAg Anti-HCV; HCV-RNA by PCR	Has characteristic histological features
Alcoholic	Blood alcohol, γ GT, MCV, desialylated transferrin	Laboratory tests are supplementary to clinical history
Drugs	May develop autoantibodies	Oxyphenisatin, methyl dopa, isoniazid, dantrolene etc.
α_1 -Antitrypsin (AT) deficiency	Low α_1 -AT concentration; typical phenotype (PiZZ ^a)	Characteristic eosinophilic globules on histology
Wilson disease	Low caeruloplasmin, high tissue copper and urinary copper concentration	Low ALP activity; low AST/ALT activity for degree of inflammation
Autoimmune type 1	Anti-SMA and/or ANA	Markedly raised γ -globulin and IgG
type 2	Anti-LKM antibodies	

^aFor explanation, see α_1 -Antitrypsin deficiency on p. 268. ANA, antinuclear antibody; LKM, liver-kidney microsomal antibody; MCV, mean corpuscular volume; SMA, smooth muscle antibody.

Differential diagnosis of chronic hepatitis

Viral hepatitis types B and C

The specific diagnosis is based on virological tests. The detection in serum of the hepatitis B surface antigen (HBsAg) indicates that the patient is infected with the

hepatitis B virus (HBV). Clinical information and the results of LFTs can be useful in deciding whether the infection is acute, but this can be confirmed by the appearance of IgM antibodies against the HBV core antigen (HBc). The gradual disappearance of HBsAg, with sequential detection of IgG antibodies to HBc and antibodies to surface antigen (HBsAb) indicates clearance of the virus, an event that occurs in the majority of adults (90%) acutely infected with it. Other markers of viraemia are derived from different components of the virus, including hepatitis B 'e' antigen (HBeAg) and HBV DNA, and these disappear with viral clearance. The decline in HBe antigenaemia is accompanied by the appearance of antibodies to the 'e' antigen (HBeAb) and is known as seroconversion. In contrast to infection acquired in adulthood, perinatal infection becomes chronic in 95% of patients, with the virus persisting into adult life. Chronic infection is associated with a number of outcomes. Many individuals are asymptomatic, with the virus detected incidentally and a serological profile in which HBsAg and HBeAb are detected and HBeAg is negative. Although such people frequently have normal liver function tests, and have long been termed 'healthy carriers' and been considered to be of low infectivity, it has become clear that a significant proportion have marked histological damage on liver biopsy and detectable circulating HBV DNA. Others have clear evidence of cirrhosis and, in such individuals, there is a 5% annual risk of developing hepatocellular carcinoma.

Hepatitis C virus (HCV) infections are identified initially by detection of antibodies (anti-HCV) to the virus and chronic infections confirmed by seropositivity for the viral RNA (HCV-RNA).

Antiviral therapy for chronic hepatitis B and C, using interferons, with or without other antiviral agents to inhibit viral replication, is now well established, and comprehensive guidelines for treatment exist. Thus, tests for genomic material of both viruses (HBV-DNA and HCV-RNA, respectively) are usually performed, initially to assess the viral load before treatment and subsequently to monitor the patient's response to treatment. Plasma aminotransferase activities are also usually monitored as an adjunct to the above, since they are cheap to perform on a frequent basis and a return to normal values suggests at least some response to treatment. In the case of HBV, successful treatment is heralded by a change from HBeAg to HBeAb positivity and this event is accompanied by an acute hepatic illness, the so-called 'hepatic flare' (Fig. 14.1). Hypothyroidism is a side effect of interferon therapy, particularly in patients with chronic hepatitis C, and thyroid function tests should be monitored before treatment and at 3-monthly intervals.

Procedures for the handling of potentially dangerous and infectious samples are not the concern of this chapter, but it is worth noting that as many as 1–2% of inner city populations may be carriers of either HBV or HCV. The majority of these will have no symptoms of liver disease and their blood samples may be referred to the laboratory for causes unrelated to liver disease. Caution should therefore be exercised in the handling of all blood products in view of the possibility of occult hepatitis viral infections.

FIGURE 14.1 ■ Changes in ALT activity in a patient with chronic hepatitis B virus infection successfully treated with interferon. Note the hepatitis response heralding clearance of HBsAg and appearance of the antibody. Clearance of the virus is also indicated by a decrease in viral DNA polymerase activity.

Alcohol

In perhaps 10% of patients with alcoholic liver disease, the histological features of interface hepatitis, similar to those in other forms of moderate/severe chronic hepatitis can be observed. There is evidence that some such cases may be related to coexistent hepatitis C virus infection or other underlying causes. The problem that this presents for differential diagnosis is discussed in detail under the heading of alcoholic liver disease.

Wilson disease

Chronic hepatitis is a rare presentation of this rare disease (see p. 267), but is of considerable importance because treatment can be instituted and further liver damage avoided. Generally, the plasma activities of aminotransferases are low in comparison with the extent of histological activity. The diagnostic work-up is considered in detail below, but the initial screening procedures include measurement of plasma copper and caeruloplasmin concentrations and ocular slit-lamp examination for Kayser–Fleischer rings. The diagnosis must be considered in all patients with chronic hepatitis, particularly those in the younger age groups.

α_1 -Antitrypsin deficiency

This is another rare cause of chronic hepatitis (see p. 266). Plasma α_1 -antitrypsin concentrations are usually low but, occasionally, because of active inflammation, they may be within the reference range. It is therefore essential that the α_1 -antitrypsin phenotype is determined, particularly in younger patients.

Autoimmune hepatitis (AIH)

This is a rare cause of chronic hepatitis. However, it is one of the few causes of chronic liver disease in which

drug treatment is highly effective in the great majority of patients, and accurate diagnosis is essential. This is established partly by careful exclusion of the other causes listed above and partly by the finding of a suggestive pattern of biochemical, immunological and histological abnormalities. The biochemical liver tests show a hepatitic pattern (see above), but plasma aminotransferase activities are often only moderately elevated and bilirubin concentrations are frequently normal. Typically, there is a marked hypergammaglobulinaemia with selective elevation of the IgG concentration (which can be as high as 100 g/L). Approximately 80% of AIH patients will also have significant titres (>1:40) of organ non-specific autoantibodies (smooth muscle antibody (SMA), antinuclear antibody (ANA) or anti-liver-kidney microsomal (LKM) antibodies). Standard treatment involves immunosuppressive therapy with prednisolone and the steroid-sparing agent azathioprine.

Monitoring response to therapy. Plasma aminotransferase activities do not correlate well with histologically assessed disease activity in AIH. However, such tests, together with plasma IgG concentrations, are cheap and can be repeated more easily than liver biopsy, so are used routinely to monitor response to immunosuppressive therapy. Some 80–95% of AIH patients respond to the standard therapy of prednisolone and azathioprine, with aminotransferase activities and IgG concentrations falling to at least 50% below their initial values within three months. Dosages are titrated against the aminotransferase and IgG values, being progressively reduced to maintenance doses as these parameters fall towards the normal range that, in most patients, is achieved within one year of starting treatment. However, this 'biochemical remission' does not represent a complete response. It usually requires at least a further year of treatment before complete histological remission is achieved. Current recommendations are that treatment should be continued for at least two years (preferably four), with regular monitoring of aminotransferase activities and IgG concentrations; before any attempt is made to withdraw treatment, histological remission should be confirmed. Withdrawal of all immunosuppression is rarely achieved, possibly because it is not routinely attempted, but gradual reduction in the dose of prednisolone to very low levels, or complete withdrawal, is feasible so that immunosuppression can be maintained with azathioprine alone. If complete withdrawal of immunosuppressive treatment is achieved, the patient should be monitored indefinitely, because even a complete histological response does not represent a true 'cure' and there is a lifelong risk of relapse of the disease. The latter is heralded by a rise in aminotransferase activities and IgG concentrations. Importantly, interpretation of biochemical test results should not focus solely on the upper reference limits for the various parameters but should take account of what may be normal for the individual patient. By definition, half of the normal population will have values below the geometric means of the reference ranges and, for such individuals, a rise in a parameter to (or just above) the upper reference limit may represent a doubling of their normal value.

PRIMARY BILIARY CIRRHOSIS (PBC)

This is a chronic cholestatic condition of unknown cause in which there is destruction of septal and interlobular bile ducts. Females are affected far more frequently than males. Most patients present with pruritus, jaundice or non-specific symptoms including tiredness and hepatic pain. However, an increasing number are detected incidentally when abnormal liver tests, particularly an increased activity of alkaline phosphatase, are detected during opportunistic screening. Although PBC is considered to be an autoimmune liver disease, and twin and family studies suggest that there is a significant genetic component, it is clearly a complex disease and little progress has been made in defining the genes responsible.

Biochemical liver function tests reveal a characteristic cholestatic picture with, as the disease progresses, increasing plasma alkaline phosphatase (ALP) (of biliary origin), increasing bilirubin concentration and falling albumin. The plasma concentrations of both pentameric and monomeric IgM are frequently raised (*cf.* AIH). The most specific serological tests are those for anti-mitochondrial antibodies (AMA), which are detectable in about 95% of patients. Antimitochondrial antibodies recognize several distinct autoantigens, but the most characteristic for PBC are the M2 antibodies that react with epitopes on the E2 components of the pyruvate dehydrogenase complex (PDC-E2), the branched chain oxoacid dehydrogenase (BCOAH-E2) and the oxoglutarate dehydrogenase complexes. Laboratory tests, particularly the plasma bilirubin concentration, are used in assessing prognosis (see p. 248).

PRIMARY SCLEROSING CHOLANGITIS (PSC)

This is a progressive disease characterized by diffuse inflammation and fibrosis of the extrahepatic and/or intrahepatic biliary system, which leads to obliteration of the intrahepatic ducts and, eventually, biliary cirrhosis (see below). It is diagnosed on the basis of characteristic cholangiographic appearances together with compatible clinical, biochemical and histological features, and exclusion of several other conditions known to cause secondary sclerosing cholangitis, such as biliary calculi and previous biliary tract surgery. Men are affected more often than women and, again, although considered an autoimmune disease, the disease is genetically complex and remains poorly characterized.

With the advent of endoscopic retrograde pancreatography (ERCP), PSC began to be diagnosed earlier in its natural history, particularly following the initial finding of persistently abnormal LFTs in patients with inflammatory bowel disease, which coexists with PSC in more than 50% of cases. In the early stages, there is usually a minor elevation of plasma aminotransferase activities and moderate elevation of ALP, which progresses, over several years, to a very severe cholestatic condition with deep jaundice. By this stage, plasma ALP activity often reaches more than ten times the upper reference limit. Death from liver failure ultimately results unless a liver

transplant can be performed. However, the disease has been known to recur in the grafted liver. Rapid clinical deterioration with a progressive cholestatic picture may indicate the development of cholangiocarcinoma, a complication with a lifetime risk of 10–15% in this condition. CA19-9 concentrations may be elevated when a cholangiocarcinoma has developed but this is not a specific finding as CA19-9 is also increased in other cholestatic liver diseases. Copper retention appears to be a general feature of chronic cholestatic conditions: in PSC most patients will have raised hepatic copper concentrations (of a similar order to that seen in Wilson disease and primary biliary cirrhosis) and urinary copper concentrations are typically raised. However, in contrast to Wilson disease, the plasma caeruloplasmin and copper concentrations will remain within the reference range (see p. 267).

ALCOHOLIC LIVER DISEASE

Excessive alcohol (ethanol) consumption is by far the commonest cause of liver disease in the Western world, although it often exists as part of a wider spectrum of social, psychological and pathological effects of alcohol-related damage. Most current evidence suggests that alcohol itself is the primary cause of the liver damage, although associated malnutrition may be a contributory factor. Considering that there is an enormous variation in the amount of alcohol drunk by different individuals, the time course over which it is consumed and individual susceptibility to tissue injury, it is not surprising that the adverse effects on the liver vary widely.

Ethanol metabolism

Alcohol is absorbed from the stomach and small bowel. Absorption is most efficient when there is no other food (particularly carbohydrate) in the gut and when its concentration in the ingested fluid is of the order of 20%.

The liver is exposed to the highest concentration of alcohol in blood, owing to the blood supply by the hepatic portal vein, and is responsible for more than 95% of its metabolism. The concentrations attained after ingestion of a standard amount of ethanol depend, among other things, on sex, weight, previous exposure to alcohol, the type of alcoholic beverage and rate of gastric emptying. Ethanol is oxidized to acetaldehyde mainly by the cytosolic enzyme alcohol dehydrogenase, but also, particularly at high concentrations, by the cytochrome P450 system. Acetaldehyde is particularly toxic. It is metabolized by aldehyde dehydrogenase in the mitochondria to acetate, which is, in turn, oxidized by peripheral tissues to carbon dioxide and water. Both enzyme systems can be induced by alcohol. The intoxicating and metabolic effects are mediated directly by ethanol but it is likely that acetaldehyde is an important factor in causing tissue damage through the formation of adducts that in turn lead to functional impairment of hepatic proteins. The metabolism of ethanol also predisposes to various metabolic problems including hypoglycaemia and non-respiratory acidosis (see Chapter 40).

Liver pathology in alcoholic liver disease

Three patterns of histological change in liver tissue have been described in association with ethanol ingestion, although there is considerable overlap and all three features can be present on occasions. Fatty liver (steatosis) appears to be a response to excessive alcohol consumption in all individuals. It is considered to be a reversible feature, resolving with abstinence, and does not progress to chronic liver disease provided abstinence is maintained. In alcoholic hepatitis, the appearances are of steatosis but also sometimes with features of interface hepatitis. This is a serious condition with a marked propensity to progress to fibrosis and cirrhosis – the third and final stage of chronic alcoholic liver disease. Additional morphological changes may be seen in patients who have other coexisting disorders. For example, people with hereditary haemochromatosis or chronic hepatitis C may be at increased risk of developing liver disease from alcohol, and porphyria cutanea tarda is often associated with excessive alcohol consumption.

Biochemical abnormalities

Alcoholic steatosis. Biochemical changes are minimal and consist of subclinical hyperbilirubinaemia and a very mild elevation of plasma aminotransferase activities. Very occasionally, a cholestatic syndrome develops, but associated alcoholic pancreatitis leading to biliary obstruction should be considered if jaundice is marked. Episodes of delirium tremens and alcoholic myopathy may give markedly raised plasma aminotransferase activities. Plasma γ GT activity is elevated in the majority of patients (although it is not a specific finding), but usually reflects enzyme induction rather than hepatic injury.

Alcoholic hepatitis. There is a wide spectrum of severity associated with this histological diagnosis, ranging from the classic syndrome of deep prolonged jaundice, hepatic failure, fever and leukocytosis through to a complete absence of symptoms and physical signs. Alcoholic hepatitis generally occurs after heavy bouts of drinking and when subjects have been drinking heavily for several years. The laboratory tests reveal anaemia, usually with a leukocytosis and, consistently raised aminotransferase activities. However, the AST values are seldom above ten times the upper reference limit and ALT values are usually lower. This results in an AST:ALT ratio of >2 , and a value below this in subjects with hepatitis suggests that alcohol is not a major aetiological factor.

Alcoholism and haemochromatosis. Iron overload is common in alcoholic liver disease, occurring in perhaps 50% of patients (see p. 265). Occasionally, this may progress to a similar degree to that seen in hereditary haemochromatosis, and the patient may have similar abnormalities in biochemical parameters of iron status and endocrine function. More commonly, it appears that excessive alcohol consumption leads to the unmasking of haemochromatosis in patients with this genetic disease.

Porphyria cutanea tarda. As with haemochromatosis, this genetically determined condition, comprising bullous skin lesions on exposure to sunlight, liver disease and iron overload, is often brought to medical attention by excessive alcohol consumption. The underlying biochemical defect is a deficiency of uroporphyrinogen decarboxylase (see Chapter 28).

Use of laboratory tests in clinical practice

Biochemical tests of alcohol intake and its misuse fall into three categories:

- measurement of alcohol or its metabolites, e.g. ethanol, ethyl glucuronide, ethyl sulphate, 5-hydroxytryptophol
- assessment of the effect of alcohol on protein metabolism, i.e. carbohydrate deficient transferrin
- assessment of the extent of liver damage associated with alcohol misuse by measurement of plasma enzymes.

Alcohol and metabolites

Saturation of the normal pathways of alcohol metabolism results in the induction of minor pathways with the formation of metabolites with high specificity for excess alcohol intake: glucuronidation leading to ethyl glucuronide (EtG) formation; sulphation to ethyl sulphate (EtS) formation, and incorporation into 5-hydroxytryptamine to form 5-hydroxytryptophol. Ethanol in blood or urine remains detectable only for 24–36h, even after ingestion of significant amounts, so false negative results may be obtained in subjects misusing alcohol if they can abstain for 1–2 days prior to testing. The urinary 5-hydroxytryptophol:5-hydroxyindole acetic acid ratio has close to 100% specificity for excess alcohol consumption, but mass spectrometry is required for its measurement and the test has not been adopted routinely. Recently, interest has grown in the use of EtG and EtS measurements as these metabolites have high specificity for alcohol misuse and can be detected in urine up to 72–90h after significant intake. A commercial immunoassay exists for EtG, but the combined measurement of EtG and EtS requires mass spectrometry. Many workers favour the latter approach because of reports of both false positive and negative EtG results in the presence of a urinary infection with bacteria capable of either removing the glucuronide or glucuronidating ethanol *in vitro*. Ethyl glucuronide and EtS do, however, offer the potential for detection of ‘binge’ drinkers that has been notoriously difficult to achieve in the past.

Effects of alcohol on protein metabolism

Carbohydrate deficient transferrin (CDT) is defined as the asialo- and disialo- forms of transferrin that usually account for <1.6% of the total transferrin found in plasma. The formation of CDT is directly proportional to alcohol intake: ethanol (or its metabolites) appears to inhibit the enzymes responsible for addition of the carbohydrate side-chains and induce sialidase that removes the terminal sialic acid residues from the side-chains.

The percentage CDT is independent of the extent of any alcohol-related liver damage except in patients with severe cholestatic liver disease, where reduced clearance may cause a falsely high result. Hepatic failure can cause analytical difficulties in CDT measurement because of low total transferrin concentrations from reduced synthesis. As the plasma half-life of CDT is 10–14 days, a raised percentage of CDT is strongly suggestive of chronic excessive alcohol consumption with sensitivity and specificity both approaching 85%. Measurement of serum immunoglobulin concentrations may also be helpful because alcoholic liver disease is often associated with a selective increase in IgA (*cf.* AIH and PBC).

Plasma enzymes

Alcoholic steatosis can cause an increase in the aminotransferases or γ -GT that is reversible with abstinence, although the degree of increase correlates poorly with the extent of liver damage assessed histologically. Progression to cirrhosis is usually accompanied by abnormal plasma enzyme activities often suggesting intrahepatic cholestasis, although in some patients with established cirrhosis who abstain from further alcohol intake, these may revert to normal. For a more detailed discussion, including the role of the measurement of mitochondrial AST, see Chapter 13.

Non-alcoholic fatty liver disease (NAFLD)

This comprises a spectrum of conditions ranging from simple hepatic steatosis (excessive accumulation of fat in hepatocytes) to end-stage chronic liver disease: these conditions are clearly associated with the epidemic of obesity and diabetes recognized in Western populations. Previously thought to be a rare and relatively benign condition, developing mainly in middle-aged females in association with obesity, insulin resistance and hypertriglyceridaemia, NAFLD is emerging as one of the commonest causes of chronic liver disease. Steatosis is an adaptive response of the liver to insulin resistance. When this is accompanied by endogenous insults such as oxidative and free radical damage, mitochondrial dysfunction and endotoxaemia, themselves resulting in part from excessive amounts of fat in liver cells, an inflammatory condition termed non-alcoholic steatohepatitis (NASH) is induced in susceptible individuals. Typical histological features include micro- and macrovesicular steatosis, mild to moderate portal and lobular inflammation (often with small clusters of polymorphs), liver cell ballooning and perisinusoidal fibrosis. Mallory’s hyaline (typically associated with alcoholic liver disease) may also be present. Non-alcoholic steatohepatitis can induce fibrosis and, in some individuals, this process will result in cirrhosis with all the attendant complications including hepatocellular carcinoma. Unfortunately, it is not possible at present to predict which individuals will experience a progressive course. Liver function tests are mildly or moderately abnormal in most patients at presentation, but longitudinal studies indicate that progression of fibrosis can occur despite return to normal of aminotransferase activities in response to weight loss.

THE CONCEPT OF CIRRHOSIS

Cirrhosis is not a clinical diagnosis, but a pathological description of the liver in which there is:

- diffuse hepatic fibrosis
- nodular regeneration
- a disturbance of the normal hepatic architecture, that is, a distortion of the normal relationship of the portal tracts to the central veins (see Chapter 13).

It is the end result of chronic liver diseases that are usually associated with recurrent episodes of necrosis, cell death and attempts by the liver to regenerate. Liver function is disturbed, not only because of the cirrhosis per se, which has little effect on standard LFTs, but because of continuing immunologically mediated liver cell damage, the capillarization of the sinusoids due to fibrosis (see Chapter 13) and, on occasions, because of the effects of the initiating agent such as alcohol. Efforts to make a diagnosis of cirrhosis on any grounds other than histological are unreliable.

A great part of clinical hepatology is taken up with the diagnosis and management of the complications of cirrhosis: hepatic encephalopathy, ascites and the hepatorenal syndrome, infections, primary hepatic malignancy and endocrine dysfunction.

Hepatic encephalopathy

This is seen in patients with advanced cirrhosis, and a precipitating factor such as administration of a sedative, a large protein intake (including blood from variceal haemorrhage), infection or electrolyte imbalance can usually be identified. It is particularly frequent in subjects who have undergone a portocaval shunt for treatment of portal hypertension. As with the encephalopathy associated with acute liver failure, the severity of the condition is graded from I–IV:

- I – alert but with asterix ('hepatic flap'), inversion of sleep rhythm
- II – confused, disorientated, slow mentation, inappropriate behaviour
- III – restless, aggressive, sleepy, uncommunicative
- IV – coma.

The diagnosis is essentially a clinical one and, although characteristic electroencephalographic appearances are described, these are not used diagnostically. Similarly, the blood ammonia concentration is usually raised but correlates only poorly with the degree of encephalopathy.

Vascular disturbances in cirrhosis

Cirrhosis is characterized by the development of systemic vasodilatation, which results in a decrease in effective arterial blood volume, low systemic vascular resistance and a hyperdynamic circulation with high cardiac output. The mechanism underlying these changes is not known with certainty, but may involve increased vascular synthesis of nitric oxide because of increased activity of inducible nitric oxide synthase, as well as increased production of prostacyclin and other

vasodilators such as glucagon, substance P and calcitonin gene-related peptide. In response to vasodilatation, several homeostatic systems are triggered, including an increase in renal sympathetic activity, activation of the renin–angiotensin–aldosterone system and increased production of antidiuretic hormone (ADH). In some patients, vascular resistance and effective arterial blood volume are restored, but in others, particularly when cirrhosis is complicated by severe portal hypertension, water retention and vasoconstriction are insufficient to restore circulating blood volume and these subjects present with hypotension and a hyperdynamic circulation, together with high plasma concentrations of renin, noradrenaline (norepinephrine) and ADH. These hormones have a profound effect on renal vasculature, causing progressive vasoconstriction and a reduction in plasma flow and glomerular filtration, resulting in marked salt and water retention. These changes have a central role in the development of ascites.

Ascites

Ascites, the excessive accumulation of extracellular fluid in the peritoneal cavity (over 30L in some patients), is usually a late complication of cirrhosis. Two key factors underlie its development, namely portal hypertension operating at the level of the sinusoids, and sodium and water retention. Portal hypertension occurs as cirrhosis develops because of progressive collagen deposition within the space of Disse and nodule formation, resulting in disruption of the vascular architecture of the liver. Increased resistance to portal flow and increased hydrostatic pressure within the sinusoids favour transudation of tissue fluid into the peritoneal cavity. Portal hypertension is a critical permissive factor in the development of ascites. The second key factor in the development of ascites is, as described above, salt and water retention with enhanced sodium reabsorption occurring in both the proximal and distal tubules of the kidneys. In some patients with ascites, normal concentrations of aldosterone are found, leading to the suggestion that enhanced renal sensitivity to the hormone underlies the increased distal tubular sodium reabsorption. The role of hypoalbuminaemia in the development of ascites in patients with liver disease is controversial. Some consider this to have a permissive role in localizing the fluid collection to the peritoneal space, while others consider that plasma albumin concentration has little influence on ascites formation. Instead, they suggest that the oncotic pressure gradient across the sinusoids is low (because albumin crosses the fenestrations) so ascites develops only when trans-sinusoidal filtration exceeds the drainage capacity of the lymphatic system, as occurs in patients with portal hypertension.

Ascites usually develops in patients with advanced, decompensated disease, but the tendency to retain salt is present before ascites actually develops and a sudden increase in dietary salt intake may lead to the generation of ascites that clears spontaneously when the salt intake is restricted. Excess water retention leading to hyponatraemia is frequent and is attributable to the mechanisms described above. There are, however, several liver and

non-liver diseases other than cirrhosis (Box 14.2) that can lead to the formation of ascites, and the establishment of a precise diagnosis is important for its correct management.

If the standard LFTs are abnormal in a patient with ascites, then it is likely that one of the liver diseases listed in Box 14.2 is responsible and it is often already known that a patient who develops ascites has cirrhosis. However, patients with liver disease can develop ascites for reasons other than cirrhosis. For example, patients with alcoholic cirrhosis may develop tuberculous ascites, pancreatic ascites or 'malignant' ascites if hepatocellular carcinoma supervenes. Cardiac causes can usually be diagnosed confidently on clinical grounds, but the other causes may be difficult to distinguish and laboratory investigations have an important role to play. Ascitic fluid should be aspirated using an 18-gauge needle and syringe (a so-called 'diagnostic tap') for analysis. The investigations and their interpretation are shown in Table 14.3. It should be recognized that sodium retention is not a diagnostic feature of cirrhotic ascites: equally intense sodium retention can occur in malignant ascites.

The figures for ascitic protein given in Table 14.3 are given only as guidelines. Exceptions are frequent and clinical utility is limited, but as the changes become more extreme, so their diagnostic specificity increases. Thus, a protein concentration <10 g/L is not infrequent in

uncomplicated cirrhosis, but virtually rules out malignant disease. Conversely, protein concentrations >35 g/L are the rule in malignant ascites and are unusual in uncomplicated cirrhosis.

Several tests have been proposed to increase the specificity of total ascitic protein measurement in differentiating between cirrhotic and malignant ascites. These include calculation of the plasma to ascites albumin gradient and measurement of ascitic lactate dehydrogenase activity or ascitic cholesterol concentration (Fig. 14.2). Adenosine deaminase activity in ascites of >60 U/L is particularly sensitive and specific for tuberculous ascites.

Monitoring treatment of ascites

Ascites due to cirrhosis is usually managed by a combination of dietary salt restriction and diuretic therapy, though paracentesis with albumin infusion is now being used more widely. The aim should be to achieve a net fluid loss of 500 mL/24h until the ascites clears. Plasma urea, creatinine, sodium and potassium concentrations should be checked daily at the start of treatment. A rising plasma urea or creatinine and falling plasma sodium concentration (<130 mmol/L) indicate impending acute kidney injury and should prompt a reduction of diuretic treatment. Diuretics should not be used when plasma sodium is <125 mmol/L. Plasma creatinine concentration is the more useful test, as impaired urea synthesis in patients with cirrhosis makes the plasma urea a less sensitive indicator of renal function. Plasma potassium needs careful monitoring if furosemide is used because of the risk of hypokalaemia, which may precipitate encephalopathy. So, too, can hyperkalaemia, which may occur with spironolactone if renal impairment supervenes.

Acute kidney injury

The onset of acute kidney injury (AKI) is indicated by rising plasma concentrations of creatinine and urea and usually, but not always, a urinary output falling to <300 mL/24h. A particularly dangerous complication, as already mentioned, is hyperkalaemia. Such developments are likely to precipitate encephalopathy in patients with liver disease. The major clinical problem in such patients is an idiopathic form of AKI that is widely known as the 'hepatorenal syndrome' (see below) and usually associated with advanced liver disease, ascites and encephalopathy. This should not be confused with

BOX 14.2 Hepatic and non-hepatic causes of ascites

Primary hepatic disease

- Cirrhosis (of any type)
- Budd–Chiari syndrome (thrombosis of the hepatic veins)
- Acute and subacute liver failure
- Portal vein thrombosis – rarely, and late in natural history

Non-hepatic disease

- Abdominal malignancy
- Cardiac failure
- Constrictive pericarditis
- Nephrotic syndrome
- Peritonitis (especially tuberculous)
- Pancreatic disease
- Protein–calorie malnutrition
- Hypothyroidism (rarely)

TABLE 14.3 Differential diagnosis of ascites based on inspection and laboratory tests

	Direct inspection	Protein content (g/L)	Cells	Bacteria
Uncomplicated cirrhosis	Clear	<25	<500/mm ³ (mononuclear cells)	None
Intra-abdominal malignancy	Clear	>25	Malignant cells (and red blood cells)	None
Tuberculous peritonitis	Turbid	>25 ^b	White blood cells (mainly lymphocytes)	Acid-fast bacilli
Abdominal lymphoma	Chylous ^a	See notes below ^c	None	None

^aChylous ascites probably represents escape of splanchnic lymph into ascites.

^bConcentrations may be lower when cirrhotic ascites is complicated by tuberculosis.

^cThe characteristic laboratory feature is a high concentration of triglycerides.

FIGURE 14.2 ■ Plasma ascites albumin gradient and ascitic fluid concentration of lactate dehydrogenase (LDH) and cholesterol in patients with cirrhosis (CIR) and peritoneal carcinomatosis (PCA). Reproduced with permission from Arroyo V et al. Ascites, renal failure and electrolyte disorders in cirrhosis. Pathogenesis, diagnosis, and treatment. In: McIntyre N et al. (eds). Oxford Textbook of Clinical Hepatology. Oxford: Oxford University Press; 1991.

several other situations in which renal disease and liver disease coexist: polycystic disease, infections such as leptospirosis, circulatory failure and the immune complex glomerulonephritis associated with hepatitis B virus infection or the presence of cryoglobulins in hepatitis C infection. Acute kidney injury may also develop when cirrhotic patients are fluid depleted, and following surgery to relieve obstructive jaundice. The latter syndrome is caused by acute tubular necrosis, but the mechanism is unknown.

The hepatorenal syndrome (HRS)

This condition is also known as functional renal failure (FRF). The characteristic feature is that the kidneys are normal when examined histologically, that is, there is disturbance of function but not of structure; specifically, the usual appearances of acute tubular necrosis are not present. Furthermore, the impairment is progressive and not reversed by fluid repletion, suggesting that this is not simply a pre-renal disorder. The precise pathogenesis is unknown, but underlying factors include those detailed in the earlier section on vascular abnormalities in cirrhosis, which lead to intense renal vasoconstriction resulting in decreased renal blood flow and a reduced glomerular filtration rate. Functional renal failure occurs classically in patients with advanced chronic liver disease, but may also occur in severe acute liver disease.

In patients known to have advanced cirrhosis, the condition can be diagnosed by simple laboratory tests and clinical observation. Reduced urine flow and rising plasma concentrations of urea and creatinine are common to all forms of AKI, but the characteristic feature of FRF, which distinguishes it from acute tubular necrosis, is the dramatic degree of sodium retention (Table 14.4). The urinary sodium concentration is usually <12 mmol/L and often <5 mmol/L. The urine:plasma osmolality is usually >1, and this contrasts with patients with acute

TABLE 14.4 Differential diagnosis of renal impairment in cirrhosis

	Prerenal disease	Functional renal failure	Acute tubular necrosis
Urinary sodium concentration (mmol/L)	<12	<12	>12
Urine:plasma osmolality	>1.15	1.1–1.15	<1.1
Response to volume expansion	Yes	No	No

It must be emphasized that although these tests are typical, exceptions do occur, particularly in patients who have been recently treated with diuretics.

tubular necrosis, in whom the urinary sodium concentration is invariably >12 mmol/L and often >20 mmol/L, and the urine/plasma osmolality is about 1. Infusion of terlipressin, a non-selective agonist of V_1 vasopressin receptors, together with albumin, reverses FRF in ~75% of patients.

Sex hormones and their binding proteins

Men with cirrhosis are frequently impotent, infertile and feminized (i.e. they may have gynecomastia, a female distribution of body hair and testicular atrophy). Workers in the USA, where alcohol is responsible for a very high percentage of all chronic liver disease, have tended to attribute these symptoms to the alcohol rather than the chronic liver disease. In the UK, where at least 50% of patients with cirrhosis have non-alcohol related disease, sexual dysfunction is still frequently seen and it seems most likely that alcohol may act both on its own and in concert with chronic liver disease to cause this disorder. The biochemical and endocrine changes

that accompany chronic liver disease are now well recognized but they correlate poorly with the clinical symptoms.

This section describes the changes in endocrine tests that are found in patients with liver disease of various causes and severity, but it is important to note that the changes described are not necessarily the cause of symptoms. The discussion below refers mainly to men; the effect of liver disease on sexual function in women has been less well studied.

Physiology and biochemistry

This topic is discussed in detail in Chapter 23 but a summary is presented here for convenience. The major circulating androgen is testosterone secreted by the testicular Leydig cells (0.17–0.35 mmol/24 h) under the control of luteinizing hormone (LH). The androgenic effect of androstenedione, and other adrenal androgens such as dehydroepiandrosterone, is probably attributable to their peripheral conversion to testosterone. Testosterone can be metabolized to its more active metabolite dihydrotestosterone (DHT) by 5α -reduction, or to oestrogens (by aromatization) or can be degraded in the liver, which is responsible for clearing about 50% of testosterone during the first pass in males. Oestrogens also circulate in men, the most potent being oestradiol (strictly 17β -oestradiol, but often abbreviated to E₂), which is derived from aromatization of testosterone. Testosterone and 17β -oestradiol circulate bound to albumin (low affinity, unsaturable binding) and sex hormone-binding globulin (SHBG, high affinity, saturable binding). Only a small amount of each hormone exists in the unbound state and this is presumed to be the biologically active fraction. Spermatogenesis is under the control of follicle stimulating hormone (FSH), although LH is also required, acting indirectly on the seminiferous tubules by stimulating testosterone secretion by the adjacent Leydig cells.

Changes in men with cirrhosis

The plasma total testosterone concentration is at the lower limit of the reference range in most men with well-compensated liver disease and falls as the disease progresses. The oestradiol concentration, on the other hand, is usually at the upper limit of the reference range and rises as the disease progresses, and the ratio of oestradiol to testosterone is thus elevated. Because SHBG concentrations are invariably also raised and the affinity of SHBG for testosterone is considerably greater than that for oestradiol, the ratio of free oestrogen to free testosterone is even greater. The low testosterone concentrations are attributable to reduced testicular production and occur despite a decrease in metabolic clearance rate caused by the high SHBG concentrations. The elevated oestrogen concentrations are not due to impaired hepatic clearance as originally thought; increased production, probably due to enhanced peripheral aromatization, appears to be the most likely mechanism.

In the presence of low testosterone concentrations, a compensatory increase in pituitary secretion of

TABLE 14.5 Changes in plasma sex hormone concentrations in men with chronic liver disease in relation to its severity

	Well compensated cirrhosis	Poorly compensated cirrhosis
Testosterone (T)	Low/normal	Low
17β -oestradiol (E ₂)	High/normal	High
SHBG	High	High
Total E ₂ /T ratio	High	Very high
LH	Normal	Low

luteinizing hormone (LH) would be expected, but this does not always occur, implying that a primary testicular defect is often complicated by hypothalamic–pituitary dysfunction. As the disease progresses, LH concentrations tend to fall. Thus, the characteristic abnormalities may be represented as a spectrum (Table 14.5). Similar, but less pronounced changes occur in postmenopausal women with chronic liver disease. Three-quarters of men with cirrhosis have oligospermia and this is associated with normal plasma concentrations of FSH. The absence of a compensatory rise in FSH has been attributed to a hypothalamic defect that is characteristic of patients with cirrhosis. Absence of testicular atrophy, a normal LH or a normal LH or FSH response to clomifene or gonadotrophin releasing hormone predict recovery of sexual function in alcoholic men who abstain from further drinking.

Hypogonadism is a prominent feature in men with hereditary haemochromatosis. Unlike the situation with other types of cirrhosis, such as that due to alcohol, impotence may occur very early in the disease (and even before the cirrhosis develops). It is probably due to a combination of hypogonadotrophic hypogonadism, concurrent hepatic cirrhosis and diabetic autonomic neuropathy. The pituitary dysfunction, which is probably the most important factor, is caused by selective iron deposition in the gonadotrophin-secreting cells. Plasma concentrations of LH (and prolactin) are subnormal in the majority of men with clinical hypogonadism associated with liver disease.

Changes in liver function during pregnancy

Abnormalities (occasionally marked) in the LFTs may occur during normal pregnancy. These have been attributed, not unreasonably, to changes in the hormonal environment and there is good experimental evidence that oestrogens are involved. Thus, similar abnormalities are also seen in women taking the contraceptive pill or other oestrogenic preparations.

The most pronounced change is a tendency towards cholestasis in the last trimester – intrahepatic cholestasis of pregnancy. The plasma activities of γ GT and ALP rise in late pregnancy but the latter is attributable mainly to placental ALP. In a small percentage of women, however, this tendency is exaggerated and symptoms of jaundice and/or pruritus develop. Although different names are given depending on the

predominant symptom, they probably form part of a spectrum. Signs and symptoms disappear within a few days, or even hours, of delivery but recur with varying degrees of severity in subsequent pregnancies or on exposure to oestrogen containing preparations. Female relatives of patients with intrahepatic cholestasis of pregnancy are at an increased risk of developing the same syndrome. Plasma total bile acid concentration is typically increased 5–10-fold and this may sometimes be the only abnormality.

Severe liver disease leading to acute liver failure is a rare complication of pregnancy. Although these conditions probably represent a clinicopathological continuum, the clinical features and timing during pregnancy, results of laboratory tests and maternal and fetal outcomes allow differentiation between acute fatty liver of pregnancy, the 'haemolysis, elevated liver enzymes and low platelets' (HELLP) syndrome and liver impairment in eclampsia and hyperemesis gravidarum. Liver rupture is a rare complication of fatty liver and the HELLP syndrome, with high mortality. With the widespread introduction of testing for viral hepatitis in pregnancy and biochemical screening, it is now clear that abnormal LFTs can occur in up to 3% of pregnancies. Details of appropriate investigations and management of liver disease in pregnancy are available in specialized texts.

Not surprisingly, the excretory defect in patients with the Dubin–Johnson syndrome (Chapter 13) is worsened by oestrogens, and such patients often first present with, or suffer from, increasing jaundice during pregnancy or on first exposure to the contraceptive pill. Pregnancy and the contraceptive pill are also associated with the development of benign liver tumours and increased blood coagulability leading to hepatic vein thrombosis, but both of these complications are very rare.

Changes in hormonal profiles during or after pregnancy can also precipitate, or exacerbate pre-existing AIH in women. Occasionally, this rare condition presents for the first time during the second or third trimesters of pregnancy or in the immediate postpartum period. More frequently, patients with pre-existing AIH, who have been in treatment-induced remission, experience flares of their disease during or after pregnancy. These flares are unpredictable and AIH patients who become pregnant, therefore, require more frequent monitoring of their serum aminotransferase activities during pregnancy and for up to six months after delivery, so that their immunosuppressive therapy can be increased (or reintroduced) at an early stage to avoid the development of subacute liver failure, which carries a high risk for both mother and fetus. The mechanisms underlying these effects of hormonal changes

on the activity of this disease are not well understood, but it is known that hormones have profound effects on the immune system. Thus, high oestrogen and prolactin concentrations promote mainly a cell-mediated response, while low oestrogen and high progesterone concentrations favour an antibody-mediated pathway.

Glucose intolerance

Most patients with hepatic cirrhosis exhibit intolerance to glucose. This is probably due to insulin resistance at the level of peripheral glucose uptake and glycogen synthesis by muscle. The fasting plasma concentration of insulin is increased because of a combination of decreased hepatic extraction, enhanced secretion and portosystemic shunting.

Hypoglycaemia, presumably because of the vast functional hepatic reserve, is rare in liver disease, being virtually confined to patients with acute liver failure, galactosaemia, fructosaemia or, even more rarely, primary hepatic malignancy. Hypoglycaemia can occur in acute liver failure and can be severe and persistent; for this reason such patients should be routinely maintained on a glucose infusion, particularly if they are being transferred between hospitals.

In patients with type 2 diabetes mellitus and liver disease who require treatment with oral hypoglycaemics, biguanides are best avoided because of the danger of lactic acidosis. Most sulfonylureas are metabolized in the liver, and those with a long plasma half-life should be avoided in patients with liver disease because of the risk of hypoglycaemia owing to accumulation of the drug.

DRUGS AND THE LIVER

Biochemical tests play a crucial role in the recognition and monitoring of adverse effects of therapeutic drugs. An International Consensus Meeting has clarified the terminology best used for reporting and recognizing such reactions, and for inferring causality by the temporal relationship between drug administration and putative hepatic dysfunction. It should be emphasized here that this discussion is not about patients with liver disease, but patients with other conditions who develop some form of liver dysfunction during or after treatment. Table 14.6 lists the definitions and gives some classic examples. In the absence of histological evidence, the term 'drug-induced liver injury' is preferred to 'hepatitis' or

TABLE 14.6 Agreed criteria for classification of drug-induced liver damage

	Laboratory test	ALT/ALP ratio (R)	Examples	
			Acute	Chronic
Hepatocellular	ALT >2×ULN	R >2	Paracetamol, isoniazid	Methyldopa, dantrolene
Cholestatic	ALP >2×ULN	R <2	Anabolic steroids	Phenothiazines
Mixed	ALT and ALP >2×ULN	2 < R < 5	Chlorpromazine	Ajmaline

ULN, upper limit of normal (reference) range.

'cirrhosis'. Almost all the pathological conditions described in this chapter can be caused by drugs, chemicals or toxins. The reader is referred to standard texts for a detailed list of possible associations between liver disease and xenobiotics.

NEOPLASTIC DISEASE OF THE LIVER AND BILIARY TRACT

As with those in other organs, liver tumours are classified as benign or malignant and the latter are subclassified as primary (relatively rare) or secondary (relatively common). Benign liver tumours are of little clinical significance other than as a very occasional association with the use of oral contraceptive preparations and their increasing incidental detection during ultrasound or computerized tomography (CT) imaging. The extent to which incidentally detected space-occupying lesions of the liver should be further investigated is difficult and controversial: most will be benign and of no clinical significance. They should be investigated, however, because of the devastating consequences of missing the occasional malignant tumour that, when detected early, may be amenable to surgical resection. In general, LFTs are normal in subjects with benign lesions, so there is little doubt that further investigation should be undertaken if LFTs are abnormal in any respect.

In the West, most malignant disease of the liver involves metastatic deposits from primary tumours of the gut, pancreas, lung or breast. Abnormal LFTs do not provide any specific information about the primary site of a tumour metastasizing to the liver. On the other hand, metastases will seldom be of sufficient size to be detectable by imaging in individuals with normal LFTs. Measurement of carcinoembryonic antigen (CEA) is of little diagnostic use, but serial measurement after resection of a primary colorectal tumour may provide early evidence of disease recurrence, particularly in the liver.

Hepatocellular carcinoma and α -fetoprotein

Primary liver cancer is relatively uncommon in the West but has been increasing due, in part, to the increased prevalence of chronic hepatitis C. However, worldwide, hepatocellular carcinoma (HCC) is one of the commonest and most rapidly progressive malignant neoplasms. In more than 75% of patients, it arises as a complication of hepatic cirrhosis. Hepatocellular carcinoma is one of the few tumours for which a serological marker, α -fetoprotein (AFP), is clinically useful and widely available, although the sensitivity of AFP is only of the order of 80% as not all tumours secrete this protein. The reference range for AFP is usually quoted as $<10\mu\text{g/L}$, while values of up to $10^7\mu\text{g/L}$ are seen in patients with HCC. Values $>500\mu\text{g/L}$, in an appropriate clinical setting, are virtually diagnostic of HCC, but there is a 'grey area' between 10 and $500\mu\text{g/L}$, where similar values can be seen in patients

with uncomplicated chronic liver disease associated with hepatic regeneration.

Unfortunately, many patients with small and potentially resectable tumours fall into this 'grey area' and, consequently, several attempts to improve the specificity of the test have been made. A steady increase in AFP concentration within the 'grey area' is particularly suggestive of malignant change. Also, there is good evidence that a high percentage of AFP originating from malignant cells is hyperfucosylated, and a routine test for this fraction may become available in the future. Apart from its use in diagnosis of HCC, AFP concentration is widely used to monitor response to therapy, since the concentration falls and rises in relation to the tumour mass.

A rare type of HCC, the fibrolamellar variant, is characterized by occurrence in adolescence, absence of AFP and a rather better prognosis than other types of HCC. The plasma unsaturated B_{12} binding protein (UBBP) and neurotensin concentrations are usually grossly elevated. The diagnosis is, however, made on histological grounds, although measurement of UBBP and neurotensin can be used to monitor treatment.

PARENTERAL NUTRITION

Abnormalities of LFTs are frequently noted in patients receiving parenteral nutrition (PN) and usually arise during or after the second week of therapy. An increase in ALP and aminotransferases to more than twice the upper limit of the reference range occurs in up to 50% of patients, but few actually develop clinical jaundice. The underlying histological lesion is usually steatosis, and there seems little doubt that over-provision of calories and infusate imbalance (particularly when glucose alone rather than glucose and fat is used as the energy source) are involved. Much anxiety has been expressed about the hepatotoxicity of fat emulsions, but this only occurs if very high concentrations are used.

The possibility that changes in LFTs might be attributable to a specific complication of the condition for which the PN is being used must be borne in mind. An additional complication of PN is the development of both gallstone disease and acalculous cholecystitis. In neonates, particularly when premature, the development of PN-related liver disease may limit its use. In such children, the hepatic lesion ranges from mild cholestasis associated with steatosis to severe cholestasis, cirrhosis and liver failure.

BACTERIAL INFECTIONS

Extrahepatic bacteraemia is frequently associated with abnormal LFTs and, particularly in the young, jaundice. The picture is usually one of cholestasis, although in certain specific instances, for example in the toxic shock syndrome (due to *Staphylococcus aureus* infection), the picture may be more hepatic.

Spontaneous bacterial peritonitis may occur in subjects with ascites and liver disease, in the absence of any

TABLE 14.7 Relation of clinical signs and ascitic fluid content in patients with ascites

	Clinical signs of peritonitis	Ascitic fluid analysis		
		PMN count	Gram stain	Culture
Normal/sterile	None	<250	–	Negative
'Bacterascites'	None	<250	±	Positive
Culture-negative neutrocytic or 'probable' peritonitis	Yes	>500		Negative
'Silent' peritonitis'	Minimal ^a	>500	±	Positive
Spontaneous bacterial peritonitis	Yes	>250	±	Positive

^aSome patients have fever or abdominal pain but without signs of peritonism. PMN, polymorphonuclear leukocytes. (Rolando N, Wyke R J. *Gut* 1991: S25–8).

apparent intra-abdominal source. The condition may be clinically silent, the only manifestations being onset of encephalopathy, deterioration in renal function and worsening LFTs. Rapid detection is essential and diagnosis is based on measurement of the polymorphonuclear leukocyte count in ascites and Gram stain of a centrifuged pellet (Table 14.7). The bacterial culture of ascites should be performed by directly injecting freshly drawn ascites into blood culture bottles at the bedside, because transporting ascites to the microbiology laboratory results in a significant reduction in the success of identifying the infecting organism. The responsible organism is usually *Escherichia coli* or other gut-related organisms and, less frequently, pneumococci.

INHERITED METABOLIC DISORDERS INVOLVING THE LIVER

Iron overload and hereditary haemochromatosis

Iron is a toxic metal, and whole body iron balance is tightly regulated at the level of the duodenal mucosa by controlling the amount of iron absorbed from the diet. Iron excretion is limited, and in the absence of a regulated pathway of iron loss, positive iron balance leads to increased tissue concentrations. The term haemochromatosis refers to the group of genetic disorders in which, as a result of excessive absorption of dietary iron and long-term positive iron balance, iron deposition causes tissue damage, particularly to the liver, pancreas, heart, anterior pituitary and joints. Haemosiderosis implies iron overload without tissue damage, often an early stage of iron accumulation, while secondary haemochromatosis occurs in conditions requiring multiple blood transfusions and in some other haematological disorders.

Although previously considered a single gene disorder, it is now known that haemochromatosis can be caused by mutations in several genes that appear to have different functions in iron metabolism. The most common form of

haemochromatosis, found almost exclusively in people of northern European descent, is caused by homozygosity for a low penetrant mutation, C282Y, in the hereditary haemochromatosis gene, *HFE*. This condition affects mainly men and is characterized by the insidious accumulation of iron, with the onset of symptoms and signs of iron overload delayed until the fourth or fifth decades of life. Heterozygotes for the C282Y mutation do not develop iron overload, although minor abnormalities in plasma iron and ferritin concentrations occur in approximately 15% of such individuals. Adult onset haemochromatosis is very rarely associated with mutations in *TfR2*, the gene encoding transferrin receptor 2, a cell surface glycoprotein involved in iron transport and uptake by cells including hepatocytes.

A contrasting group of disorders, in which the iron loading process is very rapid, presenting by the second or third decades and affecting males and females equally, is known as juvenile haemochromatosis. Although liver disease is invariably present, usually as cirrhosis, the clinical presentation in this form of genetic iron overload is with cardiac and endocrine failure. Juvenile haemochromatosis is caused by mutations in *HJV* and *HAMP*, genes that encode, respectively, hemojuvelin and hepcidin. The iron loading process resulting from the digenic inheritance of mutations in *HFE* and *TfR2*, genes normally associated with adult onset haemochromatosis, can be so rapid as to lead to the phenotype of juvenile haemochromatosis. The recent identification of the iron regulatory hormone hepcidin provides a link between *HFE*, *TfR2* and *HJV*, since mutations in these genes, and in *HAMP* itself, cause loss of hepcidin production by the liver. This peptide acts by inhibiting dietary iron absorption and iron release from recycling and storage sites. All these forms of iron overload are characterized by hepcidin deficiency and it appears that the proteins encoded by *HFE*, *TfR2* and *HJV* function as sensors of iron status on the hepatocyte membrane acting upstream of *HAMP*. Genotyping for mutations in *HFE* is now an essential part of diagnosis and screening for haemochromatosis. Mutations in the other genes are so rare that routine genetic analysis for these is not undertaken. A further variant of haemochromatosis is associated with mutations in *ferroportin*, a gene that encodes the hepcidin receptor.

The penetrance of the homozygous C282Y genotype in *HFE*-related haemochromatosis, defined in terms of severe iron overload with tissue damage manifesting as cirrhosis and type 1 diabetes, is low, probably in the order of ~1–2%. Biochemical penetrance, defined as an increase in transferrin saturation of >60% and a minimally raised plasma ferritin concentration, probably occurs in 20–50% of homozygous individuals. Other undetermined genetic loci and possibly environmental factors are likely to determine penetrance, but these are currently uncharacterized.

A clinical diagnosis of haemochromatosis in a severely iron loaded subject may be made on the basis of signs of liver disease, glycosuria and a slate-grey appearance of the skin, but confirmation of the diagnosis is entirely dependent on genetic and laboratory tests. The crucial investigations are plasma iron and ferritin concentration and transferrin saturation. In a patient

with full gene penetrance, the fasting plasma iron concentration is usually $>40\ \mu\text{mol/L}$ (reference range $10\text{--}30\ \mu\text{mol/L}$) and transferrin is usually $>60\%$ saturated. Plasma ferritin concentration, which is approximately proportional to the iron excess, is usually $>1000\ \mu\text{g/L}$ (upper limit of reference range $200\text{--}300\ \mu\text{g/L}$) and starts to rise when hepatic iron stores exceed twice the reference range.

If these tests suggest iron overload and liver function tests are abnormal, a liver biopsy should be undertaken to assess the degree of liver damage. Histological staining for iron (using Perls stain) gives a semiquantitative assessment of the degree of iron overload, but the amount of iron in a biopsy can also be quantitated directly by inductively coupled mass spectrophotometry (ICP-MS). The reference range is up to about $20\ \mu\text{mol/g}$ dry liver weight and $>40\ \mu\text{mol/g}$ dry liver weight is found in patients with haemochromatosis. In less severe disease, when the patient is <40 years of age, plasma ferritin is $<1000\ \mu\text{g/L}$, LFTs are normal and genotyping confirms the homozygous C282Y mutation, then liver biopsy is not indicated as cirrhosis is unlikely to have developed.

Treatment involves weekly venesection until the patient starts to develop iron deficiency anaemia and the plasma ferritin concentration falls to $\sim 50\ \mu\text{g/L}$. Since $500\ \text{mL}$ of blood contains about $250\ \text{mg}$ of iron, the total body iron at the time of diagnosis can be calculated from the total volume removed. In an iron loaded individual, it is usually in the order of $10\text{--}25\ \text{g}$ compared with less than $4\ \text{g}$ in the normal individual. The same figures can be obtained from knowledge of the plasma ferritin concentration, which can also be used to monitor the progress of treatment ($1\ \mu\text{g/L}$ of ferritin is equivalent to approximately $8\ \text{mg}$ of iron). Unless cirrhosis has already occurred, phlebotomy is successful in preventing progressive liver disease. The high risk of development of hepatocellular carcinoma remains in treated patients with cirrhosis. It is also important to screen the patient's relatives for haemochromatosis by *HFE* genotyping so that treatment can be instituted if appropriate before liver damage occurs. Plasma ferritin and transferrin saturation are the most sensitive biochemical tests for presymptomatic detection in population studies.

Wilson disease

Wilson disease is an autosomal recessively inherited disease of copper metabolism with a worldwide prevalence of about 1:30 000 and a carrier rate of 1:90. It leads to excessive deposition of copper in the liver, kidneys, brain, eyes and other tissues. Like haemochromatosis, it is treatable and thus has an importance in liver disease out of proportion to its rarity. Liver disease is the most prominent aspect in about 40% of patients, the remainder exhibiting neurological, psychiatric or haematological complications. The hepatic manifestations vary widely from asymptomatic development of cirrhosis to an acute onset, often accompanied by haemolysis and evidence of renal tubular dysfunction, which may progress to fulminant hepatic failure. In such patients, the finding of a very low serum alkaline phosphatase activity may be

a useful pointer to Wilson disease: the transient marked hypercupraemia is thought to lead to incorporation of copper instead of zinc into the active sites of ALP, reducing its activity. Accumulation of copper in the eyes is associated with the appearance of Kayser–Fleischer rings in the cornea (detectable by slit-lamp examination), although these may not always be present. In the brain, the copper deposition leads to neurological symptoms (see Chapter 36).

The defect in Wilson disease is attributed to mutations in the *ATP7B* gene on chromosome 13 (at the 13q14.3 locus), which cause failure of ATPase-dependent copper excretion. To date, more than 200 mutations have been identified, and most patients are compound heterozygotes. However, in some patients with classic Wilson disease, no mutations in the *ATP7B* gene have been found. Nonetheless, progress of the disease can be effectively arrested by treatment (see below) and, therefore, all first-degree relatives of patients with Wilson disease should be screened, initially by biochemical testing, to identify asymptomatic siblings who might benefit from early therapeutic intervention.

Among those presenting with chronic liver disease, the elevation of aminotransferases is said to be inappropriately low for the degree of hepatic inflammation and ALP is often within the reference range, or low in patients where zinc depletion has occurred. There may be a low-grade haemolytic anaemia leading to mild hyperbilirubinaemia, with an increased risk of pigment gallstones. Copper deposition may lead to renal tubular dysfunction with loss of potassium, glucose, amino acids and phosphate.

Diagnosis

The diagnosis, or exclusion, of Wilson disease is of crucial importance to patients and their relatives. It is seldom as straightforward as it may appear in standard texts. If there is any doubt about the diagnosis, advice should be sought from a specialist centre. The following are characteristic laboratory features (see Table 14.8).

1. **A low plasma caeruloplasmin concentration.** More than 90% of patients have values below the reference range of $200\text{--}400\ \text{mg/L}$. The only exception is when there is very 'active' liver disease, when values may be within the lower part of the reference range. About 10% of asymptomatic carriers will also exhibit a low plasma caeruloplasmin concentration. Caeruloplasmin synthesis is induced by steroids and plasma concentrations are higher in women using the oral contraceptive pill or hormone replacement therapy.
2. **A low plasma copper concentration.** This is usually below the lower limit of the reference range, but similar values can be found in association with other disorders and it therefore lacks diagnostic specificity. Approximately 90% ($10\text{--}25\ \mu\text{mol/L}$) of plasma copper is irreversibly bound to caeruloplasmin. The remainder ($<2\ \mu\text{mol/L}$), termed 'free' copper, is loosely bound to albumin and to amino acids. A 'free' plasma copper concentration $>7\ \mu\text{mol/L}$ is virtually diagnostic of Wilson disease,

TABLE 14.8 Typical laboratory findings in Wilson disease and other conditions in which Wilson disease may enter the differential diagnosis

Test (reference range)	<i>Wilson disease</i>					
	Chronic liver disease	Fulminant hepatic failure	Asymptomatic	Acute hepatic necrosis ^a	Chronic cholestasis ^b	Indian childhood cirrhosis
Liver function tests	Mildly abnormal	Grossly deranged	Normal	Grossly deranged	Cholestatic	Mildly abnormal
Plasma copper						
total (10–30 µmol/L)	Variable	>30	Variable	>15	>25	>25
free (<2 µmol/L)	>10	>10	>2	<2	<2	<2
Plasma caeruloplasmin (200–400 mg/L)	<200	<200 but may be normal	<270	100–270	200–400	200–400
Urinary copper						
basal (0.25–0.75 µmol/24 h)	>2	>15	>1	<15	>1	>0.75
penicillamine stimulated	>20-fold increase	>10-fold increase				
Hepatic copper (1 µmol/g dry weight)	4–20	20–40	1–4	<1	2–15	1–4

^aAny severe hepatitic illness.

^bConditions such as primary biliary cirrhosis and sclerosing cholangitis.

but such values are found in only ~50% of patients. Normal total plasma copper concentrations can often be seen in patients with acute hepatocyte damage owing to release of copper trapped in the liver.

3. **A high tissue copper concentration.** It is clearly important that the diagnosis of Wilson disease is entertained before liver biopsy is undertaken so that an adequate sample may be taken for estimation of liver copper concentration. It is worth taking two cores to ensure that enough material is available, one for routine histology and one for tissue copper estimation, to reduce the risk of a falsely low value due to sampling error. Liver copper concentrations can, however, be raised in cholestatic liver diseases other than Wilson disease, reducing the specificity of the test.

The combination of a very low plasma copper concentration with a very high tissue copper concentration is diagnostic of Wilson disease, especially when Kayser–Fleischer rings are detected. However, not infrequently, either a liver biopsy is contraindicated because of severe coagulopathy or tissue concentrations are not high enough to be diagnostic, so other confirmatory tests may be required. The most reliable of these (and the simplest to perform) is the penicillamine challenge test. This involves collection of two 24 h urine samples for copper estimation before and after administration of D-penicillamine. This is given as two oral 500 mg doses, one at the start and one in the middle of the second 24 h period. A 10–20-fold increase in the 24 h urinary copper excretion after penicillamine administration is virtually diagnostic of Wilson disease. Advances in DNA sequencing techniques have meant that molecular diagnosis is becoming more readily available and is particularly helpful in diagnosing asymptomatic siblings once a family mutation in the *ATP7B* gene has been identified.

Long-term management of hepatic Wilson disease

Wilson disease is treated with penicillamine, which leads to a gradual improvement in standard LFTs. The rationale for the use of penicillamine was to increase urinary copper excretion and thereby reduce body copper. Despite the undoubted efficacy of the drug in Wilson disease, it now appears that liver copper concentrations do not change significantly and that the mechanism of action of penicillamine is considerably more complex than originally thought.

Penicillamine therapy is associated with a number of adverse drug reactions, including skin rashes, proteinuria, leukopenia and thrombocytopenia. It is particularly important to test the urine for protein during penicillamine treatment, because the drug can precipitate a number of immunologically mediated conditions including a form of nephrotic syndrome and Goodpasture syndrome. Treatment must be life-long, and even short interruptions may precipitate fatal hepatic failure. Trientine hydrochloride is an effective second-line treatment in patients who are intolerant of penicillamine. Since some may find penicillamine tablets unpleasant or inconvenient to take, and some children will never have had, or will not be able to remember having had, any symptoms of the disease, compliance may be a problem. Zinc has been used as monotherapy in children with Wilson disease; it acts as an inducer of gut mucosal metallothionein, which binds copper and leads to excretion in the stools. The best indication that an effective dose is being taken is said to be that the plasma copper concentration remains low. The use of zinc monotherapy in adults is controversial and in any event should only be introduced following treatment with either penicillamine or trientine for some years. Life-long monitoring with liver function tests and urinary copper measurements is mandatory in Wilson disease.

Indian childhood cirrhosis

This condition, which affects young children, was thought to be confined to the Indian subcontinent. The liver is grossly fibrotic and concentrations of tissue copper are in the same range as those seen in Wilson disease (see Table 14.8). Variants are now seen in other geographical areas and it appears that different mechanisms can lead to the same end-stage chronic liver disease. The Indian subcontinent variety is probably a childhood cirrhosis that requires a high environmental exposure to copper for full expression, as supplied by excess dietary copper (from milk stored in copper vessels). In the USA, a cholestatic process seems to underlie a similar form of cirrhosis with high concentrations of tissue copper. A genetically deleterious excretory defect is likely to be present. Arsenic ingestion has also been implicated. Penicillamine may be effective if given before decompensation develops.

α_1 -Antitrypsin deficiency

Deficiency of this glycoprotein, which is an enzyme that acts as an anti-proteinase predominantly inhibiting elastase, is associated with both pulmonary and liver disease. The condition is inherited co-dominantly and, in the classic form of the disease, histological examination of liver biopsy specimens reveals characteristic PAS-positive, diastase-resistant globules within the portal tracts. These globules represent accumulation of the defective protein within the endoplasmic reticulum. The mechanism of liver cell damage, which often progresses to cirrhosis, is ill understood.

The gene encoding α_1 -antitrypsin (α_1 -AT) is located on chromosome 14 (at 14q32.1). More than 90 genetic variants have been described, most of which are exceedingly rare and are associated with production of normal amounts of functional enzyme. The different variants (phenotypes) can be identified by their mobility on isoelectric focusing. The conventional nomenclature describes the various phenotypes by the letters 'Pi' (protease inhibitor) followed by an alphabetical code relating to their mobilities. The commonest (normal) phenotype is designated 'M' (medium) and is further subdivided into at least eight subtypes (M1, M2, M3 etc.). Of the mutations that result in α_1 AT deficiencies, the two commonest are designated 'S' (slow) and 'Z' (ultraslow), with homozygotes being described as PiSS or PiZZ, compound heterozygotes with defective phenotypes as PiSZ, and heterozygotes as, for example, PiMS or PiMZ. The S phenotype is mainly associated with lung disease, while the Z phenotype is strongly associated with both lung and liver disease. Other rare phenotypes are also associated with liver disease (S_{Iiyama}, M_{Malton}, Pi_{King}) (see also Chapter 43).

Individuals with defective phenotypes may present (or be identified incidentally) at any time from infancy to old age. The most important period is during the first few weeks of life, with about 25% of cases of the neonatal hepatitis syndrome being due to this condition. The association with liver disease is very variable. Some children, particularly those who do not develop symptoms

in infancy, may never develop liver disease, while others may progress rapidly to cirrhosis and death from liver failure. The Z allele causes a Glu342Lys substitution in the protein that results in the formation of polymers that are retained in the endoplasmic reticulum of hepatocytes. These polymers are degraded via several pathways, including the ubiquitin–proteasome and the autophagy–lysosome systems. There is significant interindividual variation in the capacity of these systems, which might account for the variation in the extent of liver disease in affected individuals. The accumulation of polymers of α_1 -AT in the liver means that only 10–15% of the α_1 -AT molecules produced reach the circulation. This forms the basis for the initial screening test as plasma α_1 -AT concentrations are low (typically 0.1–0.2 g/L, normal 1.0–2.0 g/L). α_1 -Antitrypsin is a positive acute phase reactant and upregulation of α_1 -AT synthesis during an inflammatory response or acute hepatocellular damage can cause release of the accumulated polymers, increasing plasma concentrations to within the reference range. Strategies for investigation of possible α_1 -AT deficiency in these situations should include phenotyping and/or genotyping.

The hepatic porphyrias

These are so called because the major organ in which excessive production of the porphyrins or their precursors takes place is the liver (see Chapter 28). However, the four types (acute intermittent porphyria, hereditary coproporphyrin, variegate porphyria and 5-aminolaevulinic acid dehydratase deficiency porphyria (Doss) porphyria) do not have any hepatic manifestations other than the occasional mild rise in plasma aminotransferase activity and an increased incidence of hepatocellular carcinoma in patients with acute intermittent porphyria. Porphyria cutanea tarda has already been described (p. 258). Asymptomatic porphyrinuria (mainly due to coproporphyrin) is common in many acute liver diseases and hepatic tumours. In erythropoietic porphyria, the liver plays a minimal role in protoporphyrin overproduction, but hepatic complications may occasionally arise: these comprise gallstones and cirrhosis associated with massive protoporphyrin deposition.

Cystic fibrosis

A wide spectrum of hepatobiliary complications of cystic fibrosis is becoming increasingly recognized as larger numbers of children survive to adulthood as a result of improvements in the treatment of the pulmonary complications of the disorder. In infancy, cystic fibrosis may present as neonatal cholestasis, often in association with meconium ileus. Older children may develop a fatty liver syndrome, but the major problem is a focal biliary cirrhosis that progresses to a generalized cirrhosis with all the complications as described previously. Extrahepatic biliary disease, with stricture of the distal common bile duct, is also frequent, although this, of itself, is probably not directly involved in the pathogenesis of the liver disease. Laboratory investigation is important in the diagnosis of

this condition (see Chapter 25), but the LFTs are entirely non-specific and serve no more than to indicate that liver abnormalities are present. Liver function tests have been used to monitor response to therapy with ursodeoxycholic acid.

Other inherited metabolic diseases

Diagnosis, management and genetic counselling in children with inborn errors of metabolism form a large part of paediatric hepatology. The disorders also illustrate many aspects of applied intermediary metabolism. Most are rare and few laboratories will develop wide experience. Here, the more common types are described briefly, with more detailed accounts in the Further reading list at the end of the chapter.

Tyrosinaemia

This is an autosomal recessive condition, of which there are two types. Type I is due to deficiency of fumarylacetoacetate hydrolase (Fig. 14.3) and is the only genetically mediated disorder of amino acid metabolism that has so far been identified as a significant cause of liver disease. Type II is due to deficiency of tyrosine aminotransferase and is not associated with liver damage.

Type I tyrosinaemia usually presents at the age of 2–6 months with vomiting, diarrhoea, oedema, ascites, hepatosplenomegaly, hypoglycaemia and failure to

FIGURE 14.3 ■ Intermediary metabolism of tyrosine. Classic tyrosinaemia (type I or tyrosinosis) is caused by a defect in fumarylacetoacetate hydrolase activity, but defects in other parts of the pathway are also recognized including alkaptonuria, in which there is deficiency of homogentisic acid oxidase. There are increases of all precursors (including tyrosine) in the urine, but the diagnostic test is for succinylacetone which, by reacting with sulphhydryl groups, may in part be responsible for the tissue damage.

thrive. There is a marked bleeding diathesis owing to prothrombin deficiency. Other characteristic features include systemic acidosis and renal tubular dysfunction leading to hypophosphataemic rickets. Rapid and accurate diagnosis is essential since dietary restriction of phenylalanine, tyrosine and methionine may improve the prognosis in this otherwise fatal disease. A more chronic form of the disease may present later in childhood with cirrhosis and a high incidence of hepatocellular carcinoma, although AFP concentrations may be grossly elevated even in the absence of a tumour.

The characteristic laboratory findings are a marked amino acidemia, with tyrosine, phenylalanine and methionine concentrations being particularly elevated. There is also moderate derangement of LFTs, a raised INR and a markedly raised AFP. However, the diagnostic finding is the presence of succinylacetone in urine (or amniotic fluid, for prenatal diagnosis), usually with elevated urinary 5-aminolaevulinate (owing to the inhibition of porphobilinogen synthetase by the succinylacetone). Liver transplantation is being increasingly used in both forms of the disease. Treatment with nitisone may be beneficial in slowing progression of the condition (see Chapter 24).

Galactosaemia

Galactose is generated by intestinal hydrolysis of lactose and is converted in the liver to glucose. Classic galactosaemia (see Chapter 24) is an autosomal recessive condition that is due to deficiency of the enzyme galactose 1-phosphate uridylyltransferase (GALT), resulting in accumulation of galactose, galactitol (via an aldoreductase) and galactose 1-phosphate in all body tissues (Fig. 14.4). The disease usually becomes evident soon after birth when milk is introduced into the diet. It varies widely in severity but, in the majority, the LFTs are grossly deranged, with elevated plasma aminotransferases and a raised INR, indicating hepatocellular necrosis. There is a severe unconjugated jaundice due to haemolytic anaemia, accompanied by amino aciduria and proteinuria, indicating renal damage. Often, the condition rapidly progresses to liver failure, with bleeding and ascites. The mechanisms underlying the liver damage are poorly understood, but may be related to cellular ATP depletion owing to accumulation of galactose 1-phosphate in cells, which may restrict the availability of phosphate for formation of high-energy bonds. A less acute presentation may be with a chronic liver disease, cataracts and learning difficulties. Children with this condition have an increased risk of septicaemia.

Galactosaemia should be suspected if sugars other than glucose are detected in urine. In this context, it should be noted that conventional urine stick tests detect only glucose and not other reducing sugars. The diagnosis requires the demonstration of low or absent GALT enzyme activity in erythrocytes and confirmation by genetic testing (see Chapter 24). Treatment is by withdrawal of lactose and galactose from the diet, which can be monitored by measurement of galactose-1-phosphate in blood samples.

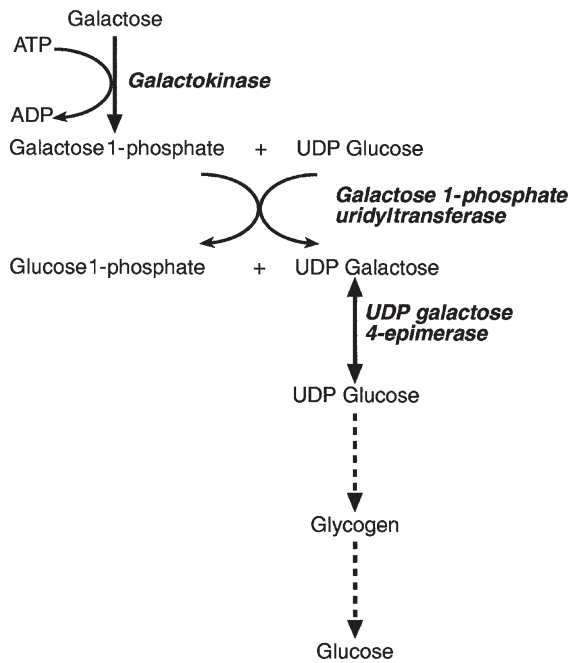

FIGURE 14.4 ■ Metabolism of galactose. The usual lesion in classic galactosaemia is a decreased activity of galactose 1-phosphate uridylyltransferase, but the other enzymes listed may also be involved in some cases. Note that the epimerase activity is normal in most affected individuals so that even on a galactose-free diet, galactosaemic individuals generate enough galactose for normal development.

Fructose intolerance

Three genetic defects in fructose intolerance have been identified: essential fructosaemia (hepatic fructokinase deficiency), hereditary fructose intolerance (fructose 1-phosphatase deficiency), and fructose 1,6-diphosphatase deficiency. All three are relatively benign conditions if fructose intake is avoided or substantially reduced. However, with high fructose intake, both hereditary fructose intolerance and fructose 1,6-diphosphatase deficiency can lead to severe liver and kidney damage. The mechanisms involved are not well understood but, by analogy with galactosaemia, the hepatic injury may be due to intracellular accumulation of phosphorylated sugars reducing availability of phosphate for ATP formation. The liver damage is reflected in grossly deranged LFTs, with markedly elevated aminotransferase activities, a conjugated hyperbilirubinaemia, hypoalbuminaemia and a raised INR, accompanied by hypokalaemia, hypophosphataemia, profound hypoglycaemia and thrombocytopenia. The renal damage leads to aminoaciduria and proteinuria.

Fructose 1,6-diphosphatase deficiency usually has less severe effects on the liver. Plasma aminotransferase activities tend to be mildly or moderately elevated and the bilirubin concentration is only mildly raised. The prominent features are hypoglycaemia, lactic acidemia, aminoacidemia (particularly alanine and glutamine) and a marked ketoacidosis. Diagnoses for all three conditions require demonstration of the deficiency of the particular enzyme in liver biopsy specimens, or genetic testing.

The sphingolipidoses and Niemann–Pick disease type C

The sphingolipidoses are recessively inherited lysosomal disorders in which there is a deficiency of a specific lysosomal hydrolytic enzyme and consequent deposition of complex lipids in various tissues. Type C Niemann–Pick disease is a relatively common inherited cause of liver disease in the UK. In most patients, the disease presents with a fatal neonatal hepatitis, but among those who survive, the liver disease becomes less prominent but death from progressive neurological damage is inevitable.

Glycogen storage diseases

There are 11 distinct types that comprise this group of autosomal recessive diseases, in which enzyme defects result in deficient mobilization of glycogen, deposition of abnormal forms in tissues and very variable prognosis. Types V and VII do not cause liver disease. In the remainder, which can affect the liver, clinical features are usually apparent in childhood and include gross hepatomegaly associated with hypoglycaemic attacks and growth failure. Descriptions of the biochemical lesions, specific clinical features and treatment of all the glycogen storage diseases are beyond the scope of this chapter and the reader is referred to specialist texts. Only type IV is consistently associated with cirrhosis. Liver function tests are abnormal in most types, particularly types III and IV, but jaundice is very rare. Hypoglycaemia is common to all and hyperuricaemia is prominent in types I, III and IX. Among those that affect the liver, the specific diagnoses in types II, III, IV and VI can be established by demonstrating the enzyme deficiencies in leukocytes, but liver biopsies are required for type I. Management revolves around dietary measures to maintain blood glucose concentrations. Liver transplantation is appropriate in some types, particularly types I and III, which can progress to hepatic adenomata and hepatocellular carcinoma.

LIVER TRANSPLANTATION

Liver transplantation is a rapidly expanding part of clinical hepatology. Improvement in survival figures over the last decade has largely been due to better defined indications, improvement in immunosuppressive regimens and organ preservation and improved surgical techniques. The main indication is end-stage chronic liver disease but, as already mentioned, the procedure is being increasingly used for acute liver failure and, in children, for treatment of certain inherited metabolic defects. Although the procedure is now routine in many centres, extensive preoperative assessment is still required and major complications are common. In any event, a liver transplantation programme will impose a heavy load on a clinical pathology laboratory. It is beyond the scope of this chapter to discuss all the problems that may arise, but they are summarized below.

Preoperative assessment

Selection of patients who are likely to benefit from a liver graft requires careful clinical judgement based both on the prognosis and on the quality of life with regard to the primary illness. The criteria are complex and depend on the aetiology of the liver failure and whether it is acute or is a consequence of chronic liver disease. The overall condition of the patient to withstand such a major surgical procedure needs to be carefully assessed. Thus, haemodynamic and respiratory status, patency of major blood vessels and concomitant diseases are essential considerations. The potential effects of the immunosuppressive drug therapy (to prevent graft rejection) on disease recurrence (e.g. in patients transplanted for malignant disorders or viral hepatitis), or on other complications such as pre-existing renal disease also need to be considered. ABO blood group compatibility is required but, in contrast to other solid organ grafting, pre-transplant tissue typing of recipients for human leukocyte antigen (HLA) matching is not essential, except with combined transplants (e.g. liver and kidney), because the liver appears to be an 'immunologically privileged' organ, and donor-recipient incompatibility leading to hyperacute rejection is a rare event (see below).

The immediate postoperative period

The quality of the functioning of the graft immediately after transplantation is a major determinant of the future clinical course and is consequently of great importance. Primary non-function of the graft, that is, a liver that does not appear to work satisfactorily from the outset, is usually due to the poor quality of the donor organ. Hyperacute rejection has been described but is a very rare cause of immediate graft failure. Its differentiation from primary non-function is difficult, but may be suspected if the graft appears to function during the first 6–24 h only to then fail.

The standard LFTs have little value during the immediate postoperative period because the patient's blood will have been extensively diluted by multiple transfusions during the operation. Plasma aminotransferase activities on the second post-operative day are more reliable and are almost always elevated. This represents so-called 'preservation injury' to the donor organ acquired during its removal from the donor, and subsequent preservation and transportation prior to transplantation. Thereafter, a progressive fall in the aminotransferase activities indicates good graft function, while persistently high values suggest that the graft will not function well. Other parameters that are essential for monitoring graft function postoperatively are the blood hydrogen ion concentration (pH), glucose and coagulation factors. Hyperglycaemia is almost always present during the very early postoperative phase but, with normal graft function, the blood glucose usually normalizes over the following 24–48 h. Persistence of the hyperglycaemia, despite increasing doses of insulin, indicates poor graft function.

Acute cellular rejection occurs in 50–70% of patients during the first three weeks after transplantation,

and requires rapid diagnosis and adjustment of immunosuppressive treatment to preserve the graft. It is manifest by an often abrupt increase in plasma aminotransferase activities and bilirubin concentrations. An increasing plasma bilirubin concentration seems to be the more sensitive indicator, but rising aminotransferases appear to be more specific. However, liver histology is required to confirm acute rejection. Some degree of renal impairment is often evident during the first 2–3 days, even if not present before the operation. Serious derangement of the biochemical liver tests, particularly in conjunction with evidence of a coagulopathy, is highly suggestive of interruption to the vascular supply to the graft.

Intermediate follow-up

Frequent monitoring of LFTs is required during the months after a liver transplant to detect signs of late acute or chronic rejection, along with frequent microbiological surveillance for evidence of infections. Late acute rejection (occurring >1 month post-transplantation) is diagnosed as for early acute rejection. Chronic rejection is suspected if the LFTs were previously more or less normal but then begin to become deranged. In this situation, the aminotransferases and INR may be only mildly elevated, but there is a progressive increase in the serum bilirubin and other cholestatic indicators. These changes can also be seen in fungal, bacterial and viral infections, to which the immunosuppressed patient is particularly susceptible, but can usually be differentiated from rejection episodes on clinical and histological criteria together with microbiological investigations.

Patients are generally metabolically unstable for some months after transplantation and require careful adjustment of their immunosuppression. The principal immunosuppressive drugs currently used are ciclosporin, tacrolimus, mycophenolate mofetil and sirolimus, alone or in various combinations, sometimes with glucocorticoids and/or azathioprine. Several of these agents are nephrotoxic and potentially neurotoxic at high doses. Their metabolism is affected by a number of factors, including graft function, other drugs (e.g. antibiotics) that may be required and individual pharmacogenetic variability in their metabolism that can affect the blood concentrations at given doses. Thus, frequent monitoring (initially, two or three times per week) of the concentrations of these drugs in the blood is required during the months following transplantation in order to maintain them within the fairly narrow therapeutic ranges that provide adequate immunosuppression with minimal toxicity.

Long-term monitoring

From the laboratory standpoint, long-term monitoring of liver transplant recipients is relatively straightforward, unless complications arise. Because of the tenuous arterial supply of the common bile duct, biliary tract complications are frequent, but the laboratory features are no different from those seen in patients

with other forms of biliary disease. By one year, most patients are well stabilized and require only three-monthly check-ups with routine LFTs, tests of renal function and haematological investigations. By this time also, they are usually well established on their maintenance immunosuppressive regimens and much less frequent monitoring of their blood drug concentrations is required.

Late graft loss, occurring more than one year after transplantation, is relatively rare and, today, many such patients can be rescued with a second transplant. The commonest causes of late graft failure are uncontrollable chronic rejection and recurrence of the primary disease. Thus, in patients transplanted for chronic viral hepatitis C, there is almost universal reinfection of the graft and consideration needs to be given to pre- and post-transplant antiviral therapy. In the case of patients transplanted for chronic hepatitis B, reinfection can be successfully prevented with regular immunoglobulin administration. The use of newly introduced antiviral agents is also under investigation. In those transplanted for hepatic malignancies, tumour recurrence is not infrequent and, as in other solid organ transplantation, there is an increased risk of non-hepatic malignancies, particularly lymphomas, arising either de novo or through reactivation by immunosuppression of extra-hepatic tumours that have previously been apparently successfully treated. Additionally, as the numbers of long-term survivors rises, recurrence of PBC and AIH (in those transplanted for these conditions) is being seen with increasing frequency.

CONCLUSION

Liver disease is best classified according to its aetiology, qualified by the nature of the resulting pathological change. There are many aetiological factors, including viruses and other infective agents, drugs and toxins, metabolic diseases and autoimmune processes. The range of pathological responses is limited; the most frequent are hepatitis, cirrhosis and cholestasis.

Hepatitis can be acute or chronic: chronic hepatitis can lead to cirrhosis and cholestasis can be a feature of both acute and chronic liver disease. Liver disease frequently has extrahepatic manifestations, reflecting the central role of the liver in metabolism.

Liver transplantation is increasingly being employed in the management of many hitherto fatal liver diseases.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF GLUCOSE HOMOEOSTASIS

Introduction: the maintenance of normoglycaemia

Blood glucose concentrations are maintained within very close limits in healthy people. Any given individual has a very strictly maintained postabsorptive (e.g. fasted overnight) blood glucose concentration of 4.5–5.2 mmol/L, with intraindividual coefficients of variation (CV) of only 1–2%. Interindividual CV (assuming similar times since previous meal, levels of activity, composition of previous meal etc.) is less than 5%, so that a fasting glucose of 6.0 mmol/L is usually 4–5 standard deviations away from the mean in most populations. Glucose concentrations in healthy people increase after meals, but typical meals will not raise blood glucose above 8–10 mmol/L and normoglycaemia is usually restored within 2–4 h. Falls in glucose concentration may be produced by severe, sudden unaccustomed exercise or prolonged fasting (or both), by the pathological conditions

discussed in Chapter 17 and by pharmacological means, but are not typically encountered in healthy adults on a daily basis.

The strictness of glucoregulation is remarkable when compared with the relative laxity of regulation of the concentrations of other circulating metabolic fuels such as ketone bodies and non-esterified fatty acids (NEFA, also known as free fatty acids, FFA). The reason for strict avoidance of low blood glucose concentrations is readily apparent in terms of the avoidance of the neurological and other consequences of hypoglycaemia, and it may be no accident that of all the hormones known to influence blood glucose concentration, insulin is the only one able to lower it. The threshold for the onset of detectable neuroglycopenia is of the order of 3.0–3.5 mmol/L, and it is thus appropriate that counter-regulatory mechanisms are set to respond to maintain glycaemia comfortably above this level.

The reason for the strict avoidance of hyperglycaemia is less immediately apparent. Symptoms of hyperglycaemia are florid (in subjects used to relative normoglycaemia) at blood glucose concentrations of >12–13 mmol/L and

may become apparent at concentrations <10 mmol/L. Such concentrations may be seen, for example following a myocardial infarction, so-called 'stress hyperglycaemia' owing to the effect of catecholamine release, and are usually transient. Stress hyperglycaemia also occurs when plasma cytokine concentrations rise, for example in sepsis, with an increase in oxidative metabolism. (The severe metabolic consequences of hyperglycaemia at concentrations usually >20 mmol/L are discussed in the section on diabetic emergencies in Chapter 16.) In contrast, mild hyperglycaemia (glucose 6–9 mmol/L) is usually asymptomatic. The only obvious teleological value of preventing mild hyperglycaemia is the avoidance of the consequences of chronic hyperglycaemia, usually referred to as 'long-term diabetic complications' or 'diabetic tissue damage' (p. 296 and 322), and the increased susceptibility to infection that may occur acutely.

The mechanisms for regulation of normoglycaemia are summarized in **Box 15.1**, which lists the counter-regulatory mechanisms responsible for preventing hypoglycaemia, and **Figure 15.1**, which outlines the main sites of insulin action relevant to prevention of hyperglycaemia.

Normal glucose metabolism

Circulating glucose derives from three main sources:

- the gut, as the result of hydrolysis or hepatic conversion of a variety of ingested carbohydrates
- hepatic and some other glycogen stores (glycogenolysis)
- new synthesis from precursors (gluconeogenesis). Gluconeogenesis takes place in the liver (~75–90%) and kidneys (~10–25%) from glucogenic amino acids, especially alanine, and from glycerol, lactate and pyruvate. Principally it involves the synthesis of a 6-carbon compound from various 3-carbon skeletons. Partial oxidative metabolism in tissues like adipocytes and muscle provides lactate and pyruvate but they can also be donated by red blood cells, in which anaerobic metabolism occurs in the absence of the enzymes of the Krebs (tricarboxylic acid) cycle. Triacylglycerol (triglyceride) released from adipocytes during lipolysis provides glycerol.

Regulation of gluconeogenesis can be via changes in the amount of substrate arriving at the liver or by the

amount that the liver itself extracts, as well as by regulation within the liver. This process is subject to direct hormonal modulation by insulin, glucagon and catecholamines and indirectly by other hormones.

Hepatic glucose output is ~2.0 mg/kg body weight/min in the resting postabsorptive state, or 200–300 g during the average 24 h period (varying with the availability of glucose from food and with the body's requirements during exercise). Plasma glucose concentration is determined by the balance between glucose influx into the circulation (principally from food and hepatic glucose production) and peripheral glucose clearance.

Glucose is stored as glycogen, a 70 kg man typically having a total of 700–1000 g (hydrated) glycogen. Most of this is in the skeletal muscle (400–600 g), and liver (60–125 g), with lesser amounts in other tissues. Glycogen is synthesized from both glucose and the gluconeogenic substrates (see above). Glycogen is a polymeric storage form of glucose. Extension of the polymer by the addition of glucose 6-phosphate subunits is catalysed by glycogen synthase, which is the main regulatory enzyme for glycogen synthesis. This enzyme is itself subject to regulation by a dephosphorylation/phosphorylation cycle controlled by a cyclic AMP dependent protein kinase. Glycogen in skeletal muscle can provide fuel for muscle but does not provide a source of glucose for release into the circulation.

Glucose provides approximately 40–60% (on a typical diet in the developed world) of the total fuel expended by the body during a 24 h period. It provides almost all the energy for the central nervous system (especially in well-nourished subjects, although sustained fasting allows cerebral ketone body utilization). During high-intensity exercise and during the 4–6 h postprandial period, glucose is the predominant fuel for the whole body. Glucose is the most efficient fuel for oxidation in terms of the liberation of energy (112.2 kcal or 6 moles ATP per mole of oxygen consumed). Many tissues can use ketone bodies, fatty acids or glucose for their basal metabolism, switching between these different fuels depending upon their availability in the circulation.

Glucose is fully oxidized to carbon dioxide and water in skeletal muscle, the brain and the liver. The brain accounts for most of the glucose oxidized in the fasting

BOX 15.1 Mechanisms preventing/reversing hypoglycaemia

Adrenergic/sympathetic response

- Promotes glycogenolysis, gluconeogenesis and increased glucose output by the liver; reduces glucose clearance by skeletal muscle and adipose tissue
- Promotes lipolysis to provide alternative fuel source(s)
- Inhibits insulin secretion

'Counter-regulatory hormones'

- Glucagon: promotes glycogenolysis, gluconeogenesis and thus increased glucose output by the liver. May increase hepatic ketone body production

- Cortisol: promotes glycogenolysis, gluconeogenesis and increased glucose output by the liver; reduces glucose clearance by skeletal muscle and adipose tissue
- Growth hormone: promotes hepatic glycogenolysis and increased hepatic glucose output; promotes lipolysis

Other mechanisms

- Insulin secretion inhibited
- Feelings of hunger promote eating
- Hypoglycaemia per se stimulates hepatic glucose output

FIGURE 15.1 ■ The principal antihyperglycaemic actions of insulin. Insulin ① reduces the production of gluconeogenic precursors such as glycerol, alanine and lactate, ② reduces activity of hepatic gluconeogenic enzymes and ③ increases hepatic glycogenolysis to glucose. These effects contribute to ④ reduced hepatic glucose output. Insulin ⑤ increases cellular glucose uptake mediated by insulin-sensitive glucose transporters (GLUT4) and ⑥ reduces competition for glucose oxidation by alternative fuels ('Randle effect'). The reduction of competing fuels involves ⑦ inhibition of NEFA release from adipose tissue and ⑧ reduced hepatic ketogenesis. ⑨ Insulin promotes glucose storage as glycogen.

state (100–125 g/24h). In the resting, fasted state, skeletal muscle takes up 10–20% of hepatic glucose output: this is not all oxidized but can be converted to lactate, pyruvate, glycerol or the carbon skeletons of amino acids, much of which subsequently return to the liver and act as precursors for gluconeogenesis. Fatty acids (or their partial oxidation products, ketone bodies) are the prime fuel of resting muscle, heart and liver. Other tissues such as red blood cells, skin, adipose tissue and the renal medulla derive energy from glycolysis to lactate and pyruvate, even in the resting state. Glycolysis to lactate is an anaerobic process to which many cells may resort when faced with hypoxia, for example skeletal muscle during high-intensity exercise. The brain can adapt to the utilization of ketone bodies as a source of fuel during a prolonged fast, but this is far from being an instantaneous process, and the more immediate response depends upon increasing glucose supply as a result of the action of the counter-regulatory hormones glucagon, cortisol, catecholamines and growth hormone. Although each can achieve the objective of restoration of blood glucose supply to the brain, the mechanism for each differs. Adrenaline (epinephrine) and glucagon are the 'rapid response' team, activating hepatic glucose formation via glycogen phosphorylation, whilst growth hormone and cortisol are the 'back up' team inducing the enzymes responsible for gluconeogenesis. Catecholamines can additionally increase circulating non-esterified fatty

acid concentrations by upregulating lipolysis so muscle uptake of glucose falls, leaving more glucose for the brain to use.

In contrast, if the counter-regulatory hormones are present in excess and there is also a relative deficiency of insulin then hyperglycaemia results; infections and trauma are common causes of increased secretion of catecholamines.

Glucose transporters

Glucose is a hydrophilic molecule that is unable directly to penetrate the lipid bilayer of cells: its uptake into cells is therefore achieved by an energy-independent process of facilitated diffusion down its concentration gradient, mediated by a family of glucose transporter proteins (GLUTs) composed of at least 12 membrane spanning helices with a larger intracellular loop connecting the sixth and seventh helices. These transporters allow uptake of glucose into cells from the interstitial fluid into which glucose diffuses from the bloodstream and, by virtue of differences in kinetics, tissue and subcellular expression profiles, and substrate specificities, mediate specific functions such as glucose sensing (GLUT2) and insulin-dependent glucose uptake (GLUT4) (Table 15.1).

The 14 facultative glucose transporters recognized to date are classified into those having high glucose affinity (class I comprising GLUTs 1–4), high fructose affinity

TABLE 15.1 Characteristics of some glucose transporters

Transporter	Tissues	Kinetics	Transport type
Facilitative glucose transporters			
GLUT1	Ubiquitous: e.g. erythrocyte, placenta, colon, kidneys	Low K_m (1–2 mmol/L)	Facilitated diffusion
GLUT2	Liver, small intestine, kidneys, β -Cells	High K_m (~25 mmol/L), high V_{max}	Facilitated diffusion; bidirectional
GLUT3	Ubiquitous: e.g. brain, placenta, kidneys	Low K_m (1–2 mmol/L), low V_{max} (6–7 mmol/L)	Facilitated diffusion
GLUT4	Skeletal muscle, adipocytes, heart	K_m 2–10 mmol/L	Facilitated diffusion, insulin responsive
GLUT5	Jejunum		Facilitated diffusion of fructose
Na⁺-glucose cotransporters (SGLTs)			
		Move glucose against concentration gradient	Active transport, symport using Na ⁺ gradient generated by K ⁺ , Na ⁺ -ATP pump
SGLT1	Intestine, renal tubules	High affinity (K_m ~0.4 mmol/L), low capacity	Intestinal glucose/galactose absorption. Some renal glucose reabsorption
SGLT2	Renal tubules	Low affinity (K_m ~2.0 mmol/L), high capacity	Most renal glucose reabsorption

K_m , substrate concentration at half the maximum velocity (V_{max}).

(class II, e.g. GLUT5) and novel transporters whose physiology is not yet fully understood (GLUTs 6–14). The different functions of the class I GLUTs are partly predictable from their differing K_m values. Glucose transporters 1, 3 and 4 have K_m values of ~2–5 mmol/L but GLUT2 has a K_m of ~25 mmol/L. This permits high rates of glucose entry into essential cells (e.g. in the central nervous system (CNS), which is relatively protected from neuroglycopenia by the low K_m of its GLUT3 transporters). Pancreatic β -Cells are able to sense increments in blood glucose over a range considerably exceeding normal values via the high K_m GLUT2 transporter protein.

Certain glucose transporters (GLUT1 and GLUT3) are present on cell surfaces at all times. In contrast, GLUT4 is stored in the cytoplasm when insulin is not present; it responds to insulin by moving from intracellular stores to cell membranes, thereby increasing total transporter number (typically 6–10-fold). When insulin concentrations decline, GLUT4 is removed from cell membranes by endocytosis and rapidly recycled back to its intracellular storage compartments. Erythrocytes are insulin non-responsive because they possess only GLUT1. Many cells can express a variety of different GLUT transporters, and the expression of GLUT receptors changes with circumstances: for example liver cells express more GLUT1 and GLUT3 during starvation. Dysfunction of the insulin-regulated GLUT4 translocation process appears to play a part in the insulin resistance syndrome, and mutations of several transporters (e.g. GLUT1, GLUT2) have been associated with inherited metabolic diseases of carbohydrate metabolism.

Tissue glucose uptake via GLUT transporters involves facilitated diffusion down a concentration gradient, the intracellular concentration of glucose being very low because of its active metabolism by phosphorylating enzymes (hexokinases and glucokinases). In resting, postabsorptive subjects, ~70% of the body's glucose metabolism occurs independently of the action of insulin. However, these insulin-independent mechanisms cannot maintain normoglycaemia for very

long without insulin orchestrating the response to food and integrating the balance between fatty acid, ketone body and glucose metabolism. Insulin-independent (as well as insulin-dependent) glucose clearance is impaired in subjects with type 2 diabetes and also in normoglycaemic subjects with a family history of diabetes. This suggests that abnormalities in insulin-independent glucose disposal manifest at a very early stage of disease development. This phenomenon of 'glucose resistance' appears to be quantitatively important: in normal subjects, as much as half an intravenous glucose load is cleared by non-insulin-mediated glucose disposal. Although polymorphisms of GLUT4 do not appear to be any more common among patients with type 2 diabetes than in the normal population, there is evidence that targeting and trafficking of this glucose transporter may be abnormal in both skeletal muscle and adipose tissue in this condition. The insulin-sensitizing agents metformin and the thiazolidinediones appear to increase cell surface expression of GLUT4, as does physical exercise.

The ability to move glucose against a concentration gradient, necessary in the special circumstances of the renal tubules and intestinal epithelium, is conferred by a family of sodium-dependent glucose cotransporters. Sodium-dependent glucose cotransporter 1 (SGLT1) is present in the gut, where it is responsible for absorption of glucose and galactose from the diet. Mutations of SGLT1 are associated with the glucose–galactose malabsorption syndrome that may cause fatal infantile diarrhoea unless these sugars are removed from the diet. Sodium-dependent cotransporter 2 (SGLT2) is a low affinity high capacity transporter that is present in the S1 segment of the proximal renal tubules and is responsible for 90% of renal glucose reabsorption, the remaining glucose being reabsorbed by the high affinity but low capacity SGLT1 transporter found in the S3 segment; reduced function mutations of SGLT2 are associated with renal glycosuria. Drugs that block SGLT2 (thus increasing urinary glucose loss) have recently been licensed in the UK as glucose-lowering agents.

The fate of intracellular glucose and its role in diabetes

Some of the principal intracellular metabolic pathways for glucose, together with their rate-limiting enzymes, are schematically illustrated in Figure 15.2, with the pathways labelled a–k.

In order to trap glucose within cells (since all the GLUTs are potentially bidirectional), glucose is phosphorylated on entry by a family of hexokinases (a). Hexokinase types I–III are widely expressed and have low K_m , but hexokinase type IV (also called glucokinase, and predominantly expressed in liver and the β -Cells of the islets of Langerhans) has a much higher K_m (up to 15 mmol/L), permitting it to function as a glucose sensor over (and beyond) the physiological range of blood glucose. Since glucokinase is also the rate-limiting step in glucose metabolism, it thus becomes the ultimate determinant of the rate of insulin secretion from β -Cells.

Loss of function mutations of glucokinase are responsible for one form of maturity onset diabetes of the young (MODY 2, which represents approximately 30% of all cases of MODY). Patients present with mildly elevated blood glucose concentrations owing to apparent elevation of the set point for blood glucose concentrations. For reasons that are not totally clear, patients with this condition appear to be at very low risk for the development of diabetic complications and are rarely symptomatic. Although a good response is typically obtained with augmentation of the insulin response by sulfonylurea therapy, this is often not necessary. Although glucokinase might be a potential candidate gene in type 2 diabetes (and a treatment target, given that activating mutations can cause hypoglycaemia in man), mutations appear to be no more common among people with type 2 diabetes than in the general population.

Dephosphorylation of glucose (the reverse reaction) is catalysed by glucose 6-phosphatase (b). This process is necessary for the export of glucose (from gluconeogenesis) by hepatic and renal cells in hypo-insulinaemic situations. Deficiency of this enzyme (or of the associated glucose 6-phosphate transport protein) is the cause of glycogen storage disease type 1 (von Gierke disease), and its overactivity is a feature of the increased and relatively insulin-insensitive hepatic glucose production typical of type 2 diabetes. The insulin sensitizing agents metformin and the thiazolidinediones appear to reduce the activity of glucose 6-phosphatase, although it is not clear whether these are direct effects or are mediated through some other upstream action.

Having entered the cell and undergone phosphorylation, glucose undergoes one of four distinct metabolic fates. It may be:

- metabolized aerobically to yield energy
- metabolized anaerobically to yield energy
- used to synthesize other molecules (glycerol and the carbon skeletons of certain non-essential amino acids)
- stored as glycogen.

The dominant flux along each pathway will depend on the tissue (e.g. gluconeogenesis can take place in the liver and kidneys, glycogen storage in liver and muscle, glycerol generation in adipose tissue) and on the prevailing metabolic circumstances such as cellular ATP requirements (requiring glycolysis), 'housekeeping' requirements (e.g. plasma membrane stability in erythrocytes), oxygen availability (determining whether glycolysis is anaerobic (yielding lactate) or aerobic (yielding pyruvate, which can be converted to acetyl-CoA and enters the tricarboxylic acid cycle) and alternative substrate availability (e.g. fatty acids or ketone bodies in the fasting state). Some of these pathways, and in particular the rate of glucose oxidation,

FIGURE 15.2 ■ Intracellular metabolic pathways for glucose. FFA, free fatty acids; G6PDH, glucose 6-phosphate dehydrogenase; GFAT, glutamine:fructose 6-phosphate amidotransferase; LDH, lactate dehydrogenase; PDH, pyruvate dehydrogenase. Broken lines indicate pathways from which intermediates have been omitted for clarity. Lower case letters refer to reactions, which are discussed in the text.

have been shown to be abnormal in subjects with type 2 diabetes and also in their non-diabetic relatives.

Glucose oxidation proceeds via the action of the rate-limiting enzyme phosphofructokinase (c) through various intermediates to pyruvate. Pyruvate may cross the mitochondrial membrane to enter the tricarboxylic acid cycle via the mitochondrial pyruvate dehydrogenase (PDH) enzyme complex (d) (releasing a net 38 molecules of ATP per molecule of glucose) or may remain in the cytosol and be converted anaerobically to lactate via the bidirectional enzyme lactate dehydrogenase (LDH) (e) (yielding only a net two molecules of ATP per molecule of glucose). Pyruvate dehydrogenase in muscle is stimulated by exercise and in most tissues by insulin, but this stimulation is reduced in diabetes. Pyruvate dehydrogenase is inactivated by phosphorylation, catalysed by PDH kinase (which is over expressed in insulin resistance). As a result, glucose metabolism is shifted away from the tricarboxylic acid cycle. This effect may be prevented by activation of peroxisome proliferation activating receptor α (PPAR α , see p. 720), one of a family of lipid-activated transcription factors. Mitochondrial diseases have been reported to cause insulin resistance or diabetes (e.g. diabetes insipidus, diabetes mellitus, optic atrophy and deafness (DIDMOAD) syndrome, Friedreich ataxia and HIV-associated lipodystrophy); indices of mitochondrial activity (e.g. mitochondrial number and size) are generally reduced in insulin-resistant states.

Lactate, generated under anaerobic conditions (and in cells such as erythrocytes, which lack the requisite enzymes) can be used as a substrate for gluconeogenesis either locally or after export to the liver (the Cori cycle), or may enter the tricarboxylic acid cycle after reconversion to pyruvate (f).

It has been postulated that an increased availability of substrates such as FFAs or ketone bodies, entering the tricarboxylic acid cycle via acetyl-CoA (g), may lead to excess generation of citrate, with the consequent inhibition of phosphofructokinase (PFK), thus shunting glucose down alternative, non-oxidative pathways (the glucose-FAA or Randle cycle). The consequent reduction in the entry of glucose into the tricarboxylic acid cycle could contribute to diminished glucose oxidation and thus to diabetes.

Glycogenolysis (h) is initiated by glycogen phosphorylase, the activity of which is stimulated by glucagon (in liver) and catecholamines (in muscle). In muscle, the glucose liberated from glycogen is used locally as an energy source: it is not exported into the circulation. Muscle glycogen storage via glycogen synthase (i) is diminished in type 2 diabetes, potentially contributing to reduced glucose disposal.

Intracellular glucose can also be metabolized through the pentose phosphate shunt (hexose monophosphate shunt) via glucose 6-phosphate dehydrogenase (j). Deficiency of this enzyme causes an X-linked form of haemolytic anaemia, owing to the fact that this pathway is the only route of glucose metabolism in red blood cells; it is prevalent in people originating from the Mediterranean littoral.

The rate-limiting enzyme of the hexosamine synthetic pathway (glutamine:fructose 6-phosphate amidotransferase,

GFAT) (k) is overactive in diabetes and hyperglycaemia; this pathway leads to the glycosylation of proteins, including transcription factors, and can affect cellular sensing of glucose. The hexosamine pathway is also relevant to the development of complications of diabetes through alterations in endothelial function mediated by endothelial nitric oxide synthase (eNOS), protein kinase A and protein kinase C. Defects in glucose oxidation and glycogen storage may cause shunting of glucose down this pathway, leading to insulin resistance, reduced insulin secretion and diabetic complications.

Animal models of glucotoxicity show many of the features of type 2 diabetes, for example reduced GLUT4 translocation (reducing glucose uptake into cells), reduced glycogen synthase activity (reducing glucose incorporation into glycogen), increased hepatic glucokinase activity (increasing intracellular glucose trapping), increased hepatic glucose output and reduced β -Cell glucokinase activity (reducing insulin secretion). Insulin resistance may thus be a defence against excessive intracellular accumulation of glucose, sensed by excessive shunting down the hexosamine synthetic pathway and mediated via the transcriptional regulation of key enzymes and pathways ('cellular satiety'). Reduced glucose oxidation in pancreatic β -Cells could lead to impairment of insulin secretion, and in other tissues could lead to diminished glucose disposal, both of which are hallmarks of type 2 diabetes. However, the extent to which these abnormalities actually contribute to diabetes rather than relate to specific experimental conditions (e.g. glucose and insulin concentrations), or are simply consequences of some other pathological processes, remains unclear.

Insulin

Biosynthesis

Insulin is a peptide hormone (51 amino acids arranged in two peptide chains linked by two disulphide bonds, molecular weight 5807 Da), which is secreted by the β -Cells of the islets of Langerhans in the pancreas. In the synthesis of insulin, translation of mRNA yields preproinsulin, a prohormone that undergoes post-translational modification prior to release of the mature insulin molecule. Removal of 24 amino acids from preproinsulin yields proinsulin, which consists of 86 amino acids. Proinsulin is stored in secretory granules prior to release from β -Cells by exocytosis. In healthy subjects, >90% of proinsulin is converted to mature insulin by the removal of the metabolically inert C-peptide component prior to secretion. The other products of the post-translational modification are either released when exocytosis occurs or are degraded within the secretory granules prior to release. C-peptide is co-secreted in equimolar amounts with mature insulin. In healthy subjects, only small amounts (<10% of mature insulin output) of proinsulin and partially split proinsulin are released. These ratios are characteristically disturbed in certain pathological states, including autonomous insulin secretion from an insulinoma and type 2 diabetes mellitus. Plasma concentrations of proinsulin and C-peptide are low or

undetectable in cases of surreptitious administration of exogenous insulin. Assay of these substances may, therefore, prove helpful in the differential diagnosis of hypoglycaemia in some circumstances. Proinsulin may accumulate in renal failure and its plasma concentration is elevated in familial hyperproinsulinaemia.

Substances stimulating the synthesis and storage of insulin include glucose, mannose, leucine, arginine and a variety of metabolizable sugars and sugar derivatives. Most of these also promote secretion.

Secretion and pharmacokinetics

The mechanisms by which insulin release is triggered are the focus of much research. It is apparent that there is an ATP-dependent, sulfonylurea-sensitive K^+ channel whose closure is a late event in the intracellular signalling mechanism within the β -Cell; closure triggers calcium influx and exocytosis. It is not clear how this K^+ channel is activated, although a wide range of secretagogues can stimulate activation of this final common pathway. The most important of these is hyperglycaemia, although mannose, lactate, arginine, leucine and other amino acids, glucagon, glucagon-like peptide 1 (GLP-1), glucose-dependent insulinotropic peptide (GIP, known formerly as gastric inhibitory peptide), cholecystokinin, vasoactive intestinal peptide (VIP), sulfonylureas and parasympathetic cholinergic (muscarinic) nerve activity also stimulate insulin release; many of these secretagogues have synergistic effects. Both neural sympathetic tone and circulating catecholamines inhibit insulin secretion.

Because of cephalic and gastric influences, oral glucose is a more potent stimulus to insulin secretion than an equivalent amount of intravenous glucose. This difference is known as the 'incretin' effect and is predominantly mediated by gut-derived hormones such as the N-terminally truncated GLP-1 (7–36) amide, and GIP. Recently, drugs have become available that augment the release of insulin via the sulfonylurea-sensitive K^+ channels of β -Cells (meglitinide analogues) and GLP-1 receptors (GLP-1 analogues), both acting in a glucose-dependent manner. These mechanisms afford the clinically desirable possibility of augmenting insulin release during conditions of hyperglycaemia, while at the same time reducing the risk of hypoglycaemia. They are discussed further in Chapter 16.

In healthy adults, insulin is secreted in pulses with a pulse periodicity of 11–15 min. Stimuli of insulin secretion increase the frequency and amplitude of these pulses. Approximately 30–40 U (210–280 nmol) of insulin are secreted per 24 h in healthy subjects of normal weight. Insulin secretion is basal (0.25–1.0 U/h) until glucose concentration exceeds a threshold of ~5 mmol/L, and becomes maximal at a concentration of 15–20 mmol/L.

Insulin is secreted into the portal venous system and thus must pass through the liver before reaching the systemic circulation. Approximately half of the insulin is cleared in the 'first pass' through the liver. The liver is exposed to insulin concentrations approximately threefold higher than other tissues during endogenous insulin secretion. The first pass clearance of insulin by the liver is variable, being controlled not only by the prevailing blood glucose concentration but also by factors released from the

gut before absorption is complete, and by the integrated action on β -Cell receptors of a range of endocrine and nutritional signals. It is, therefore, not surprising that it is difficult to replicate physiological patterns of insulin concentrations by giving exogenous insulin subcutaneously.

Autocrine and paracrine regulation of insulin secretion by pancreatic and gut hormones (which may reach very high concentrations within islets) is not well understood. Increased secretion of insulin involves recruitment of more β -Cells to the secreting mode.

Fasting peripheral insulin concentrations vary between 20 and 140 pmol/L (~2.9–20 mU/L), as measured by immunoassays in healthy subjects, the higher values being associated with increasing age and obesity. After a typical mixed meal (700–800 kcal), peak plasma insulin concentrations reach ~350–580 pmol/L (50–84 mU/L) in lean young adults. The half-life of insulin injected into a peripheral vein is 2–6 min, with most being cleared by the liver and smaller amounts being cleared by other tissues that have insulin receptors, such as skeletal muscle, although there is also non-receptor mediated clearance by a variety of tissue proteases.

Abnormalities of the synthesis and secretion of insulin

There are a number of recognized genetic abnormalities of insulin structure involving mutations of the insulin gene and hence altered amino acid sequences. Some of these are listed in Table 15.2. Each of the proinsulin and insulin variants mentioned has reduced biological activity in relation to insulin. This causes a propensity to diabetes, although individuals who can sustain a compensatory hypersecretion may not develop the condition. For example, in familial hyperproinsulinaemia, hypersecretion is usually sufficient to prevent diabetes, whereas in insulin Wakayama, diabetes is usual. There are also recognized associations between some polymorphisms affecting the insulin secretory mechanism (e.g. calpain 10, a molecule that promotes the fusion of secretory granules with cell membranes) and diabetes.

More common abnormalities of insulin secretion involve loss of the normal pulsatility of insulin release, an early feature of both obesity and type 2 diabetes. The progressive loss of insulin secretory capacity in diabetes is discussed below.

Actions of insulin

Insulin has widespread actions, some of which are listed in Table 15.3. It is the dominant hormone regulating blood glucose concentration. It should be noted that while the mechanisms of its glucoregulatory action have been the subject of extensive research, much less is known about its other actions in health or in insulin-resistant states, although vascular effects (vascular smooth muscle proliferation, vasodilatation), CNS effects (appetite, learning, memory) and effects in relation to growth, differentiation and apoptosis have all been proposed.

At present, only two receptors that mediate the actions of insulin have been identified: the insulin receptor and the IGF (insulin-like growth factor) receptor. It is apparent,

TABLE 15.2 Some genetically determined abnormal insulins

Condition	Abnormality	Consequences
Familial hyperproinsulinaemia	Failure to cleave C-peptide from proinsulin	True insulin concentrations and glucose tolerance normal
Insulin Chicago	Leu for Phe substitution at position 25 of β chain	Reduced receptor binding
Insulin Los Angeles	Ser for Phe substitution at position 24 of β chain	Reduced receptor binding
Insulin Wakayama	Leu for Val substitution at position 3 of α chain	Reduced receptor binding
Proinsulins Boston and Tokyo	His for Arg substitution at position 65	Inability to cleave proinsulin to insulin
Proinsulin Providence	Asp for His substitution at position 10 of β chain	Inability to cleave proinsulin to insulin
Proinsulin Kyoto	Leu for Arg substitution at position 65	Inability to cleave proinsulin to insulin

TABLE 15.3 The principal actions of insulin

Actions	Mechanisms
Liver	
Inhibition of hepatic glucose output	Limitation of substrate supply Inhibition of glycogenolysis Inhibition of gluconeogenesis
Stimulation of hepatic glycogen storage	Stimulation of glycogen synthase
Stimulation of hepatic glycolysis for intermediary metabolism	Stimulation of phosphofruktokinase
Stimulation of hepatic lipogenesis	Stimulation of pyruvate dehydrogenase
Stimulation of hepatic glucose oxidation	Stimulation of pyruvate dehydrogenase
Skeletal muscle	
Stimulation of glucose transport	Activation of glucose transporter (GLUT4)
Stimulation of muscle glycogen synthesis	Stimulation of glycogen synthase
Stimulation of muscle glycolysis	Stimulation of phosphofruktokinase
Adipose tissue	
Inhibition of lipolysis (stored lipid)	Inhibition of hormone-sensitive lipase
Promotion of re-esterification	? Increased supply of glycerol 3-phosphate
Stimulation of lipolysis (circulating lipid)	Stimulation of lipoprotein lipase
Increased glucose uptake	Several (? as for muscle/liver)
Central nervous system	
Satiety	Uncertain
Changes in sympathetic tone	Uncertain
Postprandial thermogenesis	Uncertain
Other	
Promotes DNA synthesis	Uncertain
Promotes RNA synthesis	Various
Stimulation of amino acid uptake	Uncertain
Na ⁺ ,K ⁺ -ATPase stimulation	? Increase in intracellular energy availability
Na ⁺ /H ⁺ antiport activation	Uncertain
Sodium retention	Probably several mechanisms

however, that there are individual dose–response curves for the different actions of insulin in different tissues. For example, the median effective dose (ED₅₀) for insulin's antilipolytic action on adipose tissue is <140 pmol/L (20 mU/L) (and may be <70 pmol/L), while those for inhibition of hepatic glucose output and stimulation of glucose uptake into skeletal muscle are 210–350 pmol/L (30–50 mU/L) and 350–490 pmol/L (50–70 mU/L), respectively. A doubling of insulin concentration inhibits hepatic glucose output by ~80% and stimulates peripheral glucose utilization by ~20%. In patients with type 2 diabetes, these differential effects on lipolysis, hepatic glucose output and glucose uptake, coupled with ongoing (if reduced) insulin secretion, are probably responsible

for the fact that most individuals are not at risk of developing ketoacidosis (at least for many years), despite the clear defect in glucoregulation that is evident.

The different actions of insulin have different time courses, with the glucoregulatory and antilipolytic occurring within a few minutes, and growth regulation and actions dependent upon synthesis of new proteins occurring over periods of hours or days. Intravenous injection of insulin typically has little effect on blood glucose for 5–10 min, the maximal hypoglycaemic action occurring after 5–15 min. Insulin stimulation of skeletal muscle glucose uptake declines with a half-life of 10–20 min after the insulinaemic stimulus has been removed.

Proinsulin and partially split proinsulins have metabolic activities generally similar to those of insulin, although their plasma half-lives are 3–5 times longer and their biological potencies are only 8–15% that of insulin. It has been suggested that the hepatic activity of proinsulin may be relatively more potent than its effect on peripheral glucose uptake.

The insulin receptor

The main glucoregulatory effects of insulin are mediated by a transmembrane receptor found on insulin-sensitive cells. This receptor is a glycoprotein, with total molecular weight of 350 000 Da, comprising four peptide chains (two α - and two β -subunits), linked by disulphide bridges (Fig. 15.3). Two isoforms of the receptor (IR-A and IR-D) are formed by alternative splicing. The gene for, and amino acid structure of, the insulin receptor have been characterized and show homology with those of the IGF-1 receptor (see below). Within the intracellular domain of the β -subunit is a tyrosine kinase capability, which is activated when insulin binds with the extracellular domain of the α -subunits. The tyrosine kinase promotes autophosphorylation of the receptor followed by activation of threonine and serine kinases.

The insulin receptor gene is located on the short arm of chromosome 19 (19p 13.2). Rare gene mutations have been described, for example leprechaunism and Rabson–Mendenhall syndrome, which result in severe glucose intolerance with resistance to exogenous insulin, and profoundly disordered growth, rather than typical insulin resistance. These conditions are usually lethal in infancy and adolescence, respectively. There are also more common, ‘milder’ polymorphisms of the insulin receptor gene. However, these appear to explain only a small proportion of the marked variance in population insulin sensitivity and they are considered to be a rare (<1%) cause of type 2 diabetes mellitus. Indeed, most mutations of the insulin gene that have been recognized are not sufficient to cause diabetes alone, although they may render it more likely to occur in the presence of other risk factors.

FIGURE 15.3 ■ The insulin receptor.

Second messengers mediating the effects of insulin

Insulin can have multiple actions, even on a single responsive cell, and hence there are probably several different intracellular pathways mediating its actions. Glucoregulatory and antilipolytic responses are rapid and probably mediated via serine and threonine kinases and cAMP. Stimulation of lipid and protein synthesis, inhibition of proteolysis, the nuclear transcription of RNA and the replication of DNA are slower and have different second messenger systems. Second messenger systems involving diacylglycerol, protein kinase C and glycosyl-phosphatidyl-inositol are under investigation, but abnormalities in them have yet been demonstrated to be necessary or sufficient to cause diabetes in man. As a result of these second messenger cascades, glucose transporter proteins are translocated from within cells to their surface membranes to increase glucose flux into the cytoplasm.

After activation, insulin–receptor complexes are internalized by an endocytotic process; receptors are later recycled to the cell surface. Internalization of the insulin is important (and possibly essential) for insulin signals to reach the nucleus and influence cell growth and protein synthesis. Internalization is an important route by which insulin is cleared from the circulation and degraded. The actions of insulin in stimulating DNA transcription and mRNA translation do not depend upon the plasma membrane insulin receptor kinase activity and the second messenger systems discussed above, or on the IGF receptors described below, but rather involve direct effects within the nucleus and on ribosomes.

Insulin-like growth factors and their receptors

In addition to its acute effects on glucose uptake and release and on lipid metabolism, insulin has growth promoting activity in a variety of tissue culture models. At least two protein hormones, insulin-like growth factors 1 and 2 (IGF-1 and IGF-2), have actions that partly resemble these actions of insulin. The amino acid sequences of these proteins and the base sequences of their coding DNA are known and show some homology with those of insulin. Insulin-like growth factors are weak agonists for the insulin receptor and hence have weak glucoregulatory and antilipolytic effects. In addition, they have growth-promoting effects mediated by two IGF receptors. Insulin itself binds only weakly to IGF receptors.

The physiological role of IGFs is not yet fully established. It has been suggested that they act as somatomedins (they were previously called somatomedins C and A, terms that are no longer recommended), in that they are induced by growth hormone and mediate its growth-promoting effects in children. In adults, they are believed to promote the growth of continually dividing cells such as osteoblasts, chondrocytes, fibroblasts and erythroid cells.

Adult growth hormone deficiency is manifest by low overall quality of life scores, reduction in lean body mass, centripetal fat distribution, loss of bone mineral,

abnormal lipid profile, insulin resistance and changes in the secretion and metabolism of other circulating hormones, for example thyroxine (see p. 367). The effects of growth hormone deficiency on insulin sensitivity are complex. While glucose intolerance is a common feature of acromegaly, in growth hormone deficiency states, adverse changes consequent upon an increase in body fat composition tend to outweigh the lack of a counter-regulatory hormone to produce insulin resistance overall. Replacement therapy in adult growth hormone deficiency produces somewhat unpredictable effects, although a period of increased insulin resistance may herald a modest longer-term improvement.

Tumour-related hypoglycaemia may be due to excess production of IGFs, specifically 'big' IGF-2. Local and systemic concentrations of IGFs are modulated by a range of binding proteins. While total IGF-2 may not be increased in tumour-related hypoglycaemia, the IGF-2 is present in an immature form which, because of impaired ability to form the normal ternary 150 kD complex with IGF binding protein-3 (IGFBP-3) and the acid-labile subunit (ALS), circulates with greater than normal bio-availability. This effect has been described in a number of tumours, especially those of mesenchymal and epithelial origin. Further discussion of this topic is presented in Chapter 17.

It was first observed many years ago that proliferative diabetic retinopathy could regress following hypophysectomy in both animals and humans. This effect appears to be mediated via reduction in IGF-1, owing to the growth hormone deficiency seen after pituitary ablation. It has been hypothesized that the metabolic derangements of diabetes reduce hepatic IGF-1 generation in response to growth hormone (i.e. induce growth hormone resistance), which is then hypersecreted (owing to a lack of negative feedback from IGF-1), reaching concentrations that are able to stimulate IGF-1 generation in non-hepatic tissues. However, studies of pegvisomant, a growth hormone analogue that antagonizes IGF-1 generation in response to growth hormone, have not shown benefit in diabetic retinopathy.

CLASSIFICATION AND DIAGNOSIS OF DIABETES MELLITUS

Introduction

Diabetes is the most common metabolic disorder, with a cumulative incidence of 5–10% in people in the developed world aged >40 years, in whom >90% of cases are due to type 2 diabetes. Population screening programmes typically reveal that up to half of the subjects found to have type 2 diabetes had previously been undiagnosed. While the burden of type 2 diabetes is increasing exponentially with the epidemic of obesity in many parts of world, the incidence of type 1 diabetes has also been increasing for many years for reasons that are much less apparent. Nevertheless, the prevalence of type 2 diabetes in children is approaching that of type 1 diabetes, having been only ~2–4% of all childhood diabetes prior

to 1994, and is predicted to outstrip type 1 diabetes by 2025 on current trends. A high proportion of these children, typically presenting around the time of puberty, require insulin from the time of diagnosis. Whether this is due to the accelerator hypothesis ('double diabetes effect'), whereby an individual's risk of contracting type 1 diabetes is increased by the prior existence of type 2 diabetes or insulin resistance, is not clear.

Although insulin has many actions, as described above, diabetes is defined only in terms of elevated blood glucose concentrations. Since blood glucose is a continuous variable, the cut-off points for diagnosis are necessarily somewhat arbitrary.

Recent changes to the diagnostic criteria for diabetes and glucose intolerance reflect the increased cardiovascular risk evident at even moderate levels of fasting hyperglycaemia (~6.0 mmol/L in some studies). However, the blood glucose threshold for this effect is almost certainly lower than that for the predominantly microvascular complications unique to diabetes mellitus. Some people so diagnosed may not, therefore, necessarily be at risk of developing the unique set of complications (nephropathy, retinopathy, neuropathy) that have traditionally characterized the disease and determined its management.

Definitions

The diagnostic criteria for diabetes mellitus set out by The World Health Organization (WHO) have been adopted by both the American Diabetes Association (ADA) and Diabetes UK, although they differ slightly for glucose intolerance. The WHO introduced diagnostic criteria in 1979, but introduced revised criteria in 2000 to reflect better understanding of 'milder' glucose intolerance. The use of glycated haemoglobin (HbA_{1c}) for diagnosis was introduced in 2011. The WHO glucose criteria for diagnosis are shown in [Box 15.2](#) and [Table 15.4](#) and its recommendations regarding the use of HbA_{1c} are shown in [Box 15.3](#). World Health Organization criteria consider fasting and 120 min values in the oral glucose tolerance test (OGTT). The reproducibility of the OGTT leaves much to be desired (the CV of 120 min plasma glucose concentrations is reported to be up to 50%). If a subject fulfils the WHO criteria for diabetes, subsequent improvement of glucose tolerance may occur (e.g. as a result of weight loss or spontaneously), but such individuals are considered to have a lifelong tendency to diabetes.

[Table 15.4](#) indicates the criteria for the diagnosis of impaired glucose tolerance (IGT) and impaired fasting glycaemia (IFG), which are metabolic states intermediate between normal glucose tolerance and diabetes. For epidemiological or population screening purposes, the fasting or 2 h value after 75 g oral glucose may be used alone. For clinical purposes, the diagnosis of diabetes should always be confirmed by repeating the test on another day, unless there is unequivocal hyperglycaemia with acute metabolic decompensation or obvious symptoms. Glucose concentrations should not be determined on serum or plasma unless red cells have been immediately

BOX 15.2 World Health Organization recommendations for glucose-based diagnosis of diabetes mellitus

Criteria for the diagnosis of diabetes mellitus

1. Symptoms of diabetes plus casual plasma glucose concentration ≥ 11.1 mmol/L. Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia and unexplained weight loss
- or*
2. Fasting plasma glucose ≥ 7.0 mmol/L. Fasting is defined as no caloric intake for at least 8 h
- or*
3. Two-hour postload glucose ≥ 11.1 mmol/L during an oral glucose tolerance test (OGTT). The test should be performed as described by WHO, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

In the absence of unequivocal hyperglycaemia or classic symptoms, these criteria should be confirmed by repeat testing on a different day.

The third measure (OGTT) is not recommended for routine clinical use.

removed, or glycolysis will result in an unpredictable underestimation of the true concentrations. It should be stressed that glucose preservatives such as fluoride do not totally prevent glycolysis. If whole blood is used, the sample should be kept at 0–4°C, and assayed as soon as possible.

Subjects with IGT and IFG are at high risk of progression to diabetes; IGT and IFG should therefore be considered as risk categories for future diabetes and/or cardiovascular disease. In certain cases, glycated haemoglobin (HbA_{1c}), the concentration of which reflects glycaemia over several weeks, gives sensitivity and specificity for diagnosis almost equal to that of glucose measurements, and a cut-off value of 48 mmol/mol (6.5%) is now accepted as diagnostic, although it is important

to note that a value below this level does not necessarily exclude diabetes. Several classifications of diabetes have been proposed. The most widely used is that proposed by the WHO and adopted by the ADA shown in Box 15.4. However, it should be recognized that unanimity in nomenclature has yet to be achieved, especially in the areas of gestational diabetes, diabetes related to pancreatitis and tropical/malnutrition-related diabetes.

Type 1 diabetes mellitus

Introduction

Approximately 5–10% of all patients with diabetes have type 1 diabetes mellitus: this is characterized by severe insulin deficiency because of β -Cell destruction. The degree of insulin deficiency is so severe that patients require exogenous insulin therapy to avoid the rapid decline into cachexia, dehydration, ketoacidosis and death that was the inevitable consequence of this disease before the discovery of insulin by Banting and Best in 1921. Dietary measures cannot prevent this problem, although they may delay its onset, and survival for several years in the pre-insulin era with harshly restrictive hypoketotic diets was not unknown. Withdrawal of exogenous insulin therapy in patients with type 1 diabetes usually results in ketoacidosis within 48 h, and this may supervene in less than 12 h when insulin has previously been administered intravenously (and therefore cleared within minutes with no depot effect) and in conditions of increased insulin requirement or counter-regulatory response such as systemic sepsis.

The severity of type 1 diabetes is such that most patients come to medical attention within weeks or, at most, months of onset, whereas the onset of type 2 diabetes is usually more insidious, so it may be present many years before diagnosis. Although the condition (including latent autoimmune diabetes of adults, LADA, see below) can present at any age, most patients present in childhood and the diagnosis becomes rare after 30 years of age.

TABLE 15.4 Glucose concentrations for the diagnosis of diabetes mellitus and other categories of hyperglycaemia in accordance with WHO guidelines (1999 and 2006)

	Glucose concentration (mmol/L)			
	Whole blood		Plasma	
	Venous	Capillary	Venous	Capillary
Diabetes mellitus				
Fasting	≥ 6.1	≥ 6.1	≥ 7.0	≥ 7.0
<i>or</i>				
2 h post-glucose load	≥ 10.0	≥ 11.1	≥ 11.1	≥ 12.2
<i>or both</i>				
Impaired glucose tolerance (IGT)				
Fasting (if measured)	< 6.1	< 6.1	< 7.0	< 7.0
<i>and</i>				
2 h post-glucose load	6.7–9.9	7.8–11.0	7.8–11.0	8.9–12.1
Impaired fasting glycaemia (IFG)				
Fasting	5.6–6.0	5.6–6.0	6.1–6.9	6.1–6.9
<i>and</i>				
2 h post-glucose load (if measured)	< 6.7	< 7.8	< 7.8	< 8.9

BOX 15.3 Diagnosis of diabetes mellitus using HbA_{1c} in accordance with World Health Organization recommendations**Criteria for the diagnosis of diabetes mellitus**

- HbA_{1c} can be used as a diagnostic test for diabetes providing that:
 - stringent quality assurance tests are in place
 - assays are standardized to criteria aligned to the international reference values
 - there are no conditions present which preclude its accurate measurement
- An HbA_{1c} of 48 mmol/mol (6.5%) is recommended as the cut-off point for diagnosing diabetes. A value <48 mmol/mol (6.5%) does not exclude diabetes diagnosed using glucose tests
- In patients with an HbA_{1c} of ≥48 mmol/mol but no symptoms of diabetes, repeat the HbA_{1c} measurement on a further sample. If the second result is <48 mmol/mol (6.5%), treat as high diabetes risk and repeat the test in six months, or sooner if symptoms develop.

Situations where HbA_{1c} is not appropriate for diagnosis of diabetes

- All children and young people
- Patients of any age suspected of having type 1 diabetes
- Patients with symptoms of diabetes for less than two months
- Patients at high diabetes risk who are acutely ill (e.g. those requiring hospital admission)
- Patients taking medication that may cause rapid glucose rise, e.g. steroids, antipsychotics

- Patients with acute pancreatic damage, including pancreatic surgery
- Pregnancy
- Haemoglobinopathies
- Anaemia (haemolytic and iron deficiency)
- Renal failure
- HIV infection.

Patients whose HbA_{1c} is <48 mmol/mol (6.5%)

- Patients may still fulfil the WHO glucose criteria for the diagnosis of diabetes
- Use WHO glucose testing in patients with symptoms of diabetes or clinically at very high risk of diabetes (although the use of such glucose tests is not recommended routinely in this situation).

Patients who are clinically at high risk of developing diabetes:

- HbA_{1c} 42–47 mmol/mol (6.0–6.4%):
 - Provide intensive lifestyle advice
 - Warn patients to report symptoms of diabetes
 - Monitor HbA_{1c} annually
- HbA_{1c} <42 mmol/mol (6.0%):
 - Patients may still have a high diabetes risk
 - Review the patient's personal risk and treat as 'high diabetes risk', as clinically indicated.

However, the distinction between types 1 and 2 diabetes is not always clear-cut and it is not always possible to categorize patients on clinical grounds alone, even after a detailed history taking into account such factors as the duration of symptoms and degree of weight loss, so that in some patients additional investigations are required to establish the correct diagnosis. Latent autoimmune diabetes of adults is a rare subtype of type 1 diabetes. Affected individuals tend to develop diabetes more insidiously and appear to respond, at least initially, to treatments other than insulin such as sulfonylureas. Some patients with autoimmune type 1 diabetes, even though they may have presented with ketoacidosis, retain sufficient islet cell reserve for some months after the diagnosis to remain ketosis free on little or even no insulin (the so-called 'honeymoon period'). Conversely, some patients with type 2 diabetes may become ketosis prone as β -Cell failure progresses from being relative to being absolute in the face of islet cell exhaustion or destruction, particularly in conditions of increased insulin requirement such as systemic sepsis. The 'accelerator hypothesis' of type 2 diabetes predisposing to type 1 diabetes via islet cell stress, and the high prevalence of the co-aggregation of features of both type 1 and type 2 diabetes is discussed above in relation to childhood onset diabetes.

Where confirmation of type 1 (autoimmune) diabetes is required, quantification of anti-glutamic acid decarboxylase (GAD) antibodies and/or islet cell antibodies (ICA) may be helpful. However, these antibodies may be detectable in healthy individuals (~2%), and the likelihood of a positive result in true autoimmune diabetes

declines from >85% at disease onset to negligible rates after 10–15 years of disease. Although normal basal or glucagon-stimulated concentrations of C-peptide (the normal response is a doubling of C-peptide concentration 6–20 min after glucagon 1 mg i.m.) rule out the existence of severe absolute insulopaenia at the time of the test, negative results are potentially harder to interpret, as endogenous insulin secretion may have been suppressed by long-term treatment with exogenous insulin.

Individuals who do not have diabetes but who have detectable anti-GAD or ICAs may be at increased future risk of developing type 1 diabetes (and other autoimmune conditions). Several studies have attempted to determine whether intervention with immunosuppressive therapy reduces this risk in those at highest risk (usually first-degree relatives of people with type 1 diabetes, with high-risk genotype and positive antibodies), or helps to preserve any residual β -Cell function at the time of diagnosis. Thus far, the side-effects of the drugs used would appear to outweigh their benefit, although some delay in progression to complete insulin deficiency has been demonstrated, at least in some of the studies.

Aetiology: genetic susceptibility and possible environmental cofactors

Type 1 diabetes typically results from an autoimmune attack upon pancreatic β -Cells. It is not understood what factors may trigger the attack. Although viral infection can provoke the attack (as seen clearly with congenital rubella), for most patients it is not clear what factor(s)

BOX 15.4 Aetiological classification of diabetes mellitus**I. Type 1 diabetes (β -Cell destruction, usually leading to absolute insulin deficiency)**

is/are responsible. In those patients with other autoimmune diseases (e.g. Addison disease, autoimmune thyroid disease, coeliac disease), it appears that the attack on the pancreas is part of a multiorgan or polyglandular process. It is marked by systemic indices of the autoimmune process such as circulating islet cell autoantibodies (which, when in high titre, may be complement fixing) and changes in circulating T and B lymphocyte subsets. The process of β -Cell destruction usually takes many months and occurs in cycles of deterioration and remission. The acute presentation of type 1 diabetes mellitus usually occurs during an acute deterioration of β -Cell function, the disorder frequently being unmasked by an intercurrent illness. After the patient recovers from the intercurrent illness, adopts a suitable diet and is treated with exogenous insulin, there is often a temporary period of improved β -Cell function, known clinically as the

'honeymoon period', during which glycaemic control may be relatively easily maintained. This honeymoon period typically lasts six, but occasionally up to 24 months, and β -Cell function may be misleadingly good during this period.

Subsequently, insulin and C-peptide secretion are almost completely lost (maximal C-peptide response following a glucose load $<0.5 \mu\text{g/L}$); however, the degree of any residual β -Cell function may determine the ease with which good glycaemic control can be achieved with exogenous insulin therapy.

Although β -Cell destruction is the cause of type 1 diabetes mellitus, secondary metabolic defects occur, including resistance to exogenous insulin, although this is more commonly seen in type 2 diabetes mellitus. There are a number of mechanisms for this, including the development of anti-insulin antibodies (relatively rare with synthetic human insulins) and abnormal body composition

due in part to the peripheral administration of insulin, or because the individual is predisposed to insulin resistance by the genetic and morphological factors that also operate in type 2 diabetes mellitus. These morphological factors are becoming increasingly common with the worldwide increase in obesity, which affects individuals with type 1 diabetes as well as those without.

Certain genetic markers are associated with a high prevalence of type 1 diabetes. Most of these are found on chromosome 6, in genes related to histocompatibility linked antigens (HLAs), which together probably account for about half the genetic risk, although recent genome-wide association studies have identified several other markers of risk. Some of the associations are listed in Table 15.5. Most type 1 diabetes associated with HLA-DR4 presents in childhood while that associated with HLA-DR3 has a more variable age of onset.

Type 2 diabetes mellitus

Introduction: the heterogeneity of type 2 diabetes

Type 2 diabetes mellitus is the commonest form of diabetes mellitus worldwide. It is often considered a diagnosis of exclusion, that is, patients are assumed to have type 2 diabetes because they do not demonstrate the typical features of type 1.

Type 2 diabetes is probably not a single condition. In all patients with the condition, there is both insulin resistance and relative insulin deficiency. Some patients with late onset diabetes initially presumed to be type 2 will turn out to have type 1 (latent autoimmune diabetes in adults, LADA). With time (over perhaps 5–15 years from diagnosis), glycaemic control in type 2 patients usually becomes more difficult to achieve; insulin deficiency becomes more apparent and a subgroup of patients becomes prone to ketosis. Data from the UK Prospective Diabetes Study (UKPDS) trial suggested that the average time to insulin use was approximately seven years from diagnosis of type 2 diabetes, and confirmed the clinical impression of a progressive rather than static disease process. The typical patient with type 2 diabetes mellitus is overweight (average BMI at presentation $>27 \text{ kg/m}^2$), with a central

distribution of obesity (most conveniently assessed by waist circumference or waist:hip ratio) conferring risk that is independent of and additional to that of elevated body mass index (BMI). The age-adjusted relative risk for diabetes begins to increase at values of BMI that are considered normal based on mortality risk (24 kg/m^2 for men, 22 kg/m^2 for women), and rises exponentially as BMI rises (Fig. 15.4). The marked increase in the prevalence of obesity is an important contributor to the increased prevalence of type 2 diabetes. Increases in abdominal fat mass, weight gain since young adulthood and a sedentary lifestyle are additional obesity-related risk factors for diabetes. In some ethnic groups (particularly those from parts of south Asia), the risk of diabetes may be higher at lower levels of obesity.

Other independent environmental risk factors include being born to a mother with gestational diabetes mellitus, being of exceptionally high birth weight and being of exceptionally low birth weight. The latter is postulated by the 'Barker hypothesis' to predispose to diabetes and obesity by, among other things, switching on 'thrifty' genes to counter the effects of intrauterine malnutrition.

Leaner patients with type 2 diabetes tend to show more severe insulin deficiency. Greater degrees of obesity are associated with more insulin resistance. A major unresolved controversy of type 2 diabetes remains whether, for the typical type seen in European individuals, the prime defect in glucose homeostasis is insulin deficiency or insulin resistance or both. Given that many individuals with severe insulin resistance do not have diabetes and that some patients with type 2 diabetes have little insulin resistance, it is probably true to say that insulin resistance is neither a necessary nor sufficient cause: rather, some degree of β -Cell dysfunction (whether as an inherited tendency or as a result of reduced β -Cell function as part of a degenerative process) is the *sine qua non* of type 2 diabetes. Such β -Cell dysfunction may take the form of a relative lack of insulin secretion or of abnormal patterns of insulin secretion. Such abnormalities have been described in patients who later developed type 2 diabetes, and include changes in the amplitude and frequency of insulin secretory pulses and the loss of first-phase insulin secretion (the initial pulse of insulin secretion seen after a meal

TABLE 15.5 Genetic associations with type 1 diabetes mellitus

FIGURE 15.4 ■ Relationship between BMI and risk of type 2 diabetes. The risk of diabetes increases with increasing BMI values in men and women.

or glucose tolerance test), with prolongation and augmentation of the second phase (the later response seen after a meal). These abnormalities of insulin secretion are reversible after certain forms of bariatric surgery for morbid obesity in patients with type 2 diabetes.

Population studies indicate that the concurrent existence in an individual of both a cause for insulin resistance (usually obesity) and of a relatively low insulin secretory reserve predicts the later onset of type 2 diabetes mellitus.

The differentiation of idiopathic type 2 diabetes and 'secondary' diabetes can be difficult. Secondary diabetes is a term that implies that another disease process has caused the diabetes (see [Box 15.4](#)). While there is good understanding of the natural history and approach to treatment in type 2 diabetes, there is less for secondary diabetes: occasionally, the diabetes can be improved significantly by treating the primary condition.

Genetic factors in type 2 diabetes mellitus

Family studies suggest that type 2 diabetes mellitus is strongly inheritable. Concordance rates for identical twins exceed 90%. Some racial groups have a very high incidence of type 2 diabetes. Notable examples of this include the Pima Indians of Arizona and Pacific Islanders, with prevalence rates of up to 50%. In the UK, the prevalence of type 2 diabetes in people of South Asian extraction is approximately two or three times that in people of European origin. African-Caribbean people show an intermediate prevalence. The natural history of type 2 diabetes and its propensity to give rise to long-term complications varies between races (examples being the relative lack of diabetic foot disease in British Asians and the high prevalence of diabetic nephropathy among those of African-Caribbean descent).

In the majority of patients with type 2 diabetes, the pattern of inheritance suggests a polygenic disorder, with an important role for environmental factors such as obesity and a low level of exercise.

Molecular biological techniques have not yet shown type 2 diabetes to be consistently associated with any abnormalities of the DNA coding of insulin, the insulin receptor or glucose transporter peptides, except in a small percentage (<1%) of cases. Abnormalities of the glucokinase gene and of certain hepatic nuclear factor genes have been shown to cause some cases of maturity onset diabetes of the young (MODY) (see [p. 292](#)), but not typical type 2

diabetes mellitus. More recent genome wide association studies have identified several predisposing genetic factors; most of these appear to relate to β -Cell function, but interestingly the strongest factor yet identified (the *FTO* gene, which is expressed in the hypothalamus and thought to be involved in body weight regulation), appears to increase diabetes risk by predisposing to a higher body weight; homozygotes for the predisposing gene variant are on average 3 kg heavier than those without.

Glucoregulatory defects in type 2 diabetes mellitus

The exact cause(s) of type 2 diabetes mellitus is (are) unknown. Hyperglycaemia is due to elevated hepatic glucose output and, to a lesser extent, failure of skeletal muscle to take up glucose and store it as glycogen. Although many factors are believed to contribute to these two defects, they can broadly be categorized into three groups: β -Cell deficiency/dysfunction, insulin resistance and abnormalities of non-insulin-mediated glucose disposal. It is also perhaps useful to indicate that, although only abnormal concentrations are observed in clinical practice, fluxes can be measured in research studies, and some of these are indicated in [Table 15.6](#).

Pancreatic β -Cell deficiency/dysfunction in type 2 diabetes mellitus. The importance of β -Cell deficiency varies between different groups and different individuals with type 2 diabetes mellitus. Abnormalities of insulin secretion are present in all patients, but the causes(s) of these defects is/are not yet established. Nor is it yet clear whether an abnormality of insulin secretion is usually the primary aetiological defect or whether other glucoregulatory defects are secondary to this pancreatic defect. Several workers have suggested that β -Cell dysfunction is the primary abnormality of type 2 diabetes, but that β -Cell dysfunction may be more subtle than that seen in type 1 diabetes.

Insulin deficiency has been described in type 2 diabetes mellitus, but may sometimes be due to misclassifying a late onset type 1 patient. Some patients with type 2 diabetes can exhibit both insulopaenia and hyperinsulinaemia (relative to normal weight controls) at different times during a single day. Some, especially obese subjects with mild glucose intolerance, may have hyperinsulinaemia throughout the whole 24h. Other patients, usually

TABLE 15.6 Some comparisons of concentrations and fluxes in obesity/insulin resistance syndrome/early type 2 diabetes

Substance or process	Concentrations	Fluxes
Glucose	Increased fasting concentration	Normal whole body disposal rate Normal whole body glucose production and clearance
Non-esterified fatty acids	Variable	Usually normal fasting total body production Impaired responsiveness to meal
Very low density lipoproteins	Increased concentration	Increased production, increased plasma half-life and increased whole body clearance
Oxidation of fuels	Whole body respiratory quotient (RQ) reflects diet	Whole body RQ reflects diet but RQ is lower in obese subjects

those who are less obese, resemble patients with late onset type 1 diabetes mellitus and have absolute insulin deficiency throughout. Fortunately, the accurate distinction between insulin-deficient type 2 diabetes mellitus and late onset type 1 diabetes mellitus rarely has significant implications for the clinical management of individual patients.

Patients with type 2 diabetes mellitus most frequently show hyperinsulinaemia during fasting, combined with reduced β -Cell reserve, relative to healthy subjects. The time course of insulin secretion in type 2 diabetes is abnormal: subjects typically exhibit relative insulin deficiency during both the early phase of insulin secretion after an oral glucose load or meal and the first-phase insulin response to an intravenous glucose load. This loss of early insulin response to glucose is paralleled by defects in the pulsatility of insulin secretion.

Assuming insulin clearance to be normal in such (hyperglycaemic) type 2 diabetes patients, hyperinsulinaemia implies hypersecretion of immunoreactive insulin compared with healthy (euglycaemic) subjects. However, secretion of insulin by β -Cells is dependent on the prevailing blood glucose concentration as well as several other factors. Thus, the level of insulinaemia can be considered a reflection of β -Cell function only if it is considered in relation to the blood glucose concentration. The hyperglycaemic drive to the islets may compensate or even overcompensate for β -Cell dysfunction, producing near-normal or even supranormal insulin concentrations. In the 1990s, it became clear that conventional radioimmunoassays for insulin failed to distinguish mature insulin from proinsulin and partially split proinsulins. Since the precursor molecules have much less biological activity than mature insulin, conventional radioimmunoassays had probably been overestimating the degree of insulinaemia typically found in type 2 diabetes. However, even modern specific assays do confirm at least some degree of hyperinsulinaemia in obese type 2 patients with milder degrees of hyperglycaemia.

With increasing time, even patients who were hyperinsulinaemic at diagnosis usually become relatively insulin deficient. This group of patients, together with those who are insulin deficient from diagnosis, often need exogenous insulin treatment to maintain near-normal glycaemia. They may then be termed 'insulin-treated' or 'insulin-requiring', but it should be recognized that such insulin-treated patients form a heterogeneous group, very different in character from type 1, insulin-dependent patients.

Amylin. Amylin (also known as islet amyloid polypeptide, IAPP) is a 39-amino acid peptide co-secreted with insulin by β -Cells in all subjects with intact insulin secretion, but not those with type 1 diabetes. The amino acid structure has some homology with calcitonin gene-related peptide. Plasma concentrations of amylin are very low ($<10^{-10}$ molar) in both diabetic and non-diabetic subjects. There is no established physiological role for the peptide in the systemic circulation, but it has been suggested that amylin may have a physiological role in the regulation of insulin secretion within pancreatic islets or some effects on bone metabolism. Possible

pathophysiological roles of amylin include the induction of insulin resistance in skeletal muscle, but this only occurs at pharmacological concentrations. Amylin fibrils (with typical amyloid features of secondary protein structure and insolubility) are deposited in islet cells in conditions of excess insulin secretion (such as insulinoma), and in situations where insulin secretion may initially have been increased but has subsequently declined (such as in old age and type 2 diabetes). The possible role of amylin in the islet damage of type 2 diabetes is under intensive investigation.

Insulin resistance in type 2 diabetes mellitus. In 1970, Berson and Yalow defined insulin resistance as 'a state in which greater than normal amounts of insulin are required to elicit a quantitatively normal [glucose] response'. The concept of insulin resistance had been suggested in the 1930s when Himsworth noted that the same amount of exogenous insulin injected into different diabetic subjects had different antihyperglycaemic effects. Those with lesser antihyperglycaemic responses were labelled insulin insensitive (or insulin resistant). When early assays showed that many patients with type 2 diabetes had high concentrations of circulating insulin as detected by radioimmunoassay, the concept of insulin resistance was reinforced. These patients were hyperglycaemic, and hence by definition relatively insulin deficient, yet they actually appeared to have more immunoreactive insulin than other people so that their true insulin requirement was believed to be larger still. Hyperinsulinaemia with eu- or hyperglycaemia is generally taken to indicate insulin resistance, since hyperinsulinaemia produces hypoglycaemia in subjects with normal insulin sensitivity. The type 2 patients who apparently needed supranormal amounts of insulin were seen to be the same group that Himsworth had found to be insulin resistant.

As insulin has several actions, resistance can take several forms. It appears that some subjects show resistance to its hepatic effects while some show resistance to its effects on skeletal muscle (activation of muscle glycogen synthase by insulin is often defective), and some show resistance to liporegulatory effects, the degree of resistance being different for different actions of insulin. There is no consensus as to the cellular mechanisms underlying insulin resistance in most patients with type 2 diabetes, though several have been suggested (see Fig. 15.2). Some workers have highlighted the competition between lipids and glucose as metabolic fuels (the glucose-fatty acid cycle (Randle cycle) hypothesis): it can be shown experimentally that high circulating concentrations of alternative fuels such as triglycerides, NEFA, lactate and ketone bodies compete with glucose for uptake and that, in their presence, glucose clearance is reduced. Others have suggested that insulin resistance is a consequence of 'cellular satiety', seen whenever intracellular sensors such as uridine diphosphate (UDP)-glucosamine detect excess energy supply, and other workers have implicated specific cellular abnormalities such as reduced numbers of insulin receptors, reduced receptor function, dysfunction of second messenger systems and intracellular antagonists of the effects of insulin.

Abnormalities of non-insulin-mediated glucose disposal in type 2 diabetes mellitus. As discussed above, most glucose clearance from the plasma occurs independently of insulin. This process, largely via GLUT1, is defective in type 2 diabetes, and contributes to hyperglycaemia, although the mechanism is uncertain. Changes in tissue blood flow in diabetes, particularly within skeletal muscle, may also reduce clearance of plasma glucose.

Associations of type 2 diabetes mellitus

The metabolic syndrome and obesity. Type 2 diabetes mellitus often occurs in patients with a syndrome of morphological and metabolic abnormalities together with associated conditions that has been termed the metabolic syndrome (also known as 'Reaven syndrome', 'syndrome X' or the 'hyperinsulinaemia syndrome'). The features include insulin resistance, dyslipidaemia, obesity (particular abdominal obesity) and hypertension among others. Unfortunately, there have been multiple definitions of these syndromes (e.g. different factors, different combinations of factors and different cut-offs for their definition) and no consensus has been reached. However, these syndromes all reflect co-segregation of factors in patients with type 2 diabetes mellitus and those with lesser degrees of glucose intolerance, as well as in individuals with normal glucose tolerance. Subjects with metabolic syndrome, with or without diabetes, have an increased predisposition to atherosclerosis, and subjects with glucose intolerance (type 2 diabetes mellitus or IGT) have an increased predisposition to atherosclerosis mediated by these associated risk factors. However, identifying metabolic syndrome itself has no unique implications for clinical management: this should focus on the management of the obesity (hence insulin resistance) and the individual cardiovascular risk factors. Some workers specifically exclude obese subjects from this syndrome, but there are many features in common between slim subjects with the metabolic syndrome and those who are obese.

The natural history of type 2 diabetes usually involves an evolution from normal glucose tolerance through impaired glucose tolerance (usually accompanied by other features of insulin resistance syndromes) to the onset of frank diabetes, followed by a continuing β -Cell failure leading to the need for exogenous insulin (Fig. 15.5). Obesity, low physical fitness or other hereditary factors can all hasten this evolution.

The morphological associations of type 2 diabetes mellitus include shorter stature (by 1–4 cm compared with non-diabetic subjects), with obesity of the android type (also known as 'apple', upper body, central or visceral obesity) marked by a high waist:hip ratio, low capillary density in skeletal muscle and high ratios of slow to fast twitch muscle fibres. Insulin resistance is a prominent feature of obesity, especially of the android type, even in the absence of diabetes, and obesity powerfully identifies individuals within a population at greatest risk of developing type 2 diabetes. Compensatory hyperinsulinaemia is marked in obesity and contributes to the associated dyslipidaemia and probably to the hypertension.

FIGURE 15.5 ■ The natural history of type 2 diabetes. (From DeFronzo et al. *Diabetes Care* 1992; 15:318, with permission).

Hypertension. The association between diabetes and hypertension has been long recognized and is strong. The prevalence of hypertension in obese patients with type 2 diabetes approaches 50% in some series. The typical body habitus of patients with type 2 diabetes is associated with hypertension even in non-diabetic subjects. Although diabetic patients are liable to develop the same secondary forms of hypertension as the non-diabetic population (and renal artery stenosis is commoner in diabetes), most diabetic hypertensive patients have a low renin hypertension that is unlike that in non-diabetic patients with essential hypertension.

Patients with either type 1 or type 2 diabetes and hypertension and characteristically have sodium retention and impaired natriuresis: exchangeable body sodium is increased by an average of 10%. This abnormality is seen even before the development of any clinically detectable complications of diabetes. Possible sodium-retaining mechanisms include hyperinsulinaemia induced overactivity of tubular sodium transporters, increased glomerular filtration of glucose leading to enhanced proximal tubular sodium–glucose cotransport, extravascular shift of fluid with sodium and, in later stages, renal impairment. Plasma renin activity, angiotensin II, aldosterone and catecholamine concentrations are usually normal in glycaemically well-controlled type 1 and type 2 patients. On the other hand, plasma natriuretic peptide concentrations are usually increased, and an exaggerated vascular reactivity to noradrenaline (norepinephrine) and angiotensin II is common even in uncomplicated types 1 and 2 diabetes.

In type 1 diabetes, hypertension is strongly linked with the development of diabetic nephropathy. Although it is uncertain whether this is initially cause or effect, it becomes a vicious circle. There appear to be familial effects, with non-diabetic relatives of diabetic nephropathic hypertensive patients showing defects in ion transport function (erythrocyte Na^+/Li^+ counter transport and leukocyte Na^+/H^+ antiport) and an increased liability to develop essential hypertension.

Data from the UKPDS confirm the clinical impression that hypertension in type 2 diabetes is often refractory to treatment. Typically, a combination of three antihypertensive agents was required to maintain good

control of blood pressure. Furthermore, the same study showed that even a modest reduction in blood pressure reduced the incidence of nephropathy and death. The relationship between blood pressure and the development and progression of diabetic nephropathy was particularly striking.

Dyslipidaemia. Diabetes is strongly associated with abnormalities of lipid metabolism. Several mechanisms are postulated for these associations. The obesity and body fat distribution common in type 2 diabetes is itself linked with dyslipidaemias in non-diabetic subjects. Non-enzymatic glycation of apolipoproteins impairs lipoprotein clearance. Insulin is the principal antilipolytic regulator, through its inhibition of hormone-sensitive lipase. This enzyme breaks down adipose tissue triglyceride and consequently mobilizes fat stores for subsequent utilization. As a result of its regulation by insulin, hormone-sensitive lipase is most active in the fasting state and least so upon feeding. In diabetes, insulin-mediated inhibition is attenuated or lost, so breakdown of fat stores carries on even if food is available. The uncontrolled release of free fatty acids is followed by their uptake by the liver in a simple concentration-dependent manner.

Free fatty acids are metabolized by β -oxidation, but once their concentration exceeds capacity for oxidation they are re-esterified with glycerol to form triacylglycerol (triglyceride) which leads to increased rate of synthesis (and thereby release) of triglyceride-rich very low density lipoprotein (VLDL). Peripheral VLDL-triglyceride clearance may be impaired because insulin is needed to synthesize and secrete lipoprotein lipase, the principal enzyme responsible for clearing VLDL-triglyceride.

Type 2 diabetes mellitus is associated with low plasma concentrations of high density lipoprotein (HDL), which, by acting as an antioxidant, may limit the lipid peroxidation that is one of the factors responsible for atheroma formation. This may contribute to increased cardiovascular risk in diabetes, but high VLDL-cholesterol and elevated triglyceride concentrations may also contribute. Total plasma cholesterol concentration is often normal in type 2 diabetes, but the HDL:LDL and HDL:total cholesterol ratios are usually low. The composition of VLDL changes such that it contains more triglyceride and cholesteryl esters relative to the apoprotein content. The size distribution of LDL changes towards smaller, denser particles. These abnormalities are particularly atherogenic and underline the need to consider the whole lipid profile rather than just total or LDL-cholesterol in the dyslipidaemia of type 2 diabetes. Improved glycaemic control only partly improves these lipid abnormalities.

In type 1 diabetes, poor glycaemic control is typically associated with high plasma concentrations of VLDL-cholesterol, LDL-cholesterol and triglycerides, and sometimes with low HDL-cholesterol. The triglyceride concentration falls in response to improved glycaemic control and the abnormalities of VLDL and LDL usually also improve. In contrast to patients with type 2 diabetes, those with well-controlled type 1 diabetes usually

achieve plasma lipid concentrations similar to those seen in non-diabetic groups; HDL concentrations may even be elevated.

Lipotoxicity and glucotoxicity

Lipotoxicity. Although adipose tissue is now known to have a large number of important functions, related, for example, to thermo-insulation, immunity, fertility and protection of tissues such as the eye in the orbit, its main function is the storage of energy in the form of triglycerides in the postprandial state and the subsequent release of lipid in the form of NEFA in the fasting state. The consequences of accumulation of lipids in lean tissues, as observed in fatless rodents and humans with generalized lipodystrophy, include hepatic steatosis, lipid-induced cardiomyopathy, insulin resistance and type 2 diabetes mellitus. This process is termed lipotoxicity (lipoapoptosis, where programmed cell death occurs) and is reversible in fatless rodents by the transplantation of small amounts of normal adipose tissue, but not by transplantation of adipose tissue from *ob/ob* mice, which lack the ability to secrete leptin. In humans with generalized lipodystrophy, long-term treatment with leptin improves insulin resistance, hyperlipidaemia and hepatic steatosis dramatically.

Non-esterified fatty acids can induce insulin resistance in muscle via at least three putative mechanisms: through the glucose-fatty acid cycle, whereby increased intracellular citrate derived from fat leads to diversion of glucose away from the tricarboxylic acid; through an effect of intermediates such as diacylglycerol that increase the activity of protein kinase C activity, thereby phosphorylating and inactivating the insulin receptor and insulin receptor substrate (IRS)-1, and via activation of the NF κ B transcription factor pathway, which has putative vascular effects that might contribute to the observed increase in vascular damage that precedes hyperglycaemia. In the liver, NEFAs inhibit the suppression of glycogenolysis by insulin. Other mechanisms include modulation of adipokines, such as tumour necrosis factor α (TNF α), which could promote insulin resistance, or adiponectin, which reduces it. The question then arises of why it is that so many individuals with obesity and elevated plasma concentrations of NEFA do not develop diabetes. One explanation for this may lie in the fact that NEFAs are potent stimulators of insulin secretion in healthy individuals, an effect that might mitigate the tendency for NEFAs to induce insulin resistance. However, both in subjects with type 2 diabetes and their normoglycaemic first-degree relatives, NEFAs do not induce a sufficient compensatory rise in insulin secretion to overcome the induced insulin resistance. Thus NEFAs may be able to cause diabetes in those with a genetic predisposition to β -Cell dysfunction but not in those with normal β -Cell reserve. Activators of PPAR γ (see p. 315) may alleviate several of these NEFA-induced abnormalities by reducing plasma NEFA concentrations, increasing adiponectin and redistributing fat from visceral to subcutaneous deposits, thus reducing the direct effects on the liver and elsewhere. Lipotoxicity may also contribute to β -Cell dysfunction – accumulation of lipid droplets has been observed in the islets in rodent

models of obesity and diabetes, and these may both interfere with insulin secretion and promote an inflammatory response leading to β -Cell destruction.

Glucotoxicity. It has long been known that acute elevation of plasma glucose concentrations to very high levels is able to induce a state of insulin resistance characterized by impairment of insulin secretion in response to glucose. Elevation of plasma glucose to concentrations just above the physiological range potentiates insulin secretion in both humans and animals when transient and in the presence of a normal β -Cell mass, but reduces it otherwise. Conversely, strict metabolic control is able to induce improvements in both insulin secretion and sensitivity, although not usually to normality. It is likely that multiple mechanisms contribute to this effect, including changes in the K_m of glucose sensing systems such as glucokinase/hexokinase, which may lead to alteration of the dose-response curve of islet cells to blood glucose concentrations, changes in the ratios of proinsulin to insulin secretion and alteration in the functional activity of the membrane sulfonylurea-sensitive K^+ channel. It is likely that the honeymoon period often observed in new onset type 1 diabetes is at least partly attributable to a reduction in glucotoxicity.

Prevention studies in type 2 diabetes

Type 2 diabetes may be prevented, or at least its onset delayed, by relatively modest degrees of weight loss. In four intervention studies, conducted in the USA, Finland, China and India in patients with impaired glucose tolerance, lifestyle interventions resulting in average weight loss of <7 kg over six months, with some later regain, resulted in up to 58% reduction in the cumulative incidence of diabetes in the intervention groups over periods of up to four years. Other studies have shown that adopting a more physically active lifestyle appears to confer useful protection, independently of body weight. For patients unable to lose weight after appropriate lifestyle interventions, treatment with metformin may bring about a modest reduction in the incidence of type 2 diabetes. Other diabetes treatments, including acarbose, thiazolidinediones and the weight loss drug orlistat also reduce progression to diabetes in those a greatest risk.

The role of bariatric surgery in managing type 2 diabetes

Weight loss is the cornerstone of the management of overweight and obese subjects with type 2 diabetes. Increasingly, patients are being considered for bariatric surgery after other methods of weight control have proved fruitless. Whereas the time course and degree of improvement in diabetes are more or less in line with predictions based on the degree of postoperative weight loss resulting from operations that physically limit food intake, such as laparoscopic gastric banding, the effects of gastric and intestinal bypass procedures appear to be quite different. Not only have improvements in glycaemia been reported well before weight loss becomes

apparent, but they appear also to exceed those expected on the basis of the amount of weight lost. It has been proposed that increased secretion of a number of gut peptides with insulinotropic actions such as glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP), and decreased secretion of orexigenic peptides such as ghrelin may be responsible for the success of bypass techniques, raising the intriguing possibility that operations of this kind have a partly endocrine mechanism of action. Many studies have purported to show 'cure' of diabetes, often associated with restoration of first-phase insulin response, in up to 80% of subjects for as long as 16 years of follow-up. However, more recent prospective studies suggest that the true rate of remission of type 2 diabetes after bariatric surgery is closer to 40%, with those patients with shorter duration of diabetes, and lower requirements for glucose-lowering drugs most likely to remain free of the need for treatment for many years. Long-term studies comparing surgery with optimal medical treatment are really needed to resolve the question as to whether surgery is a better treatment.

Gestational diabetes mellitus

The study of diabetes occurring in association with pregnancy has been characterized (and hampered) by the local adoption of many different criteria for the diagnosis of gestational diabetes, coupled with different recommendations for screening. Such local diversity is probably a consequence of different levels of provision of care for pregnant women, and the balance between the unnecessary labelling of a pregnancy as 'abnormal' or 'high risk' and the avoidance of preventable risk to mother and fetus.

Gestational diabetes mellitus (GDM) was defined by Lowy as glucose intolerance that presents in pregnancy. However, it must be appreciated that this will group together a number of conditions that are associated with a variety of qualitative and quantitative threats to the pregnancy. The offspring of women who have undiagnosed pre-existing type 2 diabetes discovered during pregnancy will, for example, have been exposed to hyperglycaemia and other metabolic abnormalities in the first trimester of pregnancy during which organogenesis occurs. They will therefore be subject to the increased risk of fetal malformation seen in pre-existing diabetes despite the diabetes being labelled 'gestational'. When the glucose intolerance is induced by the pregnancy itself, its onset is typically in the late second or early third trimester, and the risks of major fetal malformations are therefore similar to those in the non-diabetic population.

The reported incidence of GDM varies enormously between populations, not least because of local differences in screening procedures and definition. The recommendations of the UK National Institute for Health and Care Excellence (NICE) for screening and diagnosis of diabetes during pregnancy are shown in [Box 15.5](#).

Glycaemic control during pregnancy should be strictly optimized in order to minimize fetal mortality and morbidity. In patients with type 1 diabetes who are attempting to conceive, similarly strict glycaemic control

BOX 15.5 Recommendations for screening for and diagnosis of gestational diabetes mellitus in accordance with UK NICE guidelines

- Women with one or more of the following risk factors for gestational diabetes should be offered testing for gestational diabetes mellitus
 - Body mass index $>30\text{ kg/m}^2$
 - Previous macrosomic baby weighing $>4.5\text{ kg}$
 - Previous gestational diabetes
 - Family history of diabetes (first-degree relative with diabetes)
 - Family origin with a high prevalence of diabetes:
 - South Asian (India, Pakistan or Bangladesh)
 - African Caribbean
 - Middle Eastern
- Screening for gestational diabetes using fasting plasma glucose, random blood glucose, glucose challenge test and urinalysis for glucose should not be undertaken
- The 2-h 75 g oral glucose tolerance test (OGTT) should be used to test for gestational diabetes and diagnosis made using the criteria defined by the WHO
 - Fasting plasma venous glucose concentration $\geq 7.0\text{ mmol/L}$
- or*
- 2-h plasma venous glucose concentration $\geq 7.8\text{ mmol/L}$
- Women who have had gestational diabetes in a previous pregnancy should be offered early self-monitoring of blood glucose or an OGTT at 16–18 weeks, and a further OGTT at 28 weeks if the results are normal
- Women with any of the other risk factors for gestational diabetes should be offered an OGTT at 24–28 weeks

(together with folic acid supplements) is believed to reduce the incidence of congenital malformations. One large UK study showed, in an unselected population, that the infants of women with type 1 diabetes have a ten-fold greater risk of a congenital malformation and a five-fold greater risk of being stillborn than those from a representative general population. These effects are reduced but not abolished by pre-pregnancy counselling, the use of folic acid and tight glycaemic control prior to conception and throughout pregnancy. Local targets for glycaemic control vary, but most would agree that, at the least, all overnight fasting and preprandial blood glucose concentrations should be $<7\text{ mmol/L}$ during pregnancy. In practice, many adopt targets for overnight fasting concentrations of $<5.9\text{ mmol/L}$ and 1 h postprandial glucose concentrations of $<7.8\text{ mmol/L}$, in both pre-existing diabetes and gestational diabetes. Although the use of oral hypoglycaemic agents appears to be safe, they are at present not licensed for use in pregnancy, although they are recommended by many guidelines (including NICE in the UK), on the basis of a published evidence base supporting the use of both metformin and glibenclamide in pregnancy. Glibenclamide does not appear to cross the placental barrier and thus does not cause neonatal hypoglycaemia, but may cause maternal hypoglycaemia, so should be used with caution.

Despite the above, insulin treatment remains the gold standard in all forms of gestational diabetes, despite the fact that, at the time of writing, no insulin is licensed for such use. As with diabetes not associated with pregnancy, many regimens have been used with success and there is no single recommended regimen. However, the predominantly postprandial nature of the glycaemic derangements in GDM lend themselves to treatment with short-acting insulins at meal times, supplemented if necessary with a long-acting insulin, and such regimens usually prove satisfactory.

In patients with pre-existing diabetes, particularly where complicated by microvascular disease, retinopathy and neuropathy may advance rapidly during pregnancy, and screening by fundoscopy and for microalbuminuria in each trimester is probably warranted. Angiotensin-converting-enzyme inhibitors are teratogenic and should be discontinued during pregnancy.

The timing and mode of obstetric delivery merits consideration in pregnancies complicated by diabetes. Again, there is a lack of clear evidence, but many would advocate intervention at around 38 weeks in cases where diabetes was present prior to pregnancy, to reduce the risk of late placental failure; this occurs in approximately 1–2% of pregnancies, presenting with sudden and apparently unexpected late intrauterine fetal death (sometimes manifest by a sudden improvement in glycaemic control).

Gestational diabetes or delivery of a large-for-dates or macrosomic baby is strongly predictive of subsequent type 2 diabetes, and many recommend screening such women for type 2 diabetes mellitus six weeks after delivery, and periodically (every 1–2 years) thereafter.

Maturity onset diabetes of the young (MODY)

This syndrome is a rare ($<5\%$ of childhood diabetes and $<1\%$ of all type 2 diabetes) form of type 2 diabetes, inherited in an autosomal dominant fashion and typically presenting at a young age. It is sometimes known as 'Mason-type' diabetes after the index family. Strict diagnostic criteria for the condition include a diagnosis of type 2 diabetes (with preservation of C-peptide response) with onset before the age of 25 years in at least two family members, with evidence of vertical transmission through at least three generations. In clinical practice, it may not always be possible to ensure that all these criteria are met. Thus, many patients with a probable diagnosis of MODY will not fulfil the criteria by virtue of later age of onset (at least 25% present later than 25 years of age), the occurrence of new mutations and incomplete family histories.

All the six known MODY subtypes are characterized by defects in insulin secretion rather than in insulin action, although, in some, a degree of insulin resistance may supervene, probably as a result of glucotoxicity. They have been characterized as being due to mutations in genes encoding glucokinase (MODY 2) or a range of transcription factors that result in defects in insulin secretion. In patients with MODY1, abnormalities in hepatocyte nuclear factor 4a (HNF-4A) result in impaired or absent first-phase insulin

secretion, reduced peaks of insulin secretion, hyperglycaemia, a degree of secondary insulin resistance reversible by good metabolic control and fully susceptibility to the complications of diabetes expected for the degree of exposure to hyperglycaemia. In contrast, patients with MODY 2 have mild fasting hyperglycaemia, as a result of the defect in glucose sensing that correlates with the degree of functional inactivation of the enzyme. MODY 2 is associated with low risk of microvascular complications of diabetes and thus often does not require treatment. The condition often only comes to light as a chance finding. These patients are characteristically highly sensitive to sulfonylurea treatment, if used. As predicted by the actions of glucokinase in the liver, hepatic glycogen production is reduced and gluconeogenesis increased in the postabsorptive state in this condition.

Mutations in the *HNF-1A* gene that encodes hepatocyte nuclear factor 1a (HNF-1A) (MODY 3) account for up to two-thirds of all MODY diagnoses. This condition has a variable age of onset, and progressive β -Cell dysfunction that leads to potentially severe hyperglycaemia and similar microvascular complications to those encountered in type 2 diabetes. Abnormal HNF-1A function in the proximal renal tubules may lead to incomplete reabsorption of glucose, phosphate and amino acids, but nephropathy appears no more common than would be expected for the degree and duration of hyperglycaemia. These patients are characteristically highly sensitive to sulfonylurea treatment, and there are several cases reported where patients have been misdiagnosed as type 1 diabetes, treated with insulin (sometimes for many years) but later transferred safely to sulfonylurea treatment. MODY 4 results from abnormalities of IPF-1, which plays a role in pancreatic development: patients may present with varying degrees of hyperglycaemia at variable ages of onset. MODY 5 is caused by defects in HNF-1B, which plays a role in renal development as well as β -Cell function. It is characterized by renal cyst formation (which may lead to chronic kidney disease) and variable degrees of hyperglycaemia. MODY 6 is associated with abnormalities of NeuroD1, which plays a role in pancreatic development.

Clinicians need to be aware of the possibility of MODY in patients with a strong family history of early onset type 2 diabetes, and consider genetic testing. Other tests are also being developed, for example low plasma concentrations of C-reactive protein (measured with a highly sensitive assay) can be highly predictive of MODY 3 and may eventually be incorporated into diagnostic algorithms.

Secondary diabetes

Several diseases may cause diabetes or glucose intolerance. Most of these are readily diagnosed, perhaps with haemochromatosis and chronic pancreatitis being the least readily apparent. Clinical concern is frequently raised about Cushing syndrome when an obese subject presents with glucose intolerance, and a number of studies have suggested that up to 4% of patients with type 2 diabetes are in fact suffering from Cushing syndrome. Pseudo-Cushing syndrome, either idiopathic or related to alcohol excess, is a more common association.

Tropical diabetes. Fibrocalcific pancreatic diabetes is a form of secondary diabetes that occurs in the tropical developing countries. The condition has typical clinical features, pancreatic calcification being characteristic, but its aetiology has not been established. There was previously considered to be another form of tropical diabetes termed protein-deficient pancreatic, or J-type, diabetes, but this is not included in current classifications.

Alcohol-related and pancreatic causes of diabetes.

Chronic pancreatitis accounts for <1% of all diabetes in the developed world. Alcohol is the usual cause. Most patients give a history of long-term (>5 years) excessive alcohol consumption with recurrent episodes of mild abdominal pain. Hospitalization during these episodes of pancreatitis is unusual. There may or may not be pancreatic calcification, but sclerosis of islets occurs. Insulin secretion is reduced, causing diabetes, but patients are highly sensitive to exogenous insulin therapy (perhaps because glucagon secretion is also reduced). Chronic heavy alcohol consumption may also induce severe exocrine pancreatic failure and, consequently, steatorrhoea. Pancreatic resection, for example for cancer, is a rare cause of diabetes.

Acute pancreatitis is associated with transient glucose intolerance resulting from reduced insulin secretion and the insulin resistance of systemic illness. Acute haemorrhagic pancreatitis occasionally produces such damage to the pancreas that permanent diabetes mellitus results.

Mild (subclinical) abnormalities of exocrine pancreatic function and reductions in pancreatic lipase and immunoreactive trypsin are seen in 20–70% of diabetic patients. The cause for these abnormalities is not established, although the pancreas is smaller in patients with diabetes (especially type 1 diabetes). Changes in insulin secretion, glucagon secretion and autonomic neural function may also play a role in exocrine pancreatic dysfunction.

Haemochromatosis. Iron storage disease, whether owing to familial defects or repeated iron infusion, results in liver damage that may progress to cirrhosis (see Chapter 14) and β -Cell damage, as well as damage to other endocrine and non-endocrine tissues (e.g. cardiac muscle). Diabetes is a common result of such problems. Glucose tolerance improves with treatment of the iron overload, but the more severe the damage, the lower the probability of recovery with treatment. Screening diabetic clinic populations typically reveals 0.1–0.5% of type 2 diabetes mellitus to be associated with undiagnosed iron storage disorders. However, modestly elevated concentrations of ferritin are commonly associated with type 2 diabetes, particularly at the time of diagnosis, and do not of themselves necessarily suggest the diagnosis of haemochromatosis.

Endocrine disorders. In many of the conditions mentioned in this section, insulin resistance occurs but, in most subjects, β -Cell reserve is sufficient to produce compensatory hyperinsulinaemia so that, although there is mild glucose intolerance, full-blown diabetes mellitus

is unusual. The unrecognized development of an endocrine condition in a known diabetic patient may present as worsening glycaemic control or recurrent ketoacidosis. It is more common for endocrine disease to exacerbate or unmask pre-existing glucose intolerance rather than for it to be the sole cause of diabetes.

Polycystic ovary syndrome is a common condition, associated with obesity, insulin resistance and glucose intolerance or frank type 2 diabetes (see below and Chapter 22).

Active thyrotoxicosis is associated with glucose intolerance in 30–50% of patients, but this rarely extends to frank diabetes. The mechanism causing this may vary between patients. Hepatic glucose production is often increased; increased gastrointestinal motility may exaggerate postprandial hyperglycaemia; insulin clearance is increased, and hypersensitivity of β -adrenoreceptors may mediate the elevated NEFA concentrations found in hyperthyroidism.

The increased incidence of impaired glucose tolerance in patients with hypothyroidism is well established, although the mechanism for it is uncertain.

Hyperprolactinaemia causes insulin resistance and glucose intolerance, which is reversed by treating the primary condition; symptomatic diabetes is rare.

The hypercortisolaemia of Cushing syndrome, whatever the cause, results in increased hepatic gluconeogenesis and hepatic glucose output while skeletal muscle becomes insulin resistant. Glucocorticoids increase lipolysis and protein catabolism, increasing the circulating concentrations of alternative fuels and reducing glucose clearance. Glucose intolerance is found in 80–90% and frank diabetes in 15–20% of patients with Cushing syndrome. Treatment with glucocorticoids is a common cause of secondary diabetes.

Conn syndrome was originally described as including glucose intolerance. However, this is usually mild and only a small minority of patients has even moderate glucose intolerance. The cause is thought to be impaired insulin secretion owing to severe potassium depletion.

Growth hormone is a counter-regulatory hormone. Acromegaly frequently causes glucose intolerance (seen in 60–70% of cases) and even symptomatic diabetes (in 6–25%). Successful treatment of acromegaly usually improves glucose tolerance. Isolated growth hormone deficiency is also associated with glucose intolerance, probably as a result of the insulin resistance that results from the decrease in lean body mass and the increase in abdominal fat and a blunted insulin response to glucose. Diabetic microvascular disease is rare in this group.

Phaeochromocytoma is associated with multiple abnormalities of glucoregulation, adrenaline (epinephrine) having a greater hyperglycaemic effect than noradrenaline (norepinephrine). Catecholamines stimulate hepatic glycogenolysis and hepatic glucose output, and inhibit insulin secretion via α -receptors; β -receptor effects include promotion of adipose tissue lipolysis, increased skeletal muscle glycogenolysis and reduced skeletal muscle glucose uptake. Both α - and β -receptors augment glucagon secretion. Improvement of glucose tolerance occurs within a few weeks of successful surgical resection.

Hypercalcaemia and hypophosphataemia, as seen in primary hyperparathyroidism, reduce peripheral insulin sensitivity, probably through effects on intracellular second messenger systems and glucose uptake, and are associated with hyperinsulinaemia, although glucose tolerance is rarely impaired.

Gastrointestinal endocrine tumours of several types are associated with glucose intolerance. Glucose intolerance is a cardinal feature in patients with glucagonomas. Zollinger–Ellison (gastrinoma) syndrome; Verner–Morrison or watery diarrhoea hypokalaemia, achlorhydria (WDHA or VIPoma) syndrome; carcinoid syndrome; polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes (POEMS) syndrome and somatostatinoma, all have glucose intolerance as a frequent, and often florid, feature.

Autoimmune hypoadrenalism is associated with type 1 diabetes mellitus but not causative: indeed, adrenal failure is a cause of hypoglycaemia.

Iatrogenic diabetes. Treatment with steroids is the most common form of iatrogenic diabetes. Some frequently used drugs, including thiazides and β -blockers, especially in combination, may worsen glucose tolerance, their effects being most clinically relevant in diabetic patients. Other drugs may cause diabetes via effects on lipid metabolism (e.g. protease inhibitors), via weight gain or through mechanisms that are not fully understood (e.g. atypical antipsychotic agents).

Rare conditions associated with glucose intolerance. Several congenital conditions with varying degrees of impairment of glucose intolerance are listed in [Table 15.7](#). In most of these conditions, the diabetes is not the most pressing clinical problem.

Severe insulin resistance. Most of the endocrine causes of glucose intolerance are the result of circulating insulin antagonists causing insulin resistance. A variety of other medical conditions, although rare, may be associated with severe resistance to insulin.

Acanthosis nigricans is characterized by the presence of velvety brown hyperkeratotic lesions on the neck, axillae and groins. There is a well-recognized, but relatively rare association with malignancy. Acanthosis nigricans not associated with malignancy may be classified into two types, both associated with insulin resistance and obesity. Type A is a variant of polycystic ovarian syndrome where the skin changes are marked; additional features include hirsutism, polycystic ovaries, virilization, coarse features and early accelerated growth. The cause of the insulin resistance in this type has not yet been determined. Several factors may be involved: reductions in insulin binding, receptor number and receptor kinase activity, and post receptor defects have each been reported in some patients. Patients with type B acanthosis nigricans tend to be older and are usually female. They have markers of autoimmune disease including hypergammaglobulinaemia, proteinuria, hypocomplementaemic nephritis, leucopenia, arthralgia, alopecia, enlarged salivary glands and positive antinuclear and anti-DNA antibodies. They have reduced insulin binding to monocytes *in vitro*, owing to

TABLE 15.7 Congenital conditions with associated glucose intolerance

Condition	Main features
Klinefelter syndrome	Skeletal, gonadal (infertility)
Turner syndrome	Skeletal, gonadal (infertility)
Down syndrome	Neurological
Friedreich ataxia	Neurological
Ataxia telangiectasia	Neurological
Dystrophia myotonica	Neurological
Huntington chorea	Neurological
DIDMOAD	Diabetes insipidus, diabetes mellitus, optic atrophy and deafness
Refsum disease	Neurological
Alstrom syndrome	Neurological
Laurence-Biedl-Moon syndrome	Neurological, obesity
Prader-Willi syndrome	Neurological, obesity
Cystic fibrosis	Respiratory, pancreatic (malabsorption)
Werner syndrome	Growth retardation, premature senility
Fetal rubella syndrome	Neurological, cardiac
Lipodystrophy (various forms)	Metabolic, renal, vascular, hepatic
Glycogen storage disorders	Hepatic/myopathic

the presence of an autoantibody against the insulin receptor. Ataxia telangiectasia may show some overlap with the features of type B acanthosis nigricans.

Leprechaunism is a rare congenital condition with typical facies, lipodystrophy, cliteromegaly, hirsutism and acanthosis nigricans. It is usually fatal. Affected children are severely resistant to exogenous insulin. They produce large amounts of normal insulin endogenously. Several cellular defects have been described that produce the phenotype of leprechaunism. Most patients have defective kinase activity of the insulin receptor, although some show defective insulin receptor formation and others are unable to recycle insulin receptors back to cell membranes after insulin binding. The common features of acanthosis nigricans and virilism are probably an effect of stimulation of IGF receptors by high concentrations of insulin.

Lipodystrophy occurs in local and generalized forms; it is usually familial. There are several associated features but these vary from family to family. Acanthosis nigricans, hepatosplenomegaly, nephritis and hyperlipoproteinaemia have all been reported. Likewise, the cellular defect varies, with some families having reduced insulin binding and some having reduced receptor numbers. Lipodystrophy is also frequently seen as a complication of treatment of acquired immune deficiency syndrome (AIDS), particularly with protease inhibitors. This may be severe enough not only to be disfiguring, but also to cause severe hyperlipidaemia and diabetes mellitus. There is something of a paradox in the fact that type 2 diabetes is associated with increased visceral fat depots but also with lipodystrophy. This is probably explained by the role that adipose tissue has in storing fatty acids as triglycerides. In conditions where this process is impaired,

circulating concentrations of NEFA are increased and may affect hepatic insulin sensitivity in much the same way that they do when there is excess visceral adipose tissue accumulation in obesity.

Anti-insulin antibodies. A previously common form of insulin resistance was iatrogenic, owing to the induction of anti-insulin antibodies (also known as insulin antibodies) by the use of exogenous pork or beef insulins for the treatment of diabetes. Treatment with human insulin *ab initio* results in very few (if any) patients developing such antibodies. Anti-insulin antibodies bind exogenous insulin, reducing its plasma concentration and action. Clinically, the presence of significant anti-insulin antibodies manifests as either a high insulin requirement for the achievement of glycaemic control or with altered insulin kinetics (usually delayed insulin action). The antibodies may be detected by a variety of assays. Treatment is usually by changing to insulin analogues, human or (very rarely) sulfated animal insulins.

Insulin-binding autoantibodies are also seen as a result of autoimmune disease or haematological malignancy and may cause profound insulin resistance, although ketosis rarely occurs as the binding of insulin to IGF receptors is not affected and appears to allow sufficient suppression of lipolysis to prevent excess ketogenesis. These autoantibodies may be an indication for steroid therapy, although high doses of exogenous insulin may be satisfactory.

Cirrhosis. Glucose intolerance occurs in most, and fasting hyperglycaemia in 30% of patients with cirrhosis, unless the latter is due to idiopathic haemochromatosis, when diabetes is common. There are multiple gluco-regulatory defects in cirrhosis including insulin resistance, hyperinsulinaemia, impaired insulin clearance, elevated growth hormone concentrations and hyperglucagonaemia. However, in clinical practice, hypoglycaemia resulting from reduced storage, synthesis and mobilization of glucose typically dominates the clinical picture in a patient with advanced hepatic cirrhosis.

ENDOCRINE ASSOCIATIONS WITH DIABETES

Several endocrine conditions occur with increased frequency among diabetic populations. Endocrine conditions that cause secondary diabetes have been discussed above.

Abnormalities of glucagon secretion appear to be a consequence of diabetes. In normal subjects, insulin inhibits glucagon release and glucagon concentrations fall during hyperglycaemia. Hyperglucagonaemia is usual in both types 1 and 2 diabetes, and glucagon concentrations in diabetic patients are relatively insensitive to changes in glucose concentrations. The mechanisms for this are unknown but may relate to de-repression of glucagon release by the insulin deficiency of diabetes. In longstanding type 1 diabetes, the glucagon response to hypoglycaemia may be lost, which may contribute to poor recovery from hypoglycaemia.

Some other endocrine disorders show an association with diabetes, but the link is shared susceptibility rather

than causal; these include autoimmune hypoadrenalism, Graves and Hashimoto diseases. The development of thyrotoxicosis owing to Graves disease in a patient with diabetes may underlie subsequent loss of diabetic control and weight loss. The prevalence of primary hypothyroidism is reported to be 4–17% in type 1 diabetes.

Type 1 diabetes is statistically associated with coeliac disease (up to 6% of patients may be affected), and both are related to HLA-DR4. Guidelines recommend screening for coeliac disease in patients with type 1 diabetes. The combined dietetic requirements of the two conditions may be onerous for patients. The diarrhoea of unrecognized coeliac disease may be mistaken for diabetic diarrhoea, and coeliac disease should be considered as a cause of newly developing hypoglycaemia in a patient whose glycaemic control was previously poor.

DIABETES, NUTRITION AND GROWTH

In well-nourished children with well-controlled type 1 diabetes, skeletal growth is normal. Poor glycaemic control is associated with elevated growth hormone concentrations but reduced IGF concentrations and is thus a growth hormone-resistant state. It is thought that the latter is related to the reduced growth velocity seen in uncontrolled diabetes.

As a group, patients who develop diabetes as children tend to be more centrally obese than their non-diabetic siblings. It is not yet clear whether this problem is lessened by better glycaemic control.

It is important to appreciate that children with diabetes need a diet that permits healthy growth as well as maintaining good glycaemic control.

MECHANISMS OF DIABETIC TISSUE DAMAGE

Introduction

Both types 1 and 2 diabetes are associated with various long-term complications, also known as diabetic tissue damage. The acute metabolic complications of diabetes are discussed in Chapter 16. Diabetic tissue damage includes a range of 'microvascular complications' (e.g. retinopathy and nephropathy), 'macrovascular complications' (ischaemic heart disease, peripheral vascular disease, stroke and renal artery stenosis) and some complications that do not fit entirely into either category (e.g. glove and stocking peripheral neuropathy, mononeuritis multiplex, cranial neuropathies, entrapment neuropathies, proximal motor neuropathies, autonomic neuropathy, various sorts of cataract and diabetic cheiroarthropathy). Diabetic subjects have a reduced life expectancy and macrovascular disease is, in most cases, the major determinant of this.

Few organs or tissues are exempt from potential damage in diabetes; approximately half of those diagnosed with type 2 diabetes have evidence of tissue damage at diagnosis. However, only relatively few cell types are known to be vulnerable to direct damage from chronic hyperglycaemia, for example the mesangial cells of the

kidney, vascular endothelial cells, pancreatic β -Cells, Schwann cells and neurons. Many other cells appear to be able to reduce glucose uptake under conditions of extracellular hyperglycaemia and, perhaps for this reason, are relatively resistant to direct hyperglycaemic damage.

The two main clinical subtypes of diabetic tissue damage, macrovascular and microvascular disease, are differentially affected by the cumulative effect of hyperglycaemia. It has been proposed that microvascular tissue damage is the result of hyperglycaemia per se, even if accelerated by other factors. Macrovascular complications are frequently found in epidemiological studies to be associated with insulin-resistant states and hyperinsulinaemia, and their relationship to hyperglycaemia is less clearly established. Data derived from the UK Prospective Diabetes Study (UKPDS) suggest that the risk of microvascular disease increases approximately ten-fold with an increase in HbA_{1c} from 37 to 80 mmol/mol (5.5–9.5%), whereas the risk of macrovascular disease becomes apparent at values of HbA_{1c} below that typically associated with diabetes but increases only by a factor of about two-fold with the same increase in HbA_{1c}.

Pathogenesis

The pathogenetic mechanisms involved are ill understood and, for even the major forms of diabetic tissue damage, it is not easy to determine the role of purely diabetic abnormalities (e.g. hyperglycaemia per se and hypo- or hyperinsulinaemia) as opposed to abnormalities related to diabetes (e.g. hypertension, dyslipidaemia or obesity).

The first cellular mechanism to underlie purely hyperglycaemic tissue damage to be described was increased activation of the polyol pathway. The enzyme aldose reductase, usually involved in the reduction of toxic aldehydes to their respective alcohols, is diverted under conditions of intracellular hyperglycaemia to reducing excess glucose to sorbitol, which is later oxidized to fructose. This process consumes the cofactor NADPH, which is then not available for the regeneration of reduced glutathione, thus rendering cells vulnerable to the effects of oxidative stress. Sorbitol accumulation in the lens may cause cataracts, and has been demonstrated in biopsies from diabetic subjects to occur in the eye, peripheral nerves and renal glomeruli. Unfortunately, trials of aldose reductase inhibitors have conferred only marginal reduction in the progression of neuropathy in people with diabetes. This is either because the pathway is not important, is one of several mechanisms of diabetic tissue damage or is a downstream process whose correction would not be expected fundamentally to alter cellular responses to hyperglycaemia. As a result, these agents are not presently used in routine clinical practice.

The next mechanism to be proposed was mediated by the slow accumulation over time of advanced glycation end products (AGEs), which are irreversibly formed by the non-enzymatic glycation of matrix, cellular and plasma proteins. Glucose and amino acids combine to form unstable Schiff base adducts, which undergo chemical rearrangement over time to form Amadori products and, eventually, AGEs that are chemically stable, irreversibly attached to proteins and able to trap other protein elements by covalent binding

and promotion of cross linking. Advanced glycation end products are thought to cause tissue damage by alterations in the structure and function of the extracellular matrix with accumulation of PAS-positive material (e.g. in the basement membrane of blood vessels), by activation of inflammatory cytokines and growth factors via stimulation of AGE receptors (in part by the NF κ B pathway) and by alteration of cellular genetic material. These changes may contribute to the endothelial dysfunction, basement membrane thickening and increased vascular permeability observed in the diabetic microvasculature.

Another mechanism postulated to be involved in the evolution of diabetic tissue damage is that intracellular hyperglycaemia, by causing increased diacylglycerol (DAG) concentration, may cause further activation of the NF κ B pathway via activation of protein kinase C (PKC). The end result is vasoconstriction and hypercoagulability via increased endothelin-1, TGF- β and plasminogen activator inhibitor 1 (PAI-1) generation and reduced endothelial nitric oxide synthase production.

The fourth major mechanism proposed to result in diabetic tissue damage results from shunting of excessive intracellular glucose via fructose 6-phosphate to glucosamine 6-phosphate, a reaction catalysed by the enzyme glutamine:fructose 6-phosphate amidotransferase (see Fig. 15.2). Glucosamine 6-phosphate undergoes further conversion to UDP N-acetyl glucosamine, which, by binding to serine and threonine residues on transcription factors, leads to increased proinflammatory cytokine activity (TGF- β , PAI-1 and others).

A further mechanism relating to the generation of reactive oxygen species (ROS) and oxidative stress has recently been proposed. Excessive intracellular glucose or NEFAs are thought to stimulate tricarboxylic acid cycle reactions by substrate accumulation. Citrate, formed from NEFA or glucose-derived acetyl-CoA and oxaloacetate, is converted to isocitrate by the enzyme isocitrate dehydrogenase, generating mitochondrial NADH in the process. Excessive generation of NADH leads to ROS formation via increased electron transport along the inner mitochondrial membrane and, perhaps when other means of electron dissipation such as uncoupling proteins are saturated, their donation to oxygen species, generating toxic ROS. β -Cells are thought to be especially vulnerable to the resulting oxidative stress by virtue of a low antioxidant capacity. In hyperglycaemic clamp studies, glutathione infusion has been shown to restore islet cell function (particularly first-phase insulin response), and hyperglycaemia or excessive NEFA-induced endothelial dysfunction may similarly be ameliorated by antioxidant infusion. However, data from various studies do not demonstrate convincing benefits from supplemental vitamin E (an antioxidant) in diabetic or other subjects at high risk of cardiovascular disease.

The precise interrelationship between these proposed mechanisms of diabetic tissue damage, for example whether they may be downstream effects of a common maladaptive cellular response to hyperglycaemia or whether they represent independent pathways, is not yet clear. There is compelling evidence, for example that PKC activation may be stimulated by superoxide ions and AGE formation, thus linking the oxidative

stress, advanced glycation end product and PKC pathways. Ruboxistaurin mesylate (LY333531), an inhibitor of PKC, has shown promise in human and animal trials in slowing progression of, and in some cases reversing, a number of diabetic microvascular complications including nephropathy, retinopathy and neuropathy.

Other aspects of diabetic tissue damage

Although the mechanisms discussed above relate to the specific effects of hyperglycaemia, other factors such as infection, genetic susceptibility, hypertension, vascular disease, hyperlipidaemia and other associated conditions such as hyperuricaemia and gout are important and common cofactors for tissue damage in the clinical setting, and these are discussed briefly below.

Tissue damage is encountered in diabetes as a result of increased susceptibility to infection (e.g. renal scarring from repeated episodes of urinary sepsis). Phagocyte (principally neutrophil) dysfunction appears to be the main predisposing factor; this occurs via a number of mechanisms including abnormal adherence, chemotaxis, phagocytosis, respiratory burst and bacterial killing. It is not known precisely what duration of exposure to hyperglycaemia is required to produce these abnormalities in human subjects: the concentration threshold is probably ~ 11 mmol/L.

High concordance rates between twins for complications of diabetes suggest that inherited factors may influence their development. There is evidence that autoimmune processes contribute to the development of some diabetic complications (e.g. the autonomic neuropathy/iritis syndrome).

There is good evidence that growth hormone deficiency, either coincidental or induced by hypophysectomy, prevents or reverses the onset of microvascular complications. However, the results of trials using pegvisomant, a growth hormone receptor antagonist, have been disappointing.

The role of recurrent hypoglycaemia in diabetic tissue damage, especially neurological damage to CNS and autonomic neurons, is currently being investigated but hypoglycaemia is certainly not a necessary condition for its development.

Although microvascular disease and some other complications may be more characteristic of diabetes, macrovascular disease accounts for most of the excess mortality associated with the condition. Diabetic macrovascular disease is related to, but not identical to, atherosclerosis occurring in non-diabetic patients. In diabetic macrovascular disease, the age of onset is earlier and the prevalence of vascular disease in men and women is approximately equal. Differences in the ranking of the strength of associations of risk markers in diabetic and non-diabetic populations suggest some differences in aetiology: smoking is the main risk factor in non-diabetic populations, but hypertension seems relatively more important in diabetes. Furthermore, diabetic macrovascular disease has some singular clinical features, verging on the pathognomic. For example, there is a strong association with calcification of the vascular media and a predilection for involvement of multiple distal arteries (a pattern that

often precludes surgical intervention) rather than fewer proximal arteries. The well-documented higher mortality rate from myocardial infarction in patients with diabetes (compared with similar patients without diabetes) may be related to this widespread involvement of middle-sized and small arteries. Acute ('stress') hyperglycaemia may also contribute to increased mortality, but trials of strict glycaemic control in the immediate post-infarct period have produced mixed results, possibly because the magnitude of the hyperglycaemic response may also be related to the severity of the infarct.

The causation of the increased macrovascular disease risk observed in diabetes is complex; most of the conventional risk factors for vascular disease in non-diabetic individuals (e.g. smoking, hypertension, age) are associated with accelerated atherosclerosis in diabetic populations. However, there is evidence that hypertension in diabetes is in some ways distinct from essential hypertension (e.g. the relationship between plasma renin concentration and plasma renin activity is altered and renal and endothelial dysfunction may be more pronounced). The lipid abnormality most commonly linked with mortality in diabetes may not be high LDL-cholesterol, as found in non-diabetic subjects, but rather the combination of low HDL-cholesterol, small, dense LDL and hypertriglyceridaemia, as also seen in the metabolic syndrome.

Studies of blood rheology, the glycation and peroxidation of lipoproteins and endogenous thrombotic and thrombolytic mechanisms show widespread abnormalities in diabetes, which may all be relevant to the development of macrovascular disease.

The risk of macrovascular disease (whether of the 'normal' or the 'diabetic' pattern is unclear) is increased in subjects with IGT as well as in those with frank diabetes. Most physicians consider that cardiovascular risk factors in patients with IGT should be managed as if they had diabetes.

CONDITIONS ASSOCIATED WITH INADEQUATELY CONTROLLED DIABETES MELLITUS

Various conditions are associated with poorly controlled diabetes, including gout, osteopenia and hepatic steatosis. Acute diabetic emergencies are discussed in Chapter 16.

The association of gout with diabetes has been recognized for >200 years. The reason for the link is not yet clear, but alterations in renal urate clearance may contribute; high uric acid concentrations are associated with other features of the metabolic syndrome and with increased cardiovascular risk. In some patients, hyperuricaemia may be exacerbated by the use of drugs such as thiazides and β -blockers for the treatment of diabetic hypertension.

Generalized osteopenia is also clearly associated with diabetes mellitus. No specific defect in calcium or phosphate metabolism has been identified and the basis of the association is unclear. Of particular importance is local osteolysis, with loss of bone mineral, which in the feet, can be difficult to distinguish from osteomyelitis, especially

in the context of suspect Charcot foot (see p. 324). The inactivity occasioned by diabetic foot ulcers may accelerate the osteopenia. The thiazolidinedione drugs have been associated with increased fracture risk in diabetes.

Fatty change in the liver is common in obesity and in some cases may be associated with an increased risk of developing diabetes. It is also found in poorly controlled diabetes; it frequently causes elevation of plasma liver enzyme activity, notably of alanine aminotransferase and, less frequently, of other enzymes. Liver ultrasound scans will confirm fatty liver in cases of uncertainty. Historically, this has often been considered a benign process, but more recent data suggest that many cases of idiopathic cirrhosis may, in fact, have arisen in fatty livers. There appears to be a spectrum of non-alcoholic fatty liver disease from simple steatosis, which represents the benign end of the scale with little propensity to progress, through various grades of inflammation and fibrosis (steatohepatitis), to frank cirrhosis. There are few good data on selection of patients for biopsy and on measures to prevent progression from simple steatosis to more serious degrees of steatohepatitis. However, most authorities advocate measures to effect good glycaemic control, to treat dyslipidaemia (fibrates may have a particular role) and to improve insulin resistance by exercise and weight loss. Several recent studies have demonstrated beneficial effects from the thiazolidinedione group of drugs, probably as a result both of insulin sensitization and also their effects on NEFA metabolism and fat distribution. This topic is discussed in detail in Chapter 14.

Low concentrations of circulating magnesium have been reported during treatment of ketoacidosis. Hypomagnesaemia may be more common in outpatients with diabetes mellitus than in non-diabetic subjects. However, this suggestion has not been confirmed and there is no evidence that plasma magnesium should be checked routinely in patients with diabetes.

Hyponatraemia may arise in diabetes through several mechanisms. Chlorpropamide and tolbutamide (and perhaps other sulphonylureas) may cause water retention through potentiation of the action of antidiuretic hormone (see Chapter 4). Artefactual hyponatraemia may arise from the hyperlipidaemia (hypertriglyceridaemia) of ketoacidosis or poor glycaemic control. Compensatory hyponatraemia is often seen in poorly controlled diabetes, perhaps as an osmoregulatory response to high glucose concentrations. This effect may be particularly significant in the management of acute diabetic emergencies and is, in effect, a translocational hyponatraemia brought about by the movement of water from the intracellular to the extracellular space as a consequence of the increased plasma osmolality in hyperglycaemic conditions. Plasma sodium concentration should fall by ~ 1.6 mmol/L for every 5 mmol/L that plasma glucose exceeds 5 mmol/L. If the measured sodium differs significantly from this 'corrected' value, a cause should be sought, and if it lies well outside the reference range, fluid management may have to be adjusted accordingly. To what extent, if at all, osmotic tissue damage contributes to the long-term complications of diabetes is at present unclear.

Diabetic kidney damage most commonly presents as hypertension or (micro)-albuminuria in patients under

regular review. Late presentations include chronic kidney disease, nephritic syndrome, nephrogenic diabetes insipidus (sometimes associated with papillary necrosis), renal tubular acidosis (type 4) or toxicity from renally-excreted drugs.

BIOCHEMICAL MEASUREMENTS IN DIABETES MELLITUS

Glucose measurements

Measurements of blood glucose concentrations are fundamental to the diagnosis and management of diabetes mellitus. Plasma contains more glucose (per unit volume) than erythrocytes, so criteria for diagnosis of diabetes reflect these differences between samples (see Table 15.4). Since glucose enters the circulation via the hepatic vein and is cleared peripherally, arterial concentrations are higher than in venous blood samples, with capillary blood having intermediate values.

Over the last decade, home and bedside blood glucose monitoring by patients or their attendants has become widespread, using dry reagent enzymatic reactions or electrochemical methodologies on test strips. Although such techniques represent the only current practical approach to long-term self or nurse monitoring, they are prone to multiple errors if misused (especially by inadequately educated patients or healthcare professionals) and should not be relied upon for clinical decisions in seriously ill patients. They require appropriate calibration and proper technique (e.g. prior washing and drying of hands, correct sample volume and correct test strip for the metre used). Recent advances in testing include electronic transfer of results to databases including the electronic patient record, and alternative site (e.g. forearm) sampling to avoid the pain and repeated trauma associated with fingertip sampling (although forearm glucose concentrations may differ from fingertip concentrations when blood glucose concentrations are rapidly changing, e.g. during exercise or in the postprandial state). Other developments include collection of interstitial fluid by reverse iontophoresis for automated glucose analysis every 10 min, and continuous glucose monitoring systems in which a disposable subcutaneous glucose sensor that can function for several days is monitored via a wired or wireless system. This permits collection of a detailed profile throughout a 24 h period that may yield information that is hard to gather using conventional testing. It is particularly useful overnight, e.g. in patients with suspected nocturnal hypoglycaemia. Glucose concentrations determined by this method lag behind blood glucose by about 10 min, and the method is limited by the development of local skin irritation. The systems are expensive and usually only used for short-term monitoring, although they are sometimes advocated for longer periods of use in patients attempting to achieve tight control of glucose concentrations. The ultimate development of this would be a closed loop system that monitors glucose and calculates the correct amount of insulin to infuse via a pump, but this has not yet gone beyond short experimental studies.

Table 15.8 indicates some factors that may interfere with blood glucose analysis by laboratory or point of care testing methods.

Measurements of urinary glucose concentration are cheap but prone to often correlate poorly with the degree of glycaemic control. Problems include variation in the tubular threshold for glucose (e.g. increased in diabetes, reduced in pregnancy, subject to interindividual variation and altered by a range of drugs and renal tubular disorders) and the fact that the plasma glucose concentration that corresponds to the renal threshold (around 10 mmol/L) is higher than the level that clinical studies (UKPDS and Diabetes Control and Complications Trial, DCCT) have demonstrated to be the target range for blood glucose concentrations. Furthermore, urine glucose concentration is affected by fluid intake and urine concentration and provides information about the entire period since last voiding rather than giving an indication of the current level of glycaemia (unless a second voided specimen is used). The dry reagent stick chemistries used are imprecise at lower levels of glycosuria and may be affected by some drugs. Their use is declining in the developed world; however, they may be more acceptable than blood testing to some patients. They provide an adequate index of glycaemic control in some elderly patients with type 2 diabetes, controlled on diet alone or on small doses of oral hypoglycaemics, although HbA_{1c} (see below) is now the preferred method of monitoring for most of these patients.

Testing for ketones

Urine testing for ketones has an important place in the management of diabetes, particularly for patients with type 1 diabetes, who should generally be instructed in its uses and limitations. Ketone testing is particularly important when metabolic control is threatened by intercurrent illness or stress or when blood glucose concentrations are persistently high (e.g. >15 mmol/L), particularly when accompanied by symptoms compatible with ketoacidosis such as nausea, vomiting or abdominal pain. It must be appreciated that the normally approximately equimolar ratio of the major ketones, β -hydroxybutyrate and acetoacetate, may increase to approximately 6:1 during diabetic ketoacidosis (DKA), reducing during recovery. Furthermore, in recovery from DKA, excretion of urine ketones may continue long after blood acid-base balance is restored to normal. Thus, since all commercially available test sticks use nitroprusside-based reactions, which measure only acetoacetate, tests may become more positive as the patient recovers and remain positive for hours or even days after resolution of the illness. It should also be appreciated that positive results may be found in a significant proportion of normoglycaemic individuals (particularly pregnant women) when testing first-voided urine specimens after an overnight fast. Certain drugs, such as captopril and levodopa, may cause spuriously positive results, while ascorbic acid intake may cause false negative ones.

Enzymatic methods detecting β -hydroxybutyrate in blood using a stick test that can be performed by the patient or at the bedside have a number of theoretical

TABLE 15.8 Factors that may interfere with the biochemical analyses used in diabetes

Substance assayed	Biological fluid	Assay method	Interference from	Error induced
Glucose	Blood	Any	Delay in sample separation, especially if not cooled and in fluoride	Erythrocytes consume glucose giving falsely low value
Glucose	Blood	Glucose oxidase (e.g. YSI (Yellow Springs®))	Paracetamol	Reads high
Glucose	Plasma	Spectrophotometry	Haemolysis or hyperlipidaemia	Affects linearity of response
Glucose	Urine	Any	Bacteriuria	Consumes glucose
Glucose	Urine	Glucose oxidase (e.g. Multistix®, Combistix®)	Detergent (e.g. from cleaning container)	False positive
Lactate	Blood	Any	Reducing substances (e.g. vitamin C), ketones	False negative
Acetoacetate	Blood or urine	Rothera based (e.g. Ketostix®)	Delay in sample separation, especially if not in fluoride	Lactate produced in collection tube
Fructosamine	Blood	Spectrophotometry	Sweat from touching pipettes etc.	Sweat may contain high concentrations of lactate
HbA _{1c}	Blood	Any	Phenolphthalein	False positive
HbA _{1c}	Blood	Electrophoresis, ion-exchange chromatography	Hypertriglyceridaemia, bilirubin	Affects linearity of response
Albumin	Urine	Dye binding	Shortened red cell life span	Lowers value
			Haemoglobin genetic variants	Unable to distinguish glycosylated haemoglobin from haemoglobin variants
			Many detergents, salicylates	False positive

advantages over urine testing. β -Hydroxybutyrate is the most relevant ketone in ketoacidosis, and the use of a metre with the stick permits its quantitative measurement, thus enabling more accurate diagnosis and monitoring of this disorder. The sticks usually also have a longer shelf-life than the urine tests, which is an advantage given that most patients will need to test for ketones only occasionally. Blood ketone measurement is now recommended in some guidelines (e.g. Joint British Diabetes Societies guideline for the management of diabetic ketoacidosis), either by stick testing or using rapid automated laboratory methods, although it is not yet in widespread use.

Oral glucose tolerance test

The oral glucose tolerance test (OGTT) is the reference method for the assessment of glucose tolerance, despite the notoriously poor reproducibility of the test ($CV = 50\%$ for 2 h blood glucose). Most diabetic patients are diagnosed on the basis of symptoms, examination and random or fasting plasma glucose concentrations without recourse to an OGTT. However, WHO and UK guidance is that patients with intermediate fasting glucose concentrations (impaired fasting glycaemia) should undergo formal glucose tolerance testing. The test also has a particular place in the diagnosis of gestational diabetes mellitus, where fasting plasma glucose concentrations lack diagnostic sensitivity. Historically, there has been divergence of opinion as to the dose of glucose to be used. Current WHO recommendations are that this should be 75 g of anhydrous glucose (not glucose monohydrate

which is 10% water by weight). For three days before the test, the subject should be on an unrestricted weight-maintaining diet, with at least 150 g carbohydrate per day, and should exercise normally. The subject should fast overnight for at least 10 h, and should remain seated and not smoke during the test. Oral glucose tolerance tests are not recommended for subjects with fasting plasma glucose ≥ 7.1 mmol/L or hospitalized, acutely ill or immobile patients. Interpretation may be difficult in subjects taking β -blockers, diuretics, nicotinic acid or high doses of glucocorticoids.

Tests of recent glycaemic control

Several tests are available that reflect prior glycaemic control: pre-eminent among these is glycosylated haemoglobin. There are multiple potential glycation sites but the principal one is the β -chain terminal valine residue. Glycation at this site, followed by an Amadori rearrangement to a stable adduct, forms HbA_{1c}. Since the usual lifespan of an erythrocyte is 120 days and the erythrocyte membrane is freely permeable to glucose, glycosylated haemoglobin concentration reflects the glycaemic control over the preceding 120 days, although with substantial weighting towards a shorter time (see below). Many different methodologies, including cation-exchange chromatography, electrophoresis, isoelectric focusing, affinity chromatography and immunoassay can be used to measure glycosylated haemoglobin after its separation from non-glycosylated haemoglobin. All HbA_{1c} assays should be traceable to the reference

method developed by the International Federation for Clinical Chemistry and Laboratory Medicine (IFCC).

The interpretation of glycated haemoglobin measurements will be affected by any coincidental condition that reduces the lifespan of erythrocytes, especially haemolytic anaemias. Conversely, iron deficiency anaemia may spuriously increase HbA_{1c} concentrations by increasing erythrocyte lifespan. Other conditions such as raised plasma concentrations of triglycerides and bilirubin, uraemia, and the presence of haemoglobinopathies may cause interference in some assays.

As an approximation, an HbA_{1c} of 50 mmol/mol (6.7%) corresponds with a mean plasma glucose concentration of approximately 9 mmol/L, and each 10 mmol/mol (1%) increase with a 2 mmol/L increase in mean plasma glucose concentrations. Although HbA_{1c} is a measure of long-term glycaemia, it must be appreciated that more recent effects are relatively more weighted so that the 30 days prior to sampling contribute 50% of the sample result, whereas events from 90–120 days prior to the sample being taken contribute a mere 10%. In conditions where glycaemic control and insulin requirements may change from week to week (such as pregnancy) or where the patient has a structurally abnormal haemoglobin, it may be preferable to use an alternative index of glycaemic control.

Fructosamine is the name given to the ketoamine products of protein glycation formed when glucose bound to a variety of proteins by aldimine linkage undergoes an Amadori rearrangement. The major component of fructosamine in plasma is glycated albumin, but other proteins and possibly non-protein components as well contribute to the measured values. Standardization has been difficult, so reference ranges may differ between different laboratories. Fructosamine is relatively simple to measure (using a nitroblue tetrazolium assay); its concentration reflects control over the preceding 10–15 days, but is subject to spurious results in the presence of factors that affect albumin turnover (including diabetic nephropathy). There is an inverse relationship between weight and fructosamine so that fructosamine concentrations are lower than expected for the degree of control in obese patients with diabetes. Whether or not to correct fructosamine for serum albumin concentration (given that the absolute concentration, not the glycated proportion of the protein, is measured) remains uncertain. The clinical utility of fructosamine is further limited by the lack of evidence-based targets, but it has a limited role in patients with disorders such as haemolytic anaemia or haemoglobinopathies in whom HbA_{1c} cannot be used.

Screening for diabetes

It is estimated that 50% of diabetic subjects in the developed world are undiagnosed. Screening has been recommended by NICE in the UK for asymptomatic subjects who are at high risk of developing diabetes (see Fig. 15.6). This involves a two-stage check – the first is a risk assessment using a validated computer-based risk assessment tool (these usually use factors such as sex, age, BMI, waist circumference, family history, history of hypertension and ethnicity to estimate risk, see, e.g. [\[www.diabetes.org.uk/Riskscore/\]\(http://www.diabetes.org.uk/Riskscore/\)\) in those who meet the following criteria:](http://</p>
</div>
<div data-bbox=)

- adults aged 40 and above, except pregnant women
- adults aged 25–39 of South Asian, Chinese, African-Caribbean, black African and other high-risk black and minority ethnic groups, except pregnant women
- adults with conditions that increase the risk of type 2 diabetes (cardiovascular disease, hypertension, obesity, stroke, polycystic ovary syndrome, a history of gestational diabetes and mental health problems. In addition, people with learning disabilities and those attending emergency medical admissions units, vascular and renal surgery units and ophthalmology departments may be at high risk).

High-risk individuals should be offered a blood test for either HbA_{1c} or fasting plasma glucose. For individuals with results of these tests below the diagnostic threshold for diabetes, an HbA_{1c} of 42–47 mmol/mol (6–6.5%), or a fasting glucose of 5.5–6.9 mmol/L indicates high risk. These individuals should be offered advice on intensive lifestyle intervention and re-testing at least once a year.

Similar recommendations have been made by the American Diabetes Association and other organizations.

Tests for insulin resistance

In subjects who require large amounts of insulin to maintain euglycaemia, e.g. >150 units or >1.5 units/kg body weight/24h, insulin resistance is likely to be present (although it is important to ensure that the patient is compliant with therapy). Many such subjects will be morbidly obese and this is usually an adequate explanation. Measurements of fasting insulin, C-peptide and glucose will show inappropriately high concentrations. Haemolysis reduces insulin concentrations, so care should be taken to avoid this, and blood samples should be kept cool (4°C) until the plasma can be separated. Normal fasting insulin concentrations are up to 140 pmol/L (20 mU/L), depending on the assay used. If doubt remains as to whether the subject is insulin-resistant, it may be necessary to check insulin and glucose concentrations after observed insulin administration or a hyperinsulinaemic clamp may be undertaken (see below).

If insulin-binding antibodies are suspected, for example in a subject who has received non-human insulins, free insulin can be assayed by immunoassay. If the free insulin concentration is much lower than total insulin concentration, insulin-binding antibodies are likely. Subjects who have little glycaemic response to high concentrations of endogenous insulin, but who are sensitive to exogenous insulin, may have an abnormal immunoreactive insulin (see p. 279 and Table 15.2).

If a subject without insulin-binding antibodies fails to respond to intravenous insulin, an insulin receptor or post-receptor problem should be suspected and a careful family study should be undertaken. Family members should be screened for insulin resistance by measuring fasting plasma glucose and insulin concentrations. The binding of insulin to the patient's white blood cells or adipose tissue may be measured in order to indicate whether the patient has normal insulin receptor numbers and whether the receptors show normal avidity for insulin.

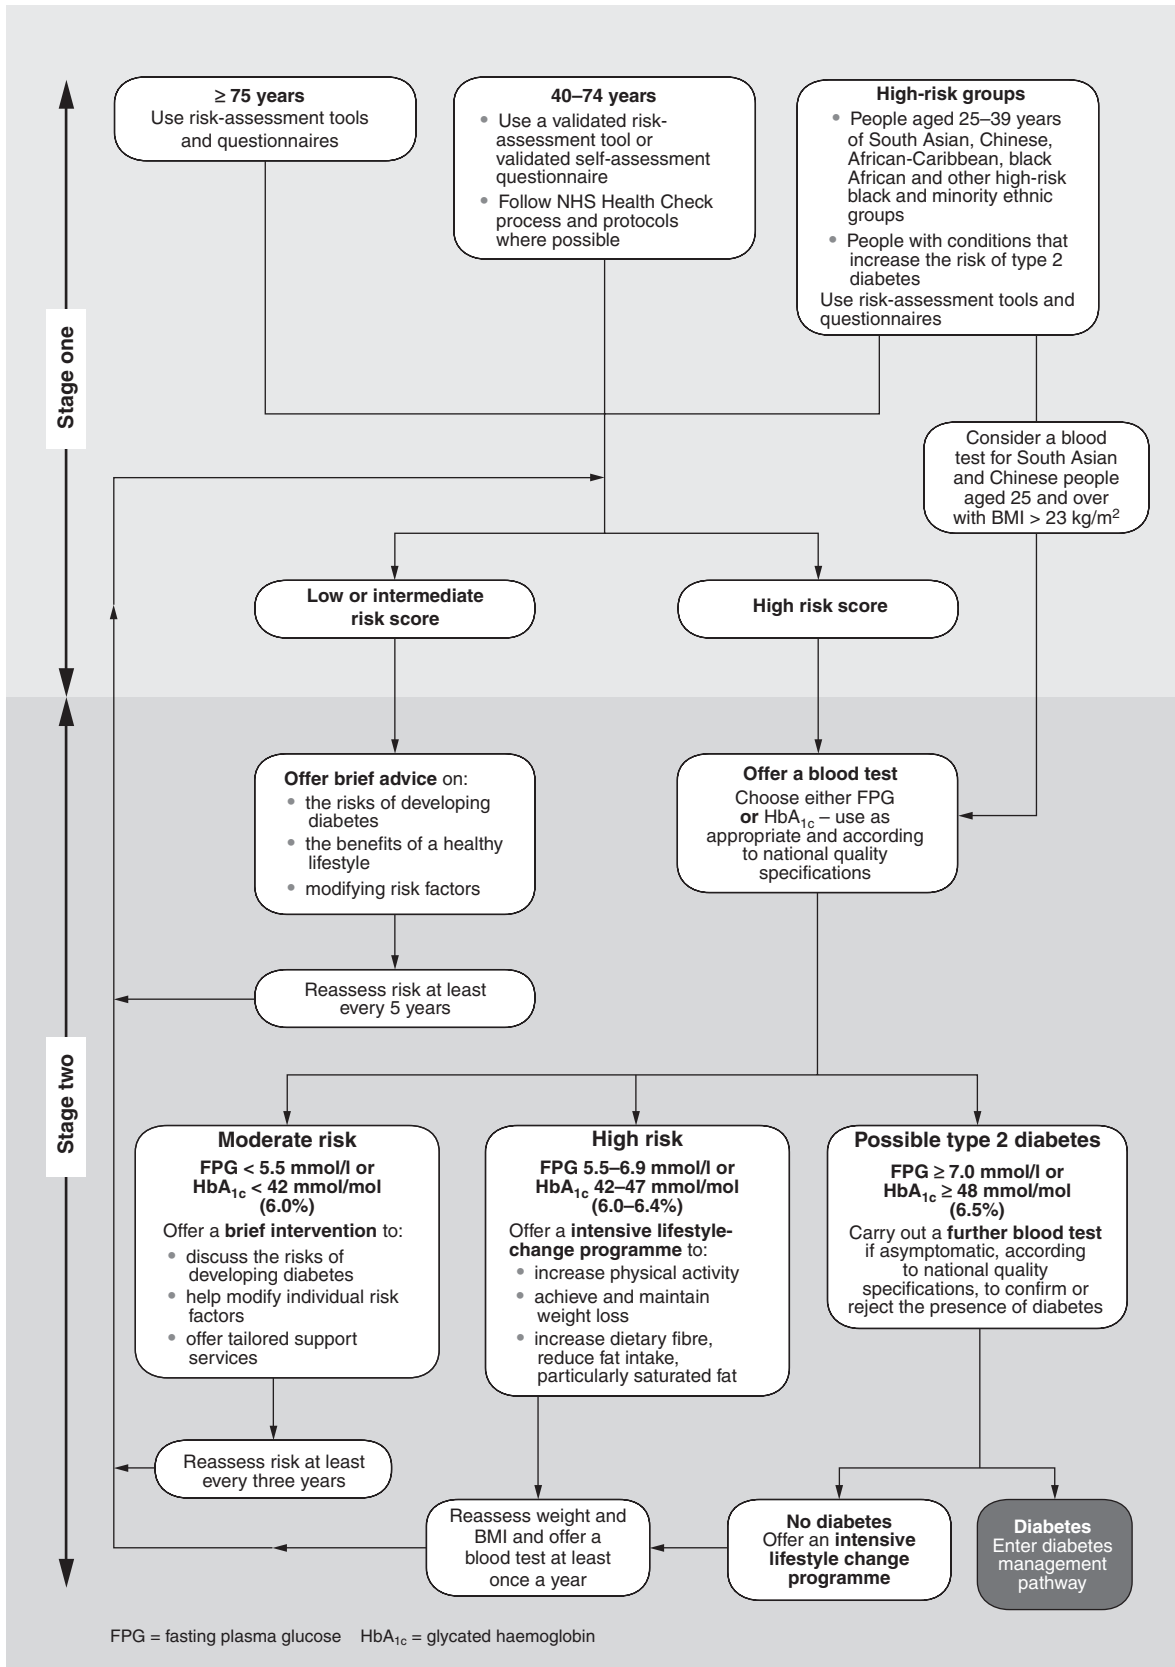

FIGURE 15.6 ■ Flowchart for the identification and management of type 2 diabetes mellitus. (From NICE public health guidance PH 38: Preventing type 2 diabetes: risk identification and interventions for individuals at high risk (2012): <http://guidance.nice.org.uk/PH38>, with permission from the National Institute for Health and Care Excellence).

Glucose transporter function can be investigated by incubating cells of interest (e.g. leukocytes, monocytes, adipocytes) with a non-metabolisable glucose analogue such as 2-deoxyglucose. The cellular content of the glucose analogue after a given time provides a measure of glucose transporter function. Glucose transporter number may be estimated by the use of specific antibodies linked to an imaging system (fluorescence or radioactivity based).

Molecular biological techniques can be used to determine DNA sequences coding for insulin, the insulin receptor and glucose transporter molecules, as appropriate, when the site of the defect has been identified.

Research investigations

Tests commonly used in diabetes research include the hyperinsulinaemic glucose clamp and the intravenous glucose tolerance test (IVGTT), as well as a variety of measures of β -Cell function.

Hyperinsulinaemic clamps. The hyperinsulinaemic clamp is the reference measure of insulin resistance. In the euglycaemic variant of the test, insulin is infused into a peripheral vein to increase the plasma insulin concentration to a target range (e.g. 250 pmol/m² per min or 35 mU/m² per min increases the insulin to around 60 mU/L). Without further intervention, the hyperinsulinaemia would induce hypoglycaemia. However, in the clamp procedure, the plasma glucose concentration is measured every 3–5 min and glucose is infused peripherally to maintain glucose concentrations within the desired range. When a steady state has been reached (usually 90–120 min), the rate of exogenous glucose infusion needed to maintain the glucose concentration is an index of the glucose clearance rate and of the subject's insulin sensitivity. Many variations on the clamp methodology are described, including use of stable isotope tracers, which permit better description of the physiological abnormalities in glucose turnover in response to insulin.

Intravenous glucose tolerance testing. The IVGTT is an alternative test of glucose tolerance in which glucose (typically 20 g/m² of body surface area) is injected as a bolus. This test has better reproducibility than the OGTT but is even less physiological. An IVGTT is a powerful stimulus to insulin secretion. It has been used in research studies to screen high-risk non-diabetic subjects for early defects of glucose tolerance and insulin response, with some success in predicting those that will subsequently progress to overt diabetes.

Measurement of β -Cell function. These tests are primarily used to determine the relative contribution of insulin deficiency and insulin resistance to glucose intolerance. There is no consensus as to which should be used in type 2 diabetes mellitus. The gold standard for research purposes is the hyperglycaemic clamp, where glucose is clamped at high concentrations and insulin secretion measured. If it is clinically important to document the severity of insulin deficiency, this is best done by measuring plasma C-peptide concentration. The DCCT trial used a basal concentration

for C-peptide of <0.2 nmol/L and a concentration of <0.5 nmol/L measured 6 min after giving 1 mg glucagon intravenously to distinguish type 1 from type 2 diabetes. Other tests of β -Cell function used for research purposes include the arginine stimulation test and mathematical models based on measures of insulin or C-peptide during oral or intravenous glucose tolerance tests.

Elevated fasting plasma proinsulin concentrations indicate subjects with abnormal β -Cell function, even if glucose tolerance is normal.

Homeostasis model assessment. The *homeostasis model assessment* (HOMA) is a mathematical model that uses fasting glucose and insulin concentrations to derive estimates of both insulin resistance and β -Cell function. It is useful for epidemiological studies where more sophisticated testing is not practical, but interpretation can be difficult especially in the context of treatment with insulin or oral drugs that stimulate insulin secretion.

CONCLUSION

There are two major types of diabetes: type 1 and type 2. Both are characterized by hyperglycaemia, but in type 1, this is a consequence of absolute insulin deficiency as a result of β -Cell destruction, whereas in type 2 the deficiency is relative, with most patients being resistant to the actions of insulin, although their production of insulin tends to decrease with time. Both conditions are associated with short-term and long-term complications. Biochemical investigations are essential for both the diagnosis and management of the conditions.

CONCLUSION 332

INTRODUCTION

The rise in prevalence of diabetes presents some of the greatest medical and economic challenges of the 21st century. Despite advances in our understanding and management of diabetes mellitus, it continues to exact a huge toll both in terms of morbidity and mortality.

In this chapter, we consider dietary, lifestyle and macrovascular risk optimization measures for people with diabetes. Glucose-lowering treatment is discussed, followed by obstacles patients face in order to achieve their glycaemic goals, particularly hypoglycaemia. Later

sections discuss the management of chronic and acute complications of diabetes, and its management in particular circumstances, for example in critical illness and during pregnancy.

GENERAL ASPECTS OF MANAGEMENT

The management of patients with diabetes should involve a multidisciplinary team composed of diabetologists, diabetes specialist nurses, dietitians, podiatrists, the patient's general practitioner and other specialists if specific complications are present.

In addition to therapies that specifically target glycaemic control, nutritional management, lifestyle modifications such as adequate physical exercise and smoking cessation, and structured patient educational programmes are key components in the management of patients with diabetes.

Nutrition

Patients with diabetes should follow a healthy diet and make appropriate nutritional choices to reduce cardiovascular risk and improve glycaemic control. A dietitian with specialist knowledge in diabetes should take the lead role in providing nutritional care. Dietary advice should be tailored specifically for each patient, considering their personal and cultural preferences, beliefs, lifestyle and the changes that the patient is willing and able to make.

The principles of diet include eating regular meals with a reduction in simple carbohydrate intake with an increase in complex carbohydrates, a high fibre content and an energy intake to achieve or maintain an ideal body weight, or in those who are overweight or obese, to achieve and sustain modest weight loss. The key aim is to balance energy input and expenditure and ensure a good quality diet.

Contrary to the general perception that a diet in diabetes needs to be unique or special, there is no special 'diet for diabetes'. People with diabetes, except perhaps in specific circumstances such as renal failure, should eat the same healthy diet as recommended to those who do not have diabetes. Thus, no more than 30% of total energy intake should be in the form of fat, and the ratio of unsaturated to saturated fats should be increased with saturated fat intake ideally making up <7% of total calories and *trans* fatty acid intake minimized. Replacement of saturated fats with mono- or polyunsaturated fats aids lowering of cholesterol.

Carbohydrate (preferably in the form of slowly absorbed complex carbohydrate with a low 'glycaemic index' rather than simple sugars) should provide approximately 55% of total energy intake with protein providing the remaining 15%. Foods that improve glycaemic control and might reduce cardiovascular risk include whole grains and green vegetables. Conversely fried foods, high glycaemic index diets and red and processed meats may increase cardiovascular risk.

Carbohydrate intake can significantly affect postprandial blood glucose concentrations. In type 1 diabetes, matching insulin doses to the amount of carbohydrate consumed (carbohydrate counting) is effective in improving glycaemic control. Patients who are on fixed insulin doses or biphasic insulin regimens should be advised to aim for consistency in carbohydrate and glycaemic index dietary intake.

In patients treated with diet only or diet and oral hypoglycaemics, total energy intake in terms of carbohydrate consumption should be monitored as this is important in achieving glycaemic control. Strategies employed may include carbohydrate counting, exchanges or food portions based on past experience. However, as each individual is different, there is no fixed recommended ideal macronutrient composition of carbohydrate, fat and protein in the

diet. Nevertheless, some studies have shown improved body weight and glycaemic control with low carbohydrate diets through a reduction in energy intake over the short term.

Sodium intake should not generally exceed 6g/day and plentiful fruit and vegetables ('five portions a day' being the current mantra) should be consumed, mindful of the fact that some fruits (e.g. grapes) may contain large amounts of sugar and should not be taken in excess. A total daily dietary fibre intake of 40g is ideal but rarely achieved in practice. Except in specific and unusual circumstances, it is a general principle that the pharmacological treatment of diabetes should be tailored to the dietary intake and lifestyle of the individual and not vice versa. Fructose reduces postprandial glycaemia when it is used as a replacement for sucrose or starch, but it may have adverse metabolic effects including causing dyslipidaemia and insulin resistance. Non-nutritive sweeteners are safe when consumed within recommended daily limits.

It is currently recommended that patients with new onset type 2 diabetes should be managed with dietary and lifestyle modification with consideration for early introduction of metformin (discussed later). The degree of adherence to a particular diet will affect the outcome and a diet that is both palatable and acceptable is more likely to be followed.

Exercise

Patients with diabetes should be encouraged to participate in regular exercise of the kind that would benefit the rest of the population. Regular low-intensity exercise, such as brisk walking (so as to be slightly breathless while talking at the same time), swimming or cycling for 30 min three to five times a week should be a realistic goal for many individuals. Exercise improves glucose disposal (by increasing the expression of type 4 glucose transporters, GLUT4) in skeletal muscle, among other mechanisms), prevents progression from impaired glucose tolerance to type 2 diabetes (by ~50%), increases basal metabolic rate and has convincingly been demonstrated to reduce the risk of cardiovascular events.

Some patients with cardiovascular disease require detailed assessment (e.g. electrocardiogram, review of medications) before taking part in exercise programmes, but the few absolute contraindications to exercise in patients with diabetes (e.g. tight aortic valvular stenosis) apply equally to individuals without diabetes.

In insulin-treated patients, exercise may be associated with either an increased frequency of hypoglycaemia or hyperglycaemia as blood glucose concentrations are influenced by the timing, type and quantity of insulin, carbohydrate intake and intensity and duration of physical activity. Careful monitoring of blood glucose concentrations is necessary to guide the adjustment of insulin therapy and carbohydrate intake, and the strategy adopted may depend on whether the exercise is planned or unplanned.

Aerobic exercise improves glycaemic control and lowers low density lipoprotein (LDL) cholesterol in patients with type 2 diabetes, but has little effect on other lipid parameters. Resistance training has effects on both

glycaemia and cardiovascular risk factors such as systolic blood pressure, fat mass and insulin resistance.

Studies have shown that it is safe for individuals with type 2 diabetes who are treated by diet alone or in conjunction with oral hypoglycaemic agents to exercise in both the fasting and post-meal states with the most beneficial effects on blood glucose concentrations observed postprandially. As with dietary modification, exercise programmes must be individually designed in order to encourage compliance.

Smoking cessation

Smoking is hazardous to all, but is particularly so in people with diabetes. The macrovascular risks of smoking are compounded with those of diabetes itself. Smoking is associated with increased mortality and predisposes to microvascular complications of diabetes such as retinopathy and nephropathy. Smoking is potentially diabetogenic: it is a risk factor for the development of type 2 diabetes, and can influence glycaemic control by impairing insulin sensitivity and glucose tolerance.

Smoking is at least as prevalent in patients with diabetes as in the general population and young women in particular may perceive the habit as an adjunct to weight management.

Many approaches to the supportive management of patients have been described. These include smoking-cessation clinics and nicotine replacement therapy. Such forms of therapy apply equally to people with and without diabetes.

Education about diabetes

Structured educational programmes have been developed in Europe and North America. In the UK, a five-day intensive educational course called the Diet Adjustment For Normal Eating (DAFNE) programme provides opportunities for support and learning for patients with type 1 diabetes. This course teaches those with type 1 diabetes how to adjust their insulin doses according to carbohydrate portion intake, and allows participants to learn about aspects of lifestyle and management related to their diabetes.

For patients with newly diagnosed type 2 diabetes, the Diabetes Education and Self Management for Ongoing and Newly Diagnosed (DESMOND) programme offers support to patients in identifying their health risks and enables goal-setting, developing confidence in self-management of their condition.

Pharmacological management of cardiovascular risk

Despite the fact that patients with diabetes are uniquely susceptible to microvascular complications, around 80% of patients with type 2 diabetes will die of macrovascular disease. Ischaemic heart disease, stroke and peripheral vascular disease are some 2–4 times more common in patients with diabetes than in the non-diabetic population. Many available risk tables do not even include powerful diabetes-related risk factors such as microalbuminuria.

Type 2 diabetes is associated with dyslipidaemia. There are elevated concentrations of small, dense LDL particles that are more prone to oxidation, which increases their ability to damage the vascular endothelium. Reduced high-density lipoprotein (HDL) concentrations result in reduced protection against atheroma: increased triglyceride-rich lipoprotein concentrations predispose to atheroma formation.

The risk of mortality from cardiovascular disease is higher in patients with diabetes and increases further with additional cardiovascular risk factors such as hypercholesterolaemia, hypertension and smoking. Diabetes is so powerful a risk factor that patients should, in most cases, be treated as if they had already suffered a cardiovascular event, rather than have their treatment assessed on the basis of primary prevention studies.

Apart from recommendations regarding the dietary and other lifestyle measures detailed above, there is a degree of uncertainty about which patients should receive preventative treatment with agents such as aspirin, lipid-lowering therapy or angiotensin-converting-enzyme (ACE) inhibitors, and what targets to pursue at any specific stage of the disease. Guidelines have been prepared by various organizations in countries with populations of differing genetic background and socioeconomic structures. None can obviate the need for individualized risk–benefit assessment, and it is important to involve patients in setting their own treatment goals, and management plans.

It is likely that future guidelines will recommend a lifetime risk calculator that uses a range of risk factors to calculate the absolute risk of an event over the rest of the patient's lifetime. This has the effect of promoting more aggressive intervention to modify risk factors from an early age. Risk calculators can also be used to help patients to understand their personal risk and how changes can affect it, in order to improve compliance.

Aspirin

Aspirin (75 mg daily) is recommended for secondary prevention of cardiovascular disease in patients with diabetes. It is effective in reducing cardiovascular morbidity and mortality in high-risk patients with previous cardiovascular disease. The risk of adverse effects associated with this dose of aspirin depends on many factors, including the age of the patient, intake of other drugs (corticosteroids and non-steroidal anti-inflammatory drugs), presence of other disease (e.g. untreated proliferative retinopathy, uncontrolled hypertension, asthma) and medical treatment (e.g. forthcoming surgery). The risks of major gastrointestinal haemorrhage appear to be increased by a factor of 1.5–2 with approximately one additional event per 500 patient years under trial conditions (approximately 0.2% per patient per year). Intracranial haemorrhages are increased by one event per 3–500 patient years.

The use of aspirin for secondary prevention of macrovascular disease in all patients in whom it is not contraindicated is well established. However, in primary prevention in patients with diabetes with no prior cardiovascular events, the use of aspirin has been more contentious.

The current Joint British Societies guidance (JBS2) recommends aspirin 75 mg daily in patients with diabetes aged >50 years, those who are younger but have had the disease for more than 10 years, and those who are already receiving treatment for hypertension, with controlled blood pressure <150 mmHg systolic and <90 mmHg diastolic. The UK National Institute for Health and Care Excellence (NICE) guidelines have stated that low-dose aspirin should be offered to patients aged >50 years if blood pressure is below 145/90 mmHg and to those aged <50 years who have significant cardiovascular risk (features of the metabolic syndrome, strong early family history of cardiovascular disease, smoking, hypertension, existing cardiovascular disease or microalbuminuria).

However, a more recent meta-analysis found no significant beneficial effects of using aspirin for primary prevention of cardiovascular disease in diabetes, and the Prevention of Progression of Arterial Disease and Diabetes (POPADAD) study demonstrated that aspirin did not significantly reduce the risk of major cardiovascular events even in patients with asymptomatic peripheral arterial disease. At present, there is little evidence to support the use of aspirin in patients aged <30 years and, in those <16 years, aspirin should be avoided because of an increased risk of Reye syndrome.

Lipid-lowering agents

Effective management of dyslipidaemia reduces the risk of cardiovascular disease; plasma lipid concentrations should be monitored at least annually in patients with diabetes. Most people in the developed world, with or without diabetes, would benefit from a less atherogenic lipid profile. Lifestyle modifications such as dietary restriction of saturated fat, cholesterol and *trans*-unsaturated fat, increased intake of ω -3 fatty acids, viscous fibre and plant sterols, achievement and maintenance of an ideal body weight and taking adequate exercise are recommended, whether or not further treatment is required. Secondary causes of dyslipidaemia such as alcohol excess, hypothyroidism or liver disease should be considered in all patients prior to initiating any lipid-lowering therapy. For patients with diabetes, poor glycaemic control (denoting inadequate insulin action) may also cause excess very low density lipoprotein (VLDL) production and hypertriglyceridaemia. Treatment with metformin, pioglitazone and insulin have all been shown to improve this, either via increasing insulin action or by other specific mechanisms (e.g. by reducing the flux of non-esterified fatty acids to the liver in the case of pioglitazone).

Many primary and secondary prevention trials have convincingly demonstrated the benefits of lipid-lowering therapy in reducing macrovascular risk in subjects with and without diabetes. Many of these studies have involved the use of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase inhibitors (statins), and have shown that lowering LDL-cholesterol is approximately linearly related to risk reduction down to concentrations of 2.2 mmol/L or even below.

The American Diabetes Association (ADA) currently recommends statin therapy, in addition to lifestyle factors, as secondary prevention for patients with diabetes who have

cardiovascular disease, with a goal for LDL-cholesterol of <1.8 mmol/L. Treatment is recommended for primary prevention in all patients with diabetes over the age of 40, and in younger people who have additional cardiovascular risk factors, with an LDL-cholesterol target of <2.6 mmol/L. Statins should be used with caution, and only on specialist advice, in children and are contraindicated in pregnant women.

The typical diabetic dyslipidaemia comprises raised triglycerides, intermediate density lipoprotein (IDL) and small, dense LDL concentrations together with low HDL concentrations. These abnormalities are particularly atherogenic, with the result that the significance of dyslipidaemia in diabetes is underestimated by routine measurements of total lipid subfractions. Fibrin acid derivatives have a role in the management of the raised triglycerides in diabetic dyslipidaemia. The ADA currently recommends targets for triglycerides of <1.7 mmol/L, and for HDL-cholesterol of >1.0 mmol/L in men and >1.3 mmol/L in women. Both the JBS2 and NICE guidelines (NICE Clinical Guideline 66) recommend a target total cholesterol <4.0 mmol/L and LDL <2.0 mmol/L. Alternatively, JBS2 recommends a 25% reduction in total cholesterol with a 30% reduction in LDL-cholesterol, if this achieves lower absolute concentrations. Both guidelines recommend statins for those with diabetes who are aged >40 years and for those aged 18–39 years with diabetes complications (retinopathy and nephropathy), poor glycaemic control, hypertension, features of the metabolic syndrome or family history of premature CVD in a first degree relative.

Combination lipid-lowering therapy, to achieve additional lowering of LDL, may be considered in order to reach desired targets if these are not reached with maximum tolerated statin doses. To date, however, there is little evidence to show that combination therapy to lower LDL produces significant cardiovascular risk reduction over and above statin therapy alone. We would advocate a strategy of: (1) assessing overall risk and choosing targets for LDL, triglyceride and HDL; (2) excluding secondary causes of hyperlipidaemia and optimizing glycaemic control; (3) optimizing lifestyle options, and (4) targeting LDL-cholesterol with a statin. These drugs may in addition produce minor favourable effects on HDL-cholesterol and triglycerides. It should be noted that therapy targeting HDL or triglycerides does not have the evidence base of statin treatment.

Severe hypertriglyceridaemia requires lifestyle and pharmacological therapy. A fibrate or ω -3 fatty acid-rich marine oils may be used to reduce the risk of pancreatitis associated with high triglycerides. Any statin–fibrate combination requires care because of the potentially increased risk of rhabdomyolysis, and monitoring of plasma creatine kinase activity may be appropriate.

Hypertension

Assiduous control of blood pressure (BP) has been shown to reduce major cardiovascular events and minimizes progression of diabetes complications. In the UK Prospective Diabetes Study (UKPDS), intensive treatment of hypertension to a median of 144/82 mmHg was compared with conventional BP treatment (median BP in the control

group was 154/87 mmHg). Intensive treatment resulted in reductions in multiple diabetes-related endpoints, including death. The majority of subjects in the tight control arm of the study required three or more agents in order to achieve this. The ADA has adopted an even more aggressive target of 130/80 mmHg on the basis of epidemiological risk studies showing an inflexion in the relationship between BP in patients with diabetes and cardiovascular risk at 115/75 mmHg.

Apart from more rigorous treatment goals, management of hypertension in patients with diabetes is similar to that in patients without the condition. Initially, lifestyle changes are recommended including weight loss, exercise and dietary modifications, such as a reduction in sodium and alcohol intake and increased consumption of fruit and vegetables. However, if blood pressure remains inadequately controlled despite lifestyle modifications, pharmacological therapy may be commenced.

Some patients will have comorbid conditions that will direct the choice of drug therapy. The presence of microalbuminuria, proteinuria, mild to moderate renal impairment, diabetic retinopathy, ischaemic heart disease, stroke and left ventricular systolic dysfunction would, for example, indicate a specific role for an angiotensin-converting-enzyme (ACE) inhibitor or angiotensin-II receptor antagonist (blocker) (ARB). Given the potentially beneficial effects of ACE inhibitors and ARBs on glycaemia and in the prevention of diabetic complications such as diabetic nephropathy (see below), they are generally considered as first-line agents in patients with diabetes if lifestyle changes do not improve blood pressure.

β -Blockers, diuretics, and calcium channel blockers have all been shown to reduce cardiovascular events in patients with diabetes, and all may be used in combination with an ACE inhibitor or ARB. Most patients will require multiple agents to manage their hypertension. Generally initial treatment will be with either an ACE inhibitor or ARB, and if required, a calcium channel blocker, then a thiazide diuretic, β -blocker, α -blocker or potassium-sparing diuretic. It is important to monitor renal glomerular function and plasma potassium concentration whenever ACE inhibitors, ARBs or diuretics are used. Thiazides are effective, but unwanted effects including hyperglycaemia, erectile dysfunction, gout and dyslipidaemia have reduced their use as first line agents. β -Blockers are specifically indicated in some situations, for example stable heart failure and ischaemic heart disease, and were found to be safe and effective in the UKPDS. However, they may promote weight gain and, in some patients with impaired awareness, hypoglycaemia may be a problem. In the Anglo-Scandinavian Cardiac Outcome Trial (ASCOT), treatment with an atenolol-thiazide-based regimen was associated with 30% greater incidence of new type 2 diabetes than treatment with an amlodipine-perindopril-based regimen, and was less effective at reducing BP and cardiovascular events in patients with established diabetes.

In the past, there were concerns about the safety of the dihydropyridine group of voltage activated calcium channel blockers. However, results from the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) and ASCOT have been reassuring, and

it now seems reasonable to recommend amlodipine as a second-line agent in combination with an ACE inhibitor or ARB (although amlodipine and other calcium channel blockers inhibit the metabolism of simvastatin, which must not be co-prescribed at high dose).

α -Blockers appear effective and have favourable effects on insulin sensitivity and LDL-cholesterol concentrations. However, ALLHAT showed an apparent doubling in the incidence of heart failure (a secondary outcome measure) with an α -blocker compared with a thiazide diuretic. For this reason, α -blockers are generally reserved for use where treatment with at least two other classes of hypotensives in combination has failed to achieve the target BP.

Angiotensin-converting-enzyme inhibitors and angiotensin-II receptor antagonists

Angiotensin II (ATII) increases hepatic glucose production and decreases insulin sensitivity. The use of ACE inhibitors or ARBs consistently increases insulin sensitivity by some 15–20% in pharmacological studies. The Heart Outcomes Prevention Evaluation (HOPE) study was terminated early after interim analysis demonstrated that 4.5 years of treatment with the ACE inhibitor ramipril, 10 mg daily, reduced major vascular events and death in subjects with preserved left ventricular function, and either pre-existing vascular disease or those with diabetes and an additional vascular risk factor. The latter group also had a reduced risk (relative risk 0.84) for the development of diabetic complications. In an extension to the study to a total of 7.2 years follow-up, there was a 31% relative risk reduction for new diagnosis of type 2 diabetes.

Results of other studies and meta-analyses have, in general, not shown such large benefits in patients who already have diabetes (unless with other clearly established indications), although they have generally been restricted to relatively small subgroup analyses. While it is not clear whether all (non-pregnant) patients with diabetes should be offered these agents, ACE or AT-II inhibition is clearly indicated for subjects with diabetes and hypertension, microalbuminuria, proteinuria, mild to moderate renal impairment, diabetic retinopathy, ischaemic heart disease, stroke or left ventricular systolic dysfunction. Caution must be exercised with the use of these agents when renal artery stenosis is present (e.g. in patients with impaired renal function and absent distal pulses or a renal bruit) and in subjects with hyporeninaemic hypoadosteronism (type 4 renal tubular acidosis), in whom dangerous hyperkalaemia may result.

GLUCOSE-LOWERING THERAPY IN DIABETES

Background

Trials in both type 1 Diabetes Control and Complications Trial (DCCT) and type 2 (UKPDS) diabetes have confirmed that microvascular, and, to a lesser extent, macrovascular, complications of diabetes may be delayed or even prevented by tight glycaemic control. The UKPDS (1998) trial in type 2 diabetes found that a 10 mmol/mol

(0.9%) reduction in HbA_{1c} from 63 to 53 mmol/mol (7.9–7.0%) over a median follow-up of ten years from diagnosis led to a reduction of 12% for any diabetes-related endpoint, 25% for microvascular endpoints and 24% for cataract extraction, and of 21% for retinopathy and 33% for albuminuria at 12 years. The improvements in macrovascular disease were less convincing and of borderline statistical significance.

The DCCT (1993) trial in type 1 diabetes showed a risk reduction of 26–63% in microvascular disease with intensive insulin therapy, but at the cost of a three-fold elevation in the incidence of severe hypoglycaemia (fits, unconsciousness) and some additional weight gain compared with the control arm of the study. However, the use of more modern insulin analogues has been associated with lower incidence of hypoglycaemia.

Insulin use in type 1 diabetes

Patients who have been diagnosed with type 1 diabetes will require insulin therapy along with general measures such as dietary and lifestyle changes. Although it is often considered that patients with type 1 diabetes have no useful islet cell function, this is not entirely true. In fact, β -Cell function is approximately 10% of normal at disease presentation, and may double after the initiation of insulin therapy, resulting in a reduced requirement for exogenous insulin and stabilization of glucose metabolism ('honeymoon effect'). This effect does not last and, in the majority of patients, insulin secretion declines again over the next 2–5 years.

The 'honeymoon effect' may reflect, in part, the amelioration of glucotoxicity or lipotoxicity (see Chapter 15) on the reduced numbers of metabolically stressed β -Cells. After initiation of insulin therapy, the toxic effects of hyperglycaemia are removed, thereby relieving this metabolic stress. In some studies, as many as 10% of patients with newly diagnosed type 1 diabetes have been maintained off insulin altogether for the first year, but this is clearly not recommended in routine clinical practice because of the risks of ketoacidosis.

In a subset (~15%) of patients, there is retention of some detectable islet function, as assessed by C-peptide secretion, for at least 40 years. These individuals also appear to have reduced susceptibility to severe diabetic ketoacidosis (DKA), less risk of retinopathy, a more robust glucagon response to hypoglycaemia and lower average insulin requirements.

A number of trials have attempted to augment residual insulin secretion with immunosuppressive drugs (e.g. steroids, azathioprine, antithymocyte globulin and ciclosporin) or by plasmapheresis, and these measures have been met with some success but, on current evidence, their benefits have not been clearly outweighed by their risks. Studies using strict metabolic control in order to mitigate any effects of lipotoxicity or glucotoxicity on the β -Cell (e.g. with continuous subcutaneous insulin infusion, CSII) have been able to demonstrate transiently preserved insulin secretion, but only for a period of a few months, with rapid regression on discontinuation of strict metabolic control.

Regular insulin

Regular human insulin (e.g. Actrapid[®], Humulin S[®]) has an onset of activity within 30–60 min after subcutaneous injection, a variable peak concentration at around 2–4 h, and a duration of action of 5–8 h, contrasting with its duration of action of only a few minutes when administered intravenously. This difference may be explained by the tendency for hexamerization in solution.

The hexameric form of regular insulin has to dissociate into dimers or monomers in order to be absorbed into the bloodstream. This is rate-limiting for its absorption and influences the pharmacokinetic profile. As such, in order to treat prandial glucose peaks, regular insulins have to be injected about 30 min before each meal so that the onset of action coincides with the rise in prandial glucose concentrations.

Insulin analogues

More recent developments in insulin technology have focused on the design and production of insulin analogues whose pharmacokinetic profiles are determined by modifications to non-receptor-binding regions of the insulin molecule.

Insulin aspart (Novorapid[®]) is homologous with regular human insulin with the exception of a single substitution of aspartate for proline in position B28 of the B chain: it is produced by recombinant DNA technology in *Saccharomyces cerevisiae* (baker's yeast). Insulin lispro (Humalog[®]) is identical to normal human insulin except that the positions of the amino acids proline and lysine at B28 and B29 are reversed. In insulin glulisine (Apidra[®]), asparagine is replaced by lysine at position B3, with glutamic acid replacing lysine at B29. As a result of these changes in amino acid sequence, the rapid insulin analogues (aspart, lispro and glulisine) have a lower tendency to form hexamers, permitting more rapid absorption and a faster onset of action (<15 min), enabling injection immediately before, or just after, eating. There is a sharper peak, more closely resembling first-phase insulin secretion in the non-diabetes state, and a shorter duration of action (3–5 h), which may reduce the incidence of hypoglycaemia before the next meal is ingested.

Intermediate-acting insulin

Isophane (NPH, Neutral protamine Hagedorn) is an intermediate-acting insulin that is a combination of soluble insulin and protamine zinc. Protamine delays the onset of action and prolongs the effects of the soluble insulin. The onset of action is within two hours, with a duration of action of 10–20 h. Most patients require two subcutaneous injections daily to provide adequate glycaemic control. Isophane has fallen out of favour because of increased risks of nocturnal hypoglycaemia and fasting hyperglycaemia.

Premixed insulin analogues

The most commonly prescribed premixed insulins are a mixture of quick acting analogue and an insulin analogue protamine complex (e.g. Novomix 30[®] is composed of

insulin aspart-protamine complex and insulin aspart in a ratio of 70:30). These are usually given as a twice-daily regimen.

Long-acting insulin analogues

Longer-acting insulin analogues (insulin glargine and insulin detemir) are produced by genetic engineering. The onset of action is within two hours and they have a longer duration of action of up to 24h. These insulins provide a steady basal insulin profile with minimal peak action and are injected subcutaneously once daily.

In insulin glargine, asparagine is replaced by glycine at position 21 of the α chain of the insulin molecule and the carboxyl terminal of the β chain is changed with the addition of arginine. This insulin is slowly released into the circulation because of its acidic pH, which causes it to precipitate when injected subcutaneously. In insulin detemir, tyrosine at position B30 is lost with acylation at B29 that results in a fatty acid side chain (tetradecanoic acid) becoming linked with lysine. With these alterations, insulin detemir forms hexamers with slower dissociation and a longer duration of action.

Insulin regimens

Most patients with type 1 diabetes use an insulin replacement regimen that comprises multiple-dose subcutaneous injections (three to four injections per day) consisting of basal and prandial insulin. Insulin is injected subcutaneously. Short-acting insulin (regular soluble or analogue) acts to control prandial blood glucose concentrations; long-acting insulin provides a constant background basal insulin concentration. This combination of short-acting and long-acting basal insulin is called the basal bolus regimen or multiple daily injection therapy. Most people take their long-acting insulin at bedtime in order to provide optimal glycaemic control overnight. Some patients learn how to adjust insulin doses according to carbohydrate intake (in the UK often through attendance at a DAFNE (dose adjustment for normal eating) course).

An alternative is a twice daily insulin regimen consisting of a premixed or biphasic mixture of longer- and shorter-acting insulins in ratios of 75:25, 70:30 or 50:50. Such regimens are commonly used in type 2 diabetes and in patients with type 1 diabetes before they progress to a basal bolus regimen. Some patients with type 1 diabetes prefer twice daily insulin to the basal bolus regimen, particularly those who dislike frequent injections, but it is not suited to those whose diet and activities tend to differ on a day-to-day basis, as there is less scope for dose adjustment in relation to carbohydrate intake, with attendant risks of hypoglycaemia. The longer-acting component may not provide effective glycaemic control overnight because of a waning of the effect of the previous evening's dose, a decrease in insulin sensitivity in the early hours of the morning, and increases in growth hormone and cortisol concentrations, all of which will increase the risk of early morning hyperglycaemia (the 'dawn' phenomenon). Premixed insulin preparations are, therefore, not recommended for long-term treatment

in type 1 diabetes and most patients are eventually recommended to convert to the basal bolus regimen for optimal glycaemic control. The relative merits and disadvantages of these two regimens, and a comparison with continuous subcutaneous insulin infusion, are outlined in Table 16.1.

Continuous subcutaneous insulin infusion

Continuous subcutaneous insulin infusion pumps ('insulin pumps') are portable devices that deliver a continuous subcutaneous infusion of short-acting insulin at a set rate. The pump is battery-driven and comprises a reservoir containing about 3 mL of insulin in a syringe. A syringe driver delivers insulin via a cannula that is inserted subcutaneously into the abdominal wall. The cannula is re-sited every 1–2 days to avoid skin infections. In addition to the continuous basal infusion, the patient triggers the delivery of an additional dose at mealtimes to provide prandial cover.

The advantages of a pump include having a basal insulin rate that is personalized to each individual, allowing more flexibility with regards to mealtimes as the basal rate can be supplemented with a corrective mealtime insulin dose according to the carbohydrate consumed. Studies have shown improved glycaemic control in pump users. However, in the event of pump failure, there is the risk of diabetes ketoacidosis occurring.

Clinical indications for pump therapy include poor glycaemic control despite high levels of care, disabling hypoglycaemia on multiple daily injection regimens, recurrent unpredictable hypoglycaemia, especially in patients with severe dawn phenomenon and pregnant women without acceptable glycaemic control with subcutaneous insulin. Before each patient is commenced on the insulin pump, they must attend a comprehensive educational pump course. They must be sufficiently motivated to use the pump, with a commitment to regular blood glucose monitoring, attendance at pump clinics and adherence to carbohydrate counting so that they will be able to manage their pump. Close liaison with the diabetes pump team is essential for the success of this form of therapy.

It should be stressed that when deciding which regimen to use, each patient's specific circumstances will need to be carefully considered in light of different needs, goals and capabilities and the level of support available. An important factor is the risk of hypoglycaemia that comes with insulin therapy. There should be a balance between achieving optimal glycaemic control whilst at the same time ensuring each patient's safety, in terms of hypoglycaemia risk, when deciding on which insulin and regimen is to be used.

Insulin administration

The recommended subcutaneous injection sites include the abdomen, upper outer thighs, upper outer arms and buttocks. It is important to avoid injecting insulin intramuscularly. This commonly occurs in the limbs of slim individuals or children and can influence insulin absorption and hence blood glucose profiles.

TABLE 16.1 Comparison of different insulin regimens

	Twice daily mixed insulin	Basal-bolus regime	Constant subcutaneous insulin infusion (CSII)
Glycaemic control	Some patients achieve excellent results but, in general, the method is inferior to basal-bolus insulin regimens and most adult patients with type 1 diabetes requiring good control should probably use an alternative regimen	Potential for very good control in most individuals. Little evidence that it is systematically less efficacious than CSII	Potential for the best possible control, but training and considerable patient expertise required. May not be suitable for patients with totally erratic control. Expensive (both unit cost and disposables)
Flexibility of eating	Hypoglycaemia during mid morning a specific problem without snacking. Most suitable for those whose diet and lifestyles are similar from day-to-day	Basal insulin dose usually sufficient to avoid ketoacidosis if a meal and its associated insulin are missed. Additional correction doses may be given if pre-meal blood glucose is elevated. Additional dose may be given to cover unscheduled eating, e.g. a snack, ice-cream	Greatest possible flexibility
Hypoglycaemia risk	Particular risk if lunch delayed or small. Risk if dose is adjusted, e.g. to cover a large meal without considering the effect this will have on the longer-acting insulin in the mixture. The longer-acting insulin component used in the early evening rather than before bed risks morning hyperglycaemia (dawn phenomenon), and increases in dose may risk hypoglycaemia earlier in the night, as peak action (6–8 h) may occur after maximum growth hormone secretion in early deep sleep	Depends on doses used and degree of control aimed for. Some evidence that insulin analogues maintain/improve glycaemic control with reduction in hypoglycaemia	Depends on doses used and degree of control aimed for. User error may lead to hypoglycaemia
Number of injections	Lowest possible in type 1 diabetes (two per day)	More injections (4–5 depending on whether a single dose of longer-acting insulin achieves adequate 24 h cover)	No injections (abdominal cannula left in situ for 24–48 h) but the needle site may be irritating/painful. Infections at insertion site are unusual but very unpleasant
Dosage titration principles	Titrate morning dose to pre-evening meal blood glucose and evening dose to pre-breakfast blood glucose. Difficult to adapt to a specific meal or situation (e.g. exercise) as adjustment of each insulin independently is not possible (use of different mixes at different times theoretically possible but rarely done). May be particularly suitable for patients who prefer not to titrate insulin doses themselves and who have little day-to-day variation in lifestyle. Consider changing the mix if necessary to provide more or less soluble insulin based on blood glucose measurements 2 h after breakfast and evening meal. Basic regimen may be adapted, e.g. supplemented with soluble insulin at lunchtime	Titrate basal insulin to fasting (especially pre-breakfast) blood glucose concentrations and bolus insulin to 2 h postprandial results for each meal. Carbohydrate counting (e.g. the dose adjustment for normal eating (DAFNE) principle) may be applied, noting that greater doses may be required for the same effect in the morning than in the evening. Correction doses may be applied according to pre-meal blood glucose concentrations if prepared to test at least thrice daily. Basic regimen may be adapted, e.g. by using an insulin mixture with breakfast to avoid the need for a lunchtime injection. Type of each insulin may be adapted to need, e.g. Actrapid® vs NovoRapid®, depending on the interval between meals and blood glucose values by the time of the next meal after optimal titration of basal insulin	Complex programming is possible (e.g. different regimens for work days and weekends). Typically 50% of the total daily insulin is given as basal insulin at 1–2 units/h during the day and 0.5 units/h at night, increasing to coincide with the dawn phenomenon with the remaining 50% given as mealtime boluses depending on the timing, size, content and glycaemic index of the meal to be ingested. Basal rates may be varied according to other activities, e.g. exercise, illness
Other	Difficult to use when sick day rules apply: risk of ketoacidosis	Less risk of ketoacidosis as patient may titrate short-acting insulin to blood glucose taken 4–6 hourly when ill, noting that the total daily dose may need to be increased when ill	Risk of ketoacidosis associated with mechanical failure (e.g. pump stops, needle falls out, blocks) becoming less of a problem with advances in design and alarming of systems

As a result of the trophic action of insulin, an accumulation of fat, called lipohypertrophy, may occur at sites of repeated subcutaneous insulin injections. Lipohypertrophy can affect insulin absorption, causing problems such as hypoglycaemia, but can be avoided by rotating injection sites. Insulin injection sites should be inspected when patients attend for their diabetes review.

Glycaemic management in type 2 diabetes

When type 2 diabetes is diagnosed, lifestyle modification should be advised initially, and metformin commenced in combination with lifestyle if HbA_{1c} does not reach target after three months. If glycaemic control remains poor after 3–6 months, further oral agents, or a glucagon-like peptide 1 (GLP-1) receptor agonist or insulin may be added. Some patients with marked hyperglycaemia may be commenced on insulin at diagnosis if it is deemed that non-insulin agents will not provide the necessary control of blood glucose.

Metformin

Metformin belongs to a class of drugs called the biguanides that act to reduce insulin resistance, therefore improving insulin sensitivity. Metformin is the only biguanide currently available. It has an established role in the treatment of type 2 diabetes in combination with diet and lifestyle measures. The UKPDS study showed that obese patients treated with metformin had reduced myocardial infarction (by 6%), stroke (by 3%) and mortality (by 7%). These effects were independent of improved glycaemic control.

Metformin has the clear advantage over many other drugs of improving glycaemic control without causing weight gain. Metformin does not cause hypoglycaemia and may even lead to weight loss by suppressing appetite. As such, it is often prescribed as first line treatment in patients who are overweight. Several of the adverse features of the metabolic syndrome, including raised circulating concentrations of non-esterified fatty acids (NEFAs), triglycerides and plasminogen activating inhibitor-1 (PAI-1), are improved by metformin. Metformin has an effect on blood glucose that is additive to, and broadly equivalent to, that of sulfonylurea monotherapy. In type 2 diabetes, metformin can be used as monotherapy, or combined with insulin or with sulfonylureas, dipeptidyl peptidase IV (DPP-4) inhibitors, GLP-1 analogues or thiazolidinediones. In type 1 diabetes it is sometimes used together with insulin for obese adults, although this usage is currently unlicensed. Metformin may also be considered in patients who are not overweight.

Metformin has a useful role in diabetes prevention; a 31% relative reduction in the progression of diabetes was observed in the Diabetes Prevention Programme (DPP) placebo-controlled study, with greatest effect in younger and more obese subjects. Metformin also has a possible role in the treatment of polycystic ovary syndrome (PCOS), alone or in combination with drugs acting on sex steroid metabolism, particularly in those patients who are also glucose intolerant.

Mechanism of action

Metformin decreases hepatic gluconeogenesis and glucose output, improves peripheral glucose uptake and utilization in insulin-sensitive tissue such as muscle and adipose tissue, and may reduce intestinal glucose transport. Its actions depend on the presence of adequate β -Cell function, and therefore insulin in the circulation. The exact mechanism of action of metformin is not clear but it may work through the activation of an intracellular AMP-activated protein kinase.

Lactic acidosis

Lactic acidosis is a rare but serious complication that can occur whilst taking metformin. Lactic acidosis was more frequently reported with phenformin, another biguanide that was subsequently withdrawn in most countries in 1977 after 306 documented cases. While phenformin excretion relies upon hepatic hydroxylation (pharmacogenetically deficient in approximately 10% of Caucasians), metformin is subject to renal tubular secretion, and its excretion depends only on renal function.

Lactic acidosis presents with non-specific symptoms such as lethargy, nausea, vomiting, altered level of consciousness and abdominal pain. Biochemical features of lactic acidosis are those of an elevated anion gap metabolic acidosis with high blood lactate concentrations. There appears to be no direct correlation between blood concentrations of metformin and lactate, and the overwhelming majority of cases of lactic acidosis have occurred in the setting of major comorbidities (Table 16.2). These include conditions associated with increased lactate formation (e.g. cardiac failure, pulmonary disease), reduced lactate metabolism (e.g. hepatic failure) and reduced metformin and lactate excretion (e.g. renal failure).

There is an increased risk of lactic acidosis in patients treated with metformin who receive radiological contrast media. This may be avoided by withholding metformin for a few days before and after the intended radiological procedure.

A systematic review has shown that there is no evidence from prospective comparative trials or from observational cohort studies that metformin is associated with an increased risk of lactic acidosis, or with increased plasma concentrations of lactate, compared with other antihyperglycaemic treatments, if prescribed as licensed. Patients with significant cardiac, renal or liver dysfunction should not receive metformin. As metformin is renally excreted, there is the attendant risk of accumulation in acute or chronic kidney disease, resulting in an increased risk of lactic acidosis. It is recommended by NICE that prescription of metformin should be reviewed in patients with a glomerular filtration rate (GFR) $<45 \text{ mL/min/1.73m}^2$ and it is to be avoided in those with a GFR $<30 \text{ mL/min/1.73m}^2$. Some physicians recommend that metformin should not be used if the patient's plasma creatinine concentration is raised to any extent; others argue that guidelines have been progressively tightened with no reduction in the incidence of lactic acidosis, which has anyway always been very low throughout the history of metformin usage. Although some formularies suggest avoiding metformin when plasma creatinine

TABLE 16.2 Cautions with and contraindications to the use of metformin

Cautions or contraindications	Reason
Old age	Renal and other organ impairment
Tissue hypoxia	Increased lactate production via anaerobic glycolysis, reduced gluconeogenesis
Pulmonary disease	Increased lactate production via tissue hypoxaemia and anaerobic glycolysis
Liver failure, ethanol	Reduced lactate clearance via inhibition of gluconeogenesis
Iodinated radiological contrast media	Risk of acute kidney injury, competition for renal tubular secretion
Cardiac impairment	Increased lactate production via poor tissue oxygen delivery
Shock states, severe dehydration	Increased lactate production via poor tissue oxygen delivery
Advanced microvascular disease	Risk of chronic kidney disease
Severe infection	Increased lactate production
Drugs affecting tubular secretion of metformin	Contrast media, cimetidine, digoxin, others
Type 2 diabetes itself	Microcirculatory disturbances, peripheral vascular disease, increased incidence of cardiac and renal disease, reduced activity of pyruvate dehydrogenase in insulin resistance favouring anaerobic metabolism

concentration is raised above certain thresholds, cardiac dysfunction is probably a more important, but less well recognized, contraindication to its use.

Other unwanted effects of metformin

The major side-effects of metformin include gastrointestinal problems such as nausea, abdominal discomfort, metal taste and diarrhoea. Many patients will experience these symptoms after commencing metformin but will eventually develop tolerance. These side-effects are generally dose dependent, and can be minimized by commencing at a low dose and then slowly titrating the dose upwards, or by using a slow-release preparation. Approximately 80% of the total benefit of metformin is seen with doses of around 1.5 g/day, which is close to the median tolerated dose. Metformin induces malabsorption of vitamin B₁₂ and folate but this is rarely clinically significant.

Sulfonylureas (and related insulin secretagogues)

First generation sulfonylurea (sulphonylurea) derivatives were first used to treat diabetes in the 1950s, following the observation in 1942 that certain sulphonamide antibiotics could provoke severe hypoglycaemia in patients treated for typhoid fever. They act as insulin secretagogues, reducing blood glucose concentrations by augmenting the first-phase release of immediately releasable (reserve) insulin from β -Cells. Unlike glucose-stimulated insulin release, there is little direct effect on insulin production. First generation sulfonylureas, such as chlorpropamide, were beset with unwanted effects including the syndrome of inappropriate antidiuresis (SIADH) and flushing. These drugs have largely been replaced by more potent and shorter acting second and third generation drugs (e.g. gliclazide) that lack these unwanted effects.

Mechanism of action

Central to the release of insulin from secretory granules (but not the only mechanism involved) is the closure of an ATP-sensitive membrane-bound inwardly rectifying 140 kDa K⁺ channel, K_{ATP}. In β -Cells, this channel is a

hetero-octamer of pore-forming units (K_{IR} 6.2) together with regulatory ATP binding cassette (ABC) protein sulfonylurea receptor 1 (SUR-1) molecules. The regulatory subunit, SUR-1, contains 13–17 transmembrane domains with a large number of possible protein kinase A or C phosphorylation sites, together with a number of distinct binding sites for other molecules (including the A and B sites to which sulfonylureas and other exogenous compounds attach, as discussed below). The existence or nature of the endogenous ligand at sulfonylurea binding sites is not clear. Closure of K_{ATP} channels depolarizes the plasma membrane, causing rapid influx of calcium ions via voltage dependent calcium channels. The resultant increase in free ionized cytosolic calcium concentration ([Ca²⁺]_i) triggers cytoskeletal trafficking of secretory granules to the plasma membrane and release of insulin by a process of exocytosis. Amplification of the signal generated by K_{ATP} closure occurs via a number of incompletely understood mechanisms, including direct mobilization of calcium from intracellular stores (e.g. by the action of glucagon-like peptide (GLP)-1 analogues). The effects of K_{ATP} channel opening are terminated by extrusion of K⁺ via a voltage gated K⁺ channel.

The principal mechanism of action of the sulfonylurea drugs is to close the K_{ATP} channel by binding to the A and B sites on SUR-1. Conversely, diazoxide, used in the treatment of certain hyperinsulinaemic conditions, is a potent opener of K_{ATP} channels, and thiazide diuretics also open β -Cell K_{ATP} channels (causing impairment of glucose tolerance).

Adverse effects of sulfonylureas

Concern has existed for many years that sulfonylurea drugs may have harmful cardiovascular effects (mainly arrhythmias). This concern was first raised in relation to tolbutamide (the University Group Diabetes Programme, UGDP). The action of sulfonylureas on cardiac K_{ATP} channels suggests a plausible mechanism for adverse cardiac effects.

In contrast to these predominantly theoretical reservations, analysis of UKPDS data does not support the suggestion of adverse cardiovascular effects from sulfonylureas. At the present time, and in the light of the Diabetes Insulin–Glucose in Acute Myocardial Infarction (DIGAMI) study results, many physicians would agree

that discontinuation of sulfonylurea drugs and substitution with insulin infusion is probably indicated in the setting of acute coronary syndromes. Some would also advocate the use of selective agents (e.g. nateglinide or glimepiride) in other cardiac patients, pending definitive data.

Other unwanted effects of sulfonylureas

Unwanted effects of the sulfonylureas include hypoglycaemia (particularly in elderly patients treated with longer-acting agents and in renal/hepatic failure), serious immunological reactions (Stevens–Johnson syndrome and other rashes), marrow dyscrasias, hepatitis, weight gain (typically 1–3 kg) and precipitation of acute porphyria. Contraindications to the use of these drugs include type 1 diabetes, pregnancy, lactation and significant hepatic and renal insufficiency.

Hypoglycaemia owing to deliberate or inadvertent overdose of sulfonylureas requires prompt and aggressive management. The first-line treatment is with a bolus of 50% glucose followed by continuous infusion of 10% or 20% glucose. If blood glucose cannot be maintained at safe levels with this treatment alone, hydrocortisone, glucagon or octreotide may be useful.

Indications and clinical usage

Sulfonylurea and derivative drugs are used to treat patients with type 2 diabetes who have adequate insulin reserve, but in whom lifestyle and dietetic improvements have failed to control hyperglycaemia. Doses are titrated to blood glucose and HbA_{1c} responses; primary failure of either to improve may indicate advanced β -Cell failure. Because of their tendency to promote weight gain, sulfonylureas are best used as first-line agents in non-obese patients, but may be added to metformin, thiazolidinediones or both in obese patients with secondary failure of these agents. Insulin therapy can be added if and when necessary. Weight gain with repaglinide and nateglinide (see below) may be less than with conventional sulfonylureas, and severe hypoglycaemia may be less common.

The extent to which postprandial hyperglycaemia rather than fasting hyperglycaemia contributes to diabetic complications remains the subject of considerable debate. Nevertheless, because of its ability to augment glucose-stimulated insulin release (as opposed to basal insulin release), meglitinides may be useful when postprandial hyperglycaemia in a patient with type 2 diabetes is the dominant clinical problem.

Meglitinides

Repaglinide and nateglinide are prandial glucose regulators that form the meglitinide class of drug. They are indicated in the treatment of patients with type 2 diabetes who have poor glycaemic control on diet control or metformin therapy. These agents are short-acting and act to increase insulin secretion by closing K_{ATP} channels of the β -Cell membrane via binding to a receptor distinct from that of sulfonylureas. Repaglinide binds to the B site of SUR-1 and nateglinide binds to the A site. The meglitinides are used in patients as monotherapy (repaglinide

only) or in combination with metformin (repaglinide and nateglinide). Given the rapid onset and short duration of action, these agents are taken between 15 and 30 min before each meal to provide postprandial glycaemic control. As repaglinide and nateglinide are rapidly metabolized in the liver and excreted in bile, these agents should not be used in patients with hepatic impairment.

Adverse effects of meglitinides

Hypoglycaemia is a common adverse effect. Other reactions include gastrointestinal effects such as abdominal pain, diarrhoea, constipation, nausea and vomiting; hypersensitivity responses such as pruritus, rashes and urticaria may occur.

Peroxisome proliferator activator γ analogues

Thiazolidinediones were originally developed as ligands for the orphan nuclear peroxisome proliferator activator receptor family (PPAR α , PPAR γ and PPAR δ). The endogenous activators of the nuclear PPAR receptors are fatty acids and fatty acid-derived eicosanoids, and it is now known that the actions of the fibrate group of lipid-lowering agents are mediated via PPAR α receptors. Activation of PPARs leads to the formation of heterodimers with the retinoid X receptor (RXR), bound to its own endogenous ligand, retinoic acid. These PPAR–RXR dimers bind to specific gene regulatory sequences (peroxisome proliferator response elements, PPREs), modulating the transcription of multiple (>40) target genes.

Thiazolidinediones are insulin sensitizers that act as ligands at the PPAR γ receptors, which regulate gene expression and transcription of glucose transporter molecules GLUT-4, lipoprotein lipase, fatty acid transporter protein and fatty acyl CoA synthase. The PPAR γ nuclear receptors are found in adipose tissue and also in liver and muscle. Their activation leads to improved insulin responsiveness by increasing glucose uptake, and adipose lipogenesis by regulating expression of adipose tissue adipokines.

Troglitazone, the first of these compounds to be introduced, was withdrawn following cases of idiosyncratic hepatotoxicity leading to acute liver failure. At present, the only thiazolidinedione in clinical use is pioglitazone. The other drug in this class, rosiglitazone has been linked to an increased risk of cardiovascular disorders such as myocardial infarction and heart failure, and to bone fractures. It is no longer recommended for use.

Mechanisms of action

It has been suggested that the insulin-sensitizing effects of PPAR γ agonists are almost exclusively a result of a ‘fatty acid steal’ mechanism, owing to their effect on adipose tissue, rather than direct effects on the pancreas, liver or peripheral insulin-sensitive tissues. This is because PPAR γ receptors are expressed chiefly in adipose tissue, with only low levels of expression in other insulin-sensitive tissues. Thiazolidinediones, acting via PPAR γ , increase free fatty acid uptake into adipose tissue (by ~60%) and also increase fatty acid oxidation in the liver, heart, kidneys and skeletal

muscle. These effects on adipose tissue are brought about by altering adipocyte gene expression, pre-adipocyte differentiation and fat distribution (favouring redistribution from central to subcutaneous depots). By such actions, hepatic NEFA uptake is reduced (by ~40%), rendering the liver more insulin-sensitive and giving these agents a potential role in the treatment of hepatic steatosis. However, thiazolidinediones have multiple actions, and it is by no means established that 'fatty acid steal' is their dominant mechanism of action.

Peroxisome proliferator activator receptor α is expressed in tissues that metabolize fatty acids extensively such as liver, kidneys, heart, and muscle. Its activation increases plasma HDL-cholesterol concentrations by transcriptional induction of the HDL apolipoproteins, apoA-I and apoA-II (see Chapter 37). Triglyceride concentrations are reduced by decreased hepatic apoC-III production and increased lipoprotein lipase expression. Low density lipoprotein subclass distribution is shifted toward larger particle species by changes in lipoprotein composition and interaction. Combination PPAR α/γ agonists are being developed in the hope that a single tablet may be able to benefit both the adverse lipid and glycaemic profiles of type 2 diabetes.

Pioglitazone may be used alone or in combination with metformin or a sulfonylurea, or with both as 'triple therapy'. While this may delay the need for insulin in some patients, the usual scenario is that pancreatic reserve is failing and that further delays in introducing insulin treatment are potentially hazardous. Pioglitazone is also licensed in the UK for prescription with insulin when metformin cannot be used. The maximum effects of pioglitazone take some 4–12 weeks to develop, and patients may experience a deterioration in glycaemic control during this period if switching from another agent. Pioglitazone is also sometimes used in the treatment of hepatic steatosis (an unlicensed indication). This use, however, should be considered carefully in each patient because of the associated risks.

Adverse effects

As pioglitazone may cause fluid retention, it is contraindicated in patients with heart failure; this risk may be increased if it is used in combination with insulin. The use of pioglitazone is associated with a small increased risk of bladder cancer it is therefore not recommended in patients with a history of bladder cancer or uninvestigated haematuria and should be used with caution in the elderly, given that the risk of bladder cancer rises with age.

Contraindications to the use of pioglitazone also include severe renal insufficiency, pregnancy, breastfeeding and hepatic dysfunction, with the possible exception of that arising from steatohepatitis. Fears over the potential to cause liver damage requires that plasma aminotransferase activity should be monitored two-monthly over the first year after starting treatment. Weight gain of 1–4 kg is predictable from the mechanism of action, but the potential for this to interfere with insulin sensitivity is more than offset by the favourable redistribution of adipose tissue. Fluid retention may cause a mild dilutional anaemia (haemoglobin typically falls by 10–20 g/L) and ankle oedema (in 5–10% of individuals, more when used in combination with insulin).

Glucagon-like peptide 1 analogues

Proglucagon is a product of the glucagon gene, which undergoes post-translational cleavage in pancreatic α -cells to form glucagon and in the L cells of the small bowel, to form glucagon-like peptide 1 (GLP-1), which is produced in response to food in the gastrointestinal tract. Glucose-dependent insulinotropic polypeptide (GIP) is secreted by the K cells in the duodenum. The incretin effect occurs when oral glycaemic stimuli, in the form of food intake, stimulate insulin secretion. It is mediated by the gastrointestinal incretins GLP-1 and GIP, which stimulate insulin synthesis and secretion. In addition, GLP-1 delays gastric emptying and intestinal transit and reduces food intake by promoting satiety.

The incretin response is reduced in type 2 diabetes and the incretin analogues (called incretin mimetics) have been developed for use in its treatment. Human GLP-1 has a short half-life because of the degradation of the N terminal by dipeptidyl peptidase IV (DPP-4) and therefore synthetic GLP-1 analogues (exenatide and liraglutide) have been developed that share the effects of GLP-1 but are resistant to cleavage by DPP-4.

Mechanisms of action

The actions of GLP-1 include increasing the insulin secretion resulting from any given glycaemic stimulus, slowing the rate of gastric emptying and intestinal transit, increasing satiety and reducing the secretion of glucagon. Glucagon-like peptide 1 also has trophic effects on β -Cells, stimulating differentiation and proliferation of progenitor cells in the pancreatic ductal epithelium and inhibiting β -Cell apoptosis. Glucagon and GLP-1 both stimulate insulin secretion by raising cytosolic calcium concentrations by mechanisms distinct from those involving the K_{ATP} channel of β -Cells. Receptor binding increases cyclic AMP generation, which impedes sequestration of calcium into intracellular organelles following glucose-stimulated K_{ATP} channel closure. Endogenous GLP-1 has a very short half-life (1–2 min) and is therefore not a practical therapy.

Exenatide is a synthetic analogue of a 39 amino acid exendin-4 peptide that was found in the saliva of the *Heloderma suspectum* (Gila monster) lizard. It requires twice daily subcutaneous injection. More recently, a once weekly preparation of exenatide has been approved. Liraglutide has a more prolonged duration of action compared to exenatide because of greater resistance to inhibition by DPP-4.

These agents are used in patients with type 2 diabetes who have inadequate glycaemic control on one or two oral agents who are intolerant of other oral agents, or in whom use of other oral agents is contraindicated. Their use should preferably be reserved for patients with a body mass index (BMI) >35 kg/m² or when BMI is <35 kg/m² and insulin therapy is not appropriate for work-related reasons because of the risk of hypoglycaemia, or when weight loss is desirable. Recently both liraglutide and exenatide have also been shown to be of benefit when used in combination with insulin, as they can help reduce insulin doses and promote weight loss.

Adverse effects

The main side-effects that limit the tolerability of GLP-1 analogues are gastrointestinal problems such as nausea, diarrhoea, vomiting and abdominal distension, and injection site reactions. Hypoglycaemia is possible when used in combination with a sulfonylurea or insulin. Renal failure has been reported with exenatide use. Pancreatitis has been reported, and should be considered in patients taking GLP-1 analogues who report severe abdominal pain. Liraglutide should not be used in patients with a history of medullary thyroid carcinoma or multiple endocrine neoplasia type 2 because of potential stimulation of thyroid C-cells, observed in rodent studies.

Dipeptidyl peptidase IV inhibitors

The GLP-1 and GIP incretins are metabolized by cleavage of the N-terminal by dipeptidyl peptidase IV (DPP-4), an enzyme that is ubiquitously expressed. Inhibiting DPP-4 activity prolongs the half-life and increases circulating concentrations of the incretins, thereby stimulating insulin secretion and inhibiting glucagon release. Members of the DPP-4 inhibitor class of drugs include: sitagliptin, saxagliptin, linagliptin and vildagliptin. These may be used as monotherapy or in combination with metformin, a sulfonylurea or pioglitazone in patients who fail to reach glycaemic targets with monotherapy; some can also be used in combination with insulin.

Adverse effects of DPP-4 inhibitors

Inhibitors of DPP-4 do not cause weight gain or weight loss. Hypoglycaemia is uncommon but may occur when they are taken with a sulfonylurea or insulin. Other adverse effects include upper respiratory tract infections, headache and nasopharyngitis. Cardiovascular outcome studies are currently ongoing but thus far, have not shown any significant reduction in cardiovascular risk.

Alpha-glucosidase inhibitors

This class of drugs (acarbose, miglitol) inhibit the α -glucosidase enzymes that break down carbohydrates into monosaccharides at the intestinal border. By delaying the breakdown of carbohydrates in the small bowel, prandial absorption of glucose is reduced, resulting in improved control of postprandial blood glucose concentrations. The use of these drugs is limited by intolerance to the gastrointestinal effects of undigested carbohydrate in the bowel, causing, in particular, excessive flatulence and diarrhoea. The gastrointestinal symptoms do, however, discourage excessive carbohydrate consumption. Hypoglycaemia may occur in association with use of insulin or sulfonylureas.

Sodium-glucose co-transporter 2 (SGLT2) inhibitors

This new class of drugs includes dapagliflozin and canagliflozin. These agents block the reabsorption of glucose by the SGLT2 transporter in the proximal renal tubules, resulting in 70-80 g of glycosuria per day. They have been shown to reduce HbA_{1c} by between 7 and 11 mmol/mol

when used as monotherapy or added to other agents such as metformin and sulfonylureas in dual or triple combinations, or with insulin. They also result in modest weight loss (about 2-3 kg) and reductions in blood pressure. Because of their mode of action, they are less effective in patients with renal impairment.

Side effects include an increased risk of fungal genital infections and a slightly increased risk of urinary tract infections. The intrinsic risk of hypoglycaemia is low. They should be avoided in patients taking loop diuretics because of the small risk of volume depletion.

Insulin use in type 2 diabetes

Insulin may be initiated in patients with type 2 diabetes when glycaemic control is poor or at presentation if symptoms and signs are such that type 1 diabetes cannot be excluded. Patients with type 2 diabetes require insulin treatment after a median of seven years from diagnosis. The decision to start insulin treatment is often a difficult one, and will depend on many factors relating to individual patient preference and circumstances as well as glycaemic status. It is apparent from the UKPDS that type 2 diabetes is a progressive condition, and that once fasting hyperglycaemia occurs, drug treatment, even when intensive, will improve glycaemic control only transiently, with the subsequent deterioration of β -Cell function and glycaemic control paralleling that of less intensively treated patients, albeit after some initial improvement. Many patients are reluctant to start insulin but are willing to take several oral hypoglycaemic agents. In some cases, the addition of a third oral hypoglycaemic (e.g. metformin, DPP-4 inhibitor plus thiazolidinedione or metformin, sulfonylurea plus DPP-4 inhibitor) may be effective, at least for a while. Responses to the addition of a thiazolidinedione are variable, but in some cases worthwhile. However, treatment failures are also common, and failure to reduce HbA_{1c} values by a pre-determined amount (e.g. >10 mmol/mol (1%)) after six months should lead to reconsideration of insulin treatment, as adequate insulin reserve is required for thiazolidinedione action.

Initial insulin treatment in type 2 diabetes is usually with either a once daily intermediate acting insulin (isophane) or long-acting insulin (glargine or detemir). Some patients are commenced on a twice daily premixed insulin regimen (e.g. 30% short-acting insulin and 70% intermediate acting insulin). Insulin treatment in individuals who are overweight may lead to further weight gain. This is because of: the anabolic effects of insulin; reduced energy loss through glycosuria; possibly increased oral intake because of need to avoid or treat hypoglycaemia, and altered lifestyle, exercise and diet with insulin therapy. With increased weight, these patients face problems of increased insulin resistance, and consequently, the required insulin doses needed to maintain glycaemic control rise, leading to further weight gain.

Bariatric surgery

Weight loss is an important component in the management of overweight and obese subjects with type 2 diabetes. Bariatric surgery may be performed in selected obese patients with diabetes, preferably before the development of irreversible complications and after the exhaustion of

conservative measures including diet, exercise and drug therapy. Surgery should be considered in patients with type 2 diabetes who have a BMI of $>35 \text{ kg/m}^2$ (as recommended by NICE and the ADA). It is likely that this will be an increasingly considered option for patients with suitable psychological and medical reserves (see Chapter 11 for further details).

Bariatric surgery improves glycaemic control, depending on the surgical procedure, with 'remission' rates of diabetes (defined as resolution of clinical and laboratory manifestations of type 2 diabetes) reported to be as high as 78% in a meta-analysis. Surgery is associated with restoration of first-phase insulin response in up to 80% of subjects. The Swedish Obesity Study compared the effects of bariatric surgery in 2010 obese subjects with 2037 obese controls and found that bariatric surgery was associated with a decreased incidence of diabetes and, in those with type 2 diabetes at baseline, increased diabetes remission rates at two years and at ten years. Not only have improvements in glycaemia been reported well before weight loss becomes apparent, but they appear also to exceed those expected on the basis of the amount of weight lost. It has been proposed that increased secretion of a number of gut peptides with insulinotropic actions such as GLP-1 and GIP, and decreased secretion of orexigenic peptides such as ghrelin, may be responsible for the success of bypass techniques, raising the intriguing possibility that operations of this kind have a partly endocrine mechanism of action. As energy intake following surgery is changed, it may be necessary to adjust glucose lowering therapy to avoid severe hypoglycaemia.

Pancreatic transplantation

Simultaneous pancreatic and kidney transplantation has been performed in patients with established renal failure, and is a reasonable option to consider at this stage in patients with glycaemic instability, who are physically fit and psychologically well prepared. Pancreas-alone transplants have also been carried out and may sometimes be considered in patients with recurrent hypoglycaemia. Although complete independence from insulin medications is possible, this form of treatment requires immunosuppressive therapy and is limited by the availability of organs for donation.

Islet cell transplantation

Islet cell transplantation may be used in patients with severe hypoglycaemia unawareness. This uses cadaveric pancreatic islets cells that are infused through a catheter placed into the hepatic portal vein. However, it is limited by donor availability and low rates of independence from insulin medications because of graft attrition. The Clinical Islet Transplantation (CIT) consortium, a network of centres in North America and Europe, is conducting studies on islet transplantation in type 1 diabetes, but the clinical outcomes are not yet known.

Immunotherapy for type 1 diabetes

Immunomodulatory therapies for type 1 diabetes are the subject of phase II and phase III clinical trials. These

treatments target specific antigens or modulate the immune system with the aim of establishing immune tolerance and preventing the destruction of pancreatic β -Cells. The concept of tolerance is important in that in autoimmune disease, the immune system loses its tolerance to a particular antigen, which may be a mechanism underlying the autoimmune nature of type 1 diabetes. Different immune-targeted treatments that target pathogenetic cells and activate regulatory cells have been developed. Nutritional studies have investigated how exposure to different dietary components may influence disease initiation.

Glutamate decarboxylase (GAD65) immunization of young non-obese diabetic (NOD) mice has prevented development of type 1 diabetes. However, in humans, there was no effect on β -Cell destruction. Inoculation with human heat shock protein 60 (Hsp60) prevented disease progression in NOD mice, whilst in humans, it produced increased C-peptide concentrations. Studies in children have not shown an improvement in β -Cell function, however. Trial evidence for anti-CD3 and anti-CD20 monoclonal antibodies therapy in humans has shown improved C-peptide concentrations and reduced insulin demand. Monthly injections with CTLA4-Ig (a T cell receptor that inhibits T cell activation) over two years in human trials also increased C-peptide concentrations. Trials of interleukin-2 showed favourable results in NOD mice. Trials with insulin therapy have not shown effects on cell function.

Nutritional studies in children showed that lower concentrations of islet cell antibodies were present in those who had been weaned in infancy onto a hydrolysed casein formula compared with those weaned to cows' milk formula. A trial of the effects of ω -3 fatty acids showed reduced risk of islet autoimmunity in children with a genetic risk of type 1 diabetes. In another trial, vitamin D did not protect β -Cell function in patients with recent onset of type 1 diabetes.

OBSTACLES TO ACHIEVING GLYCAEMIC CONTROL

Glycaemic management of diabetes is rarely as simple as making incremental additions to a patient's therapy until normoglycaemia is achieved. Hypoglycaemia is the main barrier to tight glycaemic control. For the majority of patients, achieving good glycaemic control involves a complex trade-off between the potential benefits (most of which are long term) and risks or obstacles (many of which are only too readily and immediately apparent).

The patterns of endogenous insulin secretion, which vary rapidly in response to changes in blood glucose concentration, are not easily mimicked by the injection of exogenous insulin into a subcutaneous depot, from which there is prolonged release into the systemic rather than portal circulation, thus partially bypassing hepatic action and first-pass clearance. This leads to an inherently increased risk of hypoglycaemia, which may be exacerbated by a number of factors related to the treatment, the individual and his or her circumstances.

Intensive control

The ADA recommends an HbA_{1c} concentration of <53 mmol/mol (<7%) as a treatment goal whereas the International Diabetes Federation (IDF) recommends an HbA_{1c} of <48 mmol/mol (<6.5%).

The DCCT demonstrated that in type 1 diabetes, intensive insulin treatment (multiple daily injections or CSII therapy) improved glycaemic control and reduced retinopathy, nephropathy and neuropathy complication rates. Subsequently, the Epidemiology of Diabetes Interventions and Complications (EDIC) study showed that this effect persisted for at least ten years in those subjects who had been in the intensive glycaemic control group of the DCCT.

In type 2 diabetes, the UKPDS showed reduced microvascular complications with intensive glucose control. At long-term follow-up at ten years, early intensive glycaemic control continued to reduce the risk of microvascular complications. However, a recent meta-analysis demonstrated that intensive glycaemic control in type 2 diabetes is associated with a 30% increase in the relative risk of severe hypoglycaemia. Several large trials have compared the effects of intensive versus standard glycaemic control on cardiovascular outcomes in type 2 diabetes. The Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified Release Controlled Evaluation (ADVANCE) trial showed a significant reduction in microvascular outcomes (nephropathy and retinopathy) with tightly controlled diabetes but no significant reduction in cardiovascular outcomes. The Veterans Affairs Diabetes Trial (VADT) trial found that intensive glycaemic control did not significantly lower the incidence of cardiovascular events compared with standard glycaemic control. The Action to Control Cardiovascular risk in Diabetes (ACCORD) trial found increased mortality associated with an intensive glycaemic control to a target HbA_{1c} of <42 mmol/mol (<6%), leading to the early termination of the trial.

In both type 1 and type 2 diabetes, the effect of intensive control of blood glucose on microvascular complications is therefore well established. Although the ACCORD, ADVANCE and VADT trials did not

show any improvement in cardiovascular outcomes with intensive control, glycaemic goals should still be set because of the adverse microvascular consequences associated with poor glycaemic control. Both the ADA and the International Diabetes Federation recommend individualized targets for each patient and the need to balance the risks and benefits of tight control of HbA_{1c}. Goals for patients with a history of frequent or severe hypoglycaemia, long standing diabetes, the elderly or those with limited life expectancy and patients with multiple comorbidities will need to be carefully considered. The established cardiovascular risk reduction measures such as blood pressure control, smoking cessation, lipid lowering therapy and healthy lifestyle should continue to be recommended as part of an individualized care plan.

Hypoglycaemia

The risk of hypoglycaemia often limits the achievement of good glycaemic control in diabetes. Although microvascular and macrovascular complications of diabetes typically evolve over a period of several years, hypoglycaemia may occur quickly, over a few minutes, and the consequences may be devastating or permanent. Some 2–4% of deaths and a much greater proportion of quality adjusted life years (QALYs) lost in type 1 diabetes are attributable to hypoglycaemia. Furthermore, the perceived danger, inconvenience, embarrassment and helplessness associated with hypoglycaemia is considerable, and the extent to which an individual patient will risk hypoglycaemia often influences how they manage their glycaemic goals and how they view care for their diabetes. For some patients, the risk of hypoglycaemia conflicts with occupational use of a motor vehicle (and hence possibly their livelihoods). In other patients (e.g. those with cancer or the very elderly), the primacy of goals such as freedom from osmotic symptoms and hyperglycaemic emergencies do not necessitate tight glycaemic control.

In addition to the factors mentioned in Table 16.3, it is clear that reduced glucoregulatory responses to hypoglycaemia in patients with type 1 diabetes and longstanding

TABLE 16.3 Factors that may affect the effect of insulin on blood glucose concentration

Treatment-related factors	Comments
Insulin	Dose, chemical form (human, animal, analogue, lipophilia, tendency to form complexes, albumin binding), suspension (protamine zinc etc.), site and volume of injection (lipohypertrophy, exercising limbs vs abdominal wall), timing in relation to meal (30 min before, immediately before, after), time of day (insulin resistance higher in the morning), changes in insulin clearance (decreased GFR), accidental intravenous injection of insulin, warming (e.g. shower soon after injection), weather or massage of the injection site
Diet and absorption	Glycaemic index, carbohydrate and fat content, missed meals, gastric absorption (presence of gastroparesis, drugs causing rapid transit), changes in absorption (coeliac disease), extended interval between meals (e.g. overnight, special circumstances) and dialysis (glucose removal)
Gluconeogenesis and glycogenolysis	Depletion of hepatic glycogen reserves after fasting, inhibitory effects of alcohol or other drugs, liver disease
Insulin resistance	Time of day, associated conditions and their treatment (Addison disease, hypothyroidism), exercise, intercurrent illness, sleep disturbance, mental/emotional/social stress, weight loss, improved metabolic control (glucotoxicity), obstetric delivery or intrauterine fetal death (sudden reduction in insulin resistance), cessation of steroid therapy

type 2 diabetes can markedly increase the frequency and severity of hypoglycaemic episodes.

In persons without diabetes, the first response to a falling blood glucose concentration is a reduction in insulin secretion; this typically occurs at blood glucose concentrations <4.5 mmol/L. This response is not available to subjects with type 1 diabetes or to many subjects with type 2 diabetes (either insulin or secretagogue treated). Glucagon secretion forms the next layer of defence, stimulating hepatic glycolysis and gluconeogenesis. However, most patients with either type 1 or type 2 diabetes are chronically hyperglucagonaemic and cannot respond to hypoglycaemia in this way.

The last level of defence against acute hypoglycaemia is activation of the sympathetico–adrenomedullary system, which normally occurs when blood glucose falls to <2.8 – 3.0 mmol/L. This increases lipolysis and circulating NEFA production and utilization, and mobilization of substrates for gluconeogenesis further inhibits insulin secretion and acts as a stimulus to glucagon release. Importantly, activation of the sympathetico–adrenomedullary system gives rise to the first clear symptoms of hypoglycaemia. With still lower blood glucose concentrations, patients also experience symptoms of neuroglycopenia. Although neuroglycopenia usually manifests as a generalized phenomenon, focal neurological deficits may occur in the setting of relatively normal consciousness and, for this reason, capillary blood glucose testing must be performed (and any low result confirmed by formal blood glucose measurement) in all cases of apparent stroke, confusion or other acute neurological disability, and in patients presenting with unexplained seizures.

Patients with diabetes are advised to carry dextrose (glucose) tablets or quick acting carbohydrate in case of emergency. Parenteral correction of hypoglycaemia may be necessary in cases where the patient has lost consciousness or is not able to eat food. An intramuscular glucagon injection may be used to correct insulin-induced hypoglycaemia. In severe cases of hypoglycaemia, for example where the patient is unconscious, intravenous glucose may need to be administered by medical personnel. Patients who have had recurrent episodes of hypoglycaemia should be reviewed by the diabetes team to assess potential causes and ways to avoid this from happening.

Hypoglycaemia-associated autonomic failure

Inability to reduce insulin secretion and failure of the glucagon response are described above. At this point, only the sympathetico–adrenomedullary responses stand between the patient and the development of neuroglycopenia. Failure of sympathetico–adrenomedullary responses can also occur and will lead both to a reduced awareness of, and reduced conscious and unconscious response to, hypoglycaemia (hypoglycaemia unawareness). Its particular importance is that it is associated with a greatly increased risk (possibly by a factor of 25) of severe hypoglycaemia. This potentially serious situation is usually amenable to treatment (see below).

Drugs such as β -blockers may interfere both with the action of adrenaline (epinephrine) and also with the perception of sympathetico–adrenomedullary activation,

and should be used with great caution in the context of hypoglycaemia unawareness. Autonomic neuropathy may lead to reduced sympathetico–adrenomedullary function and reduced hypoglycaemia awareness. It is also associated with unpredictable glycaemic excursions owing to erratic intestinal transit times. Perhaps most importantly, functional impairment of sympathetico–adrenomedullary responses may occur in type 1 or long-standing type 2 diabetes in response to preceding hypoglycaemia. Recurrent hypoglycaemic episodes lead to altered body responses to hypoglycaemia and susceptibility to further episodes.

Hypoglycaemia-associated autonomic failure (HAAF) may occur after a single episode of hypoglycaemia, although this is more frequently seen following recurrent hypoglycaemia. There is evidence to support a role for cortisol in mediating HAAF. The hypothalamo–pituitary–adrenal axis is stimulated by initial bouts of hypoglycaemia, but the resulting hypercortisolaemia may result in impaired adrenaline (epinephrine), noradrenaline (norepinephrine) and glucagon responses to subsequent hypoglycaemia. Muscle sympathetic nerve activity, an index of sympathetic nervous system outflow, is also impaired following hypoglycaemia. Infusion of pharmacological doses of cortisol in healthy subjects has a similar effect on their subsequent hormonal response to insulin-induced hypoglycaemia. However, this effect has not been replicated using lower dose infusions that achieve plasma cortisol concentrations similar to those found in hypoglycaemia, and hypoadrenal subjects without diabetes who are treated with fixed physiological cortisol replacement doses demonstrate almost complete preservation of counter-regulatory responses to a subsequent episode of hypoglycaemia, calling this hypothesis into question. Regardless of the underlying mechanism, however, management of HAAF is based upon avoidance of hypoglycaemia for several days, by slightly relaxing glycaemic control, thereby allowing autonomic responses to recover.

The principle of antecedent glycaemia affecting subsequent responses is further illustrated by the converse phenomenon of ‘clinical pseudohypoglycaemia’. This term denotes the observation that some patients with chronic hyperglycaemia experience symptoms of hypoglycaemia at blood glucose concentrations well in excess of those that would trigger responses in individuals with lower prevailing blood glucose concentrations. Management of this condition is empirical, and should involve measures to induce very gradual improvements in glycaemic control.

The Somogyi effect and the dawn phenomenon

After a counter-regulatory response to a hypoglycaemic episode (whether or not followed by the administration of (sometimes excessive) glucose to reverse the symptoms), rebound hyperglycaemia is common. Usual glycaemic control, glucose tolerance and insulin sensitivity may take several hours to be restored. A special variant of the rebound from hypoglycaemia is the Somogyi phenomenon, which occurs in patients with nocturnal hypoglycaemia. The patient may not be aware of the hypoglycaemia, even in retrospect, although awakening with malaise, headache and bedclothes damp from sweating are suggestive. The

rebound from the nocturnal hypoglycaemia results in the patient waking with a blood glucose concentration higher than desirable, provoking a temptation to take at least as much (or even more) insulin the next night and thereby increasing the likelihood of a subsequent episode of hypoglycaemia. Detection of this problem requires a high level of suspicion and may involve measures such as setting the alarm clock in order to self-test, the observations of another person, or continuous blood glucose monitoring.

Subjects without diabetes show circadian changes in blood glucose concentration and glucose tolerance based upon changes in counter-regulatory hormones, insulin secretion and the availability of alternative fuels for metabolism. The most marked such circadian effect is the 'dawn phenomenon', which typically occurs between 04.00 h and 07.00 h and is an increase in plasma glucose concentration and decrease in insulin sensitivity consequent upon the increased secretion of counter-regulatory hormones at that time. During this period, people with diabetes usually experience modest rises (1–2 mmol/L) in plasma glucose concentrations without recent ingestion of food. A larger rise is seen in patients in whom circulating insulin concentrations are too low at this time.

Owing to both the dawn phenomenon and the Somogyi effect, there is a risk of hypoglycaemia earlier in the night whenever longer-acting insulins, particularly when administered in the early evening, are titrated to pre-breakfast blood glucose concentrations.

Exercise

A patient's usual balance between carbohydrate intake and insulin requirements may be influenced by physical activities. The metabolic effects of exercise vary with the intensity and duration of that exercise. For example, jogging typically elicits an increase in both glucose and lipid oxidation, and plasma glucose and NEFA turnover increase. In more strenuous exercise, muscle stores of glycogen and triglycerides will become depleted. Plasma glucose concentrations may increase or decline during exercise, depending on the counter-regulatory hormonal drive to hyperglycaemia, and whether glycogen reserves are adequate.

In healthy subjects, plasma insulin concentrations decrease, permitting increased hepatic glucose output to limit the fall in blood glucose. In subjects on exogenous insulin treatment, insulin concentrations may not fall (indeed, there may be a rise if increased skin blood flow during exercise increases insulin absorption from subcutaneous injection sites) and hence hepatic glucose output may not be sufficient to prevent hypoglycaemia. After exercise, there is a phase of glycogen repletion in liver and muscle, and in subjects with diabetes, delayed hypoglycaemia may be a problem at any time up to several hours afterwards.

Strategies to control blood glucose concentrations during exercise include adjusting insulin doses that are to be taken prior to planned exercise, or ingestion of extra carbohydrate before, during or after the exercise. Because of the numerous physiological variables involved, it is

often difficult to predict the best strategy in advance, and a system of trial and error with increased frequency of blood glucose monitoring may be necessary. Many patients with diabetes lead active lifestyles as regular physical exercise is important in improving insulin sensitivity and improving and maintaining cardiorespiratory fitness.

Ethanol

Ethanol (alcohol) may inhibit gluconeogenesis; in patients with diabetes, this may reduce hepatic glucose output sufficiently to provoke hypoglycaemia. Typically, this does not occur while the patient is consuming ethanol, since most beverages contain adequate carbohydrate to prevent this (or the patient eats as well as drinks): instead, hypoglycaemia occurs during the first two hours after alcohol consumption. However, the inhibition of gluconeogenesis persists for several hours and a rebound hypoglycaemic episode may occur a few hours (typically 2–4) after consuming alcohol. If the clinical features of hypoglycaemia are dismissed as the consequences of inebriation, then the failure to treat the hypoglycaemia may be serious. In addition, the effects of alcohol may impair the judgement of an individual with diabetes, who may forget to consume carbohydrate after heavy alcohol consumption or fail to adjust their insulin dose in anticipation of planned alcohol consumption. It may even be a contributory cause of ketoacidosis when insulin doses are unintentionally omitted.

Intercurrent illness, 'sick day rules' and stress

Intercurrent illnesses such as viral infections usually cause hyperglycaemia in people with diabetes but may also give rise to hypoglycaemia. The effect on glycaemic control may persist for up to two weeks, and insulin requirements, even during simple infections (e.g. colds), may increase by 100%, although increases of ~20% are perhaps more typical.

It is likely that many episodes of hyperglycaemic crisis could be prevented by appropriate self-treatment and timely medical advice during times of intercurrent illness. Treatment plans should ideally be individualized and prepared in advance. Several general principles apply to all, however. These include the concepts that:

- glycaemic treatment generally requires augmentation rather than reduction during times of intercurrent illness
- frequent (e.g. four-hourly) blood glucose testing is needed
- medical advice should be sought if blood glucose concentrations become and remain high despite appropriate measures (e.g. >13–15 mmol/L)
- maintenance of good hydration is of the utmost importance.

For patients with type 2 diabetes, metformin should probably be discontinued for the duration of any severe illness, and a sulfonylurea (or, if necessary, insulin) substituted in the short term. Patients taking a sulfonylurea may require dose increments or the short-term use of insulin.

Patients with type 1 diabetes are at risk of ketoacidosis and should therefore be advised to test their urine regularly (at least twice daily) to ensure no more than light to moderate ketonuria is present. Where blood ketone testing is available, testing for blood ketones is preferred. Patients should be warned against the common misconception that if they are not eating (e.g. because of vomiting), they should stop taking insulin. Instead, essential fluid and glucose may be ingested in the form of regular small volumes of soup, rehydration fluid or proprietary sugar-containing drinks. Usual doses of basal insulin are continued and the day's bolus (rapid-acting) insulin divided into 4-hourly quotas, which can be adjusted on the basis of self-testing. Persistently elevated or rising blood glucose concentrations, particularly in the context of increasing ketonuria, should prompt contact with an appropriate medical advisor or admission to hospital for insulin infusion.

In patients with severe intercurrent illness such as septicæmia, pancreatitis or myocardial infarction (all these are more common in diabetes), intravenous insulin is often required, even in subjects not usually requiring exogenous insulin treatment. There are now good data to support the use of intravenous insulin infusion in such circumstances and during major surgery. It is not yet clear whether the infusion of insulin per se is of benefit or whether tight glycaemic control achieved by any means confers similar advantage. These issues are discussed in greater detail in a later section.

Emotional stress of many forms will result in changes in secretion of counter-regulatory hormones and autonomic tone, which will alter glucose tolerance. Since emotional stress is often associated with alterations in sleep, eating and exercise patterns, it may be practically impossible for patients with diabetes under emotional stress to maintain usual glycaemic control.

CHRONIC COMPLICATIONS OF DIABETES

The complications of diabetes can be divided into acute and chronic complications. Acute complications include hypoglycaemia (discussed above), DKA and the hyperosmolar hyperglycaemic state (see p. 326). Chronic complications include macrovascular disease (see above), retinopathy, nephropathy and neuropathy.

Nephropathy

Diabetic nephropathy is the leading cause of established renal failure and the most common diagnosis at initiation of renal replacement therapy. Glomerular damage is pathologically described as either diffuse or nodular glomerulosclerosis (Kimmelstiel–Wilson lesions). The pathological process involves thickening of the basement membrane and of the glomerular mesangium with the accumulation of extracellular collagen matrix material. There is glomerular podocyte loss and tubulointerstitial fibrosis. Glomerular hyperfiltration is followed by microalbuminuria, proteinuria and subsequent decline in renal glomerular function.

Some 20–30% of patients with type 1 diabetes will develop renal disease (most commonly 15–25 years after diagnosis). Risk factors for its development include longer duration of disease, an earlier age at diagnosis, earlier onset of puberty, poorer glycaemic control throughout the time course of the disease, smoking and a family history of diabetic nephropathy. Nephropathy is probably less prevalent among those with type 2 diabetes (10–20% lifetime risk), but seems likely to increase substantially with the increasingly early mean age of onset of type 2 diabetes. Diabetic nephropathy is screened for by laboratory testing for urine albumin excretion (urine albumin/creatinine ratio), serum creatinine and estimated glomerular filtration rate (eGFR). Screening should be performed at least annually. (Formulae used for the calculation of eGFR are discussed further in Chapter 7.)

Microalbuminuria

The early stages of the disease are asymptomatic and include hyperfiltration (with urine albumin excretion (UAE) <30 mg/24 h or 20 µg/min) followed by progression through microalbuminuria (UAE 30–300 mg/24 h or 20–200 µg/min) to proteinuria (UAE >300 mg/24 h or 200 µg/min). After proteinuria has become established, the glomerular filtration rate (GFR) begins to fall and progression to established renal failure is generally inevitable, although the rate of loss of renal function may still be usefully slowed by treatment.

Differences in historical ten-year progression rates from microalbuminuria to nephropathy (~80%), and more recent estimates (~30%), lend weight to the hypothesis that aggressive treatment at the stage of microalbuminuria may be able to halt or even reverse the disease in many patients. Thus, the first and best opportunity to detect the disease clinically is at the stage of microalbuminuria. Some would even contend that risk associated with UAE is a continuous variable, with detectable increases in morbidity above the normal median value of albumin excretion of approximately 2.5 mg/24 h. Conventional dip-stick testing of urine is not usually positive at such concentrations of albumin excretion. Neither this test nor the measurement of 24 h urinary protein excretion are now recommended as screening tools. Screening should probably take place at the time of diagnosis and annually thereafter in type 2 diabetes. Although it has traditionally been thought that screening could safely be delayed for five years in type 1 diabetes, a number of studies have shown significant prevalence before five years, especially where puberty has intervened or in the presence of poor glycaemic control, and many physicians now advocate annual screening from diagnosis in this group also.

Factors giving rise to falsely elevated results include unaccustomed exercise, intercurrent illness, other renal disease, haematuria, acute deterioration in glycaemic control and urinary tract infection (which should be excluded whenever tests of microalbuminuria are positive, see Chapter 8). Furthermore, considerable day-to-day variations in urine albumin excretion rates mean that a minimum of two spot urine collections for

albumin:creatinine ratio over a period of 3–6 months should be abnormal before a diagnosis of microalbuminuria can be made reliably. It should be noted that the occurrence of non-immunoreactive forms of albumin in the urine may result in underestimation of the true extent of microalbuminuria in some assays. Intermittently positive results, especially where occurring frequently without a discernible cause, do appear to increase the risk of progression to definite microalbuminuria. It is important to appreciate that microalbuminuria is not just a risk factor for the development of nephropathy, but is also an independent risk factor for coronary artery disease (indeed, one of the most potent risk factors known), being also associated with dyslipidaemia, hypertension, endothelial dysfunction and diabetic retinopathy. Patients with microalbuminuria should, therefore, undergo intensive risk factor modification, and low-dose aspirin is generally indicated for these patients. There is controversy as to whether an increase in blood pressure precedes or is a result of the development of microalbuminuria.

Management

Prevention of diabetic kidney disease is of paramount importance. It necessitates good metabolic control, adequate treatment of hypertension, avoidance of smoking, lipid-lowering therapy and avoidance of nephrotoxic drugs. Intensive glycaemic control delays onset and progression of albuminuria. However, even with these measures, data from the UKPDS and DCCT show that a significant number of patients will still develop the disease, albeit at a later stage and with slower progression. Thus, the second important feature of management remains early detection of raised UAE, which is discussed in detail above.

Good metabolic control may delay the onset of microalbuminuria and, once this is present, may halt progression or even reverse it. In general, antihypertensive therapy, maintaining systolic BP <140 mmHg and diastolic <80 mmHg, irrespective of the agent used, slows the development of diabetic nephropathy. The UKPDS provided evidence that blood pressure control could protect against nephropathy. Inhibitors of the renin-angiotensin system, i.e. angiotensin-converting-enzyme (ACE) inhibitors or angiotensin receptor antagonists (ARBs) confer superior long-term protection, probably because of a concomitant specific reduction of transglomerular filtration pressure, preventing increases in albumin excretion and reducing the severity of proteinuria. Angiotensin-converting-enzyme inhibitors reduce cardiovascular events and ARBs reduce progression of nephropathy. Combination ACE inhibition and ARB therapy lowers albuminuria further, but may increase the risk of hyperkalaemia and evidence for the clinical efficacy of this approach is limited. Increases in plasma creatinine concentrations of up to 20–30% from baseline are common on starting treatment and, although they do not mandate alternative treatments, monitoring of renal function is essential.

Dietary protein restriction to 0.8–1.0 g/kg body weight per day in early chronic kidney disease (CKD) or 0.8 g/kg body weight per day in advanced CKD is recommended.

Blood pressure control with other agents such as diuretics, calcium channel blockers and β -blockers may be used.

End-stage disease

Despite prevention, detection and aggressive treatment of diabetic nephropathy, a significant proportion of patients will nevertheless progress towards established renal failure (ERF). Early referral to a nephrology service (usually before GFR has fallen to <30 mL/min/1.73 m²) will usually be appropriate. Occult cardiac disease is common in this group of patients, but its angiographic investigation is hazardous owing to the risk of contrast nephropathy. Many patients with anaemia other than that caused by specific haematinic deficiencies will benefit from erythropoietin treatment at haemoglobin concentrations of <110 g/L. Management of metabolic sequelae such as secondary hyperparathyroidism, acidosis and hyperphosphataemia are, in general, as for patients with non-diabetic kidney disease. Treatment options for ERF include haemodialysis and renal transplantation, depending on the availability of graft donors and compatibility.

Neuropathy

Neuropathy in diabetes has many different manifestations and can be focal or diffuse. The types of neuropathy include chronic sensorimotor, autonomic, diabetic amyotrophy (proximal motor neuropathy) and mononeuropathies. An acute neuropathy may also occur in the presence of hyperglycaemia (hyperglycaemic neuropathy), possibly as a result of damage to peripheral nerves.

Chronic sensorimotor neuropathy

This is most the common type of neuropathy in patients who have had diabetes for a long time. The longest nerves are usually affected, with sensory loss in a glove and stocking distribution. The sensory loss is often accompanied by loss of power and autonomic involvement. There is loss of pain and light touch, with decreased reflexes and muscle wasting in affected parts. Some patients may report painful symptoms (e.g. tingling, burning, hyperalgesia or allodynia).

Patients should be screened for diabetic neuropathy by pinprick tests, using a 10 g monofilament and a 128 Hz vibration fork applied to the distal aspects of both feet. The diagnosis is often made clinically without the need for electrophysiological studies, although these can be performed if the diagnosis is uncertain. It is important to screen for other, potentially reversible, causes of neuropathy, e.g. vitamin B₁₂ deficiency, alcohol excess, heavy metal poisoning and neurotoxic medications, and for conditions that may require specific treatment, e.g. demyelination. Patients with sensorimotor neuropathy are at increased risk of injury to and ulceration of the feet. Charcot neuroarthropathy (Charcot foot, see below) is a common complication. All patients with peripheral neuropathy should receive regular podiatric assessment and advice regarding foot care because of the increased risk of foot ulceration.

Besides optimizing blood glucose control, the treatment for sensorimotor neuropathy includes symptomatic pain relief with agents for neuropathic pain such as duloxetine, amitriptyline, pregabalin and gabapentin.

Autonomic neuropathy

Autonomic neuropathy is seen in patients with diabetes who have longstanding poor control. Manifestations include orthostatic hypotension (a major risk factor for falls), constipation, gastroparesis (with nausea and vomiting), loss of normal Valsalva response, gustatory sweating, resting tachycardia, bladder dysfunction, erectile dysfunction and altered autonomic responses to hypoglycaemia.

Diabetic autonomic neuropathy may affect gastrointestinal motility: this condition may be occult, or manifest as constipation, diarrhoea, unexplained (or easily triggered) vomiting or malabsorption. Altered gastrointestinal motility may change the rate of absorption of nutrients from food. Rapid and unpredictable absorption is particularly unwelcome in diabetes and may completely undermine the attempts of even a well-motivated patient to maintain good glycaemic control. In some cases, diabetic ketoacidosis may be provoked as a result of repeated vomiting. If gastrointestinal motility can be improved, this renders glycaemic control somewhat easier; however, such amelioration is usually spontaneous rather than related to medical intervention. Investigations for gastroparesis include the use of isotope scintigraphy to assess solid phase gastric emptying. Prokinetic treatments such as metoclopramide, domperidone or erythromycin may be helpful in some cases to aid motility. Dietary changes may be necessary and in severe situations, parenteral nutrition may become necessary if adequate nutrition is not possible by the enteral route. A gastric pacemaker with electrodes that electrically stimulate gastric contractions may be used in severe cases.

Patients who are troubled with postural hypotension may be prescribed support stockings. In severe cases, fludrocortisone (a mineralocorticoid) or midodrine (an α -adrenergic agonist) may be used.

Autonomic neuropathy may impair hypoglycaemia awareness. This will often result in the patient (very sensibly) avoiding the possibility of severe hypoglycaemia and, as a result, glycaemic control may be more difficult to achieve. Autonomic neuropathy may be associated with increased morbidity and mortality if it affects the cardiovascular system. This is manifested by postural hypotension and resting tachycardia and is associated with an increased risk of cardiovascular events.

Erectile dysfunction and retrograde ejaculation can occur in autonomic neuropathy. If the sacral nerves innervating the bladder are affected, patients may suffer from bladder dysfunction, with bladder emptying difficulties, incontinence problems and urinary tract infections. Erectile dysfunction may be caused by multiple factors such as vascular disease, neuropathy, medication or psychological problems. Besides reviewing these factors, treatments for erectile dysfunction may include phosphodiesterase type 5 inhibitors, prostaglandins and vacuum devices (see Chapter 23).

Mononeuropathies

Mononeuropathies may result from diabetes affecting single nerves or, where multiple nerves are affected, a mononeuritis multiplex. These include third cranial nerve palsies (that may have a vascular aetiology), lateral popliteal nerve palsy and carpal tunnel syndrome.

A form of multiple mononeuropathy called diabetic amyotrophy may occur. This is caused by a reduction in the blood supply to the nerves of the lower limbs, for example the femoral nerve or the lumbar plexus, resulting in proximal weakness and wasting of muscles in the lower limbs. Amyotrophy is associated with poor glycaemic control, and optimum glycaemic control is important in attaining recovery, which is a slow process. Pain control and physiotherapy are helpful.

The feet in diabetes

Foot ulcers

Foot ulceration in patients with diabetes is a common cause of morbidity and its complications, such as sepsis, may be associated with mortality. Ulcers mainly occur in patients who have both diabetic neuropathy and peripheral vascular disease. Repeated trauma without recognition by the patient may cause infection. Foot architecture may become distorted because of callus formation, deformity and ulceration, leading to a condition called the Charcot foot (see below).

Concomitant infection of the feet does not heal well owing to repeated unrecognized foot trauma and poor vascular circulation. Infective organisms include *Staphylococcus aureus*, *Streptococcus pyogenes* and *Pseudomonas aeruginosa*.

Charcot foot

Charcot foot is a specific foot deformity, bilateral in approximately 20% of cases, which may arise on the background of severe sensory (and probably motor) neuropathy. Often precipitated by minor trauma, the disease may progress very rapidly over weeks or a few months, beginning with an unstable, warm, red and swollen foot (stage 0), the point at which treatment should be initiated for maximum benefit. A 'fragmentation' stage (stage 1) follows, with periarticular fractures, joint dislocation, instability and deformity. In the 'coalescence' stage (stage 2), reabsorption of bone debris occurs before finally a stable (stage 3), but deformed, foot is left at the end of the process.

The exact pathogenesis of this condition remains unclear, but abnormal protective motor reflexes may permit the development of abnormal loading forces within the foot which, in the presence of sensory neuropathy and osteopenia, may damage bone, joints and ligaments. Subluxation, or even dislocation, of the metatarsal, tarso-metatarsal or tarsal joints may occur and swelling may be caused by leakage of synovial fluid from joint capsules. Bone blood flow is usually substantially increased, perhaps as a result of abnormal sympathetic control, and this may contribute to the osteopenia. Later in the course of the disease, bones may become sclerotic. Fractures may

cause the tarsal bones to collapse, resulting in an outward bowing of the arch ('rocker-bottom foot' deformity), further adding to the abnormal loading and risk of ulceration. The foot can be so warm and red that osteomyelitis, cellulitis or gout is suspected. Osteomyelitis may be particularly difficult to distinguish when a plantar ulcer is present and, indeed, may be very likely if there are systemic signs of infection or if bone is encountered when the ulcer is probed. Plain radiographs usually show vascular calcification and bone changes; the latter may be difficult to distinguish from osteomyelitis. Magnetic resonance imaging or bone biopsy may be required to establish the correct diagnosis in some cases.

Intravenous bisphosphonates (e.g. pamidronate), total immobilization and offloading of the foot (e.g. bed rest, pending the fitting of a total contact cast, perhaps for four months or longer) and meticulous attention to metabolic control are helpful in the acute setting. Bone markers, such as serum carboxy-terminal telopeptide of type 1 collagen, a marker of osteoclastic bone resorption, measured in venous blood taken from the dorsum of the foot, urinary deoxypyridinoline and bone-specific alkaline phosphatase, have been used in studies alongside longitudinal measurements of foot temperature to assess the response to treatment.

Eye disease

Diabetes is a common cause of visual loss, especially in the developed nations. Risk factors for the development of diabetic retinopathy include duration of diabetes, poor glycaemic control (chronic hyperglycaemia), diabetic nephropathy, hypertension, hyperlipidaemia, smoking, obesity and rapidly improving glycaemic control, for example in pregnancy or when commencing insulin pump therapy. Retinopathy is usually present after 20 years of diabetes, although the severity varies between patients. Patients with diabetic retinopathy are predisposed to cataracts, glaucoma and macular disorders.

Patients with type 1 diabetes should have an eye examination within five years of diagnosis. The prevalence of retinopathy in type 1 diabetes after 10–15 years is 25–50%. All patients with type 2 diabetes should be screened when diagnosed, reflecting the fact that the presence of type 2 diabetes may have not been recognized for some time. About 60% of patients with type 2 diabetes have non-proliferative retinopathy. All patients should be screened annually, or more frequently depending on the findings. Women with diabetes are screened more frequently during pregnancy and in the postpartum period because of an increased risk of progression of diabetic retinopathy.

Eye examinations should be carried out by an ophthalmologist or optometrist experienced at diagnosing diabetic retinopathy. In the UK, an annual retinopathy screening service is provided for all patients with diabetes. Any patient with progressive retinopathy detected at screening is referred to an ophthalmologist for follow-up investigation and, if necessary, treatment. The UK National Retinal Screening Committee classification is based on the presence or absence of both retinopathy (graded from R0 to R3) and maculopathy (graded M0 or M1) (see [Box 16.1](#)).

BOX 16.1 The UK national screening programme for diabetic retinopathy classification system

- R0 – No retinopathy
- R1 – Background changes (microaneurysms, exudates not involving the macula)
- R2 – Preproliferative changes (venous abnormalities, intraretinal microvascular anomalies (IRMA), soft exudates)
- R3 – Proliferative retinopathy (new vessel formation, vitreous haemorrhage, rubeosis iridis)
- M0 – No referable maculopathy
- M1 – Maculopathy requiring referral to ophthalmology (macular haemorrhages, macular exudates and macular oedema or ischaemia)

Initially, there is an increase in retinal perfusion. Background retinopathy denotes the formation of microaneurysms and hard exudates. Flame-shaped or dot and blot haemorrhages may follow should the microaneurysms rupture. Retinal capillaries may leak. Leakage into the macular region may cause maculopathy. Maculopathy is characterized by the formation of hard exudates in close proximity to the fovea, along with oedema and ischaemia of the macula region. It is more common in type 2 than type 1 diabetes and is the commonest cause of loss of vision.

Preproliferative retinopathy is diagnosed on the basis of the presence of cotton wool spots (soft exudates), intraretinal microvascular anomalies and venous loops with arterial occlusion. Soft exudates occur when there is infarction of the nerve fibre layer. Intraretinal microvascular anomalies result from dilated capillary beds from capillary occlusion. Continued retinal ischaemia and hypoxia resulting from small vessel occlusion triggers the release of angiogenic factors such as vascular endothelial growth factor (VEGF). Neovascularization of the retinal vasculature leads to proliferative retinopathy. These newly formed vessels are vulnerable to rupture, leading to intraocular vitreal haemorrhages and visual loss. The neovascularization is associated with fibrous tissue that may cause traction on, and detachment of, the retina or cause haemorrhage from vessel tear. New vessel formation on the iris is known as rubeosis iridis and may lead to glaucoma. Proliferative retinopathy is more common in type 1 diabetes with a prevalence of ~25% after 15 years.

Tight glycaemic and blood pressure control reduces the incidence and progression of diabetic retinopathy. However, improving glycaemic control should be a gradual process as a transient worsening of retinopathy has been reported with rapid improvements in glycaemic control. Smoking should be discouraged. Treatment with xenon or argon laser photocoagulation is effective in reducing visual loss in proliferative retinopathy and maculopathy. The photocoagulation aims to destroy hypoxic retinal tissue. Pan-retinal photocoagulation may be performed in patients with severe proliferative retinopathy. Focal laser photocoagulation is applied to macular oedema and leaking vessels. However, this treatment cannot reverse vision that has already been lost prior to treatment. Following therapy, some patients experience

visual field constriction and night blindness. Vitrectomy may be carried out in patients with vitreous haemorrhage and this improves visual recovery. New therapies for macular oedema currently under investigation include intravitreal steroid injections and use of VEGF antagonists. Intravitreal steroid injections may be used where there is persistent loss of vision and when conventional treatment has failed. This therapy is effective but the adverse effects include an increased risk of cataracts and raised intra-ocular pressure. Concerns about chronic VEGF inhibition relate to neurotoxicity and thromboembolic events, such as myocardial infarction, stroke and thromboembolism.

Other complications

Brittle diabetes

Brittle diabetes is a term with no universally accepted definition. In 1977, Tattersall used a clinical definition, describing 'The patient whose life is constantly being disrupted by episodes of hypo- or hyperglycaemia, whatever their cause'. This definition has been modified by various workers.

Causes of brittle diabetes include: psychological abnormalities, such as eating disorders (e.g. bulimia), personality disorders, communication disorders and manipulative behaviour. Such factors are often inferred if good glycaemic control can be achieved in hospital by the use of intravenous or nurse-administered subcutaneous insulin. If intravenous insulin therapy fails to achieve good glycaemic control, then an organic cause should be sought. These include: an unsuitable insulin regimen, intercurrent illness such as thyroid disease, Addison disease, systemic lupus erythematosus (through antibodies to insulin or its receptor), disorders of intestinal motility (erratic absorption of food) and interactions with other drugs (prescribed or non-prescribed). Problems related to insulin injections, such as faulty technique, abnormalities of local anatomy (e.g. lipohypertrophy) or subcutaneous tissue blood flow (e.g. during exercise) and changing insulin requirements in the various phases of the menstrual cycle, are well-recognized causes.

Type 4 renal tubular acidosis

Hyporeninaemic hypoaldosteronism (type 4 renal tubular acidosis, RTA) may be a manifestation of diabetic nephropathy, particularly in older patients. It presents with a hyperchloraemic, hyperkalaemic metabolic acidosis, which is out of proportion to any impairment in renal function. Type 4 RTA is frequently unmasked by inhibition of the renin-angiotensin system by ACE inhibitors or ARBs, particularly when used in combination with other agents that may increase plasma potassium concentrations (e.g. spironolactone). The precise nature of the defect in this condition is unclear. Failure of renin secretion to increase in response to posture or sodium restriction suggests an interstitial (juxtaglomerular) defect, but no anatomical correlate has been described to account for this. The failure of aldosterone release to be stimulated directly by the resulting hyperkalaemia suggests the possibility of concomitant dysfunction of the adrenal zona

glomerulosa, although this may simply be a consequence of chronic hyporeninaemia.

When hyperkalaemia is modest and stable (serum potassium concentration <6.0 mmol/L), close observation may be all that is required, but more marked elevations demand measures such as stopping offending drugs (ACE inhibitors/ARBs, β -blockers, non-steroidal anti-inflammatory drugs, potassium-sparing diuretics etc.); prescription of a low potassium diet (potassium restriction); use of potassium-wasting diuretics (thiazides, loop diuretics) and/or sodium bicarbonate (although this risks causing oedema). A differential diagnosis of autoimmune hypoadrenalism may require exclusion (especially in younger subjects with type 1 diabetes). In the occasional particularly severe and refractory case, treatment with fludrocortisone may be necessary.

EMERGENCIES IN DIABETES

General medical emergencies (e.g. stroke) in persons with diabetes are usually treated much in the same way as in subjects without diabetes, although frequent monitoring of blood glucose is necessary. Specific diabetic emergencies are discussed as specific entities, although mixed forms may occur. Diabetic emergencies are common in clinical practice and the approach to such patients requires an accurate diagnosis of the condition and appropriate management.

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is a serious complication of type 1 diabetes and can be life-threatening. It is characterized by hyperglycaemia, acidosis and ketonaemia. Approximately 30% of patients with type 1 diabetes mellitus present with ketoacidosis. Fortunately, the onset in newly presenting patients tends to be slower than in known diabetic subjects, perhaps because of retention of some residual insulin secretion. An infection is found in ~35–55% of patients with ketoacidosis. Errors or omissions in treatment account for another 30%. The clinical features include dehydration, shock, vomiting, abdominal pain, acidosis (with compensatory Kussmaul respiration) and, in some cases, a breath odour of ketosis) and impaired consciousness.

Four mechanisms predispose to ketoacidosis: insulin deficiency, counter-regulatory hormone excess, fasting and dehydration. Of these, the most important is insulin deficiency. Mechanisms of the development of DKA are shown in [Figure 16.1](#). In a vicious cycle, hyperglycaemia and excess lipolysis cause dehydration and high circulating concentrations of NEFAs. The resulting acidosis and dehydration further increase the secretion of counter-regulatory hormones. The acidosis, dehydration, counter-regulatory hormones and excess lipolysis induce insulin resistance, thereby increasing hyperglycaemia and lipolysis. Protein catabolism and hypertriglyceridaemia also occur and compound the situation.

Rarely, patients may present with normoglycaemic ketoacidosis; typically, this occurs in situations where

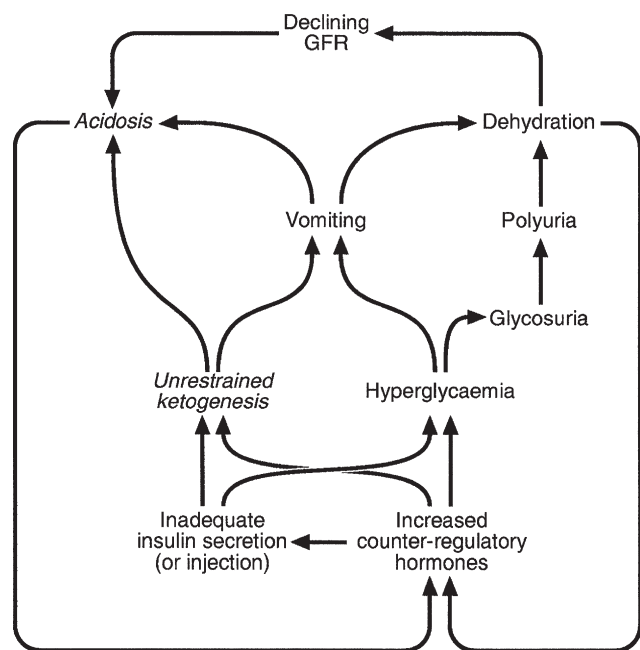

FIGURE 16.1 ■ Vicious circles in ketoacidosis and hyperosmolar states. In both conditions, the trigger event(s) causes an initial inadequate insulin supply and hyperglycaemia. In ketoacidosis, both acidosis and dehydration cycles occur. Features in italics are restricted to ketoacidosis. GFR, glomerular filtration rate.

exercise, starvation or, occasionally, infection is the major precipitant of ketosis, but more often it is seen when a patient has taken enough insulin in a bolus to bring the blood glucose down but has not been exposed to sufficient insulin over a long enough period to suppress ketogenesis while existing ketones are cleared. The important differential diagnosis of alcoholic ketoacidosis should be considered under these circumstances (see below), particularly when a malnourished patient embarks on heavy alcohol consumption for a period of several days. Despite the unfortunate use of the term ‘diabetic coma’, it is rare for a patient with DKA to have true coma as opposed to some clouding of the sensorium. Where this occurs, alternative causes such as bacterial meningitis or a cerebrovascular event should be actively considered in the differential diagnosis.

Biochemical features

Biochemical features of DKA include hyperglycaemia, ketosis (ketonaemia and ketonuria), metabolic acidosis and uraemia. Creatinine concentrations may not accurately be measurable in the presence of heavy ketonaemia. The characteristic ketosis is a consequence of increased lipolysis and decreased fat synthesis. Excess acetyl-CoA derived from β -oxidation of fatty acids is converted to the ketone bodies, acetoacetate and β -hydroxybutyrate with some decarboxylation of the former to acetone.

Bedside tests may demonstrate high blood glucose concentrations, glycosuria and ketonuria. Plasma β -hydroxybutyrate concentrations are typically three times higher than those of acetoacetate and the ratio may be even greater if there is also an element of lactic acidosis, so that the degree of ketosis may be underestimated

or not recognized by urine tests for acetoacetate (see Chapter 15). This is also important in charting the recovery from ketoacidosis where ketonuria (detection of acetoacetate) may increase at a time when the patient is, by all other measures, improving and ketonaemia resolving. This effect occurs as mitochondrial redox state improves under conditions of increased tissue oxygen delivery and reduced acidosis, favouring the formation of acetoacetate from β -hydroxybutyrate. Some typical biochemical results in ketoacidosis are shown in [Box 16.2](#).

Management

The key to successful management of ketoacidosis is early institution of therapy and repeated clinical and biochemical assessment of the patient. The essential elements of the treatment of ketoacidosis are to replace fluid losses and to reverse the underlying metabolic disorder with continuous intravenous infusion of insulin. Ketone clearance occurs mainly through renal excretion and oxidation.

General measures. As with other medical emergencies, initial stabilization with attention to airway, breathing and circulation should precede detailed assessment. It is recommended that venous (rather than arterial) blood gases and hydrogen ion concentration (pH), and bicarbonate and potassium concentrations should be used to guide management. Appropriate investigations including blood culture and chest X-ray should be undertaken where infection is suspected, but the finding of a neutrophil leucocytosis does not, of itself, imply its presence. Although abdominal pain and a slightly elevated amylase activity

BOX 16.2

Typical initial laboratory values in diabetic ketoacidosis

- Plasma [glucose] ~35 mmol/L
- Plasma [K^+] >5.3 mmol/L: whole body depletion typically 6.0 mmol/kg body weight
- Plasma [Na^+] ~130 mmol/L: whole body depletion typically 8.0 mmol/kg body weight
- Plasma [urea] >15 mmol/L
- Plasma [creatinine] >150 μ mol/L (if possible to measure in the presence of heavy ketonaemia)
- Plasma [ketones] (β -hydroxybutyrate and acetoacetate) >15 mmol/L
- Plasma [Mg^{2+}] <0.70 mmol/L: whole body depletion typically 0.5 mmol/kg body weight
- Plasma [phosphate] >1.2 mmol/L: whole body depletion typically 1.0 mmol/kg body weight
- Plasma amylase 500–1000 U/L
- Plasma osmolality ~325 mmol/kg: whole body water depletion typically 75–100 mL/kg body weight, i.e. 7 L in typical adult
- Arterial blood gases:
 - [H^+] >50 nmol/L (pH <7.30)
 - $PaCO_2$ <3.52 kPa
 - PaO_2 >12 kPa
 - [HCO_3^-] <18 mmol/L
- Anion gap ($[Na^+] + [K^+] - ([Cl^-] + [HCO_3^-])$) >20 mmol/L

do not necessarily point to the presence of pancreatitis or other intra-abdominal emergency, the possibility that DKA may have been precipitated by abdominal disease should be borne in mind.

Fluids. Fluid replacement aims to restore circulatory volume (and thereby increase the rate of ketone clearance) and correct electrolyte imbalances. There is disagreement as to the optimal rate and type of fluid replacement in DKA, partly based on fears of provoking cerebral oedema. In the UK, 0.9% saline is commonly used as the fluid of choice for initial replacement as this is available readily and comes with ready mixed potassium at the required concentrations if this is required. The disadvantage of using 0.9% saline is that of hyperchloraemic metabolic acidosis, which may lead to a slower recovery from acidosis because of renal vasoconstriction. Hartmann's solution is often less readily available and contains a fixed, relatively low, potassium concentration.

Paediatric guidelines recommend cautious fluid replacement over 48 h. For adults, initial fluid replacement is usually rapid in the first few hours, but this should be done with caution in young adults (see below, where their greater risk of cerebral oedema is explained).

When blood glucose concentrations fall below 14 mmol/L, it is important to commence an infusion of 10% glucose to prevent hypoglycaemia while the insulin infusion is continued (normoglycaemia is often attained before the ketosis and acidosis resolves).

United States' authorities advocate a 'correction' of measured serum sodium concentration for the dilution that results from osmotic movement of intracellular water to the hyperglycaemic interstitial and intravascular compartments. Various formulae have been suggested, but perhaps the most widely accepted is to add 1.6 mmol/L to measured serum sodium concentration for every 5 mmol/L that the plasma glucose concentration exceeds 5 mmol/L. If the corrected sodium starts to rise above the reference range, a switch to 0.45% saline should be considered. The possibility that the hypertriglyceridaemia sometimes encountered in DKA may give rise to pseudohyponatraemia should also be considered, particularly if the plasma is visibly lipaemic.

In general, fluid replacement of ~6 L over the first 24 h with attention to correcting shock very rapidly at the outset, and thereafter reducing the replacement rate, is appropriate for most patients. Polyuria, if still present, will not abate immediately after the start of therapy, so it is important to infuse enough fluid to achieve a positive fluid balance.

Insulin. The objective is to provide sufficient insulin for suppression of ketogenesis without causing precipitate falls in blood glucose or unnecessary hypokalaemia as a result of the insulin-driven intracellular movement of potassium. In practice, the insulin infusion rate required to achieve this objective will vary between patients, and over time in the same patient, as ketone clearance reduces ketone body-induced insulin resistance. However, a starting rate of 0.1 U/h per kg body weight is typical. The rate can be increased if recovery is slow. Initial bolus insulin doses are no longer recommended.

Patients who are normally on a long-acting basal insulin (detemir or glargine) should continue on their subcutaneous injections in order to provide a basal supply of insulin; this will facilitate better glycaemic control when they eventually revert back to their normal subcutaneous insulin regimens when the intravenous insulin infusion is discontinued.

Previously used variable insulin infusion rates ('sliding scales') are no longer used. They were designed to correct blood glucose as rapidly as possible, rather than to permit sufficient insulin to be infused to suppress ketogenesis for as long as it takes to oxidize or excrete the ketones already present in the circulation. The danger was, therefore, that large insulin doses were given in the first few hours, resulting in either too rapid a fall in blood glucose, and the need to switch to 10% glucose before sufficient saline replacement had been given or in a need to reduce the infusion rate to a level that is insufficient to suppress ketogenesis.

It should be noted that the major determinants of blood glucose reduction early in DKA are expansion of its volume of distribution and restoration of a normal glomerular filtration rate, rather than insulin-mediated glucose uptake into insulin-sensitive cells.

Potassium, magnesium and phosphate. Although whole body potassium depletion is universal in DKA, the initial serum potassium concentration may be low, normal or high. Potassium should not be given until it is clear that the patient is passing urine and renal function has been assessed. Potassium concentrations may fall precipitously with insulin treatment and frequent monitoring is necessary, especially during the early stages of therapy. In general, initial replacement rates of 5–20 mmol/h (typically 10 mmol/h), depending on the serum potassium concentration, are appropriate if the serum potassium is within the reference range. Replacement should be withheld if the potassium concentration is >5.5 mmol/L; if it is <3.3 mmol/L, a higher rate of infusion may be required (with cardiac monitoring), and insulin infusion may need to be suspended.

Phosphate and magnesium concentrations may also fall after the start of treatment. Although there is no hard evidence to support the routine use of phosphate replacement in DKA, there is good reason to suppose that severe hypophosphataemia (i.e. <0.35 mmol/L) may be deleterious. Consequences of severe hypophosphataemia include respiratory and other muscle weakness, haemolytic anaemia and reduced cardiac systolic function; these probably result from reduced generation of ATP because of substrate limitation. Severe hypophosphataemia is more likely to occur when DKA is superimposed upon chronic malnutrition. It seems reasonable to suggest that severe, symptomatic, hypophosphataemia should be treated under such circumstances, e.g. with 20 mmol in 1 L intravenous fluid over several hours. Some authorities recommend that potassium replacement be given as a mixture of the chloride (2/3) and phosphate (1/3) salts throughout.

Bicarbonate. The use of bicarbonate to correct acidosis is not recommended. This is because of the risks of hypokalaemia, hypocalcaemia, paradoxical increase in

cerebrospinal fluid acidosis, worsening intracellular acidosis and hypoxia (via a left shift in the oxygen dissociation curve), a possible increase in cerebral oedema risk (see below), delay in the fall in blood lactate concentration and increased ketogenesis.

Cerebral oedema. Cerebral oedema is one of the most feared complications of ketoacidosis, occurring particularly frequently in children and adolescents in whom it is the leading cause of death in the condition. It occurs in ~1% of cases of DKA in children and adolescents and carries a mortality of up to 90%, despite aggressive treatment with mannitol, intubation and mechanical ventilation. The most consistent associations with the subsequent development of cerebral oedema are more severe acidosis at presentation, the larger amounts of insulin administered in the first hour and higher volumes of fluid given in the first four hours. Contrary to popular suspicion, no association with initial serum sodium concentration (whether or not corrected for glucose) has consistently been shown, although it has been suggested that those who develop cerebral oedema may have a tendency to lower corrected sodium concentrations as treatment progresses.

Resolution. Once serum bicarbonate exceeds 18–20 mmol/L, the focus of management should revert to control of blood glucose, and intravenous insulin is continued using a sliding scale. Subcutaneous insulin is recommenced once the patient is eating and does not require intravenous insulin for other reasons (e.g. sepsis). As discussed above, an apparent increase in ketosis, on the basis of urine dip-stick testing for ketones, is not necessarily significant, and need not direct therapy at this stage if all other parameters are satisfactory.

After an episode of ketoacidosis, patients should always be considered insulin dependent and treated with insulin (even if they were not originally). Steps to reduce the risk of further episodes should be taken if appropriate (e.g. reinforcement of education, change of therapy).

Hyperosmolar hyperglycaemic state

Presentation and clinical features

The hyperosmolar hyperglycaemic state (HHS) was formerly known as hyperosmolar non-ketotic hyperglycaemia. The clinical features are dehydration, severe hyperglycaemia (blood glucose usually >30 mmol/L) and a hyperosmolar state (serum osmolality >330 mmol/kg). By definition, ketosis is not significant with urine ketones of less than '+' or blood ketones <1.0 mmol/L. Blood hydrogen ion concentration is usually <50 nmol/L (pH >7.3) with a normal bicarbonate, although coexistent lactic acidosis from sepsis or myocardial infarction may lead to more severe acidosis. Patients may present with osmotic symptoms such as polyuria, polydipsia, thirst, weight loss and vomiting, and are dehydrated. Drowsiness and coma may occur as a result of the high plasma osmolality; inadequate volume replacement leads to acute kidney injury, and mortality is higher than in DKA.

The HHS occurs mainly in older subjects with type 2 diabetes and most cases occur above the age of 60 years.

About half of patients have not been previously diagnosed with diabetes. Many cases arise from late presentation of diabetes with coincident cardiovascular events or infections (most commonly pneumonia or urinary tract sepsis). The cycle of hyperglycaemia, dehydration and increased counter-regulatory hormones, coincident with a history of osmotic symptoms, is similar to that which occurs in DKA, but may be more severe because of later presentation owing to the absence of significant ketoacidosis. The characteristic hypernatraemia (see [Box 16.3](#)) is caused by renal sodium resorption in response to hypovolaemia, together with osmotic diuresis and glycosuria causing persistent free water loss. The HHS usually occurs in subjects with only marginal insulin deficiency, and their insulinaemia allows sufficient glucose uptake and anti-lipolytic effect to prevent the lipolytic and ketotic problems seen in ketoacidosis.

Management

The management of HHS is similar to that of DKA. Fluid replacement is the mainstay of treatment but careful monitoring is necessary in order to avoid fluid overload, which may result in complications such as pulmonary oedema. Insulin requirements are usually less in HHS than in DKA. The plasma glucose concentration typically declines relatively quickly after the institution of insulin therapy, since patients are usually less acutely insulin-resistant than ketoacidotic patients. Rehydration will expand the volume of distribution of glucose, lowering its concentration, and restoration of a good urine output will permit glucose to be excreted in the urine in significant quantities (up to some 250 mmol/L). Together with insulin-independent uptake into tissues, the result is that blood glucose concentration tends to fall fairly rapidly with initial resuscitation, even if no insulin is administered. Rapid falls in plasma glucose or osmolality may predispose to cerebral oedema by encouraging the movement of water from plasma into the central nervous system, and most authorities recommend that the blood

BOX 16.3 Typical initial laboratory values in the hyperosmolar hyperglycaemic state

- Glucose ~60 mmol/L
- Plasma $[K^+]$ ~4.0 mmol/L: whole body depletion typically 10.0 mmol/kg body weight
- Plasma $[Na^+]$ ~155 mmol/L: whole body depletion typically 8.0 mmol/kg body weight
- Plasma [urea] ~55 mmol/L
- Plasma [creatinine] ~400 μ mol/L
- Whole body water depletion typically 80–120 mL/kg body weight, i.e. 8 L in typical adult
- Arterial blood gases:
 - $[H^+]$ <50 nmol/L (pH >7.30)
 - $PaCO_2$: normal
 - PaO_2 : normal (low if venous thromboembolism or pneumonia)
 - $[HCO_3^-]$ ~18 mmol/L (typically mildly elevated blood lactate)
- Anion gap <20 mmol/L

glucose concentration should if possible be reduced at a rate of no more than ~ 3 mmol/L/h. For this reason, insulin infusion is only required at very low rates (e.g. 0.5–1 U/h) in the initial stages of treatment. Controversy exists as to the ideal choice of fluid replacement. While some advocate the use of hypotonic fluids (e.g. 0.45% saline) after restoration of adequate intravascular volume, others argue that normal (0.9%) saline is, in effect, hypotonic to the patient's plasma and is less likely than hypotonic saline to cause rapid falls in plasma osmolality that may increase the risk of cerebral oedema.

One of the major problems in the treatment of HHS is the severe hypernatraemia that often supervenes in the hours after the initiation of therapy. Commencing treatment with fluid and insulin usually induces a decrease in plasma glucose and urea concentrations, and, therefore, osmolality. However, hypernatraemia typically develops during this period, since the falling osmolality allows water to re-equilibrate into dehydrated cells while free water loss through the kidneys continues. Since there is less acidosis and more profound dehydration, plasma potassium deficits are typically less than those occurring in DKA. The intravascular volume depletion increases plasma viscosity, resulting in a hypercoagulable state and stroke, venous thrombosis and myocardial infarction are common causes of mortality. Heparin is, therefore, recommended as prophylaxis against thrombosis. Comorbidities that may have precipitated the episode should be treated; for example, infections may require antibiotic treatment.

After successful treatment of HHS, the severity of residual glucose intolerance may be very mild and the patient can often be successfully managed on diet alone, although many will be discharged on insulin initially. Patients should be educated on steps to avoid provoking factors in the future. At all stages, it is important to involve the diabetes team in the management of patients with HHS.

Other metabolic acidoses

In diabetic subjects, the vast majority of episodes of acidosis are diabetic ketoacidosis. Other metabolic acidoses are comprehensively discussed in Chapter 5. The differential diagnosis of a metabolic acidosis in a diabetic subject may occasionally be troublesome if one forgets that patients with diabetes may sometimes develop acidosis as a result of other conditions, such as severe infection, renal failure and salicylate poisoning. Diagnostic problems may also arise where there is a mixed picture (e.g. diabetic ketoacidosis and lactic acidosis secondary to sepsis, or alcoholic ketoacidosis occurring in a patient with diabetes). Metformin-associated lactic acidosis and type 4 renal tubular acidosis have been discussed earlier in this chapter.

Alcoholic ketoacidosis

Alcoholic ketoacidosis is included here, as it occasionally presents a difficult differential diagnosis from DKA (particularly given that the latter may occasionally present with an only marginally elevated blood glucose concentration) and the treatment is different in several important

regards. This condition presents with ketoacidosis and low, normal or slightly elevated plasma glucose concentrations (rarely >12 mmol/L). Patients usually have longstanding poor nutritional intake with an alcohol binge of several days' duration, often associated with vomiting.

Ketosis is promoted by lack of insulin action in the setting of starvation, permitting mobilization of NEFAs that provide the substrate for ketone body formation as an alternative fuel. Low insulin concentrations prevent ketone body utilization by insulin-sensitive tissues and dehydration impairs ketone excretion by kidneys. Hypercortisolaemia and high growth hormone and catecholamine concentrations enhance the fatty acid release and hepatic ketogenesis consequent upon insulin deficiency.

Ketogenesis is potentiated by inhibition of hepatic metabolism of acetylcoenzyme A, owing to the action of counter-regulatory hormones such as glucagon, cortisol and catecholamines secreted in response both to the hypoglycaemia and also to extracellular fluid volume contraction (which also restricts urinary ketone elimination). In addition, alcohol metabolism depletes cellular nicotinamide adenine dinucleotide (NAD⁺). An increased ratio of NADH to NAD⁺ increases the proportion of β -hydroxybutyrate relative to acetoacetate. It also restricts pyruvate formation from lactate, leading to accumulation of lactate and depletion of pyruvate, a gluconeogenic substrate. As is the case in DKA, alterations in mitochondrial redox state favour β -hydroxybutyrate over acetoacetate production. A complex acid–base disorder ensues from the combined effects of ketosis causing metabolic acidosis, and a combination of extracellular fluid contraction and vomiting causing metabolic alkalosis, with the final [H⁺] (pH) thus not necessarily reflecting the severity of the metabolic derangements present. Treatment differs from diabetic ketoacidosis in that insulin is not required (except if patients have coexistent diabetes), and glucose infusion (which *must* be preceded by thiamine repletion) forms the mainstay of therapy, together with fluid and electrolyte replenishment.

MANAGEMENT OF DIABETES IN THE HOSPITAL SETTING

The management of diabetes in the hospital setting presents a number of challenges and has the potential to affect patient outcomes. Good glycaemic control has an established role in promoting recovery from infection, improving wound healing, and, in obstetric delivery, to prevent neonatal hypoglycaemia. In the first Diabetes Mellitus Insulin–Glucose Infusion in Acute Myocardial Infarction (DIGAMI 1) Study, insulin-based compared with conventional glucose-lowering management improved survival in patients with acute myocardial infarction and type 2 diabetes. The benefit of insulin treatment was not confirmed in the second DIGAMI trial (DIGAMI 2), in which insulin was associated with an increased risk of nonfatal cardiac events, while metformin appeared to be protective against risk of death. Therefore, the type of glucose-lowering treatment used may influence the clinical outcome.

There is mixed evidence concerning mortality and the use of intensive insulin therapy in order to achieve tight glycaemic control in the hospital setting. Recent data suggest that the use of intensive insulin therapy does not reduce mortality or length of hospital stay compared with less strict control, and may increase the risk of hypoglycaemia. This may reflect the increased prevalence of 'stress hyperglycaemia' in hospitalized patients, or be because altered insulin action *per se* in the seriously ill affects the prognosis.

Many patients admitted to hospital will require changes to be made to their diabetes treatment, at least temporarily. These changes may be made necessary by the need to fast, the use of agents such as glucocorticoids or inotropes (which can directly affect blood glucose concentration), when receiving radiographic contrast material (requiring care in the use of metformin), where there is temporarily increased risk of acute kidney injury or other conditions associated with lactic acidosis (also with metformin, see Table 16.1) or during myocardial ischaemia (possibly posing a risk with some sulfonylureas). Some patients whose blood glucose concentrations are elevated during an acute illness, but who either were not previously known to have diabetes or whose blood glucose concentrations subsequently return to levels below the threshold for diabetes diagnosis may have 'stress hyperglycaemia'.

Hospitalization presents the opportunity for a review of overall diabetes management and education: indeed, for some patients, such an opportunistic intervention may represent their only formal contact with diabetes services. It also presents an opportunity to screen for diabetes in a relatively high-risk population.

The perioperative management of patients with diabetes is to minimize changes in glycaemia brought about by the stress of surgery. Most hospitals will have formal protocols for glucose control pre- and post-surgery. Patients with type 1 diabetes will need to be on insulin at all stages to prevent diabetes ketoacidosis. Patients with type 2 diabetes will usually be able to manage on their oral agents, but may require insulin depending on the nature of the surgical procedure. Following surgery, once oral intake is adequate, most patients will be able to recommence their original treatment regimens.

PREGNANCY

For both mother and fetus, diabetes can profoundly affect the pregnancy in terms of metabolism and outcomes. Specific factors influencing the management of women who are pregnant include the presence of coexisting illness, whether they have gestational or pre-existing diabetes and whether they are likely to deliver in the relatively near future.

With pre-existing diabetes, appropriate preconceptual counselling and care is vital if a baby is planned so that glycaemic control and blood pressure are optimized and medications not recommended in pregnancy (for example statins, ACE inhibitors) are replaced. The ADA recommends a preconception HbA_{1c} of <53 mmol/mol (7%). Lipid control is by dietary measures. Folic acid is prescribed to reduce the risk of neural tube defects. These measures increase the chances of successful conception

BOX 16.4 Potential complications for the infant associated with diabetes in pregnancy

- Congenital malformation
- Polyhydramnios
- Macrosomia
- Intrauterine growth restriction
- Intrauterine mortality and still birth
- Neonatal hypoglycaemia
- Postpartum mortality
- Potentially, diseases such as obesity and diabetes in later life

BOX 16.5 Potential complications for the mother associated with diabetes in pregnancy

- Progression of diabetic retinopathy
- Worsening of gastroparesis
- Progression of diabetic nephropathy
- Complications at delivery owing to infant macrosomia

and lower the risk of complications such as congenital anomalies and miscarriage (Boxes 16.4 and 16.5).

In pregnancy, regular surveillance is important: glycaemic control should be monitored with regular measurement of blood glucose concentrations. Pregnancy induces a state of insulin resistance, leading to hyperglycaemia. This can lead to fetal malformation, macrosomia with attendant delivery complications, increased perinatal mortality and premature delivery. Strict glycaemic targets are set which increases the risk of hypoglycaemia. Retinal screening is important in patients because of the increased risk of progression of diabetic retinopathy. Tight preprandial and postprandial glycaemic targets are advised: NICE recommendations are <5.9 mmol/L fasting and <7.8 mmol/L after meals.

Insulin requirements generally rise during pregnancy because, as the pregnancy progresses, there is a reduction in insulin sensitivity, driven by human placental lactogen. This change serves to divert nutrients and the products of maternal lipolysis (fatty acids and ketones) to the fetus. It is important to recognize that a sudden fall in usual insulin requirements may be a sign of changes in placental function that herald impending delivery, and close liaison with the obstetric team is required.

During labour, it is important to monitor the mother's blood glucose concentrations; maternal hyperglycaemia is treated by intravenous insulin and dextrose infusions. On delivery of the placenta, insulin resistance dramatically declines towards non-pregnant values. Patients with type 1 diabetes and those with type 2 diabetes who were previously on insulin pre-pregnancy revert to their pre-pregnancy insulin regimens. Those with pre-existing type 2 diabetes previously on oral glucose-lowering treatment who wish to breast feed may wish to continue on either metformin or insulin (if they were taking this during pregnancy). Patients with gestational diabetes or diet-treated pre-existing type 2 diabetes do not require any medication postpartum, unless other factors, for example

sepsis or surgery, dictate otherwise. Metformin is safe whilst breastfeeding. Arrangements should be made for women with gestational diabetes to have an oral glucose tolerance test approximately six weeks postpartum if pre-discharge blood glucose values are satisfactory. Women with gestational diabetes have an approximately 50% lifetime risk of developing type 2 diabetes, and should be advised on diabetes prevention and recognition as well as being screened regularly for life.

CONCLUSION

Successful clinical management of diabetes mellitus requires an understanding of the effects of diet and exercise on glycaemic control. Type 2 diabetes is responsible for most cases of diabetes, and as ~80% of patients will die from macrovascular disease, it is essential to provide optimal management of all cardiovascular risk factors, including dyslipidaemia and hypertension.

The long-term management of patients with diabetes also aims to reduce the risk of the microvascular complications that affect the kidneys, nerves and eyes. Clinicians need to be skilled in strategies that reduce these risks and in the identification and management of complications when they occur.

Optimization of treatment with the growing range of hypoglycaemic agents depends in part on having a good understanding of their mechanisms of action. Advances in the formulation of insulin and production of insulin analogues also offers patients the possibility of improved glycaemic control. Effective management of blood glucose concentrations reduces risks of chronic complications and is particularly important during intercurrent severe illness and pregnancy.

The acute diabetic emergencies of diabetic ketoacidosis and the hyperosmolar hyperglycaemic state are still associated with significant morbidity and mortality. Their management depends on careful adherence of treatment protocols that are based on clear pathophysiological principals. Appropriate, frequent biochemical monitoring of patients with these emergencies is essential to a successful outcome.

ACKNOWLEDGEMENT

CONCLUSION 348

GLUCOSE HOMOEOSTASIS IN THE FED AND THE POSTABSORPTIVE STATES

In healthy subjects, the blood glucose concentration is maintained within relatively narrow limits through a tightly controlled balance between glucose production and glucose utilization. Fundamentally, glucose is derived either from dietary intake (in the fed state) or from glycogenolysis and gluconeogenesis (in the fasting or postabsorptive state). It is metabolized by oxidation or stored either in the form of glycogen or through conversion to fat (Fig. 17.1).

Plasma glucose regulation is a complex process involving both insulin-dependent and insulin-independent mechanisms. This regulation is a multi-organ process involving the gastrointestinal tract, pancreas, liver, muscles, adipose tissue, brain and kidneys. In the gastrointestinal tract, incretin hormones (see below), secreted in response to meals, promote glucose-mediated insulin secretion

and suppress glucagon production. In the liver, insulin regulates blood glucose concentrations by suppressing hepatic glucose output and increasing postprandial glucose storage in the form of glycogen. In muscle and adipose tissue, insulin binding to insulin receptors leads to increased expression of glucose transporter 4 (GLUT4) molecules in the cell membrane, facilitating glucose uptake. Insulin-independent mechanisms that contribute to glucose regulation are located in different organs, but mainly in the gastrointestinal tract and the kidneys. Sodium–glucose cotransporters (SGLT), such as SGLT1 in the gastrointestinal tract and SGLT2 in kidney, are important mediators of insulin-independent glucose transport across cell membranes.

In response to nutrient ingestion, glucagon-like peptide (GLP-1) and glucose-dependent insulinotropic peptide (GIP) are released from enteroendocrine cells. Glucagon-like peptide-1 enhances glucose-dependent insulin secretion and inhibits glucagon secretion.

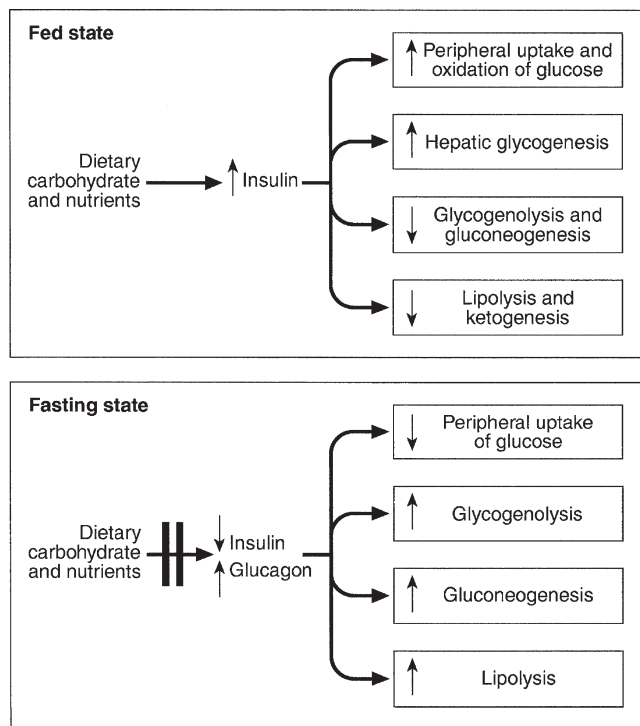

FIGURE 17.1 ■ Glucose homeostasis in the fed and fasting states.

Glucose-dependent insulintropic peptide also stimulates glucose-dependent insulin release, and the combined actions of GLP-1 and GIP account for up to 60% of the overall postprandial insulin secretion. The increase in glucose and insulin concentrations results in stimulation of glycogen synthase and inhibition of glycogen phosphorylase, causing a net increase in hepatic glycogen. Approximately 50% of an oral glucose load is taken up by the liver and 50% by peripheral insulin-sensitive tissues. Three to four hours following a meal, glucose and insulin concentrations decline and the liver switches from net glucose uptake to net glucose release. Hepatic glucose release continues to increase over the next several hours until it equals glucose utilization. Initially, about 75% of glucose production is attributable to glycogenolysis and 25% to gluconeogenesis, but as hepatic glycogen stores decline, the proportion from gluconeogenesis increases steadily.

During the early postabsorptive phase, glucose utilization continues at the rate of 0.10–0.14 mmol/kg per min, of which 40–50% is due to obligatory uptake by the brain and other non-insulin-dependent tissues. With prolonged fasting, the decline in plasma insulin concentration is accompanied by increases in plasma free fatty acid and ketone body concentrations. These can be used as alternative fuels, thereby decreasing the need for glucose.

HYPOGLYCAEMIA

The definition of hypoglycaemia is somewhat arbitrary since the glycaemic threshold at which symptoms occur differs between individuals, and depends on the age of

the patient and the prevailing plasma glucose concentration before the hypoglycaemic episode. A venous plasma glucose concentration <3.0 mmol/L, regardless of the presence or absence of symptoms, has been recommended as the biochemical definition of hypoglycaemia by The Endocrine Society in the USA. However, many apparently healthy people, especially women, may have plasma glucose concentrations <3.0 mmol/L during a prolonged fast without experiencing any symptoms. Conversely, diabetic patients may develop hypoglycaemic symptoms at higher plasma glucose concentrations. Therefore, the diagnosis of pathological hypoglycaemia necessitates the demonstration of Whipple's triad. This consists of: (1) either symptoms or signs, or both, consistent with hypoglycaemia in the presence of (2) a low plasma glucose concentration, with (3) the relief of symptoms or signs after the plasma glucose concentration is raised.

The neuroendocrine response to hypoglycaemia

Under normal metabolic conditions, in the unstressed state, the central nervous system (CNS) is wholly dependent upon glucose as its primary source of energy. The brain requires approximately 150 g of glucose each day, which must be continuously available. The presence of hypoglycaemia triggers a complex and well-coordinated metabolic process aimed at limiting and preventing a further fall in blood glucose concentration. The extent and duration of hypoglycaemia are primary factors in determining the magnitude of this counter-regulatory response, but other factors, such as age, sex, rate of fall of blood glucose and insulin per se have also been shown to influence the response.

In healthy subjects, the initial response to prevent a decline in blood glucose concentration is a reduction in insulin secretion, which begins while the plasma glucose concentration is falling but still within the physiological range. This is followed by an increase in glucagon and adrenaline (epinephrine) secretion as the glucose concentration declines further. Glucagon, secreted by pancreatic α -cells, rapidly raises plasma glucose concentration by stimulating hepatic glucose production via glycogenolysis and gluconeogenesis. The activation of the autonomic nervous system, mainly the sympathetic, increases the concentrations of noradrenaline (norepinephrine) at nerve terminals and adrenaline in the circulation. Adrenaline acts on α - and β -adrenergic receptors at several end organs and results in a more sustained increase in blood glucose concentration. It reduces insulin secretion from the pancreatic islets, increases glycogenolysis and gluconeogenesis in liver, increases glycolysis in muscle and increases lipolysis in adipose tissue. Hepatic glycogen stores provide glucose, particularly for the brain, whereas the mobilization of fatty acids from fat depots provides energy for tissues that can utilize fatty acids as their basic fuel, for example skeletal and cardiac muscles, renal cortex and liver, thus sparing glucose for use by the CNS.

As blood glucose concentration declines further, hypothalamic sensing of hypoglycaemia results in increased secretion of growth hormone (GH) and adrenocorticotrophic hormone (ACTH) and, consequently, cortisol. The increase in GH and cortisol secretion induces metabolic changes over longer periods of time by stimulating lipolysis in adipose tissue and ketogenesis and gluconeogenesis in the liver.

The glycaemic thresholds for the activation of these responses are higher than those for the development of symptoms or the impairment of cognitive function. With falling plasma glucose concentrations, the typical sequence of responses (and their glycaemic thresholds) is as follows: decrease in endogenous insulin secretion (4.4 mmol/L); increase in glucagon and adrenaline (3.8 mmol/L); increase in GH secretion (3.7 mmol/L); increase in cortisol secretion (3.2 mmol/L); development of symptoms (3.0 mmol/L), and impairment of cognitive function (2.5 mmol/L).

Symptoms of hypoglycaemia

The symptoms of hypoglycaemia are non-specific and vary depending on the degree of hypoglycaemia, the rapidity of the decline in blood glucose, the age of the patient, whether the hypoglycaemia is clinical or experimental, and on patients' differing perceptions of symptoms. The symptoms differ from one person to another, but are usually consistent from episode to episode for any one person. In some patients, symptoms are mainly due to activation of the sympathetic nervous system (neurogenic or autonomic), but in others only symptoms due to brain glucose deprivation per se may be observed. All the symptoms of hypoglycaemia, however, reflect the effects of glucose deprivation on the CNS (neuroglycopenia).

Acute neuroglycopenia (neurogenic)

This is characterized by sweating, anxiety, hunger, tremor, palpitations and weakness (Box 17.1). These symptoms result mainly from activation of the sympathetic nervous system and characteristically occur when there has been a rapid decline in blood glucose concentration. It may occur in patients with diabetes owing to excessive absorption of exogenous insulin, either from overtreatment or from rapid mobilization from the injection site during exercise. In non-diabetic subjects, reactive hypersecretion of insulin may be responsible, for example after Roux-en-Y gastric bypass for obesity. Awareness of hypoglycaemia is mainly the result of the perception of neurogenic symptoms which may be lost in patients with type 1 diabetes mellitus (hypoglycaemia unawareness). The symptoms of acute neuroglycopenia may mimic those of anxiety attacks or hyperventilation.

Subacute neuroglycopenia

Symptoms range from a generalized decrease in spontaneous activity, poor concentration, episodic disorientation, confusion, incoordination, slurred speech and behavioural

BOX 17.1 Symptoms of hypoglycaemia (Neuroglycopenia)

Acute	Subacute	Chronic
Sweating	Reduction of spontaneous activity	Personality changes
Anxiety	Behavioural change	Defective memory
Hunger	Tiredness/somnolence	Depression
Nausea	Dizziness	Psychosis
Tremulousness	Poor concentration	Dementia
Weakness	Incoordination	
Palpitations	Headache	
Restlessness	Blurred vision	
	Slurred speech	
	Disorientation/confusion	
	Amnesia	
	Paraesthesia	
	Weakness/transient hemiplegia	
	Seizures	
	Coma	

changes, to seizures, focal neurological signs and coma (Box 17.1). Patients with subacute neuroglycopenic symptoms have been misdiagnosed as having epilepsy, transient ischaemic attacks, psychosis, hysteria, chronic nervous exhaustion, personality disorder or inebriation.

Chronic neuroglycopenia

Chronic neuroglycopenia is very rare and may occur in patients with insulin-secreting tumours unsuspected for years. Symptoms include insidious progressive mental disturbance that may resemble personality disorders, schizophrenia, paranoid psychosis, depression or dementia (Box 17.1).

CLASSIFICATION OF HYPOGLYCAEMIC DISORDERS

Several classifications of hypoglycaemia are possible, for example aetiological, ketotic or non-ketotic, a classification based on the timing of symptoms in relation to meals (fasting or postprandial) or whether hypoglycaemia occurs in a healthy person or one who has an illness.

The usefulness of classifying hypoglycaemic disorders based on the timing of symptoms in relation to meals has been questioned because some conditions that are associated with fasting hypoglycaemia, such as insulinoma, may also produce symptoms postprandially, and post-gastric bypass patients, who typically have postprandial hypoglycaemia, may have symptoms when fasting. Also, patients with factitious hypoglycaemia may have symptoms that have no clear relationship to food intake. In view of this, a classification which is based on the clinical characteristics, i.e. on whether hypoglycaemia occurs in a seemingly well individual or an ill or medicated individual, is more useful (Box 17.2).

BOX 17.2 Clinical classification of hypoglycaemic disorders in adults

III, hospitalized or medicated individual

- Drugs (insulin or insulin secretagogues, alcohol, others)
- Major organ failure (chronic kidney disease, congestive cardiac failure, liver failure)
- Sepsis (including malaria)
- Inanition (anorexia nervosa or starvation)
- Non-islet cell tumour hypoglycaemia (NICTH)
- Hormone deficiencies: cortisol (Addison disease)

Seemingly well individual

- Insulinoma
- Non-insulinoma pancreatogenous hypoglycaemia syndrome (NIPHS)
- Insulin autoimmune hypoglycaemia (antibody to insulin or insulin receptor)
- Factitious or accidental hypoglycaemia (induced by insulin or insulin secretagogues)

PRACTICAL APPROACH TO THE INVESTIGATION OF HYPOGLYCAEMIA

Evaluation of hypoglycaemia in persons without diabetes mellitus

The direction of investigation will depend essentially on the clinical presentation and whether the patient appears ill or not. Hospitalized patients are often severely ill with multisystem disease. In such cases, the underlying illnesses that can produce episodes of hypoglycaemia, such as severe renal or hepatic disease, congestive cardiac failure, sepsis and anorexia nervosa, are usually obvious clinically. A review of all medications is essential since drugs (see below) are a common cause of hypoglycaemia in hospitalized patients, particularly in the presence of renal impairment. Non-islet cell tumours causing hypoglycaemia are usually, though not invariably, large mesenchymal tumours that are clinically apparent. In these cases, confirmation of the suspected mechanism of the hypoglycaemia may be sought by measuring plasma insulin, C-peptide, proinsulin and β -hydroxybutyrate (β -OHB) concentrations during an episode of hypoglycaemia. Endocrine deficiencies such as hypopituitarism and adrenocortical insufficiency should be sought and excluded by appropriate investigations if necessary.

In a seemingly well individual, with no obvious co-existing disease, the direction and extent of evaluation will depend on the clinical presentation. A thorough and detailed history of the symptoms (frequency, type, relationship to meals and exercise) is therefore essential. If symptoms are relieved by food ingestion, it is important to enquire about the type of food and speed of recovery. All medications should be inspected to exclude a prescribing or dispensing error, and the possibility of surreptitiously induced hypoglycaemia should always be considered, especially in healthcare professionals and relatives and carers of diabetic patients. Assessment of

alcohol intake and pattern of drinking is important, since alcohol can cause both fasting and reactive hypoglycaemia. A history of previous gastric surgery or Roux-en-Y gastric bypass surgery for obesity and a family history of multiple endocrine neoplasia type 1 (MEN 1) should be sought. Symptoms in individuals of Japanese or Korean ethnicity may point to autoimmune hypoglycaemia.

Investigation of hypoglycaemia

The aims of the investigation are, first, to demonstrate that hypoglycaemia is the cause of the symptoms and, second, to identify the cause of the hypoglycaemia (Fig. 17.2).

Demonstration of hypoglycaemia

Measurement of blood glucose during spontaneous symptoms. Measurement of the blood glucose concentration (and collection of a suitable blood specimen for subsequent measurement of plasma insulin, C-peptide, proinsulin and β -OHB concentrations) during spontaneous symptoms, and before glucose is given, is without doubt the best test for the diagnosis of spontaneous hypoglycaemia. The most practical way to obtain an accurate glucose concentration is to measure glucose immediately in whole blood or to separate plasma from cells within 30 min of collection, even if the specimen is collected in a tube that contains sodium fluoride. It is well recognized that the rates of decrease of glucose in the first hour after specimen collection in tubes with or without fluoride are virtually identical. The reduction in glucose after 2 h in a fluoride tube can sometimes exceed 0.5 mmol/L leading to a falsely low blood glucose concentration or 'pseudohypoglycaemia'. In addition, although arteriovenous plasma glucose concentration differences are negligible in the fasting state, antecubital venous plasma glucose concentrations are significantly lower than arterial glucose concentrations after a glucose load owing to glucose extraction across the forearm. Therefore, arterialized blood collected from a vein at the back of the hand, which has been warmed by a heat pad, is preferred.

Often, however, patients referred for a medical opinion are asymptomatic when seen in the outpatient clinic, and measuring their blood glucose concentration at such time is usually unhelpful. In this situation, reproducing the circumstances which may lead to hypoglycaemia should be attempted. In patients with a history suggestive of fasting hypoglycaemia, a prolonged fast test should be performed, whereas in patients who only experience symptoms of hypoglycaemia within a few hours of having a meal, a mixed meal test should be performed (see provocation tests, below).

Provocation tests

Prolonged fast test. The prolonged fast (up to 72 h) is the single most useful investigation employed in the evaluation of patients with suspected spontaneous hypoglycaemia. The aim of the investigation is to demonstrate spontaneous hypoglycaemia in the presence of neuroglycopenic symptoms and the resolution of the symptoms when the plasma glucose concentration

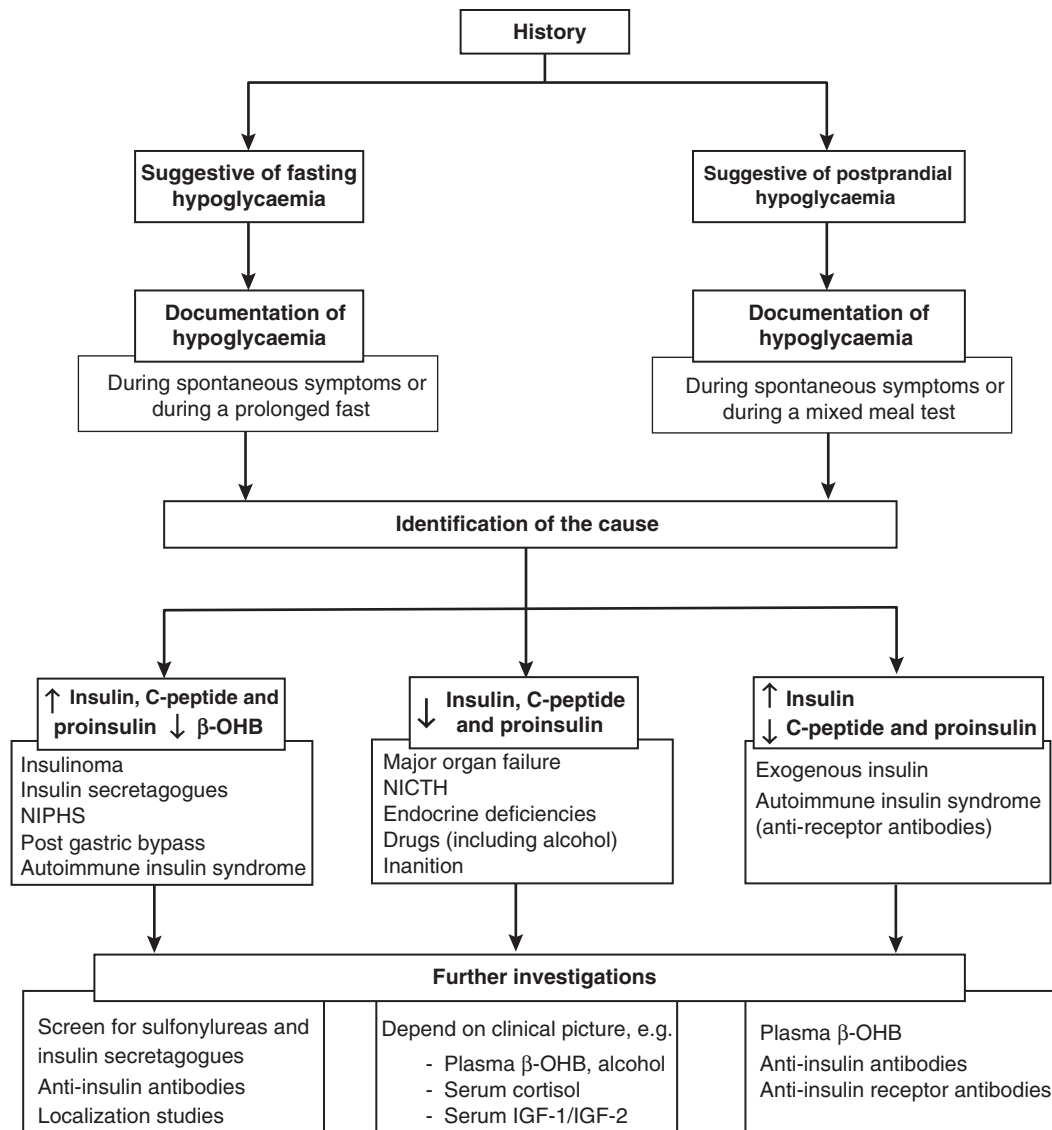

FIGURE 17.2 ■ A practical approach to the investigation and diagnosis of hypoglycaemia (β -OHB, β -hydroxybutyrate; NIPHS, non-insulinoma pancreatogenous hypoglycaemia syndrome; NICTH, non-islet cell tumour hypoglycaemia; IGF-1 and IGF-2, insulin-like growth factors 1 and 2).

is raised to within normal limits. During a prolonged fast, normal subjects rarely develop plasma glucose concentrations <3.0 mmol/L and almost never develop neuroglycopenic symptoms.

The fast must be conducted in hospital under strict medical supervision. Before initiation of the fast, a simple assessment of coordination, recent memory and calculations (e.g. counting down in sevens) should be performed as a baseline. The time for initiating the fast is determined depending on a reasonable estimate of the patient's likely tolerance for fasting. If fasting starts after the evening meal or at midnight, the majority of patients with insulinoma will develop hypoglycaemia by the middle of the following day, when adequate staff and laboratory facilities are available. Patients should have an intravenous indwelling catheter, and an ampoule of 50% glucose solution should be readily available. During the test, the patient is allowed water and non-caloric beverages and should undertake brisk

exercise under supervision. Blood, for glucose, insulin, C-peptide, proinsulin and β -OHB measurements, is collected at the beginning of the test, and every 4–6 h thereafter. Plasma glucose should be determined in the laboratory as soon as possible after collection, and plasma or serum should be stored at -20°C for subsequent analysis of insulin, C-peptide, proinsulin and β -OHB if required. Bedside glucose meters can be used to monitor the patient's blood glucose concentration frequently, but low values, especially in the absence of symptoms of hypoglycaemia, should always be confirmed in the laboratory. When the plasma glucose has fallen to <3.0 mmol/L, blood should be collected more frequently and the patient should be assessed for neuroglycopenia by repeating the same tests performed at the initiation of the fast. If neuroglycopenic symptoms develop and blood glucose is <3.0 mmol/L, several specimens should be obtained for plasma glucose, insulin, C-peptide, proinsulin and β -OHB measurements

before any remedial action, such as glucose administration, is taken. At the end of the fast, a sample should be collected to screen for hypoglycaemic agents and to measure insulin antibodies. A glucagon test (1.0 mg intravenously) has also been recommended (see below). The criteria to stop the test before 72 h are: (1) Whipple's triad has been observed; (2) plasma glucose concentration <3.0 mmol/L in a patient who had previously experienced Whipple's triad, and (3) plasma β -OHB >2.7 mmol/L. The measurement of β -OHB concentrations in real-time during the fast is quite useful because a progressive rise in plasma β -OHB concentrations indicates indirectly that the circulating insulin concentration has been suppressed and that the fast can be terminated. However, blood should always be collected in this situation to confirm suppressed plasma insulin, proinsulin and C-peptide concentrations.

In patients with insulinoma, about 40% develop hypoglycaemia within 12 h, 75% within 24 h, 95% by 48 h and 99% by 72 h.

Glucagon stimulation test. This test serves as a supplemental study in the diagnosis of hypoglycaemic disorders when results from the prolonged fast are inconclusive. The rationale is that, in patients with insulinoma, there is a greater increase in plasma glucose after intravenous glucagon due to the lesser depletion of hepatic glycogen during the fast as a consequence of the higher insulin secretion. The test is performed at the termination of a prolonged fast test, either at the time of occurrence of symptomatic hypoglycaemia with concomitant plasma glucose concentration <3.0 mmol/L, or after 72 h of fast. Glucagon 1 mg is injected intravenously over 2 min and plasma glucose is measured at baseline, 10, 20 and 30 min after the glucagon injection. An increase in plasma glucose concentration of ≥ 1.4 mmol/L after intravenous glucagon indicates mediation of the hypoglycaemia by insulin. A disadvantage of this test is the danger of causing severe hypoglycaemia after 90–180 min.

Mixed meal test. This test is used to investigate patients who experience only postprandial symptoms. The meal has not been standardized but, ideally, a meal similar in composition to the meal that usually provokes symptoms should be used. Plasma glucose concentration is monitored every 30 min for 5 h and also at any time while the patient is symptomatic. Capillary or arterialized blood (see above) should be used, since postprandial venous plasma glucose concentrations are about 10% lower than arterial concentrations owing to extraction of glucose by muscle. Samples should also be collected every 30 min for insulin, C-peptide and proinsulin measurement but should only be analysed if they have been collected at the time when plasma glucose concentration was <3.0 mmol/L and before administering carbohydrates. Patients should be observed for symptoms, and the timing of these symptoms in relation to the meal, and to the blood glucose concentrations, should be documented. If Whipple's triad is demonstrated, a sample for the measurement of oral hypoglycaemic agents and insulin antibodies should be collected. Patients who develop neuroglycopenic symptoms during hypoglycaemia, but not at other times during the test, may be considered to

have postprandial hypoglycaemia. However, in all patients with a positive mixed meal test, additional testing, including a supervised 72 h fast, is recommended. Postprandial hypoglycaemia without fasting hypoglycaemia has been documented in some patients with insulinoma and in patients with non-insulinoma pancreatogenous hypoglycaemia (see p. 343).

The diagnosis of postprandial hypoglycaemia should not be made on the basis of an oral glucose tolerance test (OGTT). At least 10% of 'normal' subjects may have plasma glucose nadirs of <2.6 mmol/L during an OGTT and 2.5% may have values <2.2 mmol/L. Moreover, symptoms during OGTT are often unrelated to the level of plasma glucose nadir or to the rate of decline of the glucose concentration.

Identification of the cause of hypoglycaemia

Plasma insulin, C-peptide and proinsulin. Although insulin and C-peptide are secreted in equimolar amounts by the β -Cells of the pancreas, the metabolic clearance of insulin is much more rapid than that of C-peptide. Therefore, C-peptide has a longer half-life and is present in peripheral blood in higher molar concentrations than insulin, making it less prone to marked fluctuations. Consequently, the measurement of plasma C-peptide concentrations may be more reliable as an indication of endogenous insulin production. However, as C-peptide is cleared by the kidneys, raised concentrations may occur in renal impairment.

Intact proinsulin undergoes enzymatic processing leading to production of des-31,32-proinsulin and des-64,65-proinsulin and then to insulin and C-peptide. Some proinsulin assays specifically measure intact proinsulin whereas others measure 'total proinsulin', i.e. intact and other molecules such as des-31,32-proinsulin. Therefore, proinsulin results depend strongly on the assay used and should be interpreted with caution. In islet cell tumours, the amount of circulating proinsulin is increased and, occasionally, tumours may secrete mainly or exclusively proinsulin. A plasma proinsulin concentration ≥ 5.0 pmol/L, when the plasma glucose concentration is <2.5 mmol/L during a 72 h fast test, represents the best criterion for the diagnosis of endogenous hyperinsulinaemia with 100% specificity and sensitivity. In view of this, the Endocrine Society has now recommended the measurement of plasma proinsulin as a first-line test, in addition to insulin and C-peptide.

Insulin and C-peptide can be measured in either plasma (lithium heparin) or serum, as long as the serum or plasma is separated within 15 min of collection and frozen immediately following separation. Plasma insulin concentrations can be artefactually modified by heterophilic antibodies, endogenous anti-insulin antibodies or haemolysis, as red blood cells contain an insulin-degrading enzyme, which may lead to underestimation of the actual insulin concentrations in haemolysed samples.

The measurement of plasma insulin, C-peptide and proinsulin concentrations, in the presence of hypoglycaemia, is the most useful test in identifying the cause

of hypoglycaemia (see Fig. 17.2). Raised plasma insulin (≥ 18 pmol/L), C-peptide (≥ 200 pmol/L) and proinsulin concentrations (≥ 5.0 pmol/L) in the presence of hypoglycaemia (plasma glucose < 3.0 mmol/L) indicate endogenous hyperinsulinaemia. Causes of endogenous hyperinsulinaemia include insulinoma, non-insulinoma pancreatogenous hypoglycaemia syndrome (NIPHS), autoimmune insulin syndrome, sulfonylurea- or meglitinide-induced hypoglycaemia, non-islet cell insulin-secreting tumours and reactive insulin-mediated hypoglycaemia in post-gastric bypass surgery patients. Factitious sulfonylurea-induced and meglitinide- (glinide-) induced hypoglycaemia may produce an identical clinical and biochemical picture to insulinoma. Therefore, screening for these drugs is essential if a false positive diagnosis of insulinoma is to be avoided.

Inappropriately raised plasma insulin concentrations in the presence of low or suppressed plasma C-peptide and proinsulin concentrations will identify patients with exogenous insulin administration. Therefore, it is important to use insulin assays that can detect the presence of insulin analogues. Another rare cause of raised plasma insulin but suppressed C-peptide and proinsulin concentrations is hypoglycaemia mediated by insulin receptor antibodies (IR-A). The diagnosis should be considered in patients with other autoimmune diseases and requires the demonstration of IR-A in the serum.

Other causes of hypoglycaemia are associated with suppressed plasma insulin, C-peptide and proinsulin concentrations. In many of these conditions, the diagnosis is usually obvious on clinical grounds. In others, the measurement of plasma β -OHB, GH and insulin-like growth factor (IGF-1 and IGF-2) concentrations may be required to establish the cause of hypoglycaemia (Fig. 17.2).

Plasma β -hydroxybutyrate (β -OHB). Lipolysis is very sensitive to circulating insulin concentrations. During fasting, normal individuals will show a gradual decline in insulin concentration and a progressive increase in lipolysis and hence ketone bodies, for example β -OHB (Fig. 17.3). In patients with hypoglycaemia due to hyperinsulinaemia, lipolysis is suppressed and β -OHB concentrations are low. A plasma β -OHB concentration of ≤ 2.7 mmol/L during a prolonged fast, and when plasma glucose concentration is < 3.0 mmol/L, indicates mediation of hypoglycaemia by insulin. Conversely, in hypoglycaemia associated with suppressed insulin secretion, such as liver disease, β -OHB concentrations are usually raised, the only exception being in severe inanition, when fat stores are depleted. Therefore, the measurement of plasma β -OHB provides an indirect measure of the prevailing insulin concentration during the hypoglycaemia. The main advantage, however, is that β -OHB is easy to measure and the result can be made available long before those of insulin or C-peptide measurements.

Insulin antibodies. The presence of circulating antibodies to insulin, due to previous exposure to exogenous insulin, may give falsely high plasma insulin concentrations (see p. 295). However, this is less common now with

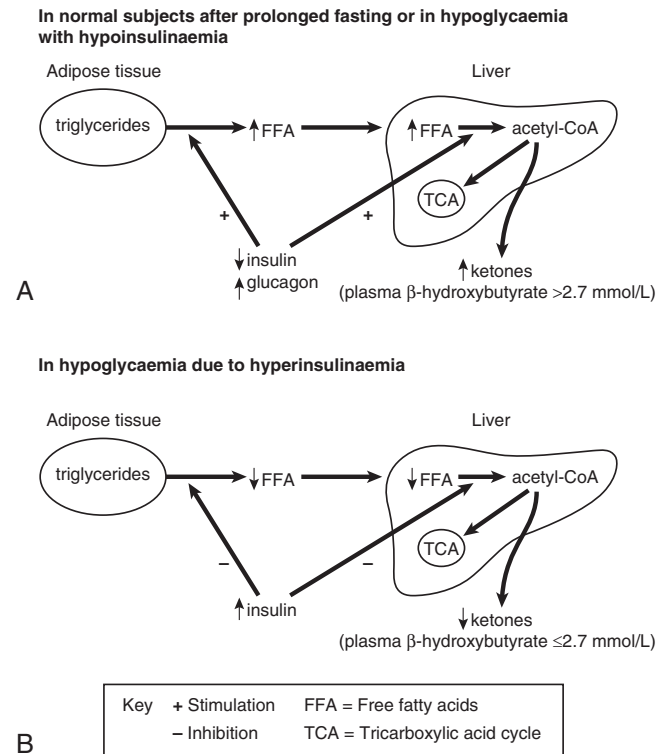

FIGURE 17.3 ■ Changes in the concentrations of hormones and metabolites in normal subjects after prolonged fasting and in hypoglycaemia with hypoinsulinaemia (A), and in hypoglycaemia due to hyperinsulinaemia (B).

the use of human insulin, which is less antigenic than the previously used animal insulin preparations. The detection of insulin antibodies is considered to be the criterion for the diagnosis of the insulin autoimmune syndrome (see below), but antibodies may be detected in persons without hypoglycaemia and even, rarely, in patients with insulinoma. Because C-peptide does not cross-react with insulin antibodies, the measurement of C-peptide in these situations can be used as an index of β -Cell function. Autoantibodies to insulin receptors cause a particularly refractory type of fasting hypoglycaemia (see below) and the diagnosis requires the demonstration of IR-A in the serum.

Screening for oral hypoglycaemic agents. In a seemingly well individual, screening for oral hypoglycaemic agents (sulfonylureas and meglitinides) should always be considered to exclude the possibility of a prescribing or dispensing error, and of surreptitiously induced hypoglycaemia.

Evaluation of hypoglycaemia in patients with diabetes mellitus

Definition

The American Diabetes Association (ADA) has published criteria for the definition and clinical classification of hypoglycaemia in patients with diabetes mellitus (Box 17.3). In patients with diabetes, hypoglycaemia is defined as all episodes of an abnormally low plasma

BOX 17.3 American Diabetes Association classification of hypoglycaemia in individuals with diabetes**Severe hypoglycaemia**

- An event requiring assistance of another person to actively administer carbohydrate, glucagon or other resuscitative actions. These episodes may be associated with sufficient neuroglycopenia to induce seizure or coma. Plasma glucose measurements may not be available during such an event, but neurological recovery attributable to the restoration of plasma glucose to normal is considered sufficient evidence that the event was induced by a low plasma glucose concentration.

Documented symptomatic hypoglycaemia

- An event during which typical symptoms of hypoglycaemia are accompanied by a measured plasma glucose concentration ≤ 3.9 mmol/L.

Asymptomatic hypoglycaemia

- An event not accompanied by typical symptoms of hypoglycaemia but with a measured plasma glucose concentration ≤ 3.9 mmol/L.

Probable symptomatic hypoglycaemia

- An event during which symptoms of hypoglycaemia are not accompanied by a plasma glucose determination (but that was presumably caused by a plasma glucose concentration ≤ 3.9 mmol/L).

Relative hypoglycaemia

- An event during which the person with diabetes reports any of the typical symptoms of hypoglycaemia and interprets those as indicative of hypoglycaemia, but with a measured plasma glucose concentration > 3.9 mmol/L.

glucose concentration (with or without symptoms) that expose the individual to harm. The workgroup recommended that persons with diabetes become concerned about the possibility of hypoglycaemia at a self-monitored blood glucose concentration ≤ 3.9 mmol/L. While that value is higher than the value used to diagnose hypoglycaemia in people without diabetes, it approximates the lower limit of the physiological fasting non-diabetic range and the glycaemic threshold for activation of counter-regulatory mechanisms. This cut-off value has been debated, with some favouring a value of < 3.5 mmol/L to avoid over-diagnosis of hypoglycaemia in asymptomatic patients.

Pathophysiology and risk factors

Hypoglycaemia in persons with diabetes is essentially the result of therapies that raise plasma insulin concentrations, such as insulin, sulfonylureas and non-sulfonylurea insulin secretagogues (e.g. nateglinide or repaglinide). The relative or absolute insulin excess during treatment, together with compromised physiological and behavioural defences in type 1 diabetes and longstanding type 2 diabetes, can result in hypoglycaemic episodes. In many patients with fully developed type 1 diabetes or with longstanding type 2 diabetes, the glucagon response to hypoglycaemia is lost and the adrenaline response is often reduced, leading to defective counter-regulation and 'hypoglycaemia unawareness'.

Factors that may increase risk of hypoglycaemia include: missed or irregular meals; incorrect use of hypoglycaemic medication (dose or timing); decreased insulin clearance (e.g. renal impairment); increased glucose utilization (e.g. excessive exercise); excessive alcohol intake, and concurrent medications (Box 17.4).

Incidence

The rates of hypoglycaemia with insulin therapy vary according to the insulin regimen and the type and duration of diabetes. Overall, hypoglycaemia is less frequent in type 2 diabetes than in type 1 diabetes, but the risk of hypoglycaemia increases substantially later in the course

BOX 17.4 Risk factors for hypoglycaemia in diabetes

- Excessive or incorrect use of insulin or insulin secretagogues (e.g. dose or timing)
- Impaired drug clearance (e.g. renal impairment, liver failure, hypothyroidism)
- Impaired counter-regulatory capacity (e.g. GH deficiency, Addison disease)
- Decreased exogenous glucose delivery (e.g. missing meals, anorexia)
- Impaired glucose absorption (e.g. malabsorption)
- Decreased endogenous glucose production (e.g. liver failure, alcohol)
- Increased peripheral glucose utilization (e.g. exercise)
- History of severe hypoglycaemia, hypoglycaemia unawareness or recent antecedent hypoglycaemia
- Concurrent medications (e.g. aspirin, warfarin)

of type 2 diabetes. According to the UK Hypoglycaemia Study Group (2007), the rate of severe hypoglycaemia in insulin-treated type 1 patients of < 5 years' duration was 22%, rising to 46% in patients with duration of > 15 years. In comparison, the rates in patients with type 2 diabetes treated with insulin were 7% for patients taking insulin for < 2 years and 25% for patients taking insulin for > 5 years. Diabetic patients who are treated with insulin are particularly prone to exercise-induced hypoglycaemia. In normal subjects, glucose uptake in skeletal muscles is increased by 20–30 times during exercise. This is compensated for by an increase in hepatic glucose release mediated by a fall in circulating insulin concentrations. In patients treated with insulin, the continuous release of insulin from subcutaneous depots inhibits glucose output from the liver. In addition, increased absorption of insulin from the injection site may occur if the site is near the muscles being exercised.

Hypoglycaemia rates with the third-generation sulfonylureas (e.g. glimepiride, glipizide and gliclazide) and the meglitinides (e.g. repaglinide and nateglinide) appear to be lower than those of previous generation sulfonylureas (e.g. glibenclamide and chlorpropamide). Elderly diabetic patients, especially those with renal or liver impairment, are particularly susceptible to hypoglycaemia

and a reduction in sulfonylurea dosages is often required. The hypoglycaemia is usually prolonged, especially as the duration of action of the sulfonylureas is generally much longer than their plasma half-lives, and may last between 36 h and seven days, despite continuous infusion of glucose. Additional treatment with glucagon and/or diazoxide may be required to prevent a fatal outcome.

The risk of hypoglycaemia with metformin and thiazolidinediones (e.g. pioglitazone) is negligible. These agents act by sensitizing peripheral tissues to insulin but do not directly alter insulin secretion. They rarely cause hypoglycaemia when used as monotherapy, but may contribute to hypoglycaemia when used concomitantly with insulin, sulfonylureas or other insulin secretagogues.

Glucagon-like peptide-1 analogues (such as exenatide or liraglutide) and the dipeptidyl-peptidase 4 inhibitors (such as sitagliptin, vildagliptin and saxagliptin) do not appear to be associated with increased risk of hypoglycaemia when used as monotherapy, or in combination with insulin sensitizers (such as metformin and thiazolidinediones) in short-term clinical studies, but the risk of hypoglycaemia appears to increase when GLP-1 analogues are used with sulfonylureas.

Management

In patients with documented symptomatic or asymptomatic hypoglycaemic events, excessive dosing, wrong type or ill-timed dosing of insulin or insulin secretagogues should be first considered. Conditions that may affect exogenous glucose delivery (e.g. missed meals), endogenous glucose production (e.g. alcohol), glucose utilization (e.g. exercise), insulin sensitivity (e.g. weight loss) or clearance (e.g. renal impairment) should be explored. Recurrent hypoglycaemic episodes or a history of hypoglycaemia unawareness should prompt a detailed review of the treatment regimen.

EMERGENCY TREATMENT OF HYPOGLYCAEMIA

Hypoglycaemia should be suspected in all patients presenting to the emergency department with altered mental state. In these patients, the diagnosis of hypoglycaemia should be expeditiously investigated by bedside glucose measurement; blood sampling for laboratory glucose testing should always be performed to confirm the results, though therapy should never be withheld pending laboratory confirmation. If hypoglycaemia is present, glucose should be administered immediately, preferably orally if the patient is awake and can swallow water safely with no risk of aspiration. The dose of oral glucose should be 10–20 g in an adult patient, and this dose may be repeated three times (if required) before giving a meal containing complex carbohydrates, to ensure long-lasting effects.

If the patient's conscious level does not allow oral therapy, parenteral glucose is indicated: the dose of glucose for an average adult is 25–50 g given as an i.v. bolus of 50–100 mL of 50% dextrose. This should be followed by a maintenance dose of 10% dextrose i.v. at 3 mL/kg per h.

Failure to respond to glucose is an indication to give glucagon subcutaneously, intramuscularly or intravenously (1 mg in adults). Steroids (e.g. hydrocortisone 1–2 mg/kg i.v. every 6 h) are given if the patient remains refractory to standard hypoglycaemia therapy or if adrenal insufficiency is suspected. Sulfonylureas are an important cause of refractory hypoglycaemia. They act by stimulating insulin secretion, and the administration of glucose to treat the hypoglycaemia further increases insulin release, thus tending to perpetuate the hypoglycaemia. Therefore, diazoxide or octreotide may be indicated for patients with sulfonylurea-induced hypoglycaemia.

CAUSES OF HYPOGLYCAEMIA

Surreptitious administration of hypoglycaemic agents (factitious or felonious hypoglycaemia)

Surreptitious or self-induced factitious hypoglycaemia should always be considered in patients presenting with spontaneous hypoglycaemia. The diagnosis should be suspected in individuals with access to insulin, sulfonylureas or meglitinides, such as diabetic patients (and their relatives, friends and carers) and healthcare professionals. Patients often vehemently deny self-administration and rarely show signs of psychiatric disturbances. Patients with diabetes may claim to have hypoglycaemic attacks despite omitting their insulin or sulfonylurea drugs. Some have the characteristics of Munchausen syndrome, with a history of frequent hospitalizations, previous surgical procedures and extensive travel.

Once suspected, the patient should be admitted to hospital for detailed observation and blood should be collected during hypoglycaemia for the measurement of plasma insulin, C-peptide, proinsulin, insulin antibodies and oral hypoglycaemic agents. A raised plasma insulin concentration and a suppressed C-peptide concentration will confirm the diagnosis of self-administration of insulin. If plasma insulin and C-peptide concentrations are both inappropriately raised, a drug screen (ideally for all available sulfonylureas and meglitinides) should be performed, in order to avoid an incorrect diagnosis of insulinoma. Once the diagnosis of factitious hypoglycaemia is made, the patient should be referred for counselling and psychiatric therapy.

Accidental intake of sulfonylurea drugs or meglitinides is rare but should be considered in all patients presenting with spontaneous hypoglycaemia. The finding that a spouse or a relation is taking these drugs should alert the physician to the possibility of accidental intake. The possibility of a prescription or dispensing error should also be considered.

Islet cell tumours (insulinoma)

Insulinomas are rare, with an annual incidence of about four cases per million persons. They can occur at any age, with approximately 80% occurring between the ages of 20 and 60 years and with, probably, a slight preponderance in women. In approximately 80% of

patients, there is a solitary benign adenoma. Benign adenomas are generally small (1–2 cm in diameter) and occur with equal frequency in the head, body and tail of the pancreas. Multiple tumours occur in about 10% of patients and approximately 10% of insulinomas are malignant, with regional or distant metastases. About 8% of insulinomas are associated with multiple endocrine neoplasia type 1 (MEN1). Diffuse islet cell hyperplasia and non-insulinoma pancreatogenous hypoglycaemia syndrome (see below) have been reported in adults. Many insulinomas contain and secrete other hormones in addition to insulin (glucagon, gastrin, somatostatin and pancreatic polypeptide), but hypersecretion of these hormones is not usually associated with clinical symptoms.

Clinical features

Hypoglycaemia is the clinical hallmark of insulinomas. Neuroglycopenic symptoms, especially confusion, weakness, slurred speech, blurred vision and irrational behaviour, typically occur before breakfast, though 50% of patients may also have symptoms late in the afternoon. More than 50% of patients have amnesia and therefore the history should always be corroborated. Nocturnal hypoglycaemia is not uncommon and can manifest as nightmares and morning headaches. Symptoms may be provoked by exercise, missing a meal or by following a restricted calorie diet. Transient hemiplegia, grand mal seizures, focal neurological signs and coma can occur, but permanent brain damage is rare and is only seen with profound hypoglycaemia that goes unrecognized and uncorrected for several hours.

Diagnosis

Insulinoma is a rare cause of spontaneous hypoglycaemia. More common causes, such as surreptitious or inadvertent administration of insulin or oral hypoglycaemic agents, should be excluded first. The diagnosis of insulinoma requires the demonstration of hypoglycaemia, unsuppressed or elevated plasma insulin concentrations during hypoglycaemia and a pancreatic tumour. Patients with suspected insulinoma should have a prolonged fast with monitoring of plasma glucose, insulin, C-peptide, proinsulin and β -OHB concentrations followed by a glucagon stimulation test (if indicated). In patients with insulinoma, plasma insulin, C-peptide and proinsulin concentrations fail to suppress despite the presence of hypoglycaemia. Diagnostic cut-off values in the presence of hypoglycaemia are plasma insulin ≥ 18.0 pmol/L, C-peptide ≥ 200 pmol/L, proinsulin ≥ 5.0 pmol/L, β -OHB concentrations ≤ 2.7 mmol/L and an increase in plasma glucose concentration of ≥ 1.4 mmol/L after intravenous glucagon. The plasma insulin/C-peptide molar ratio is of the order of 1:5, compared with approximately 1:10 in normal subjects, owing to decreased hepatic extraction of insulin. Plasma proinsulin concentrations are significantly higher in patients with insulinoma than in normal subjects, and the molar ratio of insulin/proinsulin is about 1:1 compared with approximately 6:1 in normal subjects.

Localization

Preoperative localization should only be attempted if a definitive biochemical diagnosis has been established. The mean diameter of insulinomas is usually < 2.0 cm, and non-invasive imaging techniques may fail to localize them. Computerized tomography (CT) detects 70–80% and magnetic resonance imaging (MRI) scanning about 80% of insulinomas. A substantial percentage of insulinomas express cell surface receptors for somatostatin, and somatostatin receptor scintigraphy has been reported to have a sensitivity of 80%. However, false localization is not uncommon with non-invasive modalities (i.e. the location suggested by these procedures may not correspond to the tumour found at operation). Invasive imaging procedures, such as endoscopic pancreatic ultrasonography, selective coeliac axis angiography and trans-hepatic portal venous sampling, have been reported to have sensitivities of $> 90\%$. Selective intra-arterial calcium stimulation with hepatic venous sampling (arterial stimulation and venous sampling, ASVS), using plasma C-peptide and insulin gradients, has been shown to have a high sensitivity of 94% and is used when other imaging procedures are equivocal or negative. However, it is the procedure of choice for confirming non-insulinoma pancreatogenous hypoglycaemia syndrome and post-Roux-en-Y gastric bypass hypoglycaemia, as other imaging techniques are negative in those disorders.

Treatment

Surgical resection is the treatment of choice for insulin-secreting tumours and is curative in over 90% of patients. In about 5–10% of patients, no tumour can be found at laparotomy. In these cases, the patient needs to be sent to a centre of excellence for further imaging and re-operation. The previous practice of a blind distal two-thirds pancreatectomy is no longer recommended. In some centres, the measurement of intraoperative plasma insulin concentrations has been used to ensure complete tumour removal. This may be important in patients with MEN1, who may harbour multiple insulinomas. The recurrence rate after surgical resection is 7% but is much higher, at 21%, for those with MEN1.

If surgery is contraindicated, medical treatment using diazoxide or a somatostatin analogue, such as octreotide, can reduce insulin release. Diazoxide, a non-diuretic benzothiazide, suppresses insulin release in about 50% of patients. It can also be useful, in responsive cases, in preoperative management. It directly inhibits insulin release via its effect on the K^+ -ATP channel. The standard dose is 150–450 mg daily but may be increased to as much as 800 mg/day. Its main side-effect is sodium and water retention, which can be prevented by giving a thiazide diuretic. About 50% of patients with insulinoma benefit from octreotide. The usual dose is 100 μ g injected three times daily, and side-effects, such as diarrhoea and steatorrhoea, are rare. However, the effect of octreotide is dependent on the presence of somatostatin receptor subtype 2 on insulinoma tumour cells. A positive OctreoScanTM is not a prerequisite before starting octreotide treatment

since studies have shown that, in patients with insulinoma and a negative scan, somatostatin decreased insulin concentrations significantly and reduced the incidence of hypoglycaemic episodes. In malignant insulinoma, cytotoxic chemotherapy with streptozotocin, doxorubicin and 5-fluorouracil can be used. When systemic chemotherapy is unsuccessful in patients with unresectable metastatic disease to the liver, embolization of the hepatic artery and intra-arterial chemotherapy may be used to control symptoms, to inhibit tumour growth and to improve survival.

Non-insulinoma pancreatogenous hypoglycaemia syndrome (NIPHS)

A rare syndrome of endogenous hyperinsulinaemic hypoglycaemia has been described in adult patients who suffer from postprandial insulin-mediated hypoglycaemia. The syndrome is characterized by neuroglycopenic episodes within 4 h of meal ingestion, negative prolonged fast tests, negative perioperative localization studies for insulinoma but positive intra-arterial calcium stimulation tests. Histologically, the pancreas shows diffuse islet hypertrophy, sometimes with hyperplasia, and enlarged and hyperchromatic β -Cell nuclei (nesidioblastosis). Patients do not have mutations of the *SUR1* (*ABCC8*) or *KIR6.2* (*KCNJ11*) genes, which encode the subunits of the pancreatic ATP-sensitive potassium channel responsible for glucose-induced insulin secretion, and have been described as a cause of hyperinsulinaemic hypoglycaemia in children. Therefore, it has been proposed that adult patients with endogenous hyperinsulinaemic hypoglycaemia may have mutations at other genes, as yet unidentified, that are involved in the regulation of insulin secretion.

Some patients who have undergone Roux-en-Y gastric bypass surgery for obesity develop postprandial neuroglycopenic symptoms, as a result of endogenous hyperinsulinaemia. These symptoms are different from those ascribed to the dumping syndrome, which are characterized by sweating, dizziness and flushing, but not neuroglycopenia. The precise mechanisms of hypoglycaemia in these patients have not yet been determined but increased secretion of GLP-1 and decreased ghrelin concentrations have been implicated. Nesidioblastosis was reported in some patients but not in others and, therefore, whether gastric bypass-induced hypoglycaemia is the result of a structural pancreatic abnormality or a functional dysregulation of postprandial insulin secretion remains to be established. Some patients respond to dietary measures or medications (α -glucosidase inhibitor, diazoxide, calcium channel blockers, octreotide) but others require partial pancreatectomy.

Non-islet cell tumour hypoglycaemia (NICTH)

Non-islet cell tumour hypoglycaemia (NICTH) is the term applied to hypoglycaemia caused by tumours other than insulinomas. A wide variety of tumours have been associated with hypoglycaemia (Box 17.5). Most patients are elderly and present with predominantly neuroglycopenic symptoms that may antedate the recognition of the

existence of the tumour by many years. In most cases, especially those due to large mesenchymal tumours, the tumour is readily detectable by physical or radiological examination, but in others the tumour may be small and difficult to detect.

The pathogenesis of hypoglycaemia has been related to the secretion of incompletely processed insulin-like growth factor 2 (pro-IGF-2) by these tumours. This form of IGF-2 binds poorly to its binding proteins and penetrates more freely into tissue spaces. Normally, both IGF-1 and IGF-2 circulate almost completely bound to specific IGF-binding proteins (IGFBPs). They can be found as binary complexes (IGF-1 or IGF-2 with IGFBP-3) or ternary complexes (IGF-1 or IGF-2 with IGFBP-3 and an acid-labile subunit, ALS). In normal human plasma, 70–80% of IGF-2 is associated with a ternary 150 kD IGFBP complex, consisting of IGF-2, IGFBP-3 and an ALS, while 20–30% is bound to a binary complex of <60 kD consisting of IGF-2 and IGFBP-3, and <2% is present in the free form. Ternary complexes appear to be confined to the circulation, whereas binary complexes appear to leave the circulation almost as rapidly as the free form. In NICTH, IGFBP-3 and ALS production is decreased and the ability of the binary complex to form the more stable ternary complex is impaired; thus tumour-derived IGF-2 appears mainly as binary IGF-IGFBP complexes, which have greatly increased turnover compared with ternary complexes. Although circulating concentrations of IGF-2 are usually normal, the ratio of pro-IGF-2 to IGF-2 is raised. Pro-IGF-2 interacts with insulin receptors and

IGF-1 receptors and inhibits GH secretion, which in turn leads to a decreased plasma IGF-1 concentration. The low GH concentrations also result in a reduction in IGFBP-3, contributing to the greater bioavailability of pro-IGF-2. The hypoglycaemia of tumours secreting pro-IGF-2 is therefore characterized by suppressed insulin and C-peptide, inappropriately low GH and β -OHB concentrations, and the molar ratio of total plasma IGF-2/IGF-1 is usually >10 .

Surgical removal of a benign or locally invasive tumour usually results in complete remission of hypoglycaemia. Treatment with human GH (hGH) and/or prednisolone has also been used with good effect. Growth hormone is thought to exert its beneficial effect by stimulating gluconeogenesis and hepatic glycogenolysis, and by increasing IGFBP-3 production and redistribution of plasma IGFBP-3 from binary to ternary form, potentially reducing the bioavailability of pro-IGF-2. However, this effect is induced only at supraphysiological GH doses. Prednisolone, at daily doses of 30 mg or more, alleviates hypoglycaemia by direct stimulation of gluconeogenesis and glycogenolysis, and may also suppress tumour production of pro-IGF-2. Although both treatments are effective in relieving hypoglycaemia, prednisolone may have greater long-term benefit through suppression of pro-IGF-2.

Autoimmune hypoglycaemia

Two autoimmune syndromes that can cause hypoglycaemia have been described. In one of these, antibodies bind insulin receptors and mimic the action of insulin. The hypoglycaemia may be either fasting or postprandial and is often severe. Some patients may have a preceding phase of hyperglycaemia and significant insulin resistance, whereas in other patients, the onset of hypoglycaemia may be the first manifestation of the syndrome. Most patients with this syndrome also have evidence, either in the laboratory (elevated titres of antinuclear, antithyroid, antimitochondrial or antiplatelet antibodies) or clinically, of other autoimmune diseases such as systemic lupus erythematosus, primary biliary cirrhosis or Hashimoto thyroiditis (Box 17.6). Laboratory investigations show high plasma insulin concentrations (as a result of interference with the insulin assay) but suppressed C-peptide and proinsulin concentrations, similar to the findings with surreptitious administration of insulin. Therefore, the demonstration of the presence of antibodies directed against the insulin receptor (IR-A) is essential to make the diagnosis. The hypoglycaemia seems to respond rapidly to high doses of steroids but not to immunosuppression or plasmapheresis. Prognosis is poor, but in those who survive, the antireceptor antibodies disappear and remission occurs over several months or years.

The other syndrome, the autoimmune insulin syndrome, in which antibodies are directed towards insulin, has been reported mainly in Japan and is extremely rare. Most patients are middle-aged, with no history of previous administration of insulin, and may have evidence of other autoimmune diseases such as Graves disease, rheumatoid arthritis or systemic lupus erythematosus (see Box 17.6). An association with administration of certain drugs such as carbimazole, hydralazine, procainamide, penicillamine,

glutathione and captopril has also been reported. The hypoglycaemia is most often postprandial, although fasting hypoglycaemia has been reported. Presentation can often be dramatic owing to severe neuroglycopenia with confusion and even coma. Paradoxically, hyperglycaemia may occur immediately following a meal or oral glucose challenge. Several possible mechanisms for the hypoglycaemia have been suggested. Sudden dissociation of insulin from the antibodies is the most plausible one. Laboratory investigations reveal high plasma insulin concentrations but, because the insulin is produced endogenously, C-peptide concentrations are not completely suppressed. The majority of circulating insulin is bound to antibodies, and the demonstration of the presence of anti-insulin antibodies is essential to make the diagnosis. In most cases, the hypoglycaemia is usually transient and resolves spontaneously. In severe cases, dietary treatment with frequent low-carbohydrate meals and acarbose has produced some benefit in alleviating the hypoglycaemia.

Hypoglycaemia associated with renal impairment

Renal impairment is a common predisposing factor for hypoglycaemia and is probably the second most common

cause of hypoglycaemia, after insulin therapy, in hospitalized patients. The most important predisposing factor for hypoglycaemia in chronic kidney diseases (CKD) is caloric restriction, whether acute, due to anorexia and vomiting, or chronic. Other predisposing factors include concomitant liver disease, congestive heart failure, sepsis and drug therapy such as insulin, oral hypoglycaemic agents and β -blockers. The pathogenesis of hypoglycaemia in renal failure is complex and several mechanisms have been proposed. In normal subjects, the kidneys play a major role in gluconeogenesis and may supply as much as 45% of glucose during prolonged starvation. In uraemic patients, who are often malnourished, renal gluconeogenesis may not be able to maintain an adequate glucose supply, even if hepatic gluconeogenesis is normal. Other mechanisms include impaired hepatic glycogenolysis and gluconeogenesis; increased insulin half-life due to decreased renal degradation; diminished availability of alanine, and impaired counter-regulatory mechanisms.

Therapy for diabetes mellitus, with insulin or oral hypoglycaemic drugs, is by far the most common cause of hypoglycaemia in patients with renal impairment. Decreased renal degradation of insulin, frequently leading to a reduction in insulin or sulfonylurea requirements, is the main reason. Iatrogenic hypoglycaemia may be a consequence of haemodialysis or peritoneal dialysis. In patients undergoing haemodialysis, the mechanism may be due, in part, to post-dialysis glucose-induced hyperinsulinaemia caused by high glucose content of the dialysate and partly due to impaired insulin degradation by the kidneys.

The symptoms of uraemic hypoglycaemia are mainly neuroglycopenic (drowsiness, headache, lethargy, confusion, convulsions and coma) and may be confused with the symptoms of the dialysis dysequilibrium syndrome. Spontaneous hypoglycaemia in renal failure, not associated with hypoglycaemic agents or dialysis, carries a grave prognosis, with over half of the patients dying within months of onset.

Since the clearance of insulin, C-peptide and proinsulin is impaired in CKD, these parameters are unreliable in excluding the diagnosis of insulinoma in such patients. In these situations, β -OHB, measured during a prolonged fast test, and the glucose response to glucagon have been reported to be the best diagnostic parameters.

Hypoglycaemia associated with liver disease

Although the liver plays a central role in normal glucose homeostasis, hypoglycaemia is rare in patients with liver disease. Glucose homeostasis can be maintained with the mass of functioning hepatocytes reduced to <20% of normal, and hypoglycaemia does not occur until the liver is extensively damaged. Hypoglycaemia is not usually a feature of chronic hepatic failure nor is it implicated in the production of hepatic coma. Conversely, it may occasionally be associated with mild liver disease, and has been reported in a wide variety of liver disease such as fatty infiltration, portal cirrhosis, infective hepatitis and hepatocellular carcinoma.

Frank hypoglycaemia is also uncommon in acute (fulminant) hepatic failure, whether due to viral infection or

hepatotoxic drugs. When it does occur, it can be severe and persistent. The diagnosis of hepatogenous hypoglycaemia may be difficult since the extent of liver disease, as assessed by standard liver function tests, does not correlate with the degree of hypoglycaemia. Therefore, other causes of hypoglycaemia should always be sought in a patient with hypoglycaemia and abnormal liver function tests. The hypoglycaemia associated with congestive heart failure, sepsis and Reye syndrome is thought to be due to hepatic mechanisms.

Hypoglycaemia due to endocrine deficiencies

Endocrine deficiencies, especially those involving the pituitary and the adrenal glands, can result in low blood glucose concentrations but these are rarely <3.0 mmol/L unless associated with other disorders. Spontaneous hypoglycaemia due to pituitary insufficiency is more commonly seen in neonates and children than in adults but may occasionally be the presenting feature, especially in the elderly. The hypoglycaemia is mainly due to GH deficiency, but the associated deficiency of ACTH accentuates the tendency to hypoglycaemia. Spontaneous hypoglycaemia is also recognized in isolated ACTH deficiency and isolated GH deficiency, particularly after prolonged fasting. The diagnosis is usually suspected on clinical examination and is confirmed by appropriate combined pituitary function tests (see Chapter 18). Plasma insulin and C-peptide concentrations are both appropriately suppressed, but β -OHB concentrations are not, indicating that ketogenesis may not be impaired in the absence of growth hormone. The hypoglycaemia in this setting should be treated with both glucose and hydrocortisone.

Hypoglycaemia is uncommon in primary adrenal insufficiency (Addison disease). It can be precipitated by missing a meal and by exercise and is mainly due to impaired gluconeogenesis. Alcohol, by further impeding gluconeogenesis, may also provoke hypoglycaemia in these patients. A plasma cortisol concentration at the lower end of the reference range, during a spontaneous hypoglycaemic episode, is not sufficient evidence of adrenocortical insufficiency as it may be the result of a lower glycaemic threshold to stimulate cortisol secretion in patients with recurrent hypoglycaemia but without adrenal insufficiency. Plasma insulin and C-peptide concentrations are appropriately low and β -OHB concentrations are high. Hypoglycaemia occurring in acute adrenal insufficiency (Addisonian crisis) is a medical emergency and requires immediate correction by intravenous infusion of glucose in addition to hydrocortisone and other measures.

Congenital adrenal hyperplasia is a rare cause of neonatal hypoglycaemia. In the majority of patients, cortisol deficiency is not severe owing to a compensatory increase in ACTH secretion.

Although untreated hypothyroidism is associated with some lowering of fasting blood glucose concentrations, symptomatic hypoglycaemia has only been reported in a few cases and its existence has been questioned. Deficiency of other glucogenic hormones, such as adrenaline and glucagon, does not seem to cause hypoglycaemia.

Drug-induced hypoglycaemia

Insulin, insulin analogues or insulin secretagogues (sulfonylureas and meglitinides) are by far the most common causes of hypoglycaemia. Precipitating factors are restricted carbohydrate intake and liver and renal impairment. Sulfonylurea drugs can cross the placental barrier and stimulate insulin secretion in the fetus. Life-threatening hypoglycaemia has been reported in newborn infants of diabetic mothers who were treated with chlorpropamide during the third trimester. Sulfonylurea-induced hypoglycaemia may be prolonged, especially in those with renal impairment, lasting for up to seven days and necessitating continuous treatment. Mortality is high, ranging from 7.5 to 8.4%, and in attempted suicide with sulfonylurea drugs, the mortality is even higher with seven deaths out of 20 reported cases.

Salicylate overdose has been associated with hypoglycaemia in children. In adults, therapeutic doses of salicylates have been shown to lower blood glucose concentration in both diabetic and non-diabetic patients. The mechanisms by which salicylates produce hypoglycaemia are unknown. Enhancing insulin secretion and inhibiting hepatic gluconeogenesis are possible mechanisms.

Non-selective β -blockers (e.g. propranolol), in therapeutic doses, may induce hypoglycaemia, particularly in the presence of other precipitating factors such as liver disease, fasting or strenuous exercise. Hypoglycaemia has also been reported in newborn infants of mothers who were treated with propranolol until hours before delivery. The mechanism is thought to be through the prevention of the normal glucagon-mediated glycogenolytic and gluconeogenic responses by the liver. In diabetic patients, β -blockers may change the pattern of adrenergic symptoms of hypoglycaemia by diminishing the occurrence of tremor and palpitations and by increasing the occurrence of sweating. In addition, because glycogenolysis and gluconeogenesis in liver are stimulated through β_2 -receptors, blockade of these receptors by non-selective β -blockers could prolong recovery time from hypoglycaemia. Selective β_1 -blockers (e.g. atenolol and bisoprolol), however, do not impair the recovery from hypoglycaemia in patients treated with insulin or oral hypoglycaemic agents.

Quinine stimulates insulin secretion and its intravenous use in the treatment of falciparum malaria has been associated with profound hypoglycaemia. Plasma insulin and C-peptide concentrations are both elevated, indicating increased endogenous secretion. Falciparum malaria, especially in children, can itself cause hypoglycaemia. This, however, is associated with suppressed plasma insulin concentrations and is probably due to high glucose uptake by the parasitized erythrocytes. Acute kidney injury, hepatic dysfunction and starvation are common in malaria and may be additional factors in precipitating the hypoglycaemia. Symptoms of hypoglycaemia may be mistaken for those of cerebral malaria, and blood glucose should always be monitored in these patients. Life-threatening, quinine-induced hypoglycaemia can be treated with octreotide, which blocks the insulinotropic effect of quinine.

Pentamidine, a drug used for the treatment of trypanosomiasis and leishmaniasis, has a direct toxic effect on

β -Cells, causing release of preformed insulin and hence hypoglycaemia. This can be followed by β -Cell destruction with ultimate insulin deficiency and diabetes. Pentamidine is also used for the treatment of *Pneumocystis carinii* infection, and there are at least 30 case reports of severe pentamidine-induced hypoglycaemia in undernourished patients with AIDS (acquired immune deficiency syndrome).

Disopyramide, an antiarrhythmic drug, has also been associated with severe hypoglycaemia, particularly in elderly patients with renal or hepatic impairment. Patients with non-functional endocrine tumours and liver metastases may be at risk of developing hypoglycaemia when treated with long-acting somatostatin analogues, as a result of reduced glucagon and GH secretion.

Other drugs that have occasionally caused hypoglycaemia include angiotensin-converting-enzyme (ACE) inhibitors, angiotensin-receptor antagonists, haloperidol, lidocaine, *p*-aminobenzoic acid, phenylbutazone, propoxyphene, saquinavir, tricyclic antidepressants, tyrosine kinase inhibitors and sulphonamides.

Alcohol-induced hypoglycaemia

Alcohol can be associated with both fasting and reactive hypoglycaemia. Several mechanisms may be operational in alcohol-induced fasting hypoglycaemia but the most important is direct inhibition of gluconeogenesis. This is mainly due to accumulation of NADH and increased NADH/NAD⁺ ratio resulting from the oxidation of ethanol.

Alcohol-induced fasting hypoglycaemia characteristically occurs 6–36 h after ingestion of moderate to large amounts of alcohol. Most patients are aged between 20 and 40 years, but occasionally it can occur in children after a relatively small amount of alcohol. Patients present with neuroglycopenic symptoms including stupor and coma. The patient's breath may smell of alcohol and the symptoms may be mistaken for acute alcoholic intoxication. Therefore, delayed recovery from a presumed alcoholic intoxication should alert the doctor to the possibility of hypoglycaemia.

The blood glucose concentration is usually <2.2 mmol/L and alcohol is nearly always detectable in the blood, though the concentration is not necessarily very high. Severe metabolic acidosis with high blood lactate concentration is a characteristic feature. Hyperketonaemia and ketonuria are almost invariably present but predominantly in the form of β -OHB, since the accumulation of NADH suppresses the conversion of β -OHB to acetoacetate. Ketosis may, therefore, go unrecognized if methods that only detect acetoacetate are employed (e.g. Ketostix[®]). Plasma insulin and C-peptide concentrations during the hypoglycaemia are usually appropriately suppressed. Prompt diagnosis and treatment, with intravenous glucose, is essential since mortality is relatively high. Glucagon is not effective because hepatic glycogen stores are depleted by the time hypoglycaemia ensues.

Alcohol potentiates the hypoglycaemic effect of insulin and sulfonylurea drugs. In insulin-treated patients, ingestion of alcohol may produce profound hypoglycaemia, which can be fatal. Hypoglycaemia resulting from the combined effect of alcohol and sulfonylurea drugs tends

to be less profound, possibly because diabetic patients receiving these drugs tend to be obese and, therefore, are in part protected from the hypoglycaemic effects of alcohol. This is because alcohol does not inhibit the release of glucose from pre-existing glycogen stores, and in obese subjects, these stores are generally sufficient to meet the need for glucose during fasting for 12 h or more.

Alcohol has been shown to potentiate the insulin-stimulating effect of glucose and thus increases the risk for reactive hypoglycaemia. This reaction can be demonstrated in 10–20% of healthy subjects who have consumed a mixture of alcohol and sucrose, such as ‘gin and tonic’, on an empty stomach and who refrained from eating for a few hours afterward. This effect is not observed, however, when saccharin or fructose is substituted for sucrose as the sweetening agent. Starchy foods, such as nibbles and bread, increase the risk for reactive hypoglycaemia, whereas foods providing mainly fat or protein have the reverse effect.

Hypoglycaemia due to deficient energy intake

Symptomatic hypoglycaemia is well recognized in starvation and has been observed in patients with protein-calorie malnutrition and anorexia nervosa. The hypoglycaemia is usually due to reduced hepatic glycogen reserves as well as a reduced supply of gluconeogenic substrates. In addition, the reduction in ketosis due to markedly depleted fat stores deprives the central nervous system of an alternative source of energy. The major risk factors are low body weight and intercurrent infection. Compulsive excessive exercise in patients with anorexia nervosa may also be a factor. Plasma insulin and C-peptide concentrations are appropriately suppressed. Despite low circulating insulin concentrations, β -OHB concentrations are low, owing to depleted fat stores. Hypoglycaemia in anorexia nervosa has a poor prognosis.

Septicaemia

Bacterial septicaemia, especially Gram-negative, can occasionally cause hypoglycaemia. It has been postulated that cytokines produced by macrophages, in response to endotoxin stimulation, may induce hypoglycaemia by increasing insulin secretion. The endotoxins released may also have a direct hypoglycaemic effect, probably by inhibiting gluconeogenesis. Acute kidney injury, which is often associated with septicaemia, may also be an important factor in the pathogenesis of the hypoglycaemia.

Exercise-related hypoglycaemia

Exercise is associated with a marked increase in glucose uptake by muscles. During the first 5–10 min of severe exercise, glucose is supplied by the breakdown of muscle glycogen, but by 40 min, 75–90% of the glucose is supplied by the blood, mainly from increased hepatic glucose production. Initially, 75% of increased hepatic glucose output is derived from glycogenolysis and 25% from gluconeogenesis. With prolonged exercise, gluconeogenesis becomes more important and contributes up to 45%

of the total hepatic glucose output. Decreased plasma insulin and increased catecholamines, glucagon, cortisol and GH concentrations all contribute to the increased hepatic glucose output. If hepatic glucose production is inadequate, blood glucose cannot be maintained during exercise and hypoglycaemia ensues.

Hypoglycaemia following excessive exercise is well recognized and may be severe enough to cause seizures. Although exercising to exhaustion can produce hypoglycaemia, the symptoms of exhaustion are not related to hypoglycaemia and glucose administration does not modify the time of exercise to exhaustion.

Postprandial (reactive) hypoglycaemia

Rarely, hypoglycaemia occurs only in response to ingestion of a meal. Symptoms are usually neurogenic or autonomic and generally occur 2–4 h after ingestion of food and last for about 10–20 min. These symptoms are different from those of the dumping syndrome (flushing, sweating, abdominal cramps and hypotension), which occur within half an hour of eating. The diagnosis of postprandial hypoglycaemia requires the demonstration of the Whipple’s triad.

Postprandial hypoglycaemia may occur in patients who have undergone major gastric surgery, such as Roux-en-Y gastric bypass, and is also a feature of the autoimmune insulin syndrome, non-insulinoma pancreaticogenous hypoglycaemia, or may be alcohol induced or idiopathic (see below). Postprandial hypoglycaemia is also seen in patients with hereditary fructose intolerance after ingestion of fructose. It is worth noting that conditions that are usually associated with fasting hypoglycaemia, such as insulinoma, may occasionally produce symptoms only postprandially.

‘Idiopathic’ postprandial reactive hypoglycaemia has been documented in a small number of patients in whom no obvious other cause for hypoglycaemia was found. In these patients, a diet low in refined carbohydrates and high in soluble fibres is usually sufficient to relieve the symptoms. The addition of snacks in the middle of the morning and the afternoon may also prevent the fall in blood glucose. Patients should avoid rapidly absorbable sugars and should replace sucrose with either saccharin or fructose, a non-insulinotropic carbohydrate. If symptoms persist despite following the above dietary modifications, the use of an intestinal α -glucosidase inhibitor, such as acarbose, has been shown to be successful in alleviating symptoms in some patients with idiopathic postprandial reactive hypoglycaemia.

The postprandial syndrome

Patients who have postprandial symptoms but without documented hypoglycaemia should be referred to as having ‘the postprandial syndrome’. Symptoms are generally non-specific, such as feelings of vague ill health, lightheadedness, dizziness, anxiety, palpitations, fatigue, hunger and ‘inner trembling’, which may resemble the autonomic symptoms of hypoglycaemia. Many patients, especially those who are well informed about

hypoglycaemia from the lay literature, state that symptoms are relieved by eating, thereby suggesting hypoglycaemia. However, detailed questioning often reveals that symptoms are relieved either immediately or within a few minutes of eating foods such as cheese or bread, which are unlikely to raise blood glucose concentrations in such a short period of time. Many patients complain of generalized weakness and inability to concentrate in between attacks. The symptoms are not progressive but usually persist for many years. Reliance on the use of the oral glucose tolerance test (OGTT) in the investigation of this condition in the past has led to the misdiagnosis of 'reactive' hypoglycaemia in many of these patients. The OGTT should not be used in this context since 10% of healthy individuals may have low blood glucose concentrations (<2.6 mmol/L) during the test. In addition, in many patients with postprandial symptoms, the symptoms do not correlate with the nadir blood glucose concentrations and some individuals may even experience symptoms after a placebo oral glucose tolerance test. Self-monitoring of blood glucose at home, to document hypoglycaemia, using glucose meters should not be encouraged, since self-diagnosis by patients themselves is seldom confirmed by accurate investigations.

Inherited metabolic disease

Several inborn errors of metabolism can produce hypoglycaemia as one of their major clinical manifestations. These disorders are almost invariably diagnosed in childhood (see Chapter 24), but in mild cases, the diagnosis may not be made until middle life. The hypoglycaemia is usually of the fasting type, but in some disorders, for example galactosaemia and hereditary fructose intolerance, it only occurs following the ingestion of certain types of food.

CONCLUSION

Hypoglycaemia literally means low blood glucose concentration. Many apparently healthy subjects may have low blood glucose concentrations during a prolonged fast, or 3–5 h after ingestion of glucose. Pathological hypoglycaemia should, therefore, be defined as a clinical syndrome in which symptoms or signs of hypoglycaemia occur in the presence of low plasma glucose concentration and that the symptoms or signs are relieved after the plasma glucose concentration is raised

(Whipple's triad). Although it is frequently suspected as a cause of symptoms, hypoglycaemia is rare, other than in diabetic patients who are being treated with insulin or oral hypoglycaemic drugs.

The diagnosis of a hypoglycaemic disorder requires a high level of suspicion, a thorough history and a careful assessment of possible underlying illnesses or drugs. A healthy-appearing patient with hypoglycaemia requires a different diagnostic approach from a patient who has a concurrent illness or is hospitalized. Generally, the measurement of plasma glucose, insulin, C-peptide and proinsulin concentrations during symptoms may be sufficient to confirm the diagnosis and establish the cause of hypoglycaemia. In the majority of patients, however, further investigations (insulin autoantibodies, screening for hypoglycaemic agents) and provocation tests (prolonged fast or a mixed meal test) may be necessary. An inability to demonstrate a low plasma glucose concentration when the patient is symptomatic virtually excludes the diagnosis of hypoglycaemia.

APPENDIX 371

INTRODUCTION

The investigation of disorders of the pituitary and hypothalamus and of adrenocortical function frequently causes great apprehension among non-endocrinologists, whether they are clinical biochemists or general physicians, because of their supposed complexity and the frequency of atypical, borderline or artefactual results. It is certainly true that the hypothalamo–pituitary axis plays the central role in the control of a large number of hormonal systems and of many other important aspects of homeostasis. However, the clinically relevant

physiology of each hormonal axis is well understood and the plasma concentrations of the majority of the hormones secreted by both the pituitary and the relevant peripheral endocrine glands can now be readily and accurately measured in most clinical biochemistry laboratories. Thus, a logical approach to the measurement of the relevant plasma hormone concentrations, applying basic physiological principles, can result in a relatively simple and efficient assessment of pituitary function in the majority of cases.

This chapter will outline a clinically relevant and efficient approach to the assessment of pituitary and adrenal

function. In many cases, simple measurement of basal, unstimulated plasma concentrations of the appropriate hormone(s) will give all the information required for clinical management. Some of the traditionally used dynamic endocrine tests can now be reasonably discarded, while others remain essential, and the choice of these will be discussed critically. Recommendations for clinical management of borderline or contradictory results will also be discussed.

CLINICAL ANATOMY OF THE PITUITARY AND HYPOTHALAMUS

The pituitary gland (Fig. 18.1) lies within a bony compartment, the pituitary fossa or sella turcica, beneath the hypothalamus to which it is connected by the pituitary stalk. The fossa is separated from the subarachnoid space and cerebrospinal fluid by the diaphragma sellae. The adult human pituitary consists of two lobes (the third, neurointermediate lobe of other species is not present except in fetal life). The anterior lobe (adenohypophysis) is embryologically derived from cells of Rathke's pouch. It contains a variety of cell types differentiated to secrete the majority of the peptide and glycopeptide hormones that control the function of peripheral endocrine organs: corticotrophs (adrenocorticotrophic hormone, ACTH), lactotrophs (prolactin, PRL), gonadotrophs (luteinizing hormone and follicle stimulating hormone: LH and FSH), thyrotrophs (thyroid stimulating hormone, TSH) and somatotrophs (somatotrophin or growth hormone, GH). The anterior lobe has no direct arterial blood supply but is supplied by the portal vessels that arise in the median eminence of the hypothalamus. The secretion of anterior pituitary hormones is controlled by releasing and inhibiting factors, which are predominantly peptides, released into the portal circulation from the nerve terminals of a variety of hypothalamic neurons. These neurons in turn are subject to the effects of the modulatory neurotransmitters of other neurons, within the hypothalamus and beyond.

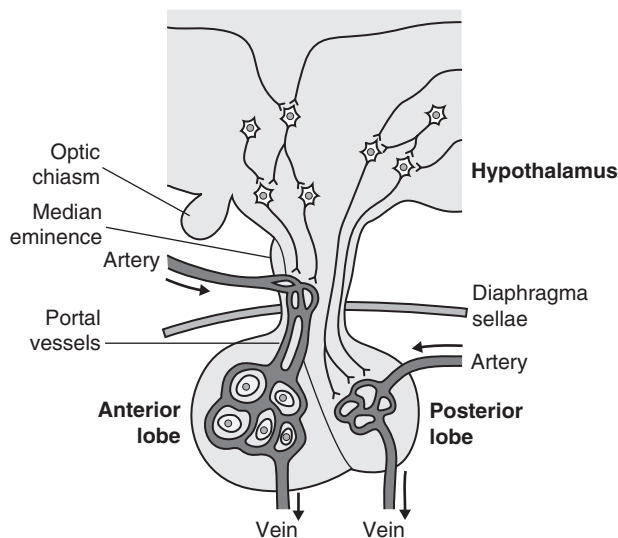

FIGURE 18.1 ■ Functional anatomy of the human pituitary and hypothalamus.

The critical role of the portal circulation in the control of anterior pituitary function means that any disease process that interferes with this blood supply, for example non-functioning tumours of the pituitary or hypothalamus, will often result in severe pituitary dysfunction, even if the actual hormone-secreting cells of the anterior pituitary have not themselves been destroyed.

The posterior lobe (neurohypophysis), in contrast, is embryologically derived from the brain, has a direct arterial blood supply and is not controlled via a portal circulation. Hormonal secretion occurs directly from the nerve terminals of vasopressin (antidiuretic hormone, ADH) and oxytocin neurons, whose cell bodies lie within the hypothalamus, primarily in the supraoptic and paraventricular nuclei.

Both the anterior and posterior lobes contain a variety of other cell types. These are not directly responsible for hormonal secretion into the peripheral circulation, although they may have important modulatory or paracrine roles in the control of pituitary function.

Many other important neural structures lie within or adjacent to the hypothalamus, notably the optic chiasm and the neural centres controlling thirst, osmoregulation, appetite, temperature homeostasis and circadian rhythm. Diseases of the pituitary and hypothalamus can result in dysfunction of any of these structures, in addition to the hormonal syndromes described here. In particular, visual field loss due to compression of the optic chiasm is a frequent finding with large pituitary tumours.

These anatomical relationships indicate that the pituitary gland is truly at the interface of the mind and body, with a central role in homeostasis, explaining its source of fascination for physiologist and physician alike.

PHYSIOLOGY OF HYPOTHALAMO–PITUITARY–END ORGAN AXES

The basic physiology of the important endocrine axes is summarized diagrammatically in Figures 18.2 and 18.3. Many additional releasing, inhibiting and modulating factors have been identified, primarily in animal experiments, but none of these has yet been shown to be of relevance clinically, nor for the understanding of the principles of pituitary function testing. Hormones that can be measured in the laboratory are indicated in the figures. Peripheral plasma concentrations of hypothalamic releasing factors can also be measured (with difficulty), but for the most part do not reflect hypothalamic activity and are not of clinical relevance.

Adrenocorticotrophic hormone (ACTH) stimulates adrenal cortisol secretion and is itself controlled by hypothalamic corticotrophin releasing factor (CRF). Corticotrophin releasing factor is now known to be a complex of factors including a 41-residue peptide (CRF-41 or corticotrophin releasing hormone, CRH) and vasopressin, which act synergistically. Adrenocorticotrophic hormone, and therefore cortisol, are secreted with a pronounced circadian rhythm: concentrations are low, typically undetectable, at midnight (if asleep), rise in the final hours of sleep to reach a peak shortly after wakening in the morning and steadily decline throughout the

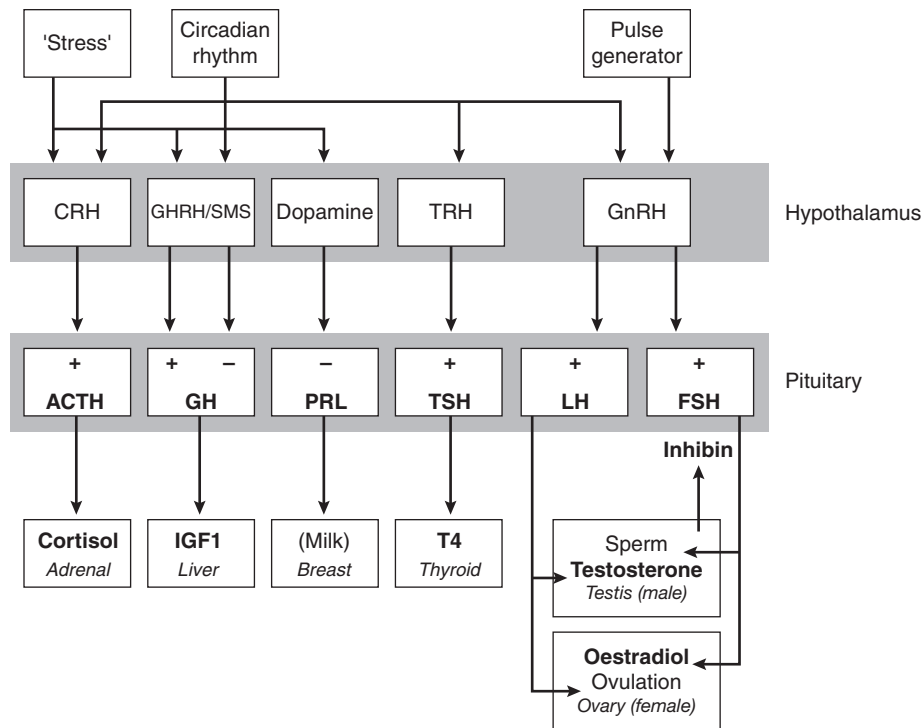

FIGURE 18.2 ■ Physiological relationships of the anterior pituitary. Hormones (in bold) can be readily measured in most clinical biochemistry laboratories. See text for explanation of abbreviations.

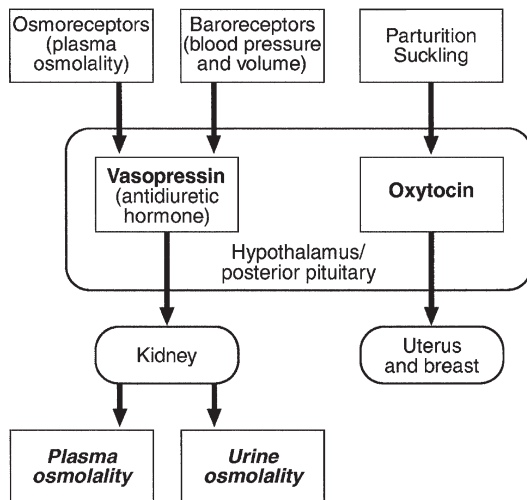

FIGURE 18.3 ■ Physiological relationships of the posterior pituitary. Osmolalities (italicized) can be readily measured in most clinical biochemistry laboratories. Hormones (emboldened) can be measured with difficulty in a few centres.

rest of the day with superimposed peaks of secretion with meals, exercise and stressful events. 'Stress' ('fight and flight', illness, hypoglycaemia, surgery etc.) is a major determinant of ACTH and cortisol secretion, which therefore means that basal concentrations in a well individual may not always reflect the ability to respond to illness, and conversely that high concentrations in an individual with other significant disease do not always imply oversecretion.

Secretion of growth hormone (GH) is controlled by complementary stimulatory and inhibitory factors, GH

releasing hormone (GHRH, a 44-residue peptide) and somatostatin (SMS, a cyclic, 14-residue peptide), respectively. Growth hormone secretion occurs in pulses, predominantly at night during the early hours of sleep. Only infrequent, small pulses occur during the day when plasma concentrations are usually undetectable, although GH secretion also occurs in response to stress. Growth hormone's effects on growth are mediated via synthesis of insulin-like growth factor 1 (IGF-1 – previously called somatomedin C), which is synthesized mostly in the liver but also in peripheral tissues.

Prolactin secretion is unique in being predominantly controlled by an inhibitory hypothalamic factor, dopamine. This fact explains why PRL deficiency is rare and why any disease that interferes with pituitary anatomy, and thus the flow of portal blood, may be associated with hyperprolactinaemia. Plasma PRL is raised physiologically during pregnancy and lactation, and release also occurs in response to stress. The physiological role of PRL in non-lactating women and in men is unknown.

Hypothalamic thyrotrophin releasing hormone (TRH), a tripeptide, controls TSH secretion, which in turn stimulates the synthesis and secretion of thyroid hormones thyroxine (T4) and tri-iodothyronine (T3). Secretion is regulated primarily to maintain normal circulating concentrations of thyroid hormones, although there is also a slight circadian rhythm.

Luteinizing hormone and FSH are both controlled by a single stimulatory decapeptide, gonadotrophin releasing hormone (GnRH or luteinizing hormone releasing hormone, LHRH). The major role of LH in the male is to stimulate testosterone secretion by testicular Leydig cells, and in the female to stimulate ovulation at mid-cycle. Follicle stimulating hormone controls spermatogenesis in the male and ovarian follicular development,

and therefore oestradiol secretion, in the female, and in both sexes stimulates gonadal secretion of inhibin, which is responsible for some negative feedback control. The most important feature of the secretion of GnRH, and thus LH and FSH, is its pulsatile nature, imposed by the hypothalamic pulse generator. It is likely that differential secretion of LH and FSH is achieved by modulation of the frequency and amplitude of pulsatile GnRH secretion, and the peripheral effects of LH and FSH are critically dependent on appropriate pulsatile variation in concentrations. Gonadotrophin releasing hormone pulses occur, on average, every 90 min, but in the female are more rapid in the follicular phase and slower in the luteal phase of the menstrual cycle. During early puberty, the majority of pulses occur at night, during sleep.

Vasopressin (antidiuretic hormone, ADH) secretion is controlled primarily by osmotic and blood volume sensing mechanisms (osmoreceptors and baroreceptors, respectively). High plasma osmolality and hypovolaemia or hypotension are the major stimulatory factors. Vasopressin acts directly on the kidney to increase water reabsorption in the renal collecting ducts and thus reduce urine volume. Corticosteroids are necessary for the excretion of free water, so deficiency may mask the symptoms of ADH deficiency.

Oxytocin is released during labour and during suckling, but mechanisms controlling its secretion have not been studied extensively in humans and there appears to be no clinical syndrome related to oxytocin deficiency.

Secretion of all pituitary hormones is controlled, to a greater or lesser extent, by negative feedback. This occurs at all levels, including the direct inhibition by a hormone of its own secretion ('ultra-short-loop'), but the most important negative effects are generally those of the peripheral 'end hormone' on hypothalamic and/or pituitary secretion. The existence of such negative feedback is of crucial importance to the interpretation of basal hormone concentrations in pituitary disease and is the basis of a number of dynamic tests of pituitary function.

CLINICAL ANATOMY AND PHYSIOLOGY OF THE ADRENALS

The two adrenal glands lie superior to the kidneys and are composed of the inner catecholamine-secreting medulla, which is controlled centrally by direct innervation, and the outer cortex, which is controlled by classic endocrine pathways. Glucocorticoid and androgen secretion is predominantly from the zona fasciculata and zona reticularis and controlled by pituitary ACTH secretion, while mineralocorticoid secretion is predominantly from the zona glomerulosa and controlled via the renin-angiotensin system (see Chapter 4). This means that the patterns of adrenal deficiency vary with aetiology: thus a disease that destroys the adrenal itself (e.g. autoimmune Addison disease, adrenal tuberculosis or bilateral adrenalectomy) results in deficiency of both glucocorticoid and mineralocorticoid secretion, whereas ACTH deficiency from pituitary disease results in glucocorticoid deficiency alone and, thus, less marked disturbances of salt and water balance. Even complete adrenalectomy does not seem to cause a clinical

deficiency of catecholamines, since secretion by the rest of the sympathetic nervous system appears to compensate for the loss of adrenal secretion.

Adrenal steroid synthesis involves a complex and intersecting sequence of enzymatic steps within the cytoplasm and mitochondria of the adrenal cell. Pathways are illustrated in Figure 18.4. The initial, rate-limiting, step in steroidogenesis in the normal subject is the conversion of cholesterol to pregnenolone. Adrenocorticotrophic hormone has rapid effects on cholesterol transport into mitochondria and longer-term effects on transcription of genes encoding a number of enzymes in the synthetic pathway. These pathways are of clinical significance in congenital adrenal hyperplasia, where inherited defects in a variety of these enzymes give rise to the various subtypes and clinical syndromes (see Table 18.1), and in clinical pharmacology, since metyrapone, a drug that inhibits 11 β -hydroxylase, can be used to decrease cortisol synthesis in Cushing syndrome.

ASSESSMENT OF NORMAL PITUITARY FUNCTION

Basal hormonal investigations

A single, basal blood sample, especially if taken at 09.00 h, can give extensive and, for some purposes, complete information regarding pituitary function. The blood should ideally be taken under resting, unstressed conditions but, while the stress of major illness or surgery significantly alters results and thus might cause diagnostic errors when investigating pituitary hyperfunction, minor anxiety regarding hospital attendance or venepuncture probably has little effect.

The pituitary-thyroid axis is fully assessed by the simultaneous measurement of plasma free thyroid hormone concentrations and TSH. Thyroid stimulating hormone deficiency is characterized by a low plasma free T4 concentration without the expected elevation of plasma TSH. In hypopituitarism, TSH may be low (although rarely undetectable) or within the normal range (inappropriately for the low T4), which represents the most potent argument against the use of TSH as the sole screening test for thyroid function in a laboratory.

Basal plasma PRL gives full physiological information regarding the function of its axis. Concentrations frequently vary from day to day (particularly minor elevations), so that 2–3 basal samples are usually necessary before any treatment is instituted.

In the male, a normal basal plasma testosterone (preferably taken at 09.00 h, in view of the significant circadian rhythm) effectively demonstrates normal LH secretion, and demonstration of a normal sperm count would confirm normal FSH secretion (although this is rarely performed unless infertility is an issue). Gonadotrophin deficiency is diagnosed by the combination of a low plasma testosterone with low or inappropriately 'normal' (rather than elevated) concentrations of LH and FSH. The significance of borderline testosterone concentrations – near or just below

FIGURE 18.4 ■ (A) The pathways of steroid hormone synthesis within the adrenals (and gonads). Enzymes are named by reaction catalysed (e.g. 21-hydroxylase) or by enzyme name (e.g. p450_{C11}). p450 enzymes are in mitochondria and other enzymes are in the cytoplasm; steroid synthesis involves repeated passage of precursors between these cellular compartments. (B) Basic structure of the steroid molecule (from Kumar and Clark 2012 Clinical medicine. 8th ed. Edinburgh: Churchill Livingstone, with permission).

TABLE 18.1 Subtypes of congenital adrenal hyperplasia

Enzyme defect	Frequency	Clinical features
21-hydroxylase p450 _{C21} /CYP21	95% of cases 1 in 15000 live births	Ambiguous genitalia in females Virilization, some salt losing
11-β-hydroxylase p450 _{C11} /CYP11B	<5% of cases	Ambiguous genitalia in females Virilization, hypertension
17-α-hydroxylase p450 _{C17}	Rare	Ambiguous genitalia and lack of virilization in males Hypertension
3β-hydroxysteroid dehydrogenase 3βHSD/HSD3B2	Rare	Ambiguous genitalia in males Mild virilization in females Occasional Addisonian crises
Cholesterol desmolase p450 _{SCC} /CYP11A	Rare	Addisonian crises

the lower end of the reference range – together with normal LH and FSH, particularly in the ageing male, is an area of growing clinical interest but still with considerable controversy and is discussed more fully later in this chapter.

Assessment of the pituitary–gonadal axis in the female is complicated by the physiological changes during the menstrual cycle. A normal luteal phase plasma progesterone is the ultimate biochemical test of the adequacy of the entire axis. Spontaneous, normal, regular menstruation also excludes gonadotrophin deficiency without the need for additional biochemical tests. Gonadotrophin deficiency is suggested in the context of amenorrhoea by the presence of a consistently low plasma LH and FSH, although a variety of ‘hypothalamic’ causes of amenorrhoea also show this combination (see below). In postmenopausal women (or, in the context of longstanding amenorrhoea, arbitrarily women aged >50 years), who are not on oestrogen replacement, the simple absence of the usual menopausal elevation of LH and FSH is sufficient to diagnose gonadotrophin deficiency.

Basal plasma cortisol is not always sufficient to diagnose ACTH deficiency or normality, because of the circadian rhythm and since concentrations that need to be achieved during physiological stress are much higher than those found under normal basal circumstances.

Nevertheless, a basal cortisol >550 nmol/L in an unstressed individual certainly excludes ACTH deficiency and, in our experience, a 09.00h cortisol <100 nmol/L is never, and >400 nmol/L is always, associated with a normal ACTH reserve (see below).

Basal concentrations of GH are usually unhelpful in the diagnosis of deficiency, since basal concentrations in normal individuals are usually undetectable. A low serum IGF-1 (using age-related normal ranges) is a good predictor of severe GH deficiency but, conversely, an IGF-1 in the normal range does not exclude severe deficiency that might respond to replacement therapy.

Plasma vasopressin and oxytocin concentrations are measured by only a few centres and are not used routinely in the assessment of basal pituitary function. Measurement of paired plasma and urine osmolality on a basal early morning sample does, however, give valuable information. A urine osmolality >600 mmol/kg excludes diabetes insipidus (DI) as long as plasma osmolality is normal (280–295 mmol/kg). Conversely, DI is suggested by an elevated plasma osmolality (>300 mmol/kg) with a urine osmolality <600 mmol/kg. Other combinations are non-diagnostic and require a water deprivation test if DI is suspected clinically. Oxytocin secretion is never investigated clinically.

The order of progression of hypopituitarism with progressively severe pituitary disease is usually predictable. Growth hormone and gonadotrophin secretion are usually most susceptible to damage, followed by ACTH and TSH, with PRL deficiency occurring only rarely and usually only after extensive pituitary damage by disease or surgery. It is thus unusual, although not impossible, for a patient with regular menstruation or normal male gonadal function to develop ACTH deficiency first in the course of their disease. Diabetes insipidus usually only occurs with inflammatory or invasive pituitary disease, after surgery or with diseases primarily involving the hypothalamus. Thus clinical background may influence the degree of investigation considered appropriate in an individual patient with borderline or equivocal results in a single axis.

Dynamic tests of ACTH–adrenal function

Insulin stress test

The insulin stress test (IST) (or insulin tolerance test, ITT) has traditionally been the ‘gold standard’ test to assess the adequacy of the ACTH–adrenal axis. After adequate hypoglycaemia (blood glucose <2.2 mmol/L), a normal rise of plasma cortisol (traditionally to >550 nmol/L) excludes ACTH and cortisol deficiency. Patients with such a response are capable of producing a normal adrenocortical response to stressful illness, without the need for replacement therapy. The increment of plasma cortisol does not add additional information. Patients with borderline peak responses (400–550 nmol/L) may only require steroid replacement during stressful illnesses, but patients with lower responses will typically be symptomatic and almost always require standard replacement therapy.

An IST is contraindicated by cardiac disease (an ECG should be normal) and by epilepsy (or other unexplained

blackouts) and always requires close medical and nursing supervision to maintain safety. For this reason, alternative, simpler tests have been sought, although none has yet achieved universal acceptance. A retrospective audit of 230 ISTs in our own laboratory indicated that patients with a basal cortisol <100 nmol/L never, and >400 nmol/L always, demonstrated a normal cortisol response, so that an IST is probably unnecessary in such patients (representing 50% of ISTs performed in our study) if the only aim is to assess pituitary–adrenal reserve. In our experience, patients who have recently discontinued steroid replacement with a basal cortisol <200 nmol/L also never have a normal response.

Short tetracosactide (synacthen, tetracosactrin, ACTH) test

This test, involving administration of tetracosactide (synthetic ACTH_{1–24}), is the cornerstone for diagnosis of primary adrenal failure, but is increasingly used in the context of pituitary disease. It has long been accepted that a normal cortisol response to tetracosactide excludes Addison disease, but to test for ACTH deficiency by administration of ACTH is clearly illogical on purely physiological grounds, since it directly tests only the adrenal response and not that of the pituitary or higher centres. However, presumably since ACTH deficiency leads to adrenal atrophy, a number of workers have shown close correlations between the cortisol responses to a simple intravenous tetracosactide test and to an IST, and have suggested that the former is a satisfactory test of the ACTH–adrenal axis as long as the test is not done within four weeks of the pituitary insult.

A majority of UK endocrinologists now accept that a normal plasma cortisol response, 30 min after tetracosactide (250 µg), adequately excludes ACTH deficiency, and several long-term clinical observational studies have confirmed the safety of such an approach. This test was originally validated with i.v. tetracosactide but responses to i.m. injection are equivalent. However, normal responses are different (typically 150 nmol/L or so higher) at 60 min, so an appropriate normal range is needed for each time point and, in practice, we recommend only measuring the 30 min value to avoid confusion.

Since the standard 250 µg dose of tetracosactide is substantially supraphysiological, many workers have advocated use of a lower dose stimulation test (typically 1 µg). However, this approach is more complicated since no suitable dose preparation exists, and it has not been demonstrated to be significantly superior in clinical practice to the traditional test.

Other tests

The glucagon test (1 mg i.m.) has been advocated to assess ACTH and GH reserve when an IST is contraindicated (usually with the same criteria for a normal response). Glucagon frequently causes nausea and vomiting, normal individuals sometimes fail to show a ‘normal’ response and sampling must continue over a 4 h period, making this test relatively unattractive as a routine alternative.

The metyrapone test (750mg orally, four-hourly for 24h) has been widely used as a test of ACTH reserve, particularly in North America; it measures the response of urinary cortisol precursors or, more recently, plasma 11-deoxycortisol, to blockade of adrenal cortisol synthesis by this drug. The test is time consuming, often unpleasant for the patient and does not test the response to physiological stress.

An intravenous short tetracosactide test is now recognized by most endocrinologists to be a more appropriate and simpler alternative to either of these tests, unless information on GH reserve is also required.

Cortisol normal ranges, borderline responses, assay precision and dynamic test reproducibility

Normal ranges for cortisol, particularly for dynamic tests, were predominantly developed and validated using old assay technologies (e.g. fluorimetry), which are no longer in use, and although a variety of adjustments (typically lowering of cortisol cut-off concentrations for a normal response) have been suggested, these have rarely been completely validated.

Detailed studies of normal responses to tetracosactide have shown substantial differences with gender and between commonly used cortisol assays (see Clark et al. in Further reading, below). Most workers and most assays report a lower limit of the normal response between 500 and 600nmol/L, but some other published studies report lower peak responses than this in some apparently healthy individuals (lowest values ~400nmol/L). Similarly, some recent studies reporting cortisol responses to IST in healthy volunteers have reported peak responses in some individuals on some occasions between 400 and 500nmol/L.

Studies of test–re-test variability for both the tetracosactide and IST tests have mostly reported a coefficient of variation (CV) of around 10%. External quality control schemes also frequently report an interassay/intermethod CV for cortisol of 10% or higher. Therefore, if we assume conservatively that the combined variability from these two sources is represented by an overall CV of 10%, then simple statistics show that the 95% confidence limits for a test response with a ‘true’ value of 500nmol/L actually extends from 400 to 600nmol/L. These considerations potentially apply to both the tetracosactide test and the IST.

All of these factors lead the authors to define basal cortisol and cortisol responses to tetracosactide and other dynamic tests broadly rather than using a single precise cut-off, and to recognize a group with borderline or equivocal responses who cannot be clearly classified as ‘normal’ or ‘abnormal’:

- 100 nmol/L: a basal cortisol below this value almost always represents severe hypoadrenalism (or treatment with steroids)
- 400 nmol/L: a basal cortisol above this value indicates a normal hypothalamo–pituitary–adrenal (HPA) axis – unless the patient is acutely unwell or has ongoing unexplained symptoms consistent with

hypoadrenalism. A cortisol response to tetracosactide or IST below this concentration usually means that routine steroid replacement is required

- 600nmol/L: a cortisol response to tetracosactide to above this concentration at 30min almost always means that ACTH deficiency or primary adrenal failure is excluded. A cortisol response to above this concentration in an IST certainly excludes the need for steroid replacement even during severe intercurrent illness
- 100–400nmol/L: basal cortisol concentrations in this range need a dynamic test to confirm the abnormality of the axis; a tetracosactide or IST peak response in this range usually indicates a requirement for routine steroid replacement
- 400–600nmol/L: peak responses to tetracosactide or IST in this range in patients with known pituitary disease may not require the patient to receive regular replacement, but do require education of the patient about the possible need for replacement and symptoms of hypoadrenalism during intercurrent illness (and often provision of an emergency supply of hydrocortisone). Responses to tetracosactide in this range can sometimes be seen in normal individuals, so if there is no other evidence of adrenal or pituitary disease, further investigation may be required (e.g. renin and ACTH concentrations, possibly followed by IST to exclude isolated ACTH deficiency if the former are normal). Interpretation of isolated responses in this range are further complicated by the fact that patients with chronic fatigue syndrome may show borderline reduced cortisol dynamic responses, although in most cases they do not respond symptomatically to steroid replacement.

Assessment of growth hormone reserve

There are several biochemical tests that are used in clinical practice to confirm growth hormone deficiency (GHD). The clinical features of GHD are non-specific, and the different GH stimulation tests have different degrees of ability to stimulate GH release. For this reason, there continues to be debate about the most appropriate test and what extent of GH response constitutes true deficiency.

Insulin stress test

The insulin stress test (IST) remains the gold standard test of GH deficiency. In adults, a peak GH response to adequate hypoglycaemia (serum glucose <2.2mmol/L) of >7µg/L indicates a normal GH reserve, whilst a peak GH <3µg/L, as defined by the UK National Institute for Health and Care Excellence (NICE), indicates severe deficiency. In children, a peak GH <6.7µg/L after two provocative tests supports a diagnosis of growth hormone deficiency, although only one dynamic test is required in children with known hypothalamo–pituitary disease. The IST is unpleasant for patients and requires close medical supervision as it is potentially hazardous and is contraindicated in ischaemic heart disease and epilepsy. As well as

being a reliable GH stimulus, the IST is also a good assessment of ACTH reserve so it a useful way of assessing GH and ACTH reserve simultaneously.

Children of both sexes may show subnormal GH responses to hypoglycaemia (and other dynamic tests) in the years immediately preceding puberty (objectively when the bone age is >10 years). At the present time, there is no consensus with respect to the practice of 'priming' with gonadal steroids prior to such tests.

Other pharmacological tests

The glucagon test can be useful in the assessment of GHD when an IST is contraindicated, but it is a less reliable stimulus of GH and a poorer test of ACTH reserve than the IST, and its mechanism of action is not well understood. The criteria for diagnosing GHD in the glucagon test are the same as for the IST described above.

Other provocative tests of GH reserve include the GH-releasing hormone (GHRH)+arginine and GHRH+GH-releasing hexapeptide (GHRP-6) test, both of which have now been evaluated in large numbers of patients. The GHRH+arginine test may be particularly useful for young patients with radiation-induced GHD as occasionally the IST can give false negative results. Because GHRH+arginine is a more powerful GH stimulus, the cut-off point for diagnosing GHD is <9 µg/L.

In an attempt to avoid an IST, a variety of other pharmacological tests of GH reserve have also been used, particularly in children, including clonidine (0.15 mg/m²) and arginine infusion (0.5 g/kg). Use of these tests tends to be a matter of local preference; all are associated with rather variable responses and the peak GH values used to diagnose deficiency vary from laboratory to laboratory.

Exercise testing

Growth hormone is released during exercise and some laboratories have used an exercise test to assess GH reserve. Intensive, well controlled exercise (bicycle ergometer or treadmill) may exclude GH deficiency (by a peak GH response >6.7 µg/L), but less well controlled exercise ('run up and down the stairs') is unreliable.

Assessment of physiological growth hormone secretion

Because GH is secreted in a pulsatile fashion with increased pulses at night, serial blood tests, which can be done overnight or over 24h, can be used to monitor the frequency and amplitude of GH pulses. Because this approach is labour intensive, requiring hospital admission with multiple blood samples, it is mainly a research tool.

Measurement of urinary GH is not part of routine clinical practice because of its low concentration in urine, but sensitive assays may make this possible in the future, particularly for the surveillance of GH replacement therapy.

Insulin-like growth factor 1 is produced by the liver in response to GH and, although measurement of its concentration is a useful diagnostic adjunct to provocative

GH stimulation tests, it should not be used alone to diagnose GHD. However, the finding of a low IGF-1 in patients with three or four other pituitary deficiencies makes the likelihood of GHD sufficiently high that a formal provocative test may not be necessary.

Re-evaluation of GH status in young adults

In patients with isolated GHD that developed in childhood, it can be difficult to know whether GH replacement should be continued into adulthood. Patients with genetic hypopituitarism or multiple hormone deficiencies are highly likely to need to continue GH replacement. However, it may be able to be discontinued in patients with isolated or less severe GHD. In this situation, patients are re-tested during the period of transition between childhood and adulthood and the current consensus guidelines suggest a cut-off of <6 µg/L during an IST to indicate a continuing need for GH replacement. In this situation, the presence of clinical symptoms can also help the decision about whether to continue GH, which is best done by evaluation of the Adult Growth Hormone Deficiency Assessment (AGHDA) score. Consensus guidelines suggest that young adults with GHD should continue GH until the age of 25 years, when peak bone mass is likely to have been achieved.

Releasing hormone tests

Thyrotrophin releasing hormone (200 µg i.v.) and LHRH (100 µg i.v.) tests have been used traditionally in combination with the IST to assess pituitary reserve in the combined pituitary function test. Growth hormone releasing hormone testing (100 µg i.v.) and CRH testing (100 µg i.v.) have also more recently been advocated as additional tests.

All these releasing hormone tests assess only the readily releasable pituitary pool of their relevant hormones and do not assess the ability of the axis to respond to appropriate physiological stimuli. When the cause of hypopituitarism is at the hypothalamic level (which is frequently the case), then 'normal' TRH, LHRH, GHRH or CRH responses may be seen in the presence of deficiency documented by other means. Conversely, 'subnormal' responses are often seen when the axis is otherwise felt to be normal. Furthermore, a 'delayed' TRH test response (peak TSH at 60 min rather than 20 min), initially considered to be characteristic of hypothalamic disease, is not infrequently seen in primary pituitary disease.

For these reasons, the authors believe that all these releasing hormone tests should now play no part in routine pituitary function testing, but be reserved (if used at all) for the rare cases requiring differentiation between pituitary and hypothalamic deficiency states.

Other tests of gonadotrophin secretion

Clomifene test

When the differentiation of gonadotrophin deficiency from other causes of 'hypothalamic amenorrhoea' is in doubt, a clomifene test (3 mg/kg, maximum 200 mg, daily

for seven days) may give additional information. Patients with organic gonadotrophin deficiency show no increase in LH and FSH (measured on days 0, 4, 7 and 10), whereas some patients with hypothalamic amenorrhoea, weight-related amenorrhoea or delayed puberty show a gonadotrophin rise, usually followed by menstruation (about 28 days later). In early puberty, LH and FSH may show a characteristic fall rather than a rise.

Assessment of luteinizing hormone pulsatility

Measurement of plasma LH every 10–15 min for 6–8 h or more, when analysed by an appropriate computer algorithm, allows detailed assessment of LH pulse frequency and amplitude. This may give considerable insight into pituitary physiology but, in view of the time and number of assays involved, is essentially a research tool.

Dynamic tests of posterior pituitary function

Water deprivation test

Water deprivation is the standard physiological test of vasopressin secretion. The patient is observed, without access to water, with serial measurements of plasma and urine osmolality, urine volumes and body weight over a period of up to 8 h. If only borderline deficiency is suspected then it is wise, in order to shorten the procedure, to ask the patient to take no fluids from midnight before a morning test; otherwise the patient should be allowed free fluids prior to the test to avoid severe dehydration. Simple measurement of 24 h urine volume prior to the test may guide which approach is most appropriate; if this is $<2\text{ L}/24\text{ h}$ then DI is unlikely in the first place. If body weight falls by more than 3% during the test, this suggests severe dehydration. The test should be stopped, and plasma osmolality measured for confirmation before allowing access to fluids.

Normal vasopressin secretion is demonstrated by a urine:plasma osmolality ratio of $>2:1$ (or, more simply, a urine osmolality $>600\text{ mmol/kg}$), in the presence of a normal plasma osmolality (280–295 mmol/kg). A high plasma osmolality ($>300\text{ mmol/kg}$) with a urine osmolality of $<600\text{ mmol/kg}$ is diagnostic of DI. Intermediate responses are non-diagnostic and water deprivation must be continued or repeated, until diagnostic values are obtained. Once a diagnostic response has been obtained, then desmopressin (2 μg i.m.) is administered, free fluids are allowed and urinary osmolality is measured hourly for 2 h. In the presence of DI, full concentration of the urine after desmopressin indicates vasopressin deficiency rather than nephrogenic DI.

Patients with primary polydipsia frequently commence the test with low urine and plasma osmolalities due to water overload, and may fail to concentrate the urine adequately after the standard period of water deprivation since the plasma osmolality is frequently only increased into the low-normal range during this time. The renal response to desmopressin may also be impaired under these circumstances due to ‘washout’ of the renal concentrating gradients.

Hypertonic saline infusion

Severe DI can be diagnosed easily by a water deprivation test, but mild or borderline DI, and other more subtle defects of osmoregulation and thirst, may lead to equivocal findings despite protracted water deprivation. Under such circumstances, a hypertonic saline infusion (5% NaCl infused at 0.06 mL/kg per min for 120 min) may be used to delineate the pathology more accurately. Plasma osmolality and vasopressin are measured every 30 min but, as vasopressin measurements are not performed in most laboratories, this test is often only carried out in specialist centres. Discussion of the interpretation of this test is beyond the scope of this chapter (see Chapter 4 and Baylis, in Further reading, below).

Summary

Outline protocol for the investigation of a patient with pituitary disease

The multiple tests available and the controversies regarding their use and interpretation mean that the detail in which pituitary function is investigated remains a matter for clinical judgement. The authors propose the following protocol for the initial assessment of a patient with suspected pituitary disease.

1. Measure basal pituitary function on a single 09.00 h sample (see [Appendix 18.1, p. 371](#)).
2. If plasma cortisol is $<100\text{ nmol/L}$, then an IST is contraindicated and ACTH deficiency can be assumed (unless Addison disease is a possibility or the patient is receiving steroids).
3. Treat thyroid or ACTH deficiencies identified on basal concentrations (hypothyroidism reduces ACTH and GH responses to hypoglycaemia).
4. If plasma cortisol is $>100\text{ nmol/L}$ then:
 - a. if cortisol is $>400\text{ nmol/L}$, ACTH reserve can be assumed to be normal unless unexplained symptoms suggest otherwise
 - b. if cortisol is $<400\text{ nmol/L}$, perform a tetracosactide test – a response above 600 nmol/L confirms a normal axis (see above)
 - c. consider IST in the presence of equivocal responses to tetracosactide (e.g. peak 400–600 nmol/L), especially if there are unexplained symptoms, or if information on GH reserve is required.
5. Treat any ACTH deficiency identified (with hydrocortisone).
6. Consider whether investigation for GH deficiency is indicated:
 - a. if ACTH, thyroid and gonadal axes and osmolalities are normal, and the patient is asymptomatic with a normal AGHDA score, then assessment of GH reserve is probably of little *clinical* benefit (although it may be of *research* interest)
 - b. in the presence of other pituitary deficiencies, severe GH deficiency becomes increasingly likely with an increasing number of other deficiencies. If the AGHDA score suggests possibility of the clinical syndrome of adult GH deficiency, then perform a dynamic test of GH reserve, even if IGF-1 is normal

- c. at the initial assessment, or first assessment after pituitary surgery, many centres routinely perform an IST to formally document ACTH and GH reserve (except where contraindicated), even in the absence of symptoms.
7. Perform a water deprivation test if indicated by symptoms or by the basal osmolalities.

A clinical approach to assessment of the whole ACTH–adrenal axis

Assessment of the ACTH–adrenal axis is probably the most common assessment of complex endocrine function undertaken in clinical medicine, and remains the subject of ongoing controversy, variation in practice, differences in interpretation, artefact due to drugs and, frequently, the use of testing in inappropriate circumstances.

Assessment of adrenal reserve is broadly undertaken to answer the following four clinical questions.

1. Does this patient have undiagnosed hypoadrenalism? This question is frequently asked in the clinical context of hyponatraemia, hypotension and/or hypoglycaemia. A basal 09.00 h cortisol <100 nmol/L strongly suggests hypoadrenalism, and a value of >400 nmol/L makes it very unlikely (unless the patient is seriously unwell, in which case higher concentrations might normally be expected and the patient could be relatively hypoadrenal with diminished adrenal reserve).

When basal cortisol is uninformative, a short tetracosactide test is usually performed. A normal response (defined by an appropriate normal range – see above) effectively excludes adrenal deficiency. A definitely subnormal response confirms hypoadrenalism (as long as it is certain that the patient is not receiving steroid therapy), but should not immediately attract a diagnosis of Addison disease, since the prevalence of hypopituitarism is higher than that of primary adrenal failure.

2. Is the proven hypoadrenalism primary or secondary? In a newly diagnosed patient with hypoadrenalism, the clinical picture may contribute significantly to this differential diagnosis. Associated features may point towards primary adrenal failure: typical ‘Addisonian’ electrolytes (hyponatraemia, hyperkalaemia and slightly raised urea), typical ACTH-dependent hyperpigmentation or a personal or family history of autoimmune endocrine disease. Conversely, if the patient has visual field defects, clinical signs of hypogonadism or a pituitary mass, then ACTH deficiency is much more likely. Many patients, however, do not have clear-cut clinical clues to the diagnosis and a biochemical diagnosis is essential before embarking on life-long treatment.

Pragmatically, assessment of basal pituitary function is often the simplest and quickest approach, since it will either give evidence of other pituitary dysfunction, or, if normal, suggest primary adrenal failure (or, less likely, isolated ACTH deficiency).

Measurement of 09.00 h basal cortisol, ACTH and recumbent renin is typically slower, but diagnostic, since ACTH and renin are both elevated in primary adrenal failure.

The depot tetracosactide test has been used traditionally in this context (tetracosactide depot 1 mg i.m. with cortisol measured at intervals over 24 h). In primary adrenal failure, there is an absent or flat cortisol response, whereas in ACTH deficiency or HPA suppression by steroids, the cortisol response slowly rises to reach a near-normal peak at 24 h.

If primary adrenal failure is confirmed, measurement of adrenal antibodies may confirm autoimmune Addison disease, but if this is negative, alternative causes of adrenal destruction (tuberculosis, metastases) need to be considered and excluded. If ACTH deficiency is present, then full assessment of pituitary function and pituitary magnetic resonance imaging (MRI) are indicated.

3. Has this patient with known pituitary disease developed ACTH deficiency? This assessment has already been outlined above.

4. Does this patient on pharmacological steroid treatment still have adrenal suppression or could they now stop treatment? Numerically, this is probably one of the most frequent situations in which adrenal function is tested (with testing frequently being performed in inappropriate circumstances or the results being incorrectly interpreted):

- there is no point in performing any test of adrenal function when patients are taking supraphysiological doses of oral steroids (more than 5–7.5 mg prednisolone or 0.5 mg dexamethasone): basal cortisol and tetracosactide responses will always be suppressed
- high doses of inhaled, intranasal, topical or injected (for musculoskeletal disorders) steroids will also frequently suppress cortisol responses (basal concentrations may be undetectable). This often causes difficulties in interpretation, since most synthetic steroids are not measured in cortisol assays and it is impossible to differentiate biochemically between appropriate suppression and untreated deficiency
- prednisolone cross-reacts in many cortisol assays – so measurement of cortisol after a dose of prednisolone may give artefactually higher values. As a result of this, tests are often advised ‘under dexamethasone cover’. In the authors’ view, this is both unnecessary and unhelpful since the basal cortisol concentration (which gives useful information about background spontaneous cortisol secretion) will be undetectable. It is easier simply to omit prednisolone after 18.00 h on the day before testing, perform the relevant tests at 09.00 h and administer prednisolone when the test has been completed.

The authors therefore advise the following regimen when assessing whether or not pharmacological steroids can be discontinued:

- in a patient who is otherwise well, slowly reduce steroid doses to the lower end of the physiological replacement range indicated above before performing *any* hormonal tests

- then check the basal 08.00–09.00h cortisol one morning 24h after the last dose of steroid and before the steroid dose is taken that morning (tablets can be taken as usual immediately after the blood test). Interpretation:
 - <100 nmol/L: the patient still has profound adrenal suppression – further dose reduction would be unwise. Steroid replacement in the lower physiological range should be continued (if clinically well) and the test repeated in 6–12 months
 - >400 nmol/L: the adrenal axis is probably completely normal; steroids could be stopped (or slowly reduced if the underlying disease process contraindicates complete cessation immediately); further tests of adrenal axis are unnecessary unless there are unexplained symptoms
 - 200–400 nmol/L: adrenal function is not completely suppressed (and might be normal or partially suppressed); steroid doses can be slowly and cautiously reduced and the tests repeated
 - 100–200 nmol/L: significant adrenal suppression is more likely but will only remit if the steroid dose is reduced. Reduce steroid dose more slowly and cautiously; repeat 09.00h cortisol 2–3 months after each dose reduction.
- if concentrations are >300 nmol/L, and if the patient is clinically well, then steroid replacement can safely be stopped completely for several weeks in order to carry out a dynamic test of the adrenal using tetracosactide – otherwise the test may be indicated when on half-physiological dose as reassurance (it is unlikely to be normal, but profound suppression, for example a peak cortisol <300 nmol/L, would militate against further dose reduction). It may also be worth changing from a synthetic steroid to hydrocortisone, since this is shorter acting and therefore potentially less suppressive.

Even if the results of investigation are normal, it is important to remember that patients in whom the adrenal axis has been suppressed by long-term supraphysiological steroid administration may still require replacement during severe intercurrent illness for at least a year after steroids are discontinued.

Monitoring of pituitary function in disease states

Reassessment after pituitary surgery

Pituitary surgery, usually by the trans-sphenoidal route, is the recommended therapy for many pituitary adenomas. Following surgery, residual pituitary function requires careful monitoring and reassessment.

Transient DI is very common in the immediate postoperative period. However, the presence of nasal packs (required by the surgery) frequently results in a dry mouth so that the patient may drink excessive fluid, thereby causing polyuria in the absence of DI. Patients cured of acromegaly may also show polyuria in the absence of DI owing to rapid resolution of soft tissue enlargement. It is thus essential that DI is confirmed biochemically before replacement therapy is commenced. Paired urine and

plasma osmolalities should be checked daily for the first few postoperative days (and measured urgently if symptoms develop) and interpreted as outlined above. In borderline cases with persisting polyuria or nocturia, a formal water deprivation test may be required following recovery.

Most surgeons and physicians give glucocorticoid replacement therapy during the immediate perioperative period. One week postoperatively, or earlier if considered clinically appropriate and the patient is well, the evening replacement dose should be omitted and 09.00h plasma cortisol measured the following morning prior to the next dose. If a same-day cortisol result is available, the patient can remain off replacement, which should otherwise be restarted pending the result. A 09.00h cortisol <100 nmol/L indicates the need for continued, possibly life-long, replacement therapy. Patients with a 09.00h cortisol >300 nmol/L can be safely discharged without regular replacement therapy pending further investigations, but those with cortisol <400 nmol/L require steroid cover for intercurrent illnesses until the results are known. Patients with cortisol in the 100–300 nmol/L range usually need steroid replacement until definitive assessment is possible, but this must be determined by individual clinical assessment. In a retrospective review of our own practice, in which patients were investigated one week after pituitary surgery, 13% had a cortisol <100 nmol/L and 57% >400 nmol/L – so that only a minority of patients have equivocal responses at this stage.

Basal thyroid and gonadal function should be checked one week postoperatively. In view of the long plasma half-life of T₄, thyroid function should be reassessed at one month. At one week, a frankly low plasma testosterone in the male is usually diagnostic of ongoing gonadotrophin deficiency requiring replacement therapy. Lack of elevation of gonadotrophins in the postmenopausal female is also diagnostic. In both cases, borderline results require a repeat at one month. In the premenopausal female, early results may be misleading and it is wise to wait 2–3 months to assess the return of menstrual cyclicity prior to commencing replacement therapy.

A tetracosactide test is invalid as a test for ACTH reserve until at least two weeks postoperatively: the authors' practice is to perform this test approximately one month postoperatively in patients with a non-diagnostic basal cortisol concentration. The authors only perform a dynamic test of GH reserve in patients with symptoms suggestive of GH deficiency in whom replacement is being considered, but other centres prefer an IST at this stage to document fully postoperative pituitary function.

Monitoring after pituitary irradiation

Pituitary irradiation may be employed in the treatment of pituitary tumours (although its use is declining), and the hypothalamus and pituitary are also within the field of whole brain irradiation used for other diseases. All affected patients are at risk of slowly progressive hypopituitarism over at least the next 20 years and require regular monitoring. The order of progression is typically GH deficiency occurring early, LH and FSH deficiency next, and TSH and ACTH deficiency at a later stage. The lesion appears to be primarily at hypothalamic level and PRL deficiency therefore occurs rarely, if ever.

The development of GH deficiency in children is best assessed by careful monitoring of growth – and in adults, annual screening with the AGHDA questionnaire may be appropriate to identify patients in whom a dynamic test of GH reserve is required. For all other hormones, basal 09.00h pituitary function (see [Appendix 18.1, p. 371](#)) should be checked annually, with a subsequent tetracosactide test when serum cortisol is <400 nmol/L. (A routine annual tetracosactide test may actually prove to be a more efficient use of both the patient's and the laboratory's time.)

Monitoring in other pituitary disease states

Not all pituitary diseases result in progressive pituitary failure, so the need to monitor pituitary function in such patients is a matter of clinical judgement.

Patients with large pituitary mass lesions, granulomatous disease of the pituitary or hypothalamus, or unexplained acquired partial hypopituitarism certainly require monitoring of remaining pituitary function, which should be performed annually as above, at least for the first few years of follow-up. Conversely, patients with microprolactinomas whose PRL is suppressed on therapy, or patients with clearly defined isolated pituitary deficiency syndromes such as Kallman syndrome, are at minimal risk of progressive hypopituitarism and do not require regular monitoring in the absence of symptoms. Isolated GH deficiency in childhood is sometimes followed by other pituitary deficiencies in adult life, but it is as yet unclear whether this occurs sufficiently frequently to justify regular monitoring and, conversely, some such childhood cases are shown to have normal GH reserve when retested as young adults.

OTHER DIAGNOSTIC TECHNIQUES IN PITUITARY DISEASE

Clinical assessment

Endocrinologists continue to rely on clinical assessment to determine the need for further biochemical confirmation of diseases of the pituitary and hypothalamus. Investigations for possible Cushing syndrome and acromegaly are thus rarely performed unless they are suspected clinically because of the relevant symptoms and signs. Similarly, gonadotrophin deficiency is usually suspected by the development of loss of libido in both sexes, amenorrhoea in females and impotence and loss of secondary sexual hair in males. Diabetes insipidus results in thirst and polyuria, usually manifest in the earliest stages by nocturia (since urine is normally maximally concentrated overnight). Indeed, a biochemical nihilist might reasonably argue that there is no point in assessing these axes unless these clinical symptoms or signs are present.

Thyroid stimulating hormone deficiency may lead to typical symptoms and signs of hypothyroidism (see [Chapter 19](#)), although these are usually less severe than in primary thyroid disease. Adrenocorticotrophic hormone deficiency may result in general malaise, postural hypotension, headaches and abdominal pains and weight loss (pituitary cachexia). These symptoms of deficiency

are clearly non-specific and biochemical assessment is essential to confirm or deny deficiency. Growth hormone deficiency in adults results in impairment of quality of life in some patients – the pattern of symptomatology is non-specific, but can be recognized clinically or through testing with quality of life questionnaires.

Masses enlarging within the pituitary or hypothalamus frequently exert pressure on the optic chiasm and thus cause visual field loss, typically a bitemporal hemianopia. Clinical assessment of visual fields by confrontation and by formal charting is thus an essential part of the assessment of patients with pituitary disease. Large lateral extensions of pituitary tumours may more rarely result in cranial nerve deficits, the cavernous sinus syndrome or even temporal lobe epilepsy, and inferior extensions very rarely cause spontaneous cerebrospinal fluid rhinorrhoea.

Finally, panhypopituitarism is an unusual cause of unexplained hyponatraemia or hypoglycaemia and should always be considered during the investigation of these disorders.

Pituitary imaging techniques

Magnetic resonance imaging (MRI) scanning of the pituitary, with and without gadolinium enhancement, is the investigation of choice and allows detailed anatomical assessment. Computed tomography (CT) scanning of the pituitary gives less detailed information, but is used when MRI is contraindicated or impossible due to the presence of metallic implants or claustrophobia.

PITUITARY HYPERSECRETION STATES

Pituitary adenomas

Pituitary hypersecretion states are most usually associated with benign pituitary adenomas synthesizing and secreting the relevant hormone. Tumours may be subdivided into microadenomas (<10 mm diameter) and macroadenomas (>10 mm). Pituitary tumours may be invasive but are only very rarely malignant. Hyperplasia of the various cell types has also been described but, except when secondary to ectopic secretion of hypothalamic releasing hormones, is poorly defined. Non-functioning pituitary adenomas are more common in clinical practice.

Prolactinoma

Differential diagnosis of hyperprolactinaemia

A prolactinoma, or prolactin-secreting pituitary adenoma, is the commonest functioning pituitary adenoma. However, hyperprolactinaemia has many causes other than a prolactinoma ([Fig. 18.5](#)).

Any pituitary tumour or mass that is large enough to impede pituitary portal blood flow can result in hyperprolactinaemia by preventing hypothalamic dopamine from reaching the pituitary lactotrophs. Adenomas causing acromegaly also occasionally secrete PRL directly, in addition to GH. The differentiation of a prolactinoma from a functionless pituitary tumour may therefore sometimes be difficult, although biochemical results give some assistance. A plasma PRL >5000 mU/L

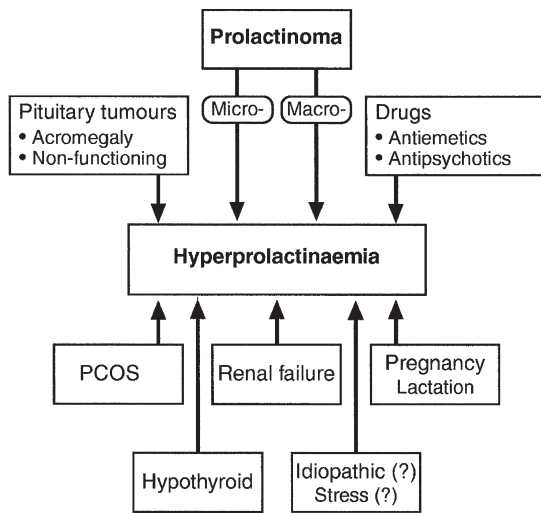

FIGURE 18.5 ■ Causes of hyperprolactinaemia. PCOS, polycystic ovary syndrome.

almost always indicates a prolactinoma, and concentrations may reach several hundred thousands. Plasma PRL <5000 mU/L may result from a prolactinoma, a functionless pituitary tumour (adenoma, craniopharyngioma etc.) or any of the other causes shown in [Figure 18.5](#). It is most unlikely for a large macroprolactinoma to be associated with PRL concentrations in this range. Conversely, while a small macroprolactinoma may be associated with an elevated PRL at any concentration, a small functionless microadenoma is unlikely to elevate plasma PRL into the thousands. Thus, when PRL is raised, but <5000 mU/L, the smaller the adenoma seen on CT or MRI scan, the more likely it is to be a prolactinoma and vice versa.

Any drug with dopamine antagonist effects may cause hyperprolactinaemia; this includes almost all antiemetics (e.g. metoclopramide, prochlorperazine, domperidone) and most major tranquilizers (chlorpromazine and other phenothiazines, haloperidol, risperidone etc.). A careful drug history is therefore essential in the assessment of hyperprolactinaemia. Antiemetics can often be discontinued but antipsychotic medication usually needs to be continued, although change to a newer antipsychotic with less effect on PRL may be possible (e.g. quetiapine, olanzapine and other ‘atypical antipsychotics’).

Primary hypothyroidism may be associated with hyperprolactinaemia in the low thousands (mU/L) (and with galactorrhoea and oligo- or amenorrhoea) that resolves with thyroid replacement therapy. Chronic kidney disease causes hyperprolactinaemia of a similar degree. Measurement of thyroid and renal function is thus essential in any patient with hyperprolactinaemia.

Mild and often intermittent hyperprolactinaemia (usually <1000 mU/L) is often seen in polycystic ovary syndrome (PCOS). In the appropriate clinical context (hirsutism, acne, obesity), assessment of plasma androgen concentrations and sex hormone-binding globulin (SHBG) may therefore be indicated (see [Chapter 22](#)). Major ‘stress’, for example hypoglycaemia, also elevates plasma PRL but it is far from clear whether psychological stress or fear of venepuncture is able to do so.

Finally, it should be remembered that by far the commonest causes of a state of hyperprolactinaemia and amenorrhoea are pregnancy and lactation: a pregnancy test may be indicated.

Role of dynamic tests of PRL secretion

In order to assist the differential diagnosis of hyperprolactinaemia, a number of dynamic tests of PRL secretion have been advocated and used, particularly in continental Europe. Such tests include the TRH test, metoclopramide test and domperidone test. None of these tests gives clear differentiation between prolactinomas and other causes of hyperprolactinaemia and they have no role in routine biochemical assessment.

Assessment of remaining pituitary function

Few patients with small macroprolactinomas have deficiencies of other pituitary hormones, but, conversely, a functionless macroadenoma can cause severe hypopituitarism associated with mild hyperprolactinaemia. Clearly not every patient with a high PRL requires full pituitary function testing. The authors’ own (arbitrary) practice is to perform basal anterior pituitary function tests and a pituitary MRI whenever the plasma PRL is consistently >1000 mU/L, but not otherwise unless there are relevant symptoms or signs.

Outline of presentation and management of prolactinoma

In females, hyperprolactinaemia causes oligo- or amenorrhoea, galactorrhoea and breast tenderness, poor libido and infertility. Patients may present with any combination of these symptoms, with or without other signs of pituitary enlargement such as visual field defects. In males, poor libido and impotence are the only early symptoms and patients frequently present at a later stage with visual field loss, with or without headaches. Development of a prolactinoma in the peripubertal period can also result in delayed or arrested puberty in both sexes, and a serum PRL measurement is thus an essential part of the assessment of such patients.

The management of prolactinomas is primarily medical, using dopamine agonist therapy, which can suppress plasma PRL to normal and cause clinical remission of all symptoms. The long-acting dopamine agonist cabergoline is now most commonly used – bromocriptine and quinagolide are alternatives. Bromocriptine may be preferred when pregnancy is planned, in view of its longer safety record, although there is no evidence of fetal harm with the newer drugs. In addition to lowering PRL and relieving symptoms, dopamine agonist therapy also causes dramatic shrinkage of macroprolactinomas in a majority of cases, with resolution of pressure effects such as visual field loss. Such tumour shrinkage is the ultimate non-invasive method to distinguish a prolactinoma from other pituitary lesions causing hyperprolactinaemia. In a majority of prolactinomas the hyperprolactinaemia will recur if dopamine agonist therapy is stopped, so that treatment is usually long term, although a significant minority may be able to discontinue therapy.

Alternative therapies for a prolactinoma include trans-sphenoidal surgery and, rarely, pituitary irradiation.

Monitoring the response to dopamine agonist therapy

The aim of dopamine agonist therapy is to suppress plasma PRL concentrations into the normal range. The dose of dopamine agonist is usually slowly increased with sequential PRL estimations until this is achieved. Thereafter, plasma PRL would normally be measured at each clinic visit, although these need only be annual in patients on long-term therapy. Fibrotic reactions have been described as rare side-effects of long-term dopamine agonist therapy (pulmonary, retroperitoneal and pericardial); some form of monitoring is advised and the authors' practice is to monitor for symptoms and measure urea and electrolytes, full blood count and C-reactive protein (CRP) (or plasma viscosity or erythrocyte sedimentation rate (ESR)) annually.

Macroprolactinaemia

In some patients, PRL circulates bound to immunoglobulin forming an immunoreactive PRL of high molecular weight (macroprolactin). This is biologically inactive but in molar terms may considerably exceed the concentration of free PRL. Commonly used immunoassays for PRL cross-react with macroprolactin to a variable extent, and with some assays macroprolactin is a common cause of hyperprolactinaemia. This can usually be detected by polyethylene glycol (PEG) precipitation, although gel filtration chromatography is more reliable. Laboratories should know the susceptibility of their own assay to this artefact, and always arrange to screen for macroprolactinaemia if persistent hyperprolactinaemia does not correlate with clinical symptoms or expected responses to treatment.

Hook effect

Extremely high PRL concentrations (say >100 000 mU/L) in patients with large pituitary macroprolactinomas may, rarely, exceed the usual linear range of the assay calibration curve when homogeneous assays are used, and give apparently only modest elevations not suggestive of a large prolactinoma. This can be detected by assays of doubling dilutions of serum (when measured PRL concentration fails to fall as expected and may begin to rise).

Acromegaly

Diagnosis of acromegaly

The diagnosis of acromegaly is usually suspected clinically before any biochemical tests are performed. However, by the time acromegaly is clinically obvious, the patient may have already suffered considerable morbidity from soft tissue changes, arthritis, hypertension, diabetes and consequent cardiovascular disease. Because of this, the aim should be to diagnose acromegaly at an early stage, when clinical signs are less clear cut and differentiation from normality can only be confirmed by biochemical investigations.

Basal GH and IGF-1 estimation. Random plasma GH measurements are never diagnostic of acromegaly, since high concentrations may occur with normal pulses of secretion and with stress. Nevertheless, a low plasma GH (<0.4 µg/L), together with a normal IGF-1 essentially excludes the diagnosis, whereas a high IGF-1 with consistent GH concentration makes the diagnosis very likely. It is therefore the authors' practice to measure a random GH and IGF-1 concentration as a simple first test when acromegaly is suspected. An age-related normal range for IGF-1 must be used for interpretation since concentrations vary considerably throughout life.

Glucose tolerance test. The 75 g glucose tolerance test (GTT) remains the gold standard test for the diagnosis of acromegaly. After glucose, plasma GH in normal individuals is suppressed to <0.4 µg/L. Patients with acromegaly fail to show complete suppression and may show a paradoxical rise of plasma GH. Failure of GH to fall to <0.4 µg/L is highly suggestive of acromegaly, even if substantial suppression of GH has occurred, and an elevated IGF-1 will normally confirm the diagnosis.

Failure of normal glucose suppression of GH may occur in the absence of acromegaly in liver disease, poorly controlled diabetes, chronic kidney disease, malnutrition (including anorexia nervosa) and primary growth hormone insensitivity (Laron syndrome). Diabetes can be a particular diagnostic challenge, since a GTT is inappropriate in established disease. Insulin-like growth factor 1 concentrations, however, are typically normal in uncomplicated diabetes, and, if elevated, the authors usually recommend a four-point GH day curve to confirm circulating GH concentrations consistently above the 'safe' range.

Other diagnostic tests. Patients with acromegaly may show a paradoxical rise in plasma GH during standard TRH or LHRH tests. When acromegaly has been clearly diagnosed by other means, these tests give no additional clinically useful information, but they may help confirm mild acromegaly in patients when the results of other tests are equivocal.

In normal individuals, plasma GH shows a transient rise during a dopamine infusion (4 µg/kg per min for 3 h), whereas patients with acromegaly characteristically show a fall in plasma GH. This test can also be used to confirm an equivocal diagnosis but is not used routinely.

Ectopic secretion of GHRH, for example from a pancreatic endocrine tumour, is a rare cause of clinical acromegaly. The diagnosis is not usually suspected until somatotroph hyperplasia is found at trans-sphenoidal surgery rather than the expected adenoma. In these circumstances, peripheral plasma GHRH concentration (available only in a few specialist centres) is elevated and diagnostic.

Outline of presentation and management of acromegaly

Acromegaly is usually diagnosed clinically when the patient presents with an incidental illness to a doctor who recognizes the typical physical appearance, which is frequently longstanding and only slowly progressive.

Growth hormone-secreting tumours that develop in childhood result in gigantism, but after puberty, fusion of the major epiphyses means that growth in height is no longer possible. Patients with acromegaly do, however, develop excessive growth of soft tissues and small bones of the skull, face, hands and feet, which results in the characteristic clinical features. They have large, 'spade-like' hands and large, broad feet, usually with a history of increasing ring size and shoe size over a number of years. Facial appearance is characteristic with prognathism, prominent supraorbital ridges, large nose and tongue and generalized coarsening of the features. Examination of old photographs will frequently demonstrate that these changes have been progressive over 5–10 years or more. Headaches, often severe, and troublesome, inappropriate sweating are common symptoms; other findings frequently include a multinodular goitre, kyphosis, hypertension and diabetes mellitus, the last two presumably contributing to the observed increase in cardiovascular morbidity and mortality in this condition.

Patients with acromegaly often develop deficiencies of other pituitary hormones, and full investigation of pituitary function is mandatory once the diagnosis has been made.

Although acromegaly frequently goes undiagnosed for many years, treatment is almost always indicated since, if left untreated, the condition results in disfigurement, morbidity (primarily due to kyphosis and osteoarthritis) and mortality (primarily cardiovascular, but possibly also an increase in malignancies).

First-line therapy in almost all patients is transphenoidal surgery, which is able to cure at least 75% of microadenomas but a much smaller proportion of large macroadenomas, some of which are locally invasive. A number of studies have shown substantial differences in success rates between surgeons and centres, and an experienced pituitary surgeon is essential. Unsuccessful pituitary surgery is traditionally followed by pituitary irradiation, which steadily lowers GH secretion, but may require 10–20 years to normalize GH concentrations in patients where the initial GH is very high (over 40 µg/L). Medical therapy with dopamine agonists such as high-dose cabergoline (e.g. 0.5 mg daily) is useful in a proportion of patients. The potent, long-lasting somatostatin analogues octreotide and lanreotide are able to normalize GH concentrations in the majority of patients (but not all), albeit at the expense of monthly injections and a high economic cost. Both classes of drugs may allow significant shrinkage of a somatotroph adenoma preoperatively. More recently, the GH antagonist pegvisomant has been shown to be capable of normalizing IGF-1 in almost every patient, but treatment requires daily injections and is extremely expensive. The success of these drugs has led some authorities to recommend long-term medical therapy instead of radiotherapy (or even surgery), but this is not currently routine practice in most centres.

Monitoring the response to therapy

There has been considerable controversy over the years regarding the appropriate biochemical criteria to diagnose remission or cure of acromegaly after therapy, but results of large retrospective studies and consensus

meetings have achieved much greater uniformity. The current consensus criteria for disease control in acromegaly define active and controlled disease. The criteria for active disease are a random GH >1 µg/L *and* nadir GH after OGTT ≥0.4 µg/L with an elevated IGF-1. Patients with active disease usually require closer monitoring to ensure the clinical and biochemical picture does not deteriorate, and would be considered for additional treatment if the clinical picture were to deteriorate or the GH increases to >2 µg/L. The criteria for controlled disease are a random GH <1 µg/L *or* nadir GH after OGTT <0.4 µg/L and an age-sex normalized IGF-1 for age and sex. Occasionally after treatment for acromegaly there is a discrepancy between GH and IGF-1 concentrations, most commonly involving a normal GH and elevated IGF-1 concentration. Although the aim of management should be to normalize both GH and IGF-1, it is currently felt that a normal GH level concentration is probably the more important determinant of cardiovascular risk reduction. The current literature suggests that a GH <2 µg/L is probably within the safe range for cardiovascular disease, although there remains debate about whether adjuvant treatment is indicated for patients who have discordantly elevated IGF-1 despite acceptable growth hormone concentrations.

Diagnosis and differential diagnosis of Cushing syndrome

Endogenous Cushing syndrome is rare, with an incidence of approximately 5 per million population per year. However, many of the clinical features of the syndrome are very common (weight gain, hypertension, hirsutism, diabetes) so that biochemical tests are frequently requested to exclude the diagnosis and are essential to confirm its presence. Clinical features certainly increase the suspicion of Cushing syndrome (easy bruising, thin skin, red/purple abdominal striae, proximal myopathy, specific distribution of fat, e.g. supraclavicular and dorsal fat pads in addition to central obesity). However, many patients with biochemically and surgically proven Cushing disease are not as grossly 'cushingoid' as seen in a patient on high-dose pharmacological steroids or as illustrated in older medical student textbooks; they are often overweight rather than obese but with a history of unexpected recent weight gain and change towards central distribution of fat.

Measurement of urinary free cortisol (UFC) is frequently used as a first-line screening test for Cushing syndrome. It has the advantage of simplicity, but the disadvantage that the diagnosis may be missed if urine collection is incomplete, and of false positive elevations of urinary free cortisol in obesity and stressful illness.

Many clinicians will therefore use some form of low-dose dexamethasone suppression test as their preferred first-line screening test.

Low-dose dexamethasone suppression test. Dexamethasone 0.5 mg is administered 6-hourly for 48 h commencing at 09.00 h, with plasma cortisol measured at 09.00 h at the end of the test. Normal response is a plasma cortisol <50 nmol/L (and undetectable in most normal individuals). Many regard this test as too

complex – but it still potentially involves only one blood sample and one prescription, and patients can easily follow the administration protocol as an outpatient if given a simple information sheet. It is sensitive and much more specific than the overnight test and is the authors' preferred screening test.

Overnight dexamethasone suppression test.

Dexamethasone 1 mg is administered on going to bed at 23.00 h and plasma cortisol is measured at 09.00 h. Suppression of cortisol to <50 nmol/L is unequivocally normal and because it is a simple and sensitive investigation, it is preferred by many clinicians, although it has a higher false positive rate than a formal 48 h test.

Midnight salivary cortisol. This test is gaining increasing popularity for diagnosis of Cushing syndrome, particularly in the USA. In normal individuals, plasma cortisol concentration is low at midnight, when resting or asleep, whereas in Cushing syndrome, the circadian rhythm is lost or reduced. A midnight sleeping plasma cortisol <100 nmol/L has traditionally been used to exclude Cushing syndrome, but the practicalities of inpatient bed and junior staff availability mean that this test is now rarely practical in the UK. More recent data suggest that an awake value >207 nmol/L may have a higher specificity and is easier than sampling whilst the patient is asleep. A saliva sample can be collected by the patient at home and midnight salivary cortisol has been shown to be a useful screening test, although the precise cut-off value depends upon the local reference range and the assay is not yet widely available in clinical practice.

Other tests. All tests for diagnosis and differential diagnosis are subject to false positive and false negative results. Where the result of first-line screening tests are in conflict with the clinical findings, or where doubt exists, then other tests are sometimes performed: repeated UFC measurements to establish the presence or absence of 'cyclical Cushing syndrome'; a formal 'circadian rhythm' assessment of plasma cortisol as an inpatient; an insulin stress test (IST) to demonstrate suppression of the cortisol response to stress, which is typically seen in Cushing syndrome. The desmopressin stimulation test, where patients with pituitary Cushing disease typically show a response, and normal individuals do not, is no longer felt to be sufficiently useful for routine clinical practice.

At this stage, advice from a specialist tertiary centre is usually required. Scanning of the adrenals or pituitary is not advised until the diagnosis of Cushing syndrome is clearly established, since 'incidentalomas' of both the pituitary and adrenals are common and may lead to an inappropriate diagnosis.

Once Cushing syndrome has been diagnosed, measurement of plasma ACTH can readily distinguish primary adrenal causes from ACTH-dependent Cushing syndrome. The former can be readily confirmed on CT or MRI scan of the adrenals, but the differential diagnosis of the latter remains a challenging clinical problem (see Fig. 18.6).

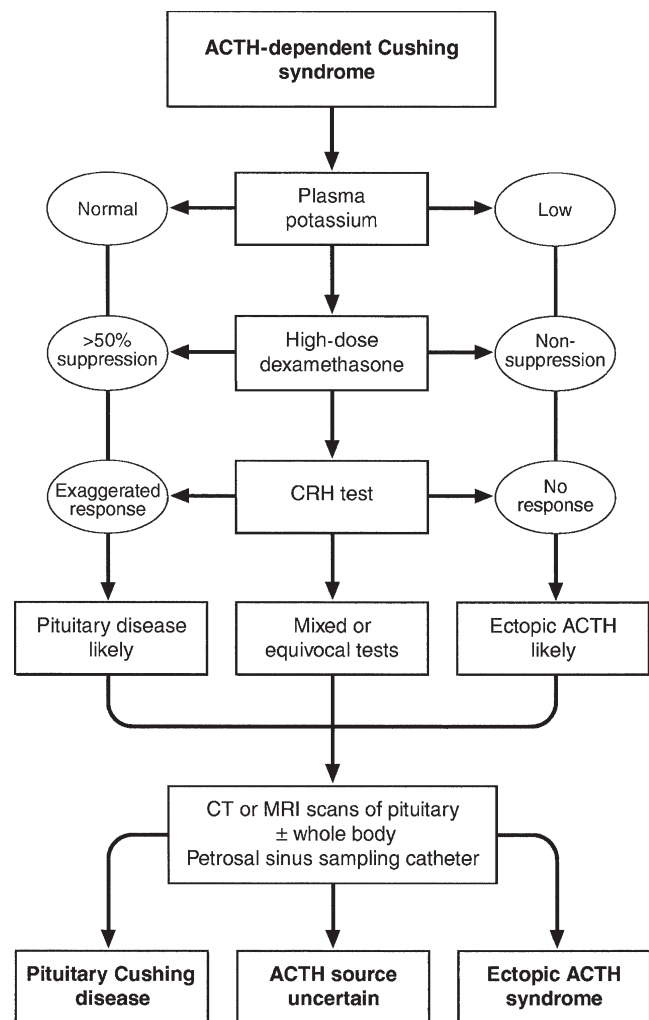

FIGURE 18.6 ■ Strategy for the differential diagnosis of ACTH-dependent Cushing syndrome.

Clinical context of ACTH-dependent Cushing syndrome

Adrenocorticotrophic hormone-dependent Cushing syndrome may be due either to pituitary Cushing disease, usually associated with a corticotroph microadenoma, or to ectopic ACTH secretion (and very rarely ectopic CRH secretion) by a variety of tumours elsewhere.

Numerically, the commonest source of ectopic ACTH secretion is small cell carcinoma of the bronchus. In this case, the clinical presentation is usually rapid and is often with symptoms directly related to the primary tumour. Although plasma ACTH and cortisol concentrations can be extremely high, such patients are rarely clinically cushingoid but may have pigmentation (due to the ACTH), proximal myopathy and hypokalaemic alkalosis. Such patients rarely present diagnostic difficulties.

In contrast, other, often relatively benign neuroendocrine tumours, can also secrete ACTH, particularly carcinoid tumours of the lungs (the commonest), mediastinum and elsewhere; pancreatic endocrine tumours; medullary thyroid carcinomas and, rarely,

phaeochromocytomas. Such tumours are small, slow growing and clinically occult and these patients may present with typical Cushing syndrome indistinguishable from that seen in pituitary-dependent disease. Such cases represent 10–15% of ACTH-dependent Cushing syndrome in most large series. Since these tumours may be only a few millimetres in diameter and thus hard to localize clinically or by conventional imaging techniques, biochemical tests are of paramount importance in their differentiation from pituitary Cushing disease.

Plasma cortisol and ACTH concentrations

In pituitary disease, plasma ACTH is often <100 ng/L, but higher values (up to at least 400 ng/L) are not infrequently seen. While, on average, plasma ACTH (usually >100 ng/L), and thus plasma cortisol, are higher in occult ectopic ACTH secretion than in pituitary disease, there is overlap and values usually lie within the range observed in Cushing disease.

Chromatography of plasma ACTH has been employed in the past to identify large molecular weight ACTH precursors, which are frequently secreted ectopically by tumours, but also occasionally by pituitary tumours. The complexity of these techniques means that they are no longer generally available, although immunometric assays specific for ACTH precursors may sometimes provide equivalent information.

High-dose dexamethasone suppression test

The high-dose dexamethasone suppression test was initially described in 1960 for the differentiation of adrenal from pituitary causes of Cushing syndrome. While largely superseded in this role, it remains useful in the differentiation of occult ectopic ACTH secretion.

A number of dosage regimens have been described, but the authors prefer the original regimen, with which there is greatest experience. Dexamethasone is administered orally, 2 mg strictly six-hourly for 48 h, commencing at 09.00 h. Plasma cortisol is measured at 09.00 h (basal value) and after 24 h and 48 h of treatment. 'Significant suppression' is arbitrarily defined as a fall in plasma cortisol to 50% or less of the basal value.

Using such criteria, about 80% of patients with Cushing disease, but only 10% of patients with occult ectopic ACTH secretion, show significant suppression of plasma cortisol. Thus differentiation is far from absolute, but since pituitary disease is far more common this means that significant suppression during the test statistically favours pituitary disease by approximately 70:1, whereas patients showing no suppression at all are equally likely to have a pituitary or ectopic source.

Corticotrophin releasing hormone test

Following the isolation and synthesis of the 41-amino acid CRH, the CRH test (see [Appendix 18.1, p. 372](#)) has gained an important role in the differential diagnosis of ACTH-dependent Cushing syndrome.

Following administration of CRH (in the UK, usually human CRF-41, but in the USA, typically ovine CRF-41, in both cases 100 µg i.v.), most patients with pituitary Cushing disease show a rise in plasma ACTH and therefore cortisol (defined as an increase of 25% above basal). In about 80% of patients with pituitary disease, the rise in plasma cortisol is 'exaggerated', that is, above the peak value observed in normal individuals. It is of interest and of practical importance that patients who fail to suppress with high-dose dexamethasone usually do show a cortisol response to CRH. In contrast, a significant cortisol response to CRH in ectopic ACTH secretion is extremely rare and limited to one or two isolated case reports in the world literature.

Other tests

An unprovoked hypokalaemic alkalosis remains an important clue to the presence of ectopic ACTH secretion, since over 90% of such patients present with hypokalaemia, compared with only 10% of patients with pituitary Cushing disease.

In the context of ectopic ACTH, tumours frequently also secrete other peptide hormones so that one or more tumour markers may be positive in the blood of such patients. It is therefore the authors' practice in patients with equivocal tests to screen plasma for tumour markers including calcitonin, human chorionic gonadotrophin (hCG), α -fetoprotein, carcinoembryonic antigen (CEA) and 'gut hormones', any of which may occasionally prove to be positive.

Petrosal sinus sampling for ACTH

It can be seen from the discussion above that no test is completely reliable in the differential diagnosis of ACTH-dependent Cushing syndrome. Because of this, techniques have been developed to ascertain directly the source of ACTH secretion via bilateral, simultaneous, inferior petrosal sinus sampling (IPSS) for ACTH after CRH stimulation.

Venous sampling catheters are passed from both femoral veins to lie in the respective inferior petrosal sinuses, which drain blood from the cavernous sinus and pituitary gland. The patient is partially heparinized prior to the final placement of the catheters to avoid the risk of venous thrombosis affecting the brain, which has been reported rarely. Blood for ACTH estimation is obtained simultaneously from both sides and from a peripheral vein, at timed intervals before and after an intravenous bolus of CRH. It is the authors' practice to administer TRH (200 µg) at the same time to measure central secretion of TSH and PRL to confirm the equivalence of catheter placement since, in the authors' experience, unequal sampling is frequently seen despite good radiological appearances.

After a technically successful procedure, the vast majority (all in most series) of patients with pituitary Cushing disease show a central:peripheral gradient of ACTH concentration of >2:1 basally or >3:1 after CRH, which is diagnostic of pituitary disease. Significant lateralization of ACTH secretion may also be observed and may guide

the surgeon and improve the surgical cure rate. It is the authors' practice to perform IPSS in almost every patient with ACTH-dependent Cushing disease without an obvious ectopic tumour or pituitary macroadenoma, as part of the routine differential diagnostic work-up; others reserve the test for situations where other tests are contradictory. The relative complexity of the technique means, however, that it should be restricted to those centres with experience in its use.

Venous sampling for ACTH from a wide variety of sites throughout the body, using a catheter in the central veins, occasionally may also give useful information, especially when directed towards a suspicious lesion detected on body CT, MRI or positron emission tomography (PET) scanning.

Imaging

Although imaging plays an important role in the differential diagnosis of Cushing syndrome, it is important to interpret the biochemical findings as the imaging may be misleading. An MRI scan of the pituitary is frequently normal in pituitary Cushing disease, and may be abnormal in 10% of normal individuals (and therefore in ectopic ACTH patients). In some patients, where the suspicion of ectopic ACTH secretion is high on biochemical grounds, detailed CT scanning of the entire thorax and abdomen may be necessary. An appropriate diagnostic strategy is summarized in [Figure 18.6](#).

Outline of management

The first-line treatment of Cushing disease is now selective adenectomy at trans-sphenoidal surgery, which results in cure in about 75% of cases, varying from series to series and with the biochemical criteria used to diagnose 'cure' (see below). The earlier alternatives of bilateral adrenalectomy or pituitary irradiation are now usually reserved for patients who are not cured by pituitary surgery.

Medical therapy is also possible for Cushing disease of all types, but is usually reserved for preoperative preparation or in patients where surgery has failed or is impossible. Commonly used drugs include metyrapone and ketoconazole. The aim of therapy is to maintain mean circulating cortisol concentrations between 150 and 300 nmol/L, but care must be taken to ensure that the cortisol assay used does not cross-react with precursors above the drug-induced block in cortisol synthesis (11-deoxycortisol in the case of metyrapone).

Reassessment after pituitary surgery

As with acromegaly, definition of 'cure' after trans-sphenoidal surgery for Cushing disease remains a controversial area. Many of the larger series reporting success of this type of surgery have failed to define their criteria for 'cure', and some appear to be assessed only by clinical remission or return of UFC to within the reference range.

After successful pituitary surgery, most patients have adrenal insufficiency, since the normal

hypothalamo-pituitary axis is fully suppressed by the longstanding hypercortisolaemia. To be confident of 'cure', a 09.00 h cortisol, off replacement therapy, at the early preoperative reassessment should be subnormal, that is, <100 nmol/L (some authors insist on undetectable concentrations). Other authors suggest that a concentration <140 nmol/L in the context of clinical improvement may suggest remission. Occasionally, delayed remission may occur, although a basal cortisol >140 nmol/L after six weeks post-pituitary surgery is an indication that further treatment is needed. In cases of doubt, a formal 48 h low-dose dexamethasone suppression test should be performed (0.5 mg, orally, strictly six-hourly for 48 h, commencing at 09.00 h); normal individuals suppress plasma 09.00 h cortisol to undetectable values (<25 nmol/L in the authors' laboratory) at the end of this test, and failure to show such complete suppression indicates residual disease, albeit mild in many cases.

Patients in remission from Cushing disease require glucocorticoid replacement therapy for several months or even years. To assess the possibility of steroid withdrawal, a 09.00 h cortisol should be measured periodically, having omitted the early morning replacement dose and the evening dose the day before. When cortisol rises to >100 nmol/L, the replacement dose can be slowly reduced, with continued monitoring of cortisol concentrations and a tetracosactide test or insulin stress test (IST) performed once replacement is completely withdrawn. Patients successfully withdrawn from replacement therapy require periodic monitoring, with UFC and/or low-dose dexamethasone suppression testing to detect early evidence of relapse.

Thyroid stimulating hormone-secreting adenomas

Thyroid stimulating hormone-secreting pituitary adenomas (TSHomas) are rare, but occasional cases will be encountered in most centres. Patients typically present with mild clinical and biochemical thyrotoxicosis with an inappropriately 'normal' or slightly elevated plasma TSH.

The differential diagnosis of a patient with a raised free T4 and normal or elevated plasma TSH should include thyroid hormone resistance (THR), and assay interference. Although only patients with TSHomas should be clinically hyperthyroid, it is often difficult to distinguish TSHomas from THR or assay interference on clinical grounds alone, and other tests are often needed. Patients with THR typically show a rise in TSH after injection of TRH, whereas a flat response is usually seen with a TSHoma, aiding the differential diagnosis. The α -subunit (of TSH) can also be measured by some centres and is typically elevated with a TSHoma but not with THR. Analysis of the thyroid hormone receptor gene (or more simply measuring thyroid function in family members) may clinch the diagnosis of THR. Measurement of sex hormone binding globulin (SHBG) is helpful in the differential diagnosis because SHBG tends to be normal in the thyroid hormone resistance and elevated in the

TSHoma due to the increase in SHBG produced by the liver in response to thyrotoxicosis.

Treatment of TSHoma is by somatostatin analogue therapy and/or pituitary surgery, with or without pituitary irradiation and carbimazole therapy.

Gonadotrophin-secreting adenomas

Clinically functioning gonadotrophin-secreting adenomas of the pituitary are extremely rare. In the male, they present with elevated plasma testosterone, usually with enlarged testes, in the presence of 'normal' or elevated LH and FSH. In the female, the condition may mimic premature ovarian failure, with amenorrhoea and elevated gonadotrophins. Of theoretical interest, however, is the experimental observation that a majority of so-called functionless pituitary adenomas are able to synthesize and secrete LH, FSH or their common α -subunit *in vitro*, the significance of which is unclear.

HYPOTHALAMIC AND PITUITARY DEFICIENCY STATES

Diseases that may lead to generalized hypopituitarism

Non-functioning pituitary adenomas

Pituitary adenomas that do not result in the hypersecretion syndromes described above are described as non-functioning or functionless pituitary adenomas. As mentioned above, these can frequently be shown experimentally to be capable of synthesis of LH and FSH and occasionally of any other pituitary hormone, in subclinical amounts. Such patients usually present either with symptoms and signs of hypopituitarism or with other signs of pituitary tumour enlargement, primarily visual field loss. Treatment is by pituitary surgery, followed by irradiation where appropriate. Although such adenomas do not show dramatic shrinkage in size with dopamine agonist therapy, recent evidence suggests that these drugs may reduce the risk of recurrence after successful surgery (or during conservative observation with smaller tumours).

Other pituitary and parasellar tumours

Craniopharyngiomas, derived from remnants of Rathke's pouch, are the only other common type of primary pituitary tumour. These usually present in childhood with poor growth, hypopituitarism and signs of pituitary enlargement, but may also present for the first time in adult life. Malignant tumours from elsewhere in the body occasionally metastasize to the pituitary; in addition to the usual signs of pituitary tumour, severe headache is a frequent symptom.

A wide variety of other tumours may also present with symptoms and signs of a pituitary or hypothalamic mass including hypothalamic germinomas, meningiomas, optic nerve and other gliomas, chordomas, hamartomas and pineal tumours.

Inflammatory diseases and disorders of unknown aetiology

Inflammatory conditions involving the hypothalamo-pituitary axis are rare and typically present with an unusual pattern of hypopituitarism in conjunction with diabetes insipidus. Sarcoidosis may cause granulomatous masses in the pituitary and hypothalamus, with or without evidence of disease elsewhere; measurement of plasma angiotensin-converting-enzyme concentration may, therefore, occasionally be helpful in the diagnosis of unexplained pituitary masses. Other granulomatous diseases that may present in the same way include tuberculosis and histiocytosis X.

Lymphocytic hypophysitis is an inflammatory disorder of unknown but possibly autoimmune aetiology; it occurs most frequently during pregnancy or the puerperium, but may occur at other times and less frequently in the male. Granulomatous hypophysitis is probably part of the same spectrum of diseases. Idiopathic pituitary fibrosis is also rarely seen and may be associated with other midline fibrosis syndromes. All these conditions may present with hypopituitarism or with signs of a pituitary mass.

Other conditions

Sheehan syndrome is hypopituitarism due to pituitary infarction secondary to massive postpartum haemorrhage and usually presents with failure of lactation and amenorrhoea in the puerperium. New cases should be rare with modern obstetric management, but some patients continue to present in later life, usually with a history of amenorrhoea since the birth of the last child, sometimes 30–40 years previously; diagnosis of such patients is usually precipitated by intercurrent illness.

Pituitary apoplexy is caused by pituitary haemorrhage or infarction, often associated with a previously undiagnosed pituitary adenoma. Patients may present with headache, visual loss, symptoms of hypopituitarism and, sometimes, meningism due to the presence of blood in the subarachnoid space; an initial working diagnosis is often meningitis or sub-arachnoid haemorrhage. Surgical decompression is frequently required. Head injury, especially when associated with skull fractures through the pituitary fossa, may also be associated with hypopituitarism, including diabetes insipidus. Congenital developmental disorders, such as septo-optic dysplasia, may also have hypopituitarism as part of a larger syndrome.

Finally, a substantial number of patients with isolated and generalized hypopituitarism have 'idiopathic' disease, with no lesion demonstrable on CT scanning. These presumably represent selective failure of the hypothalamic neurons that secrete the relevant releasing hormone. At least some of these cases may be autoimmune in origin, but more research is required to define their precise aetiology.

Growth hormone deficiency

Growth hormone deficiency most frequently arises in the context of other pituitary diseases discussed above. Isolated, idiopathic GH deficiency is, however, also

relatively common and usually presents with short stature and poor growth in childhood. The most important feature of the management in childhood is accurate measurement of growth and growth velocity, usually followed by assessment of GH reserve if growth is falling away from the third centile on standard charts. Treatment of established GH deficiency is with biosynthetic human GH (somatotrophin).

There are, however, many other causes of short stature in the absence of GH deficiency. These include hypothyroidism, chronic kidney disease, malabsorption, Crohn disease and other inflammatory disorders (which may be otherwise asymptomatic), asthma, congenital heart disease, Turner syndrome and other congenital disorders, and familial short stature. Laboratory investigations clearly have a major role in excluding a number of these possibilities.

Primary growth hormone insensitivity (Laron syndrome) is a rare congenital cause of severe short stature caused by absence or mutation of the GH receptor. Circulating GH concentrations are high and nonsuppressible, in the presence of low or absent circulating IGF-1 concentrations. Therapy with recombinant IGF-1 is possible.

Growth hormone deficiency in adults was previously considered to be of no significance. However, many studies have now shown that treatment of such adults with somatotrophin may improve quality of life, decrease body fat and increase bone density and muscle mass and strength. In the UK, the National Institute for Health and Care Excellence (NICE) have recommended replacement therapy under strictly defined circumstances.

Gonadotrophin deficiency

Gonadotrophin deficiency may present at birth with an undervirilized male, with failure of pubertal development or with loss of previously normal gonadal function. Isolated gonadotrophin deficiency may be idiopathic, but is sometimes familial and associated with anosmia (Kallman syndrome) and sometimes cleft lip or palate.

Treatment of gonadotrophin deficiency is with the relevant gonadal steroids, testosterone or oestrogen, given by mouth, injection, implant or transdermally. If fertility is desired, complex regimens involving gonadotrophin therapy or pulsatile subcutaneous administration of GnRH are required.

Gonadotrophin deficiency is diagnosed by the combination of low plasma gonadal steroid concentrations with low or inappropriately 'normal' concentrations of LH and FSH. However, a large number of other conditions may also produce this biochemical pattern in the absence of organic gonadotrophin deficiency, particularly in the female (see Fig. 18.7).

Interpretation of borderline testosterone concentrations

A common clinical and biochemical dilemma is the interpretation of an isolated testosterone that is near or below the lower end of the reference range (say 7.5–12 nmol/L), with normal gonadotrophins, in the presence of commonly occurring symptoms that might indicate hypogonadism (e.g. low libido or erectile dysfunction). The

FIGURE 18.7 ■ Inter-related conditions causing amenorrhoea and the biochemical picture of low oestradiol without elevation of gonadotrophins.

challenge is to differentiate gonadotrophin deficiency from artefact or from normal outliers, the effects of ageing, obesity and insulin resistance, or other illness.

One of the most common reasons for this pattern is blood sampling in the afternoon or evening, since testosterone concentrations show a significant circadian rhythm. The first approach is therefore to repeat the sample at 09.00h, together with measurement of PRL (since hyperprolactinaemia may suppress LH/FSH and cause this picture). If a low testosterone is confirmed, then it is essential to assess remaining basal pituitary function (see above); measurement of SHBG and calculation of bioavailable testosterone may also assist, although total testosterone seems to be an equally effective measure in all but borderline cases (see Morris et al. in Further reading, below). Magnetic resonance imaging of the pituitary is also usually indicated to exclude a structural lesion.

However, even after such assessments, one is frequently left with a low or borderline testosterone and no other biochemical or radiological evidence of pituitary disease. In this situation, controversy remains: testosterone falls slowly with ageing and some workers (and many pharmaceutical companies) have advocated testosterone replacement for men with borderline testosterone and a wide variety of specific and non-specific symptoms of ill health, while others argue that this represents the normal pattern of ageing and does not require treatment. Long-term outcome studies are still awaited to answer this question. Low testosterone concentrations have also recently been described in patients with cardiac disease, with improvements in general health and cardiac function on replacement, but these data remain preliminary.

Delayed puberty

Prepubertal children have low or undetectable concentrations of testosterone or oestradiol, with low-normal concentrations of gonadotrophins. In the absence of a demonstrable pituitary lesion or other pituitary deficiencies it is, therefore, impossible to differentiate biochemically isolated gonadotrophin deficiency presenting with failure of sexual development from constitutional delayed puberty, the only difference being that the former does not resolve with time.

Constitutional delay of growth and puberty (see also Chapter 21) presents a combined problem of short stature and delayed puberty mimicking combined GH and gonadotrophin deficiency. Such patients, usually male, present in their mid-teens growing poorly, with height below the third centile and with minimal or no signs of pubertal development. The aetiology is unknown, but a family history is common and most patients eventually enter a delayed puberty with a growth spurt to attain normal adult height. Growth hormone reserve, assessed by standard dynamic tests, is usually normal. Treatment, if any, is usually with low doses of appropriate gonadal steroids to slowly advance puberty and initiate a normal growth spurt.

Hypothalamic amenorrhoea

As illustrated in [Figure 18.7](#), a variety of related conditions in the female can lead to amenorrhoea associated with the typical basal biochemistry of gonadotrophin deficiency.

Weight-related amenorrhoea frequently occurs when body weight falls below the normal healthy range for height (BMI 18.5–25 kg/m²). Anorexia nervosa is an extreme example, almost always associated with amenorrhoea and regression of secondary sexual characteristics, but dieting to achieve a weight which is ‘socially acceptably skinny’ can also induce amenorrhoea. Weight gain to a normal weight will usually restore menstruation, but chances of resumption of regular cycles are <10% with a BMI <18 kg/m² and only 50% at a low-normal BMI of 20 kg/m². Low body weight is also an important cause of delayed puberty in both sexes.

A large proportion of international standard competitive athletes develop exercise-related amenorrhoea owing to their intensive training regimens. Non-competitive athletes undertaking excessive exercise may also develop amenorrhoea or delayed puberty, often exacerbated by low body weight. The incidence of amenorrhoea is directly related to the amount of exercise taken, and if exercise is discontinued for any reason, including injury, menstruation usually returns.

Psychological stress is frequently quoted anecdotally as a cause of amenorrhoea, for example in female students attending university for the first time or undertaking examinations. ‘Hypothalamic amenorrhoea’ is a descriptive label applied to such patients and to other cases of amenorrhoea with low oestradiol and gonadotrophins and no identifiable cause, in whom organic gonadotrophin deficiency is felt to be unlikely.

There is no absolute way to differentiate these causes of hypothalamic amenorrhoea from gonadotrophin deficiency, except by their reversibility. If the disorder is mild (e.g. borderline underweight), then a clomifene test (see above) may clinch the diagnosis by inducing a rise in gonadotrophins and subsequent menstruation, but lack of response to clomifene may also occur if the disorder is severe.

If the cause of the amenorrhoea cannot be reversed, then treatment is usually with oestrogen replacement therapy to prevent the long-term effects of oestrogen deficiency.

Other isolated anterior pituitary deficiencies

Isolated ACTH deficiency occurs rarely and can only be diagnosed by full pituitary function testing. The adrenals themselves may be shown to be normal either by the finding of a low plasma ACTH prior to replacement therapy or by a depot (long) tetracosactide test. A proportion of such patients show an ACTH and cortisol response to the CRH test, indicating that the deficit is one of hypothalamic CRH secretion, but this is largely of academic interest.

Isolated TSH deficiency is also a rare occurrence.

Diabetes insipidus

Since vasopressin is synthesized by cell bodies within the hypothalamus and not controlled by the portal venous system, vasopressin deficiency is rarely found in primary pituitary disease, unless treated surgically. Diabetes insipidus is therefore a most unusual presenting symptom of a pituitary adenoma and its presence should suggest that the lesion is either a craniopharyngioma or other rarer type of tumour or inflammatory disease.

Isolated central DI may occur spontaneously. Its aetiology is unknown; some cases may be due to hypothalamic autoimmunity and it may also be familial, presenting in early childhood and typically associated with mutations in the vasopressin-neurophysin-II gene. Diabetes insipidus is discussed further in Chapter 4.

ADRENAL DISEASE

Clinical features of Addison disease

Addison disease implies primary adrenal failure: it is rare, with an incidence of 3–4/million per year and overall prevalence of 40–60/million. The disease involves destruction of the whole adrenals, today most commonly caused by autoimmune adrenal failure; in Addison’s time, tuberculosis of the adrenals was also a common cause and this remains an occasional cause today, as do other infiltrations and tumours involving the adrenals.

In the absence of another acute stressful illness, the symptoms of Addison disease are often vague and non-specific, including tiredness, weight loss, anorexia, depression, abdominal pains, nausea and vomiting and other aches and pains. The rise in plasma ACTH caused by loss of feedback results in increasing pigmentation, classically in palmar creases, scars, pressure areas and buccal mucosa, but which often simply appears as an increased ‘tan’ and is ignored. Patients who are not acutely unwell may often have normal biochemistry unless plasma cortisol concentration is measured.

During acute intercurrent illness including infection, trauma or surgery but especially with vomiting and diarrhoea or other causes of fluid loss, the undiagnosed or untreated patient may become very unwell. Features of an ‘Addisonian crisis’ include dehydration, hypotension, hypoglycaemia and a typical biochemical picture of hyponatraemia, hyperkalaemia and slightly raised plasma urea and creatinine concentrations; untreated this may

proceed to circulatory collapse and death. Treatment is a medical emergency and involves intravenous steroids (hydrocortisone 100 mg i.v. stat, repeated six-hourly), 0.9% saline and 5% dextrose if hypoglycaemic. Ideally, plasma cortisol concentration should be measured on the sample taken prior to steroid treatment, and this alone may be diagnostic if found to be low in the face of severe illness.

Patients commonly have a personal or family history of other autoimmune disease including vitiligo, primary hypothyroidism, hypoparathyroidism, premature ovarian failure, pernicious anaemia and occasionally inflammatory bowel disease. Full blood count, calcium and thyroid function should therefore always be measured both acutely and after steroid replacement (since untreated hypoadrenalism is also associated with hypercalcaemia, elevation of TSH with low free T₄, and macrocytosis, all of which may resolve when appropriate steroid replacement is given).

Congenital adrenal hyperplasia

A gene mutation resulting in deficiency of an enzyme involved in steroid biosynthesis (see Fig. 18.4) will cause inability to secrete adequate circulating cortisol, increased ACTH concentrations and adrenal stimulation due to loss of feedback, and therefore increase in steroid precursors prior to the malfunctioning enzyme. These conditions are described as congenital adrenal hyperplasia (since the adrenal increases in size under ACTH stimulation) and are summarized in Table 18.1. Of the subtypes, only 21-hydroxylase deficiency is at all common.

The diagnosis is typically made in the neonatal period in the context of ambiguous genitalia in females, or evidence of acute hypoadrenalism (including a neonatal 'salt-losing crisis'), but is sometimes delayed and, rarely, occurs at or after puberty in so-called 'late onset' 21-hydroxylase deficiency. Biochemical diagnosis involves demonstration of elevated concentrations of steroid precursors in plasma (17 α -hydroxyprogesterone in the case of 21-hydroxylase deficiency) or in urine by gas chromatography-mass spectrometry (GC-MS). In common forms of the condition, adrenal androgen concentrations are also raised (dehydroepiandrosterone sulphate (DHEAS), androstenedione, testosterone), which causes virilization in the female, but the rarer 17 α -hydroxylase deficiency prevents androgen as well as cortisol synthesis, and causes a female phenotype in genetic males as well as hypertension due to increased mineralocorticoid production.

Treatment is by steroid replacement. A variety of regimens (hydrocortisone, prednisolone and dexamethasone) is used with no hard evidence regarding the best; fludrocortisone replacement is also required in salt-losing types. In 21-hydroxylase deficiency, treatment may be monitored biochemically by measurement of 17 α -hydroxyprogesterone (a low concentration indicating overtreatment) and adrenal androgens (a high concentration indicating undertreatment). In childhood, treatment success is assessed by the close clinical monitoring of growth and puberty in the setting of a specialist paediatric endocrine service.

Assessment of adrenal incidentaloma

The increasing use of CT and MRI scanning of the abdomen in clinical medicine has revealed that small lesions consistent with adenomas in the adrenal are very common. Such incidentally discovered lesions are often described as 'adrenal incidentalomas' and require appropriate investigation to exclude malignancy and excess hormone secretion. The risk of malignancy can be assessed on radiological grounds: evidence of invasion of surrounding tissues, calcification and heterogeneity, and the lipid content of the lesion, which, if high, increases the likelihood of the adenoma being benign. However, the risk of malignancy can also be assessed simply on the basis of size, with most authorities advising removal of lesions >4 cm in diameter. In the absence of obvious clinical features of Cushing syndrome, however, the exclusion of a functioning lesion is primarily biochemical and includes exclusion of pheochromocytoma (by measurement of urine catecholamines) and Conn syndrome (see p. 760), and usually exclusion of subclinical excess cortisol secretion by a formal 48 h low-dose dexamethasone suppression test. Most clinicians would advise excision of a functioning lesion, whereas non-functioning lesions <4 cm in diameter are typically managed conservatively. There is current controversy regarding the significance of 'subclinical Cushing syndrome', which describes incomplete dexamethasone suppression in the absence of frank cushingoid symptoms. Some groups believe that this confers increased cardiovascular risk, while others believe it is a statistical 'fall out' of normal individuals.

MONITORING PITUITARY AND ADRENAL REPLACEMENT THERAPY

The clinical biochemist is often called upon to monitor the adequacy of hormone replacement therapy in pituitary disease. Clinical assessment of adequacy of replacement is imprecise and may, for example, lead to over-replacement with adrenal or thyroid hormones in response to unrelated, vague malaise.

There is no general agreement regarding the most appropriate way to monitor glucocorticoid replacement and it is difficult to validate whatever approach is taken. The authors' practice for a patient taking hydrocortisone (which is cortisol) is to measure plasma cortisol at 09.00 h (having taken the morning dose on rising), at 12.30 h (just before any lunchtime dose) and at 17.30 h (before the evening dose) and to perform a 24 h UFC measurement beginning and ending with the morning replacement dose. The aim of therapy is then to achieve a 24 h UFC within the normal range and 09.00 h cortisol within the 09.00 h normal range (to avoid over-replacement), with neither 12.30 h or 17.30 h cortisol <50 nmol/L (and ideally not <100 nmol/L to avoid under-replacement). Using these criteria, most patients require thrice-daily hydrocortisone dosage, typically 10 mg on rising, 5–10 mg at lunchtime and 5 mg in the early evening, which is consistent with current estimates of normal cortisol secretion rates. Random measurements of plasma cortisol on replacement therapy are of little or no value.

In primary adrenal failure, mineralocorticoid replacement is also required, and adequacy of replacement can be assessed biochemically by measuring lying plasma renin (which is markedly elevated in untreated patients and ideally should be normal on fludrocortisone replacement). Since the renin–angiotensin system is intact in patients with pituitary disease, fludrocortisone replacement, with monitoring of plasma renin, is not necessary.

The aim of levothyroxine replacement in hypopituitarism should be to achieve a plasma free T4 in the middle- or upper-third of the normal range. Measurements of TSH are clearly unhelpful in this context, and a common mistake is to reduce the dose of thyroxine because of the incorrect conclusion that a low TSH indicates over-replacement.

Biochemical assessment of gonadal steroid replacement presents greater difficulty. In a male on testosterone ester depot preparations, plasma testosterone may reasonably be measured a few days after an injection and just prior to the next dose to ensure that adequate concentrations are being achieved. Plasma testosterone measurement is also useful in patients on transdermal or mucoadhesive testosterone preparations. In patients on oral testosterone undecanoate therapy, however, there is preferential conversion of testosterone to dihydrotestosterone, and plasma total testosterone concentrations are frequently below normal despite adequate replacement therapy. In the female, the best approach to therapy is probably to use the endometrium as a natural *in vivo* bioassay for oestrogen and aim simply to achieve regular withdrawal bleeds. It is possible to measure plasma oestradiol in patients receiving oral or transdermal oestradiol replacement, but other oral preparations of modified synthetic or equine oestrogens cannot logically be monitored biochemically.

Desmopressin replacement therapy can be monitored by measurement of plasma osmolality, aiming to maintain a normal osmolality and avoid dehydration or fluid overload. Patients should be instructed to allow the diuresis to resume prior to each treatment dose.

Patients with hypopituitarism and with primary adrenal failure require appropriate information and education about the nature of their replacement therapy and, in particular, the need to increase steroid hormone replacement in the face of intercurrent illness. They should be advised to carry a 'Steroid card' or alert bracelet and ensure that all doctors and dentists who carry out treatment are aware of their condition and the need for increased treatment during stress.

CONCLUSION

In the last decades of the 20th century, clinical neuroendocrinology was revolutionized by the introduction of reliable assays for the relevant pituitary and adrenal hormones. The relationship between endocrinologist and clinical biochemist must remain a close one, since the biochemical investigations to be performed depend closely on the clinical assessment of the patient, while the treatment which the patient will receive is equally dependent on the biochemical results obtained. In this chapter, it is hoped that a logical framework for such a harmonious relationship has been laid down.

APPENDIX 18.1 TEST PROTOCOLS

Assessment of basal pituitary function

A basal 09.00 h blood sample for measurement of:

- cortisol
- free T4
- TSH
- testosterone (male) or oestradiol (female)
- LH, FSH
- prolactin
- IGF-1 in the context of proven pituitary disease (but not simply as a screening test)
- osmolality^a.

^aSimultaneous random urine for osmolality.

(^aAssessment of posterior pituitary function is only required if indicated by the clinical context.)

Insulin stress test

Indications: assessment of ACTH/cortisol and GH reserve. *Contraindications:* ischaemic heart disease, epilepsy or unexplained blackouts, severe longstanding hypoadrenalism.

Precautions: electrocardiograph must be normal, basal 09.00 h cortisol must be >100 nmol/L. Free T4 must be normal.

Procedure: fasting from midnight, *i.v.* cannula, soluble insulin, 0.15 U/kg *i.v.* at 09.00 h. Observe and record signs of hypoglycaemia. Hypoglycaemia only needs to be

reversed with i.v. dextrose if severe and prolonged or with impending or actual loss of consciousness or fits.

Sampling: blood for glucose, cortisol, GH at 0, 30, 45, 60, 90 and 120 min.

Interpretation: blood glucose must fall below 2.2 mmol/L to achieve an adequate hypoglycaemic stress. If adequate hypoglycaemia is not achieved then cortisol or GH deficiency cannot be diagnosed. Untreated hypothyroidism can also give subnormal results.

A normal response is traditionally defined as a rise in plasma cortisol to a peak of ≥ 550 nmol/L (but see comments in text (p. 355) on normal ranges) and a rise in plasma GH to ≥ 7 μ g/L (most normal individuals actually rise to a peak >15 μ g/L). 'Severe GH deficiency' is arbitrarily defined as a GH peak <3 μ g/L.

Patients who show such a normal cortisol response can withstand major surgery without corticosteroid replacement. Patients with responses in the range 400–550 nmol/L may not require regular replacement therapy, but do require cover for major illnesses and surgery. All other patients with subnormal responses require hydrocortisone replacement.

Children with bone age <12 years and GH peak <6.7 μ g/L generally benefit from GH therapy.

Short tetracosactide (synacthen) test

Indication: screening test for adrenocortical insufficiency, including ACTH deficiency.

Procedure: synacthen (tetracosactide) 250 μ g i.v. or i.m. Plasma cortisol before and after 30 min.

Interpretation: plasma cortisol of ≥ 600 nmol/L at 30 min is highly correlated with a normal ACTH response to hypoglycaemia and a normal pituitary-adrenal axis. However, normal responses vary with gender and between commonly used cortisol assays – an appropriate normal range for the assay methodology must, therefore, be used (see p. 355).

Responses >600 nmol/L can be considered normal for almost all assays and circumstances. Peak cortisol responses between 400 and 600 nmol/L may be regarded as equivocal – they require appropriate patient education and may need confirmation by a formal IST (if not contraindicated).

Water deprivation test

Indications: diagnosis of vasopressin deficiency.

Procedure: if mild DI is suspected, the patient should have no fluids from midnight the night before (dry foods allowed). If severe DI is likely, free fluids and a light breakfast should be allowed prior to the test.

Commence test at 09.00h or earlier if practicable. Measure plasma and urine osmolality basally, then hourly until the end of the test (after 8 h or when diagnostic osmolalities achieved). Record all urine volumes passed.

Osmolalities should be measured prospectively as the test proceeds. If this is not possible, weigh the patient every 2 h and arrange for urgent plasma osmolality if body weight falls by more than 3%.

When osmolalities diagnostic of DI have been achieved, give desmopressin 2 μ g i.m., allow free fluids and measure urine osmolality hourly for 2 h.

Interpretation: diabetes insipidus is diagnosed by a rise in plasma osmolality above 300 mmol/kg, without appropriate concentration of urine osmolality (to >600 mmol/kg). Adequate concentration of the urine after desmopressin indicates central, cranial DI and lack of concentration indicates nephrogenic DI.

Normal vasopressin secretion is shown by concentration of the urine to >600 mmol/kg, in the presence of a normal plasma osmolality (280–295 mmol/kg).

Normal concentration of the urine at the expense of elevation of plasma osmolality (>295 mmol/kg) is not a strictly normal response and may indicate mild DI or other subtle defects of thirst, osmoregulation or vasopressin secretion. Further investigations may be indicated.

Failure to concentrate either plasma or urine osmolality by the end of the test is non-diagnostic, but usually represents primary polydipsia. Such patients typically start the test with very dilute urine and often dilute plasma as a result of fluid overload. If clinically indicated, more prolonged water deprivation is required to make the diagnosis.

Glucose tolerance test for the diagnosis of acromegaly

Procedure: fasting from midnight, i.v. cannula, 75 g glucose at time 0.

Sampling: blood glucose and plasma GH at 0, 30, 60, 90, 120 and 150 min.

Normal response: growth hormone suppresses to <1 μ g/L after glucose in normal subjects.

Interpretation: failure of growth hormone to suppress completely after glucose is highly suggestive of acromegaly, even if a substantial fall has occurred.

CRH test

Indications: differential diagnosis of Cushing syndrome.

Differential diagnosis of isolated ACTH deficiency.

Procedure: i.v. cannula, human CRF-41, 100 μ g i.v. at 09.00h.

Notes: in North America it is usual to administer CRH in the evening rather than early morning. Ovine CRF-41 was originally used but is not readily available in the UK. Most patients notice facial flushing after CRH, but there are no other side-effects.

Sampling: plasma cortisol and ACTH at –15, 0, 15, 30, 45, 60, 90 and 120 min.

Normal response: plasma cortisol rises by 25% or more above the basal concentration. The peak response to hCRF-41 in normal individuals is <600 nmol/L (<800 nmol/L with ovine CRF-41).

Interpretation: patients with Cushing disease show a normal or exaggerated response to CRH. Patients with ectopic ACTH-secreting tumours and adrenal tumours show no response (see text).

Responses in ACTH deficiency remain to be defined but a response of plasma ACTH would imply hypothalamic CRH deficiency. Patients with depression show a normal cortisol but reduced ACTH response. Patients with massive obesity show a blunted cortisol response.

SCREENING 401

INTRODUCTION

Thyroid hormones are essential for normal growth, development and metabolism, and their production is tightly regulated through the hypothalamic–pituitary–thyroid axis. Thyroid disease is common, particularly in women, with a prevalence in the community of 3–5%. With the exception of iodine deficiency, which affects millions of people worldwide, diseases that directly

affect the thyroid gland are the most common causes of thyroid dysfunction. Pituitary disease and the use of certain drugs that alter thyroid hormone synthesis or metabolism can also give rise to thyroid dysfunction. Any severe illness can produce abnormalities in the results of thyroid function tests that resolve as the patient's illness improves. Once diagnosed, thyroid disease is usually easily treated, with an excellent long-term outcome for most patients. This chapter outlines thyroid physiology and the

pathways of thyroid hormone synthesis and metabolism. The investigations used in diagnosis and management of thyroid disorders are described, together with guidance on their interpretation. The various thyroid disorders are described together with current views on their treatment.

NORMAL THYROID PHYSIOLOGY

The thyroid gland

The thyroid gland is brownish-red in colour and consists of left and right lobes connected by a midline isthmus, typically forming an 'H' or 'U'. It is located anteriorly in the neck deep to the platysma, sternothyroid and sternohyoid muscles. The isthmus lies just below the cricoid cartilage and the lobes extend upward over the lower half of the thyroid cartilage. The pretracheal fascia encloses the thyroid gland and attaches it to the trachea and larynx. This explains why the thyroid gland is seen to move upwards with swallowing.

The thyroid is a highly vascular organ with blood flow ~ 5 mL/min/g of tissue (nearly twice that of the kidneys). It consists of thousands of follicles, each a spheroidal sac of epithelial cells (thyrocytes) surrounding a lumen containing colloid, mainly comprising thyroglobulin (Fig. 19.1). It also contains parafollicular C cells, which secrete calcitonin; calcitonin is discussed in Chapter 6.

Embryologically, the thyroid is derived from the floor of the pharyngeal cavity and migrates from the base of the tongue to its final position in the neck along the thyroglossal duct. Abnormalities of this migration give

FIGURE 19.1 ■ Structure of the thyroid follicle.

FIGURE 19.2 ■ Structures of the iodothyronines.

rise to ectopic glands that may not function normally. Occasionally, the gland is completely absent.

The primary function of the thyroid is to synthesize and secrete thyroid hormones (Fig. 19.2). Under normal circumstances the gland synthesizes approximately $80 \mu\text{g}$ (110 nmol) of thyroxine (T4) per day and $6 \mu\text{g}$ (10 nmol) of 3,5,3'-tri-iodothyronine (T3).

Biological actions of thyroid hormones

Thyroid hormones produce enhancement of many intracellular events and promote differentiation and growth; they are essential for normal fetal and neonatal development.

Thyroid hormones increase mitochondrial oxidative phosphorylation and maintain amino acid and electrolyte transport into cells. They increase calorogenesis and oxygen consumption in most tissues, though not in brain. Thyroid hormones stimulate the synthesis of proteins, including structural proteins and enzymes. They regulate all aspects of carbohydrate metabolism, including increasing gluconeogenesis and accelerating insulin degradation. Thyrotoxicosis can, therefore, lead to a deterioration of glycaemic control in diabetes mellitus.

Stimulation of lipid metabolism leads to a fall in plasma cholesterol concentration, as degradation is increased to a greater extent than synthesis. Bone turnover is stimulated, resorption more so than mineralization, raising plasma calcium concentration in some patients. In general, the effect of thyroid hormones on the turnover of any substance will depend on the relative effects on synthesis and degradation. The actions of thyroid hormones increase demand for coenzymes and vitamins.

Complex interactions occur with the sympathetic nervous system and many of the signs and symptoms of hyperthyroidism, including palpitations, tremor and

sweating may be attributed to these. For example, thyroid hormones amplify the adrenergic system through the α_1 and β_3 adrenergic receptors and are also the main determinant of basal metabolic rate (BMR). The increase in metabolic rate involves inhibition of AMP-activated protein kinase (AMPK) in the hypothalamus. However, the mechanisms responsible for many interactions between thyroid hormone and the sympathetic nervous system have not been identified.

Most changes in biochemical parameters produced by changes in thyroid status are not sufficiently specific or of such magnitude to be useful as tests of thyroid function, though the association may be sufficiently close that the finding of an abnormality should provoke a request for testing for previously unsuspected thyroid disease. For example, hypothyroidism is a relatively common and easily treatable cause of raised plasma cholesterol; however, the effect on lipids in subclinical hypothyroidism is modest. Equally, it may be helpful (and avoid unnecessary investigations) to anticipate these changes in cases of known thyroid dysfunction and to expect their normalization after treatment of the thyroid disorder. Some examples are listed in [Box 19.1](#).

Synthesis, storage and release of thyroid hormones

Synthesis of T₄ and T₃ occurs on thyroglobulin (Tg), a glycoprotein of molecular weight 660 000 Da that contains many tyrosyl residues. Thyroglobulin is synthesized by the thyrocytes and exported to be stored within the colloid of the follicular lumen. Incorporation of iodide into Tg requires hydrogen peroxide and thyroid peroxidase (TPO), an enzyme that is synthesized within the follicular cell and transported to the apical membrane. Thyroid hormones are synthesized at the interface between the

BOX 19.1 Effects of thyroid hormones on metabolic indices

Parameters increased by hyperthyroidism

- Basal metabolic rate
- Plasma
 - Calcium
 - Sex hormone-binding globulin
 - Angiotensin-converting-enzyme
 - Liver enzymes (alkaline phosphatase, aminotransferases, γ -glutamyl transferase)
- Glucose tolerance tests may show a degree of glucose intolerance

Parameters increased by hypothyroidism

- Plasma
 - Cholesterol
 - Creatine kinase (CK-MM isoenzyme)
 - Creatinine
 - Thyroxine binding globulin
 - Prolactin

Parameters decreased by hypothyroidism

- Plasma sodium

apical membrane of the thyrocyte and the colloid of the follicular lumen.

The process of thyroid hormone synthesis, storage and secretion requires a series of highly regulated steps ([Fig. 19.3](#)).

- *Trapping of iodide.* Iodide from plasma is actively transported by a sodium-iodine symporter situated in the basal membrane of the thyrocyte. This process allows iodide to be actively taken up against a steep concentration gradient. At the apical membrane of the cell, pendrin, a relatively non-specific anion transporter, mediates iodide efflux. The

FIGURE 19.3 ■ Sites of biochemical processes within the follicular cell (thyrocyte).

sodium-iodide symporter is competitively inhibited by anions of similar size to iodide. Perchnetate is also transportable and thus is used for radioactive imaging of the gland. Perchlorate is used to block the uptake of iodide, for example after accidental exposure to radioactive iodide. Thiocyanates (found in certain foods, e.g. cassava) competitively inhibit the iodide pump but are not taken up into the gland.

- *Oxidation of iodide to iodine by thyroid peroxidase.* This occurs on the luminal side of the apical membrane and requires TPO and hydrogen peroxide, which is generated by a calcium-dependent flavoprotein enzyme system situated at the apical membrane.

Recently, the dual oxidase molecules DUOX1 and DUOX2, which contain peroxidase-like and NADPH oxidase-like domains have been identified as essential for H_2O_2 production. They require maturation or activation factors (DUOXA1 or 2) for translocation of DUOX from the endoplasmic reticulum to the apical plasma membrane where H_2O_2 production occurs. Mutations in DUOX2 and DUOXA2 have both recently been identified as causes of hypothyroidism, resulting from diminished H_2O_2 production.

Halogenases collect the iodide removed from thyroglobulin as it is broken down in the cell.

Antithyroid drugs such as propylthiouracil and mercaptoimidazoles (methimazole and carbimazole) exert their action through inhibiting the action of TPO.

- *Incorporation of iodine into tyrosyl residues on thyroglobulin.* Mono-iodotyrosine and di-iodotyrosine (MIT and DIT) are formed through the actions of TPO (organification).
- *Coupling of two iodotyrosyl residues in the thyroglobulin molecule.* This is also catalysed by TPO and produces T3 and T4 that remain linked to Tg. When iodine supply is limited, the proportion of T3 produced on Tg increases. Iodinated Tg is stored in the follicular lumen.
- *Internalization of Tg and release of T4 and T3.* When there is a demand for thyroid hormone, this is signalled by an increase in plasma thyroid stimulating hormone (thyrotrophin; TSH) concentration. Thyroglobulin is then internalized by pinocytosis and appears as colloid droplets that fuse with lysosomes and undergo proteolytic degradation to release T3 and T4. Any MIT and DIT is deiodinated and the iodine conserved.
- *Delivery of T4 and T3 into the circulation.* This is probably achieved by thyroid hormone transporters. The large stores of T4 and T3 incorporated into thyroglobulin allow secretion of T4 and T3 more quickly when required than if it had to be synthesized.

Thyroid stimulating hormone appears to stimulate each of the above processes. It also stimulates the expression of many genes in thyroid tissue including thyroglobulin, sodium iodide symporter (NIS) and interleukin-8. It also causes thyroid hyperplasia and hypertrophy.

Iodine and thyroid hormone synthesis

Iodine deficiency represents a major public health issue for over two billion people who live in areas of iodine deficiency and especially for the 43 million in whom the deficiency is severe enough to cause learning difficulties. The recommended intake of iodine is 150 $\mu\text{g}/\text{day}$ for adults but this may rise to 250 μg during pregnancy and lactation. Iodine is obtained from the ingestion of foods such as seafood, seaweed, kelp, dairy products, some vegetables (e.g. soybeans and potatoes) and iodized salt.

High iodine intakes can induce hypothyroidism, goitre and sometimes hyperthyroidism (see later). A large excess of iodide, when given acutely, results in acute inhibition of thyroid hormone release. It also inhibits the adenylate cyclase response to TSH (see below) and iodination of thyroglobulin; this is termed the Wolff–Chaikoff effect. After a few days of exposure to high iodide concentrations, thyroidal iodide uptake is very low, the intrathyroidal iodide concentration falls and the synthesis of iodinated thyroglobulin recommences. This effect can be used to prepare a thyrotoxic patient for thyroidectomy. However, if high iodine intake persists for more than ten days, then thyrotoxicosis can occur in individuals with a pre-existing multinodular goitre or those from iodine deficient areas; this is termed the Jod–Basedow effect.

Transport of thyroid hormones in blood

When T4 and T3 are secreted into the bloodstream, they become bound to plasma carrier proteins. Three proteins share this function: in order of decreasing affinity for iodothyronines they are thyroxine binding globulin (TBG); thyroxine binding prealbumin (TBPA, also known as transthyretin), and albumin. These binding proteins bind approximately 70% (TBG), 20% (TBPA) and 10% (albumin) of the circulating thyroid hormones. T4 is more tightly bound than T3 to each of these proteins. Approximately 0.02% of T4 and 0.2% of T3 are in the unbound or 'free' form in plasma in normal subjects, so that, although the total molar concentration of T4 is some 50 times that of T3, the concentration of free T4 is only about three times that of free T3. The half-life of T4 is 5–7 days; that of T3 is 1–2 days.

Free hormone hypothesis

For most of their actions, thyroid hormones need to enter the cell and bind to nuclear receptors. The free hormone hypothesis suggests that only the unbound (free) fraction of thyroid hormone is able to cross the plasma membrane and enter the nucleus. This hypothesis is supported by the observation that, in clinical practice, thyroid status correlates better with the concentration of the free hormone fraction than with the protein-bound fraction. The precise function of TBG and TBPA is unclear, but a number of roles have been suggested including acting as a reserve or buffer to prevent rapid changes in free hormone concentration in blood and also to prevent loss of thyroid hormones through filtration and excretion at the kidney. One further hypothesis

is that TBG may be involved in targeting the delivery of thyroid hormone in a differential manner to different organs or facilitating the efflux of thyroid hormones from some tissues. Whatever their function, the absence or overexpression of the transport proteins is not associated with any obvious detrimental effects. There are difficulties in measuring the concentrations of free hormones and this is discussed later in this chapter.

Entry of thyroid hormone into tissues

Specific transporters appear to be required to facilitate the entry of the free thyroid hormones into cells. A number of important thyroid hormone transporters have been characterized. The organic anion transporting polypeptides (OATPs) are one group of important transporters. OATP1C1 appears to be specific for T4 and reverse tri-iodothyronine (3,3′5′-tri-iodothyronine: rT3); it is expressed exclusively in the capillaries of the brain and may be important for T4 transport across the blood–brain barrier. Two L-type amino acid transporters (LAT1 and LAT2) have been identified among the members of the heterodimeric amino acid transporter family, that transport thyroid hormone in many tissues. Human monocarboxylate transporter 8 (MCT8) is another active thyroid hormone transporter. It has a preference for T3 and is expressed in a variety of tissues including the brain, where it appears to be involved in the uptake of T3 by neurons, the primary target for thyroid hormones during brain development. The MCT8 gene is located on the X chromosome and mutations in the gene have been identified in a small number of boys with severe psychomotor retardation and elevated plasma T3 concentration (Allan–Herndon–Dudley syndrome). These mutations result in an inhibition of T3 supply to neurons leading to a defect in brain development. The characteristic pattern of thyroid function tests remains unexplained.

Entry of thyroid hormone into liver cells appears to be ATP-dependent. In rat hepatocytes, it is inhibited by a range of compounds that accumulate in plasma during illness. These compounds include free fatty acids, bilirubin and indoxyl sulphate. The uptake of thyroid hormones by the pituitary appears to occur through a different mechanism from that occurring in the liver. For example, unlike in the liver, the pituitary thyroid hormone transporters are not energy dependent; they can maintain or increase the uptake of T4 and T3 in low energy states and are not inhibited by bilirubin.

Thyroid hormone deiodination and regulation of extrathyroidal T3 production

Thyroxine is produced entirely by the thyroid gland, approximately 80 µg being produced each day. However, only 20% of T3 is produced directly from the thyroid gland; 80% is produced by the extrathyroidal deiodination of T4. Approximately 6 µg of the T3 in blood originates from thyroidal synthesis; 25 µg is formed by 5-deiodination of T4 in extrathyroidal tissues, a reaction catalysed by the D1 and D2 isoenzymes of iodothyronine

deiodinase. T4 is considered to be a prohormone, T3 being responsible for the biological actions of thyroid hormones. Most tissues express one or more of a family of three iodothyronine deiodinases (D1, D2 and D3) that are responsible for providing a local source of T3 from T4 or for providing a source of T3 in plasma. In humans, it has proved difficult to determine which deiodinase and which tissues are responsible for providing most of the circulating T3. Classically it has been thought that D1 in liver and kidney provided most circulating T3, but some studies have suggested that, in humans, D2 may also provide an important source. Genetic association studies may provide more conclusive evidence. To date common genetic variants (single nucleotide polymorphisms) in *DIO1* have been robustly associated with variation in the T3/T4 ratio in serum at genome wide levels of significance ($p = < 1 \times 10^{-8}$), but as yet no associations have been observed with single nucleotide polymorphisms in *DIO2*.

Figure 19.4 summarizes the characteristics of the three deiodinases. All are selenoenzymes requiring adequate intake of dietary selenium for their expression. D1 carries out either 5′-deiodination, giving T3, or 5-deiodination, giving the inactive compound rT3. D2 appears to provide a very important local source of T3 in some tissues, including the brain, pituitary and brown adipose tissue. D3 catalyses the conversion of T4 to rT3 and is thought to be an important extrathyroidal control mechanism to regulate delivery of T3 to its receptors, particularly in the developing fetus.

Catabolism of thyroid hormones

Sulphation, glucuronidation, deamination, oxidative decarboxylation, ether cleavage and deiodination form the main routes for the inactivation and degradation of thyroid hormone. These metabolites are excreted via bile or in urine.

Nuclear action of thyroid hormones

Tri-iodothyronine exerts its effects through interaction with nuclear thyroid hormone receptors (TR) that have a high affinity and high specificity for T3. Nuclear thyroid hormone receptors are a family of ligand-regulated transcription factors that are associated with chromatin. Several α and β isoforms of TR are produced and these usually dimerize with the retinoid X receptors (RXRs). TR α 1 is widely expressed with particularly high expression in cardiac and skeletal muscles, whereas TR β 1 is predominantly expressed in the brain, liver and kidney and TR β 2 is primarily limited to the hypothalamus and the pituitary.

The TR/RXR complex binds to target response elements located in the promoter region of the target genes. The formation of the T3-TR/DNA complex and subsequent recruitment of a variety of transcriptional coactivators leads to activation of the target genes, giving increased mRNA and protein production. In some circumstances, gene expression may be switched off. Mutations in the *TR β* gene lead to a decreased affinity of the receptor for T3, leading to the autosomal dominant clinical syndrome of ‘thyroid hormone resistance’ (discussed later in this chapter).

FIGURE 19.4 ■ Characteristics of the iodothyronine deiodinases. In non-thyroidal illness, 5'-mono-deiodination is impaired leading to a decreased production of T3 and impaired breakdown of rT3. BAT, brown adipose tissue; CNS, central nervous system; (H), human not rat; (R), rat not human; T₂, 3,3'-di-iodothyronine. Control of thyroid hormone synthesis and secretion

Classic feedback regulation

The most important regulator of thyroid homeostasis is TSH. This dimeric peptide hormone comprises a β -subunit, required for binding to the TSH receptor, and an α -subunit. The α -subunit is the same as that of luteinizing hormone, follicle stimulating hormone and human chorionic gonadotrophin. The β -subunit is specific for TSH: both subunits are required for bioactivity. The subunits contain carbohydrate chains that are essential for the biological activity of the molecule. Modifications to these carbohydrate residues occur in different thyroid states, which alter both the bioactivity of the molecule and its plasma half-life. For example, in primary hypothyroidism, TSH has increased bioactivity and an increased plasma retention time, while in secondary hypothyroidism the bioactivity of the molecule is diminished. Most immunoassays are unable to recognize modifications to the carbohydrate chains. There is a circadian rhythm of TSH secretion, plasma concentrations being highest between midnight and 04.00h and lowest at about midday. Thyroid stimulating hormone release also occurs in a pulsatile fashion. These changes in TSH are not reflected in the serum thyroid hormone concentrations.

The production of TSH is controlled by a stimulatory effect of the hypothalamic tripeptide, thyrotrophin releasing hormone (TRH, thyroliberin), mediated by a negative feedback from circulating free T3 and free T4 (Fig. 19.5). Free T3 and free T4 inhibit TSH synthesis and release directly, by inhibiting transcription of the TSH subunit genes and indirectly by inhibiting TRH release. Free T3 and free T4 also decrease TSH glycosylation and therefore its biological activity. It is thought

FIGURE 19.5 ■ The 'classic' hypothalamo-pituitary-thyroid axis. The production of thyroid stimulating hormone (TSH) is controlled by a stimulatory effect of the hypothalamic tripeptide, thyrotrophin releasing hormone (TRH, thyroliberin), mediated by a negative feedback from circulating free T3 and free T4. Thyroid stimulating hormone may also exert autoregulatory fine control on its own production. Dopamine, somatostatin, glucocorticoids, leptin and catecholamines all may have an influence on the axis.

that the hypothalamus, via TRH, sets the level of thyroid hormone production required physiologically, and that the pituitary acts as a 'thyroid-stat' to maintain the level of thyroid hormone production that has been determined by the hypothalamus. Twin studies have shown that in individuals without thyroid disease, TSH and thyroid hormone concentrations are largely genetically determined. The setpoint in an individual is relatively narrow with intraindividual variation being less than half the interindividual variation.

Other mechanisms

The classic feedback regulation of TSH release described above is an oversimplification. Dopamine, somatostatin and glucocorticoids inhibit TSH release, and these agents, together with cytokines, may be important modifiers of plasma TSH, particularly in patients with non-thyroidal illness (NTI) (Fig. 19.6). Leptin and catecholamines regulate TSH indirectly by stimulating TRH production. There is accumulating evidence that TSH can provide autoregulation via a direct action of TSH on the hypothalamus and at the pituitary. In the pituitary, folliculo-stellate cells have been identified that express TSH receptors: interaction of TSH with these cells may produce fine control on TSH release through the release of cytokines, which in turn inhibit TSH release from thyrotrophs. It has been argued that interaction of TSH receptor antibodies with the folliculo-stellate cells explains why patients with Graves disease may continue to have suppressed TSH weeks or months after normal thyroid hormone concentrations have been achieved through carbimazole therapy.

Thyroid stimulating hormone modifies thyroid hormone synthesis by binding to a specific receptor on the surface of the thyrocyte. The TSH receptor is a single protein with a large extracellular amino-terminal domain involved in the binding of TSH, seven transmembrane domains and a short intracellular carboxy-terminal domain involved in the activation of G-protein modulators of the adenylate cyclase-protein kinase-A system. These characteristics are shared with receptors for gonadotrophins: their extracellular domains show some 40% homology, the remainder being more highly conserved. This may explain the weak thyroid-stimulating activity of human chorionic gonadotrophin (hCG). Binding of TSH results in activation of adenylate cyclase and accumulation of cyclic AMP. The calcium and phosphoinositol signalling pathways may also be activated by TSH. After about an hour, an increase in release of thyroid hormones is seen. In the longer term, TSH increases the synthesis of iodinated thyroglobulin and also causes a general increase in the metabolism, size and activity of the follicular cells.

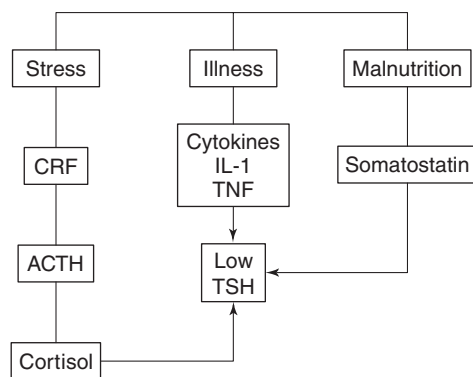

FIGURE 19.6 ■ The hypothalamo-pituitary-thyroid axis in non-thyroidal illness. Dopamine, somatostatin, and glucocorticoids inhibit TSH release, and these agents together with cytokines may be important modifiers of serum TSH, in particular in patients with non-thyroidal illness. ACTH, adrenocorticotrophic hormone; CRF, corticotrophin releasing factor; IL-1, interleukin-1; TNF, tumour necrosis factor.

Extrathyroidal factors that may affect thyroid function

Age

Fetus. Thyroxine and TSH are detectable in fetal plasma at 10–12 weeks of gestation. Plasma concentrations of total and free T₄, total and free T₃ and TBG increase during gestation, total and free T₄ reaching adult concentrations at about 36 weeks, but total and free T₃ reaching only the lower limit of the adult range at this time. The concentration of TSH also increases with gestational age but is within or above the adult reference range throughout gestation. Marked time- and organ-specific changes occur throughout gestation in the expression of the deiodinases, which are thought to coordinate the orderly maturation of enzyme systems responsible for development of the brain and the other organ systems in the fetus.

Neonate. During the first 24 h after birth, there is a rapid, transient increase in the release of TSH, T₃ and T₄ that is considered to be an adaptive response to birth. Thyroid stimulating hormone peaks during the first 30 min, which then stimulates T₃ and T₄ production during the first 24–36 h of postnatal life. This effect may be attenuated in infants delivered prematurely. Screening for congenital hypothyroidism should be carried out after at least three days to avoid spurious results.

Infancy and childhood. Plasma concentrations of TSH are within the adult range but free T₃ is higher than in adults. Free T₄ concentrations tend to be at the lower end of the adult range. This hormone pattern suggests it may arise as a result of increased D1 activity in children. After puberty, no major changes in thyroid function occur, except in the pregnant woman.
