Elderly. In old age, there is little change in thyroid function tests and age-related reference ranges are not required. There is a modest decrease in T₄ secretion but without an accompanying change in circulating T₄. A slight fall in T₃ may occur in those over 80 years of age. In patients on T₄ replacement, the dose of T₄ may have to be decreased with age. There is also increasing evidence that the normal TSH distribution curves appear to be shifted towards higher value ranges in individuals aged over 80. Age-specific analysis of TSH concentrations and anti-thyroid antibody titres measured in the National Health and Nutrition Examination Survey (NHANES) demonstrated that 12% of subjects aged 80 and older without any evidence of underlying autoimmune thyroiditis had TSH concentrations >4.5 mU/L. What is currently unclear is whether higher TSH concentrations confer a survival advantage or simply represent a degree of non-autoimmune age-related thyroid failure.

Pregnancy

In normal pregnancy there is a large increase in plasma TBG concentration that arises from both an oestrogen stimulated increase in synthesis and diminished clearance

of the protein. There is also an increase in the pool size of extrathyroidal T4 distribution and an increase in the deiodination of thyroid hormones in the developing placenta. The result of these changes is that, during pregnancy, there is a marked increase in the requirement for iodine and an approximately 50% increase in T4 production occurs if the supply of iodine is adequate.

In order to maintain homeostasis, an increase in total T4 and total T3 concentrations occurs, which reach a new steady state around mid-gestation. This requirement for increased thyroid hormone production requires an ideal iodine supply during pregnancy of approximately 250 µg/day. Similarly, women with hypothyroidism taking T4 replacement will need an increase in the dose of T4 of approximately 25–50 µg/day during pregnancy within the first six weeks of gestation, aiming for a TSH no higher than 2.5 mU/L. Some centres recommend that women double their pre-pregnancy levothyroxine dose on two days a week as soon as pregnancy is confirmed to reduce the risk of maternal hypothyroidism. Thyroxine replacement should be monitored carefully using both TSH and free T4, since even modest degrees of hypothyroxinaemia in early pregnancy have been associated with an impaired IQ in the infant.

In pregnancy, free T4 and free T3 concentrations may initially show a slight rise, thought to be due to the weak thyroid stimulating action of hCG, present in very high concentration in early pregnancy. This increase in free hormones can lead to suppression of TSH, such that low or sometimes undetectable concentrations may be found in up to 20% of patients during the first trimester. It is important that these changes in early pregnancy are not construed as suggesting that the patient has thyrotoxicosis. As pregnancy progresses, the concentrations of free thyroid hormones fall and TSH begins to rise, although rarely increasing above the reference range seen in non-pregnant subjects. Free thyroid hormone concentration may be lower than those found in non-pregnant women. It is important that trimester-related reference ranges are used for both TSH and free thyroid hormones. Patients can usually return to their pre-pregnancy levothyroxine replacement regimen immediately post-delivery; however, they should be monitored to ensure that this is still the optimal dose.

Hyperemesis gravidarum (severe vomiting in the first trimester of pregnancy) is associated with high plasma total and free thyroid hormone and low TSH concentrations, making it difficult to distinguish this condition from severe true thyrotoxicosis (thyroid crisis). It is believed that hCG is responsible for the thyroid stimulation; the condition usually resolves by the second trimester. Thyroid stimulating hormone receptor antibodies are negative in patients with hyperemesis but positive if the patient has Graves disease.

Thyrotrophin releasing hormone can cross the placenta from mother to fetus, but TSH does not. Thyroid hormones cross the placenta, but this transplacental flux is regulated in part by changes in expression of placental deiodinase as pregnancy progresses. A maternal supply of thyroid hormones (particularly T4) to the fetus is particularly important in the first trimester until a functional fetal thyroid has developed. However, since a fetus with

congenital thyroid deficiency develops relatively normally in utero, this suggests that some maternal-fetal transfer of thyroid hormone must be maintained throughout pregnancy. Iodide and antithyroid drugs also pass to the fetus. Indeed, antithyroid drugs are transferred more readily than thyroid hormone, and for this reason treatment of thyrotoxicosis in pregnancy with a 'block and replace' regimen (high dose antithyroid drugs 'rescued' by simultaneous thyroid hormone replacement) is contraindicated in pregnancy as it would result in a relatively hypothyroid fetus. The treatment of hyperthyroidism in pregnancy requires careful consideration. Radioactive iodine is contraindicated and the choice of antithyroid drug is currently the subject of debate. Propylthiouracil has been traditionally preferred to carbimazole/methimazole owing to fears of scalp and gastro-oesophageal defects in fetuses exposed to carbimazole/methimazole in the first trimester. However, recent concerns have arisen owing to the occurrence of propylthiouracil induced hepatitis, which has occasionally required liver transplantation and rarely has resulted in maternal death. Autoantibodies may cause additional problems in managing patients with hyperthyroidism in pregnancy. In patients with Graves disease, the transplacental passage of thyroid stimulating immunoglobulins may cause transient neonatal thyrotoxicosis, while the presence of anti-TPO antibodies is associated with an increased risk of maternal hypothyroidism and miscarriage.

Non-thyroidal illness

Patients attending or admitted to hospital suffering from any of a wide range of chronic or acute non-thyroidal illnesses (NTI), often have abnormalities in thyroid function tests. A low T3 may often be found even though the patients are clinically euthyroid; this has been termed the *sick euthyroid syndrome*.

Several mechanisms are involved, including:

- alterations in the hypothalamic–pituitary–thyroid axis leading to decreased hypothalamic stores of TRH and suppression of TSH release due to increased concentrations of dopamine, cytokines, cortisol and somatostatin (see Fig. 19.6). While the degree of TSH suppression in NTI is often not as great as that found in hyperthyroidism, there is considerable overlap in TSH concentrations found in the two conditions
- changes in the affinity characteristics and in the plasma concentrations of the thyroid hormone-binding proteins. These changes give rise to alterations in the plasma concentrations of both the free and total thyroid hormones
- impaired uptake of thyroid hormones by the tissues
- decreased production of T3 in the peripheral tissues
- changes in the T3 occupancy and function of the T3 receptors.

The contribution of each of the above mechanisms may vary with the severity and stage of the illness, and thus the pattern of thyroid function tests may be extremely variable and may mimic the profile seen in either primary or secondary thyroid disease. Interpretation of

thyroid function tests is complicated further by the effects of drugs and methodological problems associated with free hormone measurements.

Thyroid hormone metabolism is markedly affected by fasting and illness, with the magnitude of these changes tending to be proportional to the severity of the illness (Fig. 19.7). Extrathyroidal conversion of T₄–T₃ is reduced, leading to a marked decline in plasma total and free T₃, which may fall to undetectable concentrations. Reverse T₃ concentration increases, primarily owing to impaired catabolism rather than increased synthesis. These changes are often considered to be an adaptive response for energy conservation, as rT₃ is not metabolically active. Concentrations of free fatty acids and other substances that can compete with thyroid hormones for binding to plasma proteins may rise. This can produce a transient increase in free T₄. Drugs that compete for T₄ binding sites will have a similar effect. Uptake of thyroid hormone into cells may be impaired, either directly by endogenous inhibitors or indirectly as a result of impairment of the active transport systems of the cells. Finally, administration of corticosteroids or dopamine may suppress TSH release.

Methodological shortcomings render the results of free hormone analysis liable to serious error. Equilibrium dialysis methods usually show a normal or slightly raised free T₄ in patients with illness of mild to moderate severity, but most commercial assays tend to show normal or low free T₄ results in sick patients. Normalization or transient rebound changes of thyroid parameters may be seen during recovery from NTI or refeeding after starvation. In particular, TSH may rise transiently into the hypothyroid range. It should be noted that, although TSH is in general the most reliable test of thyroid function, in hospitalized patients a TSH of <0.1 mU/L is twice as likely to be due to NTI as to hyperthyroidism, and an increased TSH is as likely to be due to recovery from illness as to hypothyroidism. Because of the poor predictive value of thyroid function tests in hospitalized patients, these tests should only be requested if the reason for hospital admission is considered, on clinical grounds, to be related to a thyroid problem. Also, abnormal thyroid function tests during illness may need to be rechecked after the acute illness has resolved.

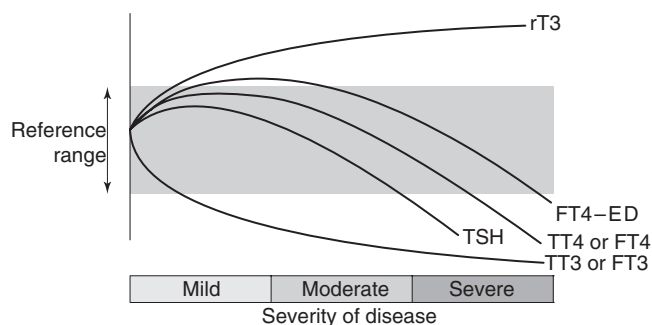

FIGURE 19.7 ■ The effects of illness on the concentration of thyroid hormones and thyrotrophin. The profile for free T₄ obtained using equilibrium dialysis is shown (FT4-ED). The concentration of free T₄ found using routine assays is method dependent, with some assays showing the profile of FT4-ED, while others follow the profile of total T₄ (TT4). Free T₃ (FT3) shows a similar profile to total T₃ (TT3).

While the changes in thyroid hormone metabolism associated with illness might theoretically lead to tissue hypothyroidism, most trials of T₄ and T₃ administration in severe non-thyroidal illness have not shown improved outcome.

Drugs

Drugs may interfere with TSH secretion or the production, secretion, transport and metabolism of thyroid hormones (Table 19.1). Some drugs modify thyroid status while others produce abnormal thyroid function test results in clinically euthyroid subjects. Certain agents (in particular iron preparations) impair the absorption of T₄ from the gut, and patients on thyroxine therapy should be advised to take their T₄ at least 4 h apart from these medications. Patients should also be advised to avoid caffeine within 45 min of taking levothyroxine as caffeine can also impair absorption. Patients taking levothyroxine are likely to require an increase in replacement dose if drugs such as phenytoin or carbamazepine are also prescribed as they increase hepatic metabolism of T₄. Phenytoin, carbamazepine, furosemide and salicylate compete with thyroid hormone binding to plasma binding proteins and may increase plasma free T₄ concentrations. The influence of

TABLE 19.1 Drugs affecting thyroid function

Mechanism	Example of drug
Decrease in TSH secretion	Dopamine, glucocorticoids, octreotide, cytokines
Decrease in thyroid hormone secretion	Lithium, amiodarone, iodide
Increase in thyroid hormone secretion	Lithium, amiodarone (rare), iodide
Decrease in thyroidal synthesis ^a	Carbimazole, propylthiouracil, lithium
Increase in TBG	Oestrogens, tamoxifen, heroin, methadone, clofibrate, raloxifene
Decrease in TBG	Androgens, glucocorticoids, anabolic steroids
Displacement of thyroid hormones from plasma proteins	Furosemide, fenclufenac, salicylates, mefenamic acid, carbamazepine
Increased hepatic metabolism	Phenytoin, carbamazepine, rifampicin, barbiturates
Impaired T ₄ and T ₃ conversion	β-antagonists, amiodarone ^a , radiocontrast dyes, e.g. iopanoic acid
Impaired absorption of thyroxine ^b	Cholestyramine, aluminium hydroxide, ferrous sulphate, calcium salts, sucralfate, soya protein
Altered immunity ^c	Interleukin-1, interferons, tumour necrosis factor-α, interleukin-2

^aCause decrease in thyroid hormone synthesis or secretion and alter thyroid status.

^bInterfere with absorption from GI tract. Patients on T₄ therapy should be advised to take their T₄ at least 4 h apart from these medications.

^cThese cytokines can cause transient hypothyroidism or thyrotoxicosis, the mechanism of which is unclear.

Other drugs listed produce abnormal thyroid function tests but patients remain euthyroid. Amiodarone is the exception (see text).

drugs on modifying free thyroid hormone concentrations may be method specific. For example, depending on the method, free T4 may be measured as being normal, high or low in patients given heparin or taking phenytoin or carbamazepine. Amiodarone, lithium and interferon can induce thyroid dysfunction and are covered in detail later in this chapter.

THE EVALUATION OF THYROID FUNCTION

This section describes the methods that have been developed in order to assess the functional state of the thyroid gland. In most cases, the presenting clinical features will lead to thyroid function tests being performed for confirmation of the provisional diagnosis.

Clinical evaluation of thyroid status

Disordered thyroid function may be detected clinically by demonstrating both changes in the thyroid gland itself and the systemic effects of under- or overproduction of

thyroid hormones. In some instances, the clinical presentation may be virtually diagnostic of a specific condition and investigations are required only for confirmation. In others, the clinical features may be less specific and more thorough investigation is required. The signs and symptoms of thyroid dysfunction are listed in Tables 19.3 and 19.6. The normal thyroid can often be palpated and may also be apparent on inspection of the neck, particularly in young, thin women. Abnormal thyroid enlargements may be diffuse or asymmetrical. As a result of connective tissue attachments to the trachea, thyroid swellings move upwards on swallowing and a similar phenomenon is found with tongue protrusion in the case of thyroglossal cysts. The normal gland has a 'rubbery' feel; in Graves disease and diffuse colloid goitre, the consistency is softer. By contrast, the thyroid in Hashimoto disease is often rather firm, often with a palpable pyramidal lobe. Thyroid carcinoma (anaplastic) and Riedel thyroiditis result in a rock-hard gland that may, in the case of carcinoma, be irregular in outline. Increased blood flow through a hyperactive gland is often associated with a bruit. This may be maximal over the superior thyroidal

TABLE 19.2 Interpretation of thyroid function tests

	TSH low	TSH normal	TSH high
Free T4 low	Severe non-thyroidal illness: repeat test when non-thyroidal illness resolved	Non-thyroidal illness or drugs: repeat tests when non-thyroidal illness resolved	Hypothyroidism: no confirmation needed but look for cause—autoimmune, drugs, congenital etc.
Free T4 normal	Recent treatment for hyperthyroidism Hypopituitarism: other tests of pituitary function abnormal Subclinical hyperthyroidism: free T3 normal; check autoantibodies (antiperoxidase) Over-replacement with T4 Non-thyroidal illness, drugs: free T3 normal or low; only common in hospitalized patients T3-hyperthyroidism: free T3 high; check autoantibodies Treated thyrotoxicosis: free T3 normal or high	Recent treatment for hyperthyroidism Hypopituitarism: other tests of pituitary function abnormal Euthyroid: no confirmation needed. Also applies to adequate T4 replacement	Inadequate T4 replacement Subclinical hypothyroidism: check autoantibodies Inadequate T4 therapy Recovery from non-thyroidal illness; repeat tests after illness fully resolved
Free T4 high	Hyperthyroidism: free T3 usually high; check autoantibodies Over-replacement with T4 Hyperthyroidism with coexistent non-thyroidal illness: total T4 raised, free T3 may be normal; check autoantibodies Hyperemesis gravidarum or very early pregnancy: free T3 normal, sometimes raised; check TSH receptor antibodies to exclude Graves disease Non-thyroidal illness: total T4 usually normal; free T3 usually normal or low	T4 replacement: either erratic compliance with T4 replacement therapy or consistent with adequate replacement in some patients Non-thyroidal illness, drugs Autoantibodies to T4 (and T3): free T3 may be high; test for autoantibodies to thyroid hormones; try a different method for free T4 Genetic albumin variants: try a different method for free T4. Resistance to thyroid hormones: free T3 high; SHBG normal; normal or exaggerated response of TSH to TRH; family studies TSH-secreting tumour: free T3 high; SHBG high; no TSH response to TRH or T3; other tests of pituitary function abnormal; α -subunit increased	Erratic compliance with T4 therapy Resistance to thyroid hormones: free T3 high; normal or exaggerated response of TSH to TRH; family studies TSH-secreting tumour: free T3 high; no response of TSH to TRH or T3

Bold type shows most common diagnoses in each category.

artery rather than the gland itself and, in some cases, may also produce a palpable thrill.

In vitro tests of thyroid activity and pituitary–thyroid status

The tests used to investigate thyroid dysfunction can be grouped into:

- tests that establish whether there is thyroid dysfunction, e.g. serum TSH and thyroid hormone (T4 and T3) measurements
- tests to elucidate the cause of thyroid dysfunction, e.g. thyroid autoantibody and serum thyroglobulin measurements, thyroid enzyme activities, biopsy of the thyroid, ultrasound and isotopic thyroid scanning
- thyroglobulin measurements, which are used to monitor treatment and detect recurrence in patients with follicular or papillary carcinoma.

Measurement of TSH and thyroid hormones should be performed to determine the patient's thyroid status before requesting the additional tests that seek to determine the cause of any thyroid dysfunction.

Measurement of thyroid stimulating hormone

The measurement of TSH in a basal serum sample by a sensitive immunometric assay provides the single most sensitive, specific and reliable test of thyroid status in both overt and subclinical primary thyroid disorders. In primary hypothyroidism, TSH is increased, while in primary hyperthyroidism TSH is usually <0.02 mU/L. However, TSH alone is not a reliable test for detecting thyroid dysfunction arising from hypothalamic–pituitary dysfunction and in other specific instances as outlined below.

Thyroid stimulating hormone is now measured by immunometric assays (IMAs) that utilize non-competitive labelled antibody methods with non-isotopic labels. These IMAs use highly specific monoclonal antibodies raised to epitopes on α - and β -subunits of the TSH molecule. The IMA technique uses a sandwich-assay configuration using two antibodies. The 'functional sensitivity' of a TSH assay defines the minimum concentration of TSH that can be quantified in routine use. To obtain the functional sensitivity of a routine assay, a precision profile is constructed using data obtained over many assay runs with multiple batches of reagent and different operators. The concentration of TSH that has a coefficient of variation of 20% taken from the precision profile defines 'functional sensitivity'. It is essential that TSH assays are sufficiently sensitive for clinical diagnostic purposes and they must have a functional sensitivity of <0.02 mU/L.

Free T4 and free T3 measurements

Theoretical considerations

The plasma concentrations of free thyroid hormones are extremely low and their quantification in the presence of large concentrations of bound hormones has proved challenging. Poor assay design of many free

hormone methods has produced a mass of conflicting literature regarding the typical ranges of free thyroid hormone concentrations in patients with NTI and taking a variety of drugs.

The free hormone concentration results from the equilibrium between the bound (BP) and free hormone.

The proportion of T4 that binds to the binding protein is dictated through the law of mass action by the affinity of the binding protein (K_{eq}) multiplied by its concentration. This is known as the 'relative binding capacity'. Thus, if the affinity or concentration of the binding protein decreases, the proportion of T4 bound will also diminish and the free hormone concentration will increase. In humans, the free T4 fraction is mostly affected by changes in the affinity and concentration of TBG; changes in the affinity and concentration of albumin or transthyretin have little effect on free T4.

Free hormone measurements involve sampling the free hormone fraction. This can be done using physical separation of the free from bound hormone using a semipermeable membrane (equilibrium dialysis or ultrafiltration) or, alternatively, by adding an antibody that 'captures' a proportion of the free hormone pool. The removal of free hormone from the original equilibrium will result in further hormone dissociating from the binding protein to create a new equilibrium. A crucial requirement of any valid method for free hormone measurement is that during the assay process there should be minimal disruption of the original equilibrium, and this can be achieved by minimizing the dilution of the specimen and sampling only a small proportion of the hormone pool. The pH and the ionic composition of any buffer also need to be controlled. The inadequacies of many commercial assays have led to the suggestion that the term *free hormone estimate* is used for all free hormone assays used in clinical practice.

Methods for measuring free thyroid hormones

Equilibrium dialysis and ultrafiltration methods

These are widely regarded as reference methods, although neither is completely satisfactory. The long dialysis period (~12–18 h) used for equilibrium dialysis can, in certain samples (e.g. patients given heparin), lead to the production of non-esterified fatty acids (NEFAs) from triglyceride, which may displace thyroxine from its binding proteins and thus increase the free T4 concentration. A similar increase in free T4 will occur if such patient samples are stored unfrozen prior to analysis.

Validity of commercial methods for free hormone analysis

Routine assays are given a variety of names depending on the methodology used, but all usually involve: (1) adding an antibody to diluted serum to 'capture' a proportion of the free T4 pool and (2) estimating the

unoccupied T4 binding sites on the antibody by adding labelled T4. These commercial assays have additional problems over those of equilibrium dialysis. First, the antibody used will tend to disrupt the original equilibrium, an effect that is dependent on the overall thyroxine binding capacity of the sample and the affinity and concentration of the antibody. Second, the binding capacity of the patient sample may be quite different to that used in the assay calibrators. The overall effect of this is that samples with low binding capacity (NTI, low TBG etc.) tend to have a negative bias introduced, while samples with high binding capacity (high TBG, e.g. pregnancy) may have a positive bias introduced. Many commercial assays include albumin, added in an attempt to reduce non-specific binding and nullify the effects of NEFA on free T4 concentrations. Unfortunately, albumin binds T4 and, if present in sufficient concentrations, will cause significant disruption of the equilibrium. Again, samples with low serum binding capacity will be more prone to this effect than samples with normal or high binding capacities. These various effects explain why free T4 assays may appear to produce low, normal or raised free T4 concentrations in the same sample taken from patients with NTI.

In a true free hormone assay the calculated and measured free hormone concentrations in a set of serially diluted serum samples should be closely approximate. Assays that show a significant reduction in free T4 at these dilutions are likely to produce heavily negatively biased results in patients with low serum binding capacity. Many current commercial assays for free T4 fail these validation tests. The development of free T3 assays has been even more problematic than for free T4.

Nomenclature of free thyroid hormone assays

The names given to free hormone assays include one-step analogue, two-step back-titration and labelled antibody assays. The principles for each of these assays are widely reviewed in the literature but the name given to an assay does not guarantee its validity or performance.

The free T4 and free T3 index methods, that estimate the free hormone concentration in the presence of protein-bound hormone, have now largely been replaced by the direct measurement of free T4 and free T3.

Total T4 and total T3

Plasma concentrations of total T4 and total T3 are measured by immunoassay using diluents that incorporate a chemical agent that releases the thyroid hormones from their binding proteins. In clinical practice, most problems associated with total hormone measurements arise in patients with modified hormone binding capacities that, in turn, may increase or decrease the total hormone concentration. Pregnancy and oestrogen medication give rise to increased concentrations of TBG and thus increases in total T3 and total T4. Some causes of abnormal TBG concentration (and thus, abnormal total thyroid hormones) are given in [Box 19.2](#). Genetic variants of TBG, transthyretin and albumin have been described that have

BOX 19.2 Causes of abnormal plasma thyroid binding globulin (TBG) concentrations

High TBG

- Genetic (hereditary TBG excess X-linked dominant)
- Physiological (pregnancy, neonatal period)
- Hydatidiform mole
- Oestrogens, including oestrogen-containing oral contraceptives, tamoxifen,
- Other drugs, e.g. phenothiazines, opiates, clofibrate
- Hepatitis
- Acute intermittent porphyria

Low TBG

- Genetic
- Androgens
- Protein-losing states, e.g. nephrotic syndrome
- Malnutrition
- Malabsorption
- Severe illness
- Acromegaly
- Cushing disease
- Corticosteroid therapy (high dose)
- Liver disease (chronic)

altered hormone-binding characteristics, which in turn modify the total concentration of thyroid hormones in the circulation. Non-thyroidal illness results in the production of modified TBG with diminished affinity for thyroid hormone. Many drugs may also lower the hormone binding capacity of plasma. Some patients produce autoantibodies to the thyroid hormones that increase the hormone binding capacity of plasma and, in addition, produce marked assay interference.

The use of total hormone measurements is now less popular following the introduction of more reliable methods for free hormone measurements. However, total hormones are still considered to have a role in clarifying thyroid status in some patients with NTI where the results of free thyroid hormone and TSH measurements do not concur.

Selective use of thyroid function tests

Many laboratories measure random TSH as the initial test of thyroid function. This approach is not infallible, but is least likely to produce an abnormal result in NTI and in patients on various forms of drug treatment. It can detect both overt and subclinical disease. A normal TSH concentration effectively excludes *primary* thyroid dysfunction. If an abnormal result is obtained, thyroid hormone measurements are then made to confirm that thyroid dysfunction is present, and to determine the severity of the disease.

Initial measurement of both TSH and free T4 together can provide a more satisfactory method of assessing thyroid status, since in some situations a single TSH result may be misleading. If this strategy is followed, a significant number of cases will arise in which one test is abnormal while the complementary test is normal. It is thus essential to understand and appreciate the factors that can affect the results of thyroid function tests.

Interpreting results of thyroid function tests

Table 19.2 provides a guide to the interpretation of thyroid function tests.

Situations in which TSH usually provides the correct estimate of thyroid status

Overt primary hyperthyroidism. Thyroid stimulating hormone is nearly always $<0.1\text{mU/L}$ and often $<0.02\text{mU/L}$, owing to feedback inhibition on the pituitary. Free and total T4 and T3 concentrations are nearly always increased, but in a very small percentage of hyperthyroid patients, total T4 and free T4 are both normal, whereas both total T3 and free T3 are increased: this condition is known as T3 hyperthyroidism or T3 thyrotoxicosis.

Overt primary hypothyroidism. Thyroid stimulating hormone is invariably increased, often to $>20\text{mU/L}$, as feedback inhibition of the pituitary is diminished, and free T4 and total T4 are low. Free T3 and total T3 measurements are of no value here, since normal concentrations are often observed because of increased peripheral deiodination of T4–T3.

Subclinical thyroid disease. Thyroid disease presents as a spectrum of clinical and biochemical features of varying severity. The clinical diagnosis of mild thyroid disorders is often difficult, and the only biochemical abnormality may be an abnormal serum TSH concentration. For example, many clinically euthyroid patients with multinodular goitre or with exophthalmic Graves disease have a TSH $<0.1\text{mU/L}$, but normal free and total thyroid hormone concentrations. The combination of a low TSH together with normal thyroid hormone concentrations in a patient is known as ‘subclinical hyperthyroidism’, but this description is unsatisfactory, since it rests solely on the results of chemical investigations. Similarly, a diagnosis of ‘subclinical hypothyroidism’ is given to those patients with an increased TSH but normal thyroid hormone concentrations.

Before the diagnosis of subclinical thyroid disease can be made, causes of an abnormal plasma TSH other than thyroid disease must be excluded. These include pregnancy, NTI, drug treatment and assay interference.

Common situations in which TSH results may be misleading

Assay interference from endogenous heterophilic antibodies

Some individuals have antibodies in their plasma that react with a range of animal immunoglobulins (heterophilic antibodies). These antibodies interfere with a wide range of immunoassays. For example, a normal or even elevated TSH result may be found in some thyrotoxic patients owing to this type of assay interference.

Pregnancy

Thyroid stimulating hormone is a reliable indicator of thyroid status in the second and third trimester of

pregnancy, but in the first trimester, a low TSH may be found in up to 20% of women. Thyroid function testing in pregnancy is covered earlier in this chapter.

Secondary thyroid disorders

Thyroid stimulating hormone concentration is normal in about half of patients with central (pituitary) hypothyroidism, and in a few, TSH may be slightly elevated. Circulating TSH has been shown to have reduced bioactivity in central hypothyroidism and thus free T4 and total T4 concentrations are usually low. When pituitary disease is known to be present, TSH concentrations should not be used to assess the thyroid status.

Very rarely, hyperthyroidism is due to a TSH-secreting tumour. Persistent hyperthyroid symptoms associated with elevated free T4 and free T3 but raised or normal TSH are consistent with this diagnosis, once the common problems of assay interference or NTI have been eliminated. Serum α -subunit concentrations are often increased in these patients.

Abnormal pituitary T3 receptor function, due generally to mutations in the thyroid hormone β receptor, can result in disordered thyroid function not reflected by changes in TSH. In this disorder, the thyrotroph is resistant to the normal negative feedback regulation, so that plasma thyroid hormone concentrations are raised in the presence of a normal or raised TSH. Depending on the balance of effects between receptor function in the pituitary and the rest of the body, the patient may be clinically euthyroid, hyperthyroid or even mildly hypothyroid. This condition is termed ‘thyroid hormone resistance’.

Reference ranges and significant changes

By convention, a reference range usually only comprises 95% of values from a reference population; therefore 2.5% of the population will have values above the reference range and 2.5% below. Thyroid hormone concentrations show a normal distribution in reference populations. For TSH, the reference population shows a log normal distribution even when subjects who are thyroid peroxidase (TPO) antibody positive are excluded. Thyroid stimulating hormone reference ranges should be established using specimens collected between 08.00 h and 18.00 h and using 95% confidence limits from log transformed data. The reference population should have no personal or family history of thyroid dysfunction, be on no medication known to alter TSH secretion and have no thyroid antibodies detectable by a sensitive assay. Method-related reference ranges need to be used for all thyroid function tests. Typical adult reference ranges are: TSH 0.3–4.0 mU/L, total T4 60–160 nmol/L, total T3 1.2–2.6 nmol/L, free T4 9–25 pmol/L and free T3 3–8 pmol/L.

In neonates, infants and children, age-related reference ranges are recommended. Trimester-related reference ranges should be available for use in pregnancy.

Knowledge of the analytical variability and estimates of the intra-individual and inter-individual variability allows a calculation of differences in the results of thyroid tests that can be considered as clinically significant

when monitoring serially a patient's response to therapy. These changes may be method dependent but are in the order of:

TSH	0.8 mU/L
Total T4	15 nmol/L
Free T4	6 pmol/L
Total T3	0.6 nmol/L
Free T3	1.5 pmol/L

Miscellaneous tests

Thyrotrophin releasing hormone test

In this dynamic test of pituitary-thyroid function, the TSH response to an intravenous dose of thyrotrophin releasing hormone (TRH) is measured. Formerly, it was used as a test of hypothyroidism when TSH estimates were insensitive (exaggerated TSH response) and as a test of pituitary function. Nowadays it is only occasionally used in the diagnosis of thyroid hormone resistance or TSH-secreting adenoma.

Thyroglobulin

Thyroglobulin (Tg) is normally present in the circulation in very small amounts and, although concentrations may be raised in many thyroid disorders, its measurement (by immunoassay) is essentially reserved for follow-up of patients with thyroid cancer (post total thyroidectomy and radioiodine ablation), in whom elevation of previously suppressed concentrations may indicate tumour recurrence. The measurement of Tg is challenging, as up to 30% of patients with thyroid cancer have antithyroglobulin antibodies in their serum that may interfere with the assay. Rarely, demonstration of suppressed Tg concentration in the presence of raised T4 and T3 is used to diagnose factitious hyperthyroidism due to illicit abuse of thyroid hormone.

The measurement of serum thyroglobulin is also useful in identifying the cause of congenital hypothyroidism as all patients with organification disorders, and those with severe thyroid-stimulating hormone receptor defects, will have raised concentrations when their circulating TSH is increased, except for those with thyroglobulin synthesis defects where the thyroglobulin concentration usually remains low. Thyroglobulin measurements can also provide useful information about the presence of thyroid tissue, for example, if serum thyroglobulin is measurable where there is apparent athyreosis on imaging, this implies that radiologically undetectable hypoplastic thyroid tissue is present.

α -Subunit

The pituitary glycoprotein hormones TSH, follicle stimulating hormone (FSH) and luteinizing hormone (LH) are composed of two subunits, the α -subunit being common to all three hormones and the β -subunit specific to each hormone. The plasma concentration of the α -subunit can be measured by immunoassay, without cross-reaction from complete hormone molecules, and it

may be raised in patients with pituitary tumours. Raised concentrations are also found in some postmenopausal women.

Autoantibodies to thyroidal antigens

Antibodies to thyroid peroxidase (TPOAb)

Originally known as thyroid microsomal antibodies, these antibodies are found in almost all (95%) patients with autoimmune hypothyroidism secondary to Hashimoto thyroiditis early in the course of the disease, and in some patients with other autoimmune thyroid diseases. The antibodies are polyclonal and their target antigen has been identified as the thyroid peroxidase enzyme, which plays critical roles in thyroid hormone synthesis. These antibodies are frequently present in individuals with subclinical hypothyroidism as well as in 2–5% of biochemically euthyroid women (rising to over 10% over the age of 70). The prevalence of these antibodies is lower in men, but also increases with age, being present in 2.5% of the male population aged over 75. They may play a pathogenetic role in some patients with destructive autoimmune thyroid disease, as they have been shown both directly to fix complement on the thyrocyte and to direct cell-mediated cytotoxic reactions against thyrocytes, but in the majority of cases the damage to the thyroid is believed to be T cell rather than antibody mediated.

Knowledge of the presence of this group of antibodies can be of value in several circumstances. The presence of a high titre of TPOAb in the presence of goitrous hypothyroidism is characteristic of Hashimoto disease; they may also be seen in association with the early, transient hyperthyroidism sometimes associated with this condition. In pregnancy, the presence of antithyroid peroxidase antibodies is a significant risk factor for miscarriage, maternal hypothyroidism and the future development of postpartum thyroiditis with disturbed thyroid function. In more general terms, the finding of TPOAb in high titre is indicative of thyroid autoimmunity and may hence be associated with present or future occurrence of other organ-specific autoimmune disease. Patients with ophthalmic Graves disease (eye signs typical of Graves ophthalmopathy but without a present or past history of hyperthyroidism) are often found to have these antibodies, confirming the association with autoimmune thyroid disease despite normal thyroid function. In patients with subclinical hypothyroidism, the presence of TPOAb is an indicator to consider commencing T4 replacement, as such patients are at significant risk of developing overt hypothyroidism in the future (50% will progress to biochemical hypothyroidism over the next 20 years).

Antibodies to thyroglobulin (TgAb)

Antibodies to thyroglobulin are also found in patients with thyroid autoimmunity, but at lower frequency than the TPOAb. These antibodies do not fix complement and are not known to play a direct pathogenetic role in the aetiology of autoimmune thyroid disease in man. The only reason to measure these antibodies is in patients

being treated for follicular or papillary cancer, to indicate possible assay interference in Tg assays. Antibodies to thyroglobulin can interfere with assays for Tg, giving falsely elevated Tg concentrations in radioimmunoassays and falsely decreased concentrations in IMAs. In patients being monitored for differentiated thyroid cancer, a rising titre of TgAb is associated with a poor prognosis.

Antibodies to the thyroid stimulating hormone receptor

The hyperthyroidism of Graves disease is mediated via the effect of IgG class autoantibodies that bind to the TSH receptor and produce an increase in intracellular cyclic AMP concentration. Serum concentrations of such antibodies can be correlated with thyroid gland hyperfunction. Two types of assay system are in use: the first measures the capacity of the autoantibody to inhibit the binding of labelled TSH to its receptor on human thyroid membrane preparations (TSH-binding inhibiting immunoglobulin or TBII), and the second measures the increase in cyclic AMP concentrations in thyroid preparations following stimulation by the patient's IgG (thyroid stimulating antibody or TsAb). During periods of thyroid overactivity, these assays will be positive in 90–95% of patients.

Knowledge of TSH receptor antibody status in patients with Graves disease during pregnancy is of prognostic value: the infants of patients with a high antibody titre during the third trimester have an increased risk of neonatal hyperthyroidism secondary to transplacental passage of maternal autoantibody. Such neonatal hyperthyroidism is transient, settling as maternal antibody disappears from the child's circulation.

Other TSH receptor antibodies ('blocking' antibody), although infrequently demonstrated, can inhibit gland function and lead to hypothyroidism; the predominant effect (stimulation vs blocking) may vary in a single patient with time. However, stimulation is far more commonly found.

Antibodies and ophthalmopathy of Graves disease

The aetiology of the ophthalmopathy of Graves disease, which is present in about a third of patients, is still poorly understood, but current evidence suggests an autoimmune pathogenesis and an association with smoking. Orbital muscle, connective tissue and adipose tissue become infiltrated with lymphocytes and macrophages. The extracellular compartment of the extraocular muscles and orbital fibro-adipose tissue becomes oedematous owing to water deposition caused by production of glycosaminoglycans by orbital fibroblasts and pre-adipocytes. Evidence of autoimmune responses to thyroid antigens is often present in patients with Graves ophthalmopathy. The most promising candidate autoantigen is the TSH receptor that is expressed in orbital connective tissue and in particular orbital fat (pre-adipocytes). It seems most likely that TSH receptor binding antibodies activate orbital fat cells by signaling through this receptor in a way that is subtly different from activation of thyroid

cells, explaining why Graves ophthalmopathy is often, but not always, associated with stimulation of the thyroid gland. A role for activation of the insulin-like growth factor (IGF-1) receptor in orbital fat has also been proposed.

Imaging the thyroid

Standard radiography gives only limited information in the case of thyroid enlargement and is not used routinely. X-ray of the chest may show a superior mediastinal mass in patients who have retrosternal extension of a goitre, and the presence of tracheal deviation with or without narrowing of the lumen may also be noted.

Thyroid ultrasound can demonstrate the type of thyroid enlargement (diffuse or localized) and nature (solid or cystic, single or multiple) of thyroid nodules. It is, however, not possible definitively to exclude malignancy using ultrasound alone and biopsy of the nodule may be required. There is increasing use of ultrasonography to improve the quality of the content of fine needle aspirations of thyroid nodules. Colour-flow Doppler sonography is also increasingly being used to distinguish between type 1 amiodarone-induced thyrotoxicosis (increased uptake) and type 2 amiodarone-induced thyrotoxicosis (decreased/absent uptake); these conditions are covered later in this chapter.

The ability of the thyroid to concentrate radioisotopes of iodine and other substances has been utilized for many years to identify areas within the gland that are or are not functionally active. These imaging systems are of particular value in the evaluation of thyroid nodules, where the presence of nonfunctioning solid tissue is associated with a much higher risk of malignancy. Although subject to important limitations, the level of overall gland activity can also be assessed.

Thyroid scintiscanning

Using intravenous administration of radioisotopes and a scintillation camera, qualitative images of functioning thyroid tissue can be obtained and the proportion of the total dose taken up by the gland can be quantified. Of the available isotopes, ^{99m}Tc , given intravenously as pertechnetate, is concentrated within the gland but not organified into thyroid hormones and therefore diffuses out of the gland with time. This fact, together with its short half-life, means that large doses can be administered without delivering a high radiation dose to the thyroid. The gland is imaged 20 min after injection.

Disadvantages of use of this isotope are that it cannot reliably be used to identify retrosternal glands (as confusion may arise with intravascular radioactivity) and the lack of information regarding iodine organification. The use of radioisotopes of iodine circumvents this latter problem, ^{123}I perhaps being the best isotope to use when imaging thyroid tissue in its normal site as, by comparison with other isotopes of iodine, it delivers a much lower total radiation dose to the gland. Iodine-131, with higher energy and a longer half-life, is useful where deep thyroid tissue is sought or where there is a need to detect, and treat by irradiation, functionally active metastatic thyroid carcinoma.

By quantifying the proportion of the total administered dose of isotope concentrated within the thyroid gland during a given time period, it is possible to estimate the activity of the gland, uptake increasing with increased gland activity and vice versa. However, gland uptake of isotopes of iodine may be critically influenced by many factors other than gland activity (such as dietary iodine content, coincidental administration of iodine-containing drugs such as amiodarone and previous administration of iodine-containing contrast media for radiological investigations) and the results of such uptake studies should be interpreted with caution. Biochemical tests of thyroid function have therefore superseded uptake studies in the measurement of gland activity. However, uptake studies are useful in identifying those patients with hyperthyroidism and a negligible uptake (painless thyroiditis, previous treatment with amiodarone) for whom ^{131}I therapy would be inappropriate.

Perchlorate discharge test

Rarely, hypothyroidism and/or goitre result from defects in enzymes responsible for the organification of iodine into thyroid hormone. In such cases, iodine will be trapped within the thyrocyte but is not organified. Perchlorate, given orally as potassium perchlorate, will cause inhibition of the active transport of iodine across the thyrocyte membrane and hence lead to a loss of non-organified iodine from the gland.

HYPERTHYROIDISM

Clinical features

The clinical symptoms and signs which may result from the hyperthyroid state are summarized in Table 19.3. The clinical picture may be modified by the presence of coexisting systemic diseases and may depend on the age of the patient. Some of the thyroid diseases themselves also produce characteristic physical signs, for example the orbital and cutaneous manifestations of Graves disease. The changes seen in the major organ systems are described below.

Cardiovascular system

Many of the manifestations of hyperthyroidism relate to the increased demands placed upon the cardiovascular system. High circulating concentrations of thyroid hormones have a direct stimulatory effect on cardiac muscle. Heart rate and stroke volume are both increased at rest (including during sleep) and peripheral vascular resistance is reduced, leading to a marked rise in cardiac output in patients who have no pre-existing cardiac disease. Overt cardiac failure may result from this high output state but can also be triggered by the occurrence of arrhythmias. Atrial flutter/fibrillation is seen in over 10% of patients with hyperthyroidism and may be the presenting feature in some cases. Patients who suffer from ischaemic chest pain typically find that angina worsens as a result of the increased metabolic demands placed on the myocardium.

TABLE 19.3 The symptoms and signs of hyperthyroidism

	Common	Uncommon	
Symptoms	Increased irritability	Increase in appetite	
	Increased sweating	Leg swelling	
	Heat intolerance	Menstrual irregularity	
	Palpitation	True diarrhoea	
	Lethargy	Loss of appetite	
	Loss of weight	Weight gain	
	Breathlessness		
	Increased bowel movement		
	Signs	Tachycardia	Palmar erythema
		Goitre	Finger clubbing
Warm, moist peripheries		Splenomegaly	
Tremor		Pretibial myxoedema	
Arrhythmias		Gynaecomastia	
Eye signs			
Proximal myopathy			
Thyroid bruit			
Cardiac failure			
Onycholysis			
Muscular weakness			

Thyroid crisis

Florid hyperthyroidism may result in a life-threatening illness (thyroid 'crisis' or 'storm'). In these – fortunately uncommon – cases, cardiovascular symptoms and signs predominate. Circulatory collapse is characteristic and results from arrhythmia and high output cardiac failure. High output cardiac failure usually occurs in younger individuals with longstanding thyrotoxicosis; despite doubling of the cardiac output, the increase in preload and blood volume in thyrotoxicosis causes a rise in ventricular filling pressure leading to pulmonary and peripheral congestion. Pharmacological attempts to correct abnormal cardiac rhythms are usually unsuccessful in the face of continuing hyperthyroidism. Management aims to control the hyperthyroidism rapidly (using large doses of antithyroid drugs, including iodine) while treating the patient symptomatically. β -Blocking drugs such as propranolol are used, and measures to cool the patient are often needed. Use of steroids under these circumstances may be of additional value.

Gastrointestinal system

Weight loss is a classic feature of hyperthyroidism, often occurring despite an increased appetite. Increases in gastrointestinal motility lead to increased frequency of bowel movement, though true diarrhoea does not usually result. Nausea and vomiting are also uncommon, but may precede the onset of a thyrotoxic crisis. In severe hyperthyroid states, liver function can be markedly deranged, with hypoalbuminaemia and elevation of plasma aminotransferase and alkaline phosphatase activities. Paradoxically, alkaline phosphatase concentrations (of mixed bone and liver origin) can rise further initially after treatment for thyrotoxicosis, settling after 2–3 months.

Central and peripheral nervous system

Generalized hyperkinesia is very often seen in hyperthyroid individuals, frequently being accompanied by emotional lability. A fine tremor of the outstretched fingers is also characteristic. Patients complain of inability to sleep, despite often profound feelings of tiredness.

Locomotor system

Muscular weakness particularly affects proximal muscles. The aetiology of the weakness may be related to impaired phosphorylation of creatine. Muscle biopsy shows loss of type IIb muscle fibres, with replacement by fat and occasional lymphocytic infiltration. These changes reverse when euthyroidism is restored, but muscle power can take several weeks or months to return fully to normal. Periodic paralysis, associated with hypokalaemia during attacks of weakness, is also seen in association with hyperthyroidism, particularly in people of oriental descent. Myasthenia gravis is found in approximately 1% of patients with Graves disease and, similarly, myasthenia sufferers have an increased incidence of Graves disease.

Respiratory system

As part of the generalized myopathy, respiratory muscle function may be impaired and pulmonary compliance may also be reduced. Dyspnoea may result from these changes and breathlessness secondary to cardiac dysfunction may also be exacerbated. All these changes are reversible with appropriate antithyroid therapy.

Skin and hair

With prolonged elevation of thyroid hormone concentrations, diffuse hair loss is common; the nails are brittle and may become elevated from the nail bed (onycholysis). Palmar erythema may be found; the skin itself feels warm and moist due to increased cutaneous blood flow and sweating.

The skeleton

Prolonged hyperthyroidism may result in significant loss of mineral from the skeleton, which results from increased bone turnover, with resorption of bone exceeding accretion. Hypercalciuria and hyperphosphaturia are also found and urinary hydroxyproline excretion is increased, reflecting the increase in collagen turnover. Although hypercalcaemia is commonly found in hyperthyroid individuals, it is usually mild and resolves with effective antithyroid therapy.

The kidneys: mineral and water balance

Hyperthyroid individuals often complain of increased thirst and mild polyuria, even in the absence of hypercalcaemia or hyperglycaemia, and osmoregulation may be disturbed while biochemical hyperthyroidism persists, though this is rarely clinically significant. Plasma sodium and potassium concentrations do not usually alter, but urinary magnesium excretion increases and plasma magnesium concentrations may be low.

Other endocrine systems

In the female hyperthyroid patient, menstrual irregularities occur sometimes, with scanty menstrual loss and/or irregular cycle length. Although cycles usually remain ovulatory, fertility is significantly reduced. In general, plasma concentrations of free sex steroids are reduced as a consequence of increases in binding proteins, but total sex steroid concentrations may be high. Preferential metabolism of androgens to oestrogens may be responsible for the gynaecomastia seen in a small proportion of hyperthyroid males. Hypothalamo-pituitary responsiveness to exogenous gonadotrophins and basal concentrations of LH and FSH are usually normal.

The turnover of cortisol is increased in hyperthyroidism, but basal concentrations remain normal and the response to physiological stress is preserved in the absence of coincidental adrenal or pituitary disease.

Hyperthyroidism in the elderly

Although weight loss is variable, there may be anorexia leading to a clinical suspicion of malignancy. Patients are often tired and withdrawn with reduced mobility due to proximal myopathy, and the term 'apathetic thyrotoxicosis' has been used to describe this presentation. Atrial fibrillation, which may be associated with cardiac failure, is a common presentation in patients over 70 years, especially in those with multinodular goitre, in whom mild hyperthyroidism may have been present for some years. Any co-existing osteoporosis will be accelerated. Elderly patients often present with a single feature of hyperthyroidism (e.g. weight loss, atrial fibrillation) without the other systemic features more commonly seen in younger patients.

Causes of hyperthyroidism

Table 19.4 lists the causes of hyperthyroidism and summarizes their pathogenesis.

Thyroid stimulating hormone measurement demonstrates suppression of TSH concentrations in all cases of hyperthyroidism (except those due to inappropriate pituitary secretion of TSH, as described later). Free T4 is usually elevated in association with raised free T3 concentrations, though true T3 toxicosis (elevation of T3 alone) may be present. Specific diagnostic biochemical and immunological tests are outlined below.

When following the response of hyperthyroidism to treatment, TSH concentrations should be measured, but as it is clear that TSH suppression may persist for a variable period of time after restoration of normal free T4 and T3 concentrations, the measurement of TSH should not be used unsupported to follow response to therapy. The authors recommend that, ideally, concentrations of free T4 and T3 be measured with TSH until TSH secretion returns to normal.

Graves disease

Graves disease, an autoimmune condition of unknown aetiology, is characterized by the presence of diffuse thyroid enlargement, orbital tissue involvement (Graves

TABLE 19.4 The major causes of hyperthyroidism

Cause	Pathogenesis
Graves disease	Hyperthyroidism due to TSH receptor stimulating antibody
Toxic multinodular goitre	Autonomous function in areas of a nodular gland
Toxic nodule	Autonomously functioning nodule
Chronic iodine excess	High thyroidal iodine ± areas of autonomously functioning gland or thyroid stimulating antibody
Thyroiditis	Transient phenomenon resulting from release of stored thyroid hormone from damaged gland
Pituitary tumour secreting TSH	Inappropriate release of TSH stimulating the thyroid
Amiodarone	High iodine content; alteration of thyroid hormone metabolism
Thyrotoxicosis factitia	Exogenous administration of thyroid hormone
Ectopic thyroid tissue	Functionally active and autonomous thyroid tissue present in extrathyroidal tumours
Trophoblastic tumours	Secretion of thyroid stimulator

ophthalmopathy) and, less commonly, skin involvement (pretibial myxoedema and thyroid acropachy) in addition to thyroid dysfunction. The disease predominantly affects females, with a female:male ratio of approximately 6:1, and peak incidence in the fourth and fifth decades. As with other autoimmune diseases, there is clearly an inherited predisposition to develop the disease, although other family members may have hypo- rather than hyperthyroidism. Excess iodine may induce hyperthyroidism in susceptible individuals, and observational studies indicate a relationship between major stress, such as loss of a close relative, and the onset of hyperthyroidism some months later. It is now well established that stress may modify the immune response.

Graves disease is also seen as the immune system recovers after a period of immunosuppression. This occurs in around 3% of patients with HIV disease after initiation of retroviral therapy and up to 15% of patients with multiple sclerosis 9–12 months after treatment with Campath® monoclonal antibody therapy as the T cell compartment repopulates.

Thyroid involvement. In Graves disease, thyroid enlargement (goitre) is typically moderate and diffuse, and the gland has a soft consistency. Because of increased blood flow through the hyperactive gland, a vascular bruit may be heard over the thyroid.

Eyes. Hyperthyroidism produces a characteristic staring expression, with the sclera being seen above and below the iris (lid retraction) and a tendency for the lid movement to lag behind that of the globe as patients look downward from a position of maximum upward gaze (lid lag). These signs may be present in any patient with hyperthyroidism. Additional and specific orbital signs and symptoms may be found in patients with Graves disease (Fig. 19.8). Similar changes may rarely occur with other

FIGURE 19.8 ■ The appearance of a patient with severe Graves ophthalmopathy. Significant proptosis, periorbital swelling, chemosis and conjunctival infection are all present. The dilated left pupil is a consequence of the use of mydriatic eyedrops and not the disease process. (© University Hospital of Wales, Heath Park, Cardiff Medical Illustration Dept).

TABLE 19.5 The eye signs found in thyrotoxicosis

Sign	Examination finding
Proptosis ^a	Forward protrusion of the globe
Lid retraction	Sclera visible above/below iris
Lid lag	Lid movement lags behind that of globe
Ophthalmoplegia ^a	Failure of full ocular movement often producing diplopia
Chemosis ^a	Oedema of conjunctival sac
Periorbital oedema ^a	Oedema and prolapsed orbital fat present around eye
Conjunctival infection ^a	Inflammatory response
Visible ocular muscle ^a	Enlarged extraocular muscle visible anteriorly
Loss of vision ^a	Compressive optic neuropathy or corneal exposure with scarring
Ptosis (rarely)	Drooping of upper eyelid

^aEye signs specific to Graves disease rather than thyrotoxicosis.

autoimmune thyroid diseases such as Hashimoto thyroiditis and are listed in Table 19.5. Patients with Graves ophthalmopathy should be managed in a multidisciplinary eye clinic with the joint input of ophthalmologists and endocrinologists.

Skin. Patients with Graves disease may sometimes develop indurated purple skin lesions, classically over the anterior tibia. These areas (pretibial myxoedema) contain large amounts of glycosaminoglycans and tend to be seen in patients with high concentrations of thyroid stimulating antibody and ophthalmopathy. Acropachy (similar to clubbing) is a recognized but rare feature of Graves disease.

Diagnosis. The diagnosis of Graves disease is not difficult when the typical triad of hyperthyroidism, goitre and extrathyroidal involvement is present. The diagnosis may be made in other circumstances by demonstrating the presence of thyroid stimulating antibody and is supported by the finding of diffuse, increased uptake of radioisotope on thyroid scintiscanning (see Figure 19.9A).

FIGURE 19.9 ■ Isotope scans of patients with various thyroid disorders. The figure shows ^{99m}Tc scan images of (A) Graves disease showing characteristic diffuse uptake of isotope; (B) multinodular goitre with patchy uptake of isotope and inadequate activity in relation to the autonomously functioning nodules; (C) toxic adenoma causing 'T3 thyrotoxicosis'. The suppressed TSH secretion leads to atrophy of the normal thyroid tissue, which recovers following removal of the adenoma by surgery or ^{131}I ablation; (D) a 'cold nodule' with reduced uptake in relation to the rest of the gland. Fine needle aspiration revealed papillary carcinoma confirmed histologically following thyroidectomy.

Natural history. The natural history of the hyperthyroidism of Graves disease is that of successive relapse and remission over many years in the majority of patients. In about 30% there is a single episode of hyperthyroidism, lasting several months, followed by prolonged remission and even the eventual development of hypothyroidism 10–20 years later. Unfortunately, it is not possible at first presentation to identify which patients are destined to have a single episode. The antithyroid drugs, which do not influence the natural history of Graves disease, are given for an empirical period of 9–18 months, thereby identifying the 'single episode' patient and avoiding the use of destructive therapy.

Treatment. There are three forms of treatment of the hyperthyroidism of Graves disease: antithyroid drugs, surgery and ^{131}I . Each is effective but none is perfect. Medical therapy with antithyroid drugs offers the only chance of lasting remission without resulting in permanent hypothyroidism. However, medical treatment is required for at least 9–18 months in most instances and overall success rates are <50%. Surgery or radioactive iodine therapy provide rapid control of hyperthyroidism, but incur the need for lifelong thyroid hormone replacement. Radioiodine treatment with ^{131}I may be associated with a rise in thyroid stimulating antibody concentrations and a worsening of ophthalmopathy and is absolutely contraindicated in pregnancy or the puerperium. Surgery is generally safe and effective, but carries the risks associated with anaesthesia and can be complicated by vocal cord damage or transient or permanent hypoparathyroidism. These complications are, however, minimized in the hands of an experienced surgeon.

The antithyroid drugs carbimazole (and its active form methimazole) and propylthiouracil exert their action principally by inhibiting the action of thyroid peroxidase and, therefore, thyroid hormone synthesis. Treatment is given for 9–18 months. Shorter treatment periods are associated with higher relapse rates, but treatment periods extending beyond 18 months carry no advantage. The antithyroid drugs can be given either in titrated doses or as part of a 'block and replace' regimen using both carbimazole and thyroxine. Both approaches are equally effective but the block and replace regimen, although generally resulting

in more stable thyroid function and a reduced frequency of follow-up visits for dose titration, may be associated with slightly more side-effects than the titration. Lasting remission is only achieved in 30–40% of cases: adverse prognostic indicators include younger age, male gender, high pretreatment concentrations of T3, the presence of a large goitre and persistence of TSH receptor antibody at the end of the planned treatment period. As the drugs do not affect release of thyroid hormone from the gland, there is typically a delay of 4–8 weeks before euthyroidism is restored. Although persistently raised TSH receptor antibody concentrations at the end of therapy are associated with an increased risk of relapse, they are not sufficiently predictive to be of value in guiding clinical decision-making and testing is currently recommended only for diagnostic and not for prognostic purposes.

Symptomatic relief can be obtained in nearly all patients by also using β -blocking drugs for these first few weeks of therapy in order to reduce their tremor and tachycardia. In pregnant thyrotoxic patients, careful monitoring is required in order to keep the dose of antithyroid drugs to a minimum, especially during the last trimester, as these compounds cross the placenta and may render the fetus hypothyroid. 'Block and replace' treatment should not be used as T4 crosses the placenta only poorly. It is generally recommended to maintain free T4 and free T3 concentrations in the high-normal range to ensure sufficient transfer of thyroid hormones to the fetus to counter the effects of transplacental passage of the antithyroid drugs.

Iodine-131 can be used therapeutically to treat hyperthyroidism due to Graves and other thyroid disorders. Radioiodine works initially by interfering with organification of iodine, but later predominantly inhibits replication of thyrocytes, by inducing radiation damage in the gland and hence controlling thyroid overactivity, after a delay of weeks or months. The major side-effect of this form of therapy is long-term hypothyroidism, with up to 80% of patients becoming hypothyroid within the first year, if a standard dose of 400 MBq is used. In some individuals, there is a transient rise in thyroid hormone concentrations in the first few weeks after radioiodine before they begin to fall. In patients with Graves disease, the appearance or worsening of thyroid

eye disease may occur, and in patients with active eye disease it is recommended that radioiodine is avoided and/or steroid prophylaxis for 6–8 weeks is given (e.g. prednisolone 20 mg reducing by 5 mg every two weeks). Graves ophthalmopathy is associated with smoking and cessation should be advised, particularly prior to radioiodine treatment. There is no evidence of an increase in the risk of malignancy following therapeutic doses of radioiodine. The dose should be repeated if hyperthyroidism persists after six months. Note that transient hypothyroidism at three months is occasionally seen with return of thyrotoxicosis by six months following radioiodine requiring repeat therapy.

Thyroidectomy is a highly effective treatment for Graves disease. Patients should be rendered euthyroid prior to operation using antithyroid drugs. In some centres, the drug is stopped for two weeks prior to surgery and potassium iodide substituted; this reduces the size and vascularity of the gland and makes surgery technically easier. To avoid the risk of relapse and the requirement for repeat surgery, near-total thyroidectomy (rather than subtotal thyroidectomy) is now routinely performed for thyrotoxicosis, rendering all patients hypothyroid post-operatively, and treatment with thyroid hormone is routinely administered immediately post surgery.

Treatment of Graves ophthalmopathy. A third of patients with Graves disease have thyroid eye involvement; sight loss is rare but may occur if untreated in 3–5% of patients. In addition, most patients have impaired quality of life and suffer significant psychological distress due to the disfiguring appearance of the eyes. In its classic form thyroid eye disease is easily recognizable. However, some patients suffer with eye disease for months to years before a diagnosis, which may be missed in patients without eye symptoms, patients with unilateral eye disease or patients who are euthyroid at presentation since orbitopathy may precede or post-date the development of hyperthyroidism. General management measures include smoking cessation and maintenance of normal thyroid status. Radioiodine therapy is best avoided in patients with moderate to severe eye disease (see above) but may be administered with glucocorticoid cover in mild cases. Local measures, e.g. lubricants, ointments and corrective prisms, will be adequate for mild disease. Glucocorticoids are first-line therapy in active moderate to severe disease. Other treatments that have been tried include ciclosporin, methotrexate, intravenous immunoglobulins, orbital radiotherapy, and the B cell depleting agent, rituximab. Selenium is an antioxidant with a non-specific anti-inflammatory effect that has been shown to reduce symptoms in mild Graves ophthalmopathy.

Toxic multinodular goitre

Hyperthyroidism arising in a previously multinodular goitre occurs in an older population than that affected by Graves disease; patients are typically over the age of 50, with females being affected more than males.

Clinical features. The cardiovascular features of hyperthyroidism tend to be prominent in this, often elderly,

group of patients, though all the features of hyperthyroidism mentioned earlier may occur. The goitre itself is classically nodular and may be large, often having been present for many years prior to the onset of thyroid dysfunction.

Diagnosis. The biochemical diagnosis of hyperthyroidism in this situation is fairly straightforward, with suppression of TSH, though thyroid hormone concentrations may not be grossly elevated, in some cases lying at the upper limit of normal. Thyroid autoantibodies are not usually present. Thyroid scintiscanning shows a patchy uptake of isotope, with multiple hot and cold areas being seen throughout the gland (Fig. 19.9B). Radioiodine uptake values may lie at or above the upper limit of normal, but are not usually grossly elevated, and thyroid ultrasound can be used to confirm the multinodular nature of the gland.

Treatment. In general, radioiodine is the treatment of choice for the patient with toxic multinodular goitre as relapse invariably occurs after withdrawal of antithyroid drug therapy. Antithyroid drugs can be used until radioiodine becomes effective. Where compressive symptoms result from gland enlargement, surgery should be used in place of radioiodine.

Toxic adenoma

Isolated, autonomously functioning adenomas within the thyroid account for 5% of cases of hyperthyroidism. Half of these patients have 'T3-thyrotoxicosis' and the resulting clinical hyperthyroidism is usually mild.

Diagnosis. Scintiscans of the gland in cases of toxic adenoma show an area of high uptake in the region of the nodule, with suppression of uptake in the remaining, normally responsive, areas of the gland (Fig. 19.9C).

Treatment. Patients with proven toxic adenoma may be treated successfully either with radioiodine, which is concentrated by the hyper-functioning adenoma, or by surgery. Radioiodine is usually the treatment of choice and post ¹³¹I hypothyroidism is less common than with Graves disease.

Thyroid stimulating hormone-secreting pituitary tumour

Very rarely, adenomas of the pituitary gland secreting TSH (TSHomas) may produce hyperthyroidism.

Diagnosis. The biochemical key to making this diagnosis is the persistence of TSH secretion despite definite overproduction of thyroid hormones. The differential diagnoses are thyroid hormone resistance (see p. 400), drugs (amiodarone/amphetamine), and acute psychotic illness. Interference with one or other of the thyroid function assays should always be excluded, for example by repeating the tests on another assay platform. In TSHomas, high circulating concentrations of the α -subunit of TSH may be found in the serum, TSH secretion is not increased by

the administration of TRH and a goitre is present in the absence of immunological evidence of thyroid autoimmunity. Pituitary MRI or CT imaging should be performed, but not before the biochemical diagnosis is established, as the lesion may be too small to visualize and because incidental non-functioning microadenomas of the pituitary are common. If large, the pituitary lesion may produce local damage, with reduction or loss of secretion of other anterior pituitary hormone and impairment of the visual fields. TSH secreting pituitary adenomas may co-secrete other anterior pituitary products such as prolactin and growth hormone.

Treatment. Treatment consists of surgical removal of the tumour or, alternatively, pharmacological reduction of TSH secretion. The long-acting somatostatin analogue octreotide has been reported to reduce TSH secretion and tumour size in individual cases and dopaminergic agonists such as bromocriptine and cabergoline may also be effective. Ablative antithyroid therapy will lead to control of hyperthyroidism, but will not deal with the primary problem and is, therefore, not generally indicated.

Other causes of hyperthyroidism

In some of the areas discussed below, the term 'hyperthyroidism' is strictly not applicable, as the elevation of thyroid hormones derives from extrathyroidal sources. However, for continuity, this term will be used to represent states of clinical and biochemical thyroid hormone excess.

Iodine. In individuals with goitre due to previous iodine deficiency, chronic administration of excess iodine in the diet can induce a hyperthyroid state. This phenomenon (sometimes called the Jod-Basedow phenomenon) is particularly likely to occur in patients who already have a degree of pre-existing thyroid autonomy, expression of which may have been masked by the lack of iodine. In iodine-replete areas, a similar phenomenon may be seen, especially in individuals with a multinodular goitre and in some cases the hyperthyroidism reverses completely when the source of additional iodine is withdrawn from the diet. The precise relationship between iodine dose and thyroid response is clearly complex, since it is dependent not only on the individual's prior exposure to iodine and the degree of gland autonomy, but also on the time course of iodine administration; use of large doses of iodine as a therapeutic means of rapidly treating hyperthyroidism has quite the opposite of the effect seen with chronic administration of more moderate doses. In iodine-induced hyperthyroidism, radioiodine uptake is characteristically reduced and urinary iodine excretion increased, with coincident TSH suppression and evidence of elevated T4 and elevated or high normal T3 concentrations.

Amiodarone. This anti-arrhythmic drug contains iodine and, at therapeutic dosage, generates 6–12 mg of free iodine per day compared with the recommended iodine intake of 0.2 mg/day. The drug can produce abnormalities in thyroid function tests in up to 50% of patients, but may also induce true thyroid dysfunction. Amiodarone has a

structure similar to that of thyroid hormones and inhibits the peripheral conversion of T4 to T3 catalysed by iodothyronine deiodinase D1. Resulting concentrations of T4 may, therefore, be high and T3 low, with an increase in rT3. Thyroid stimulating hormone may rise transiently during the first few weeks of treatment, but by four months, most patients who are euthyroid will have normal or sometimes suppressed concentrations of TSH. The drug inhibits both iodine uptake by the thyroid and entry of T4 into cells and can also cause both iodine-induced hypothyroidism and hyperthyroidism. The frequency of these two conditions depends on the ambient iodine intake. In areas of high iodine intake (e.g. Worcester, USA), amiodarone produces hypothyroidism in up to 20% of patients receiving the drug, while hyperthyroidism only occurs in about 2% of patients. Conversely, in areas of Italy, where iodine intake is low, hypothyroidism occurs in 5% of patients and hyperthyroidism in 10%. In patients with an underlying thyroid abnormality (e.g. multinodular goitre or subclinical Graves disease), the high iodine content can induce thyrotoxicosis (amiodarone-induced thyrotoxicosis type I) that is treatable with antithyroid drugs), but the drug may also induce a destructive thyroiditis (amiodarone-induced thyrotoxicosis type II) that is not readily responsive to antithyroid drugs, but is often responsive to steroids. A mixed picture is also seen, and occasionally urgent thyroidectomy is required for thyrotoxicosis refractory to both forms of therapy. It is therefore important to evaluate patients before they commence therapy with amiodarone. This should include clinical examination and a basal measurement of TSH, free T4, free T3 and TPOAb. After starting treatment, thyroid function tests should be repeated at six months and thereafter every six months, including the year after the drug is stopped. The long half-life of the drug means that changes in thyroid test results may persist for some time after ceasing therapy.

Thyrotoxicosis factitia. Cases of hyperthyroidism occur due to self-administration of thyroid hormone, taken either as T3 or T4. Radioiodine uptake is low, goitre is absent and thyroglobulin concentrations are low. Unless there is a prior history of thyroid autoimmunity, thyroid-directed antibodies will be absent. Thyroid stimulating hormone will be undetectable; total and free T4 concentrations will be high if the patient is taking T4 and suppressed if the patient is taking T3, and total and free T3 concentrations will be high in both cases. Careful supervision of patients with serial measurement of thyroid function in hospital may be necessary, and specific psychological assessment and counselling may be required after the diagnosis has been made.

Ectopic thyroid tissue. Metastatic thyroid follicular carcinoma may rarely produce sufficient thyroid hormone to result in hyperthyroidism. Other tumours, such as ovarian teratomata, may contain functional thyroid tissue in sufficient quantity to produce symptoms and signs of thyrotoxicosis (struma ovarii): endogenous thyroid radioisotope uptake will be suppressed and functioning tissue demonstrable in the tumour under these most uncommon circumstances.

BOX 19.3 Indications for treatment in patients with subclinical hyperthyroidism

- Cardiac arrhythmias
- Congestive cardiac failure
- Osteoporosis
- Presence of hyperthyroid symptoms
- Goitre
- Pregnancy
- Infertility

Other thyroid stimulators. Trophoblastic tumours such as choriocarcinoma, hydatidiform mole and metastatic embryonal testicular carcinoma may secrete human chorionic gonadotrophin (hCG) and produce hyperthyroidism.

Subclinical hyperthyroidism. This term is used to describe patients with the biochemical picture of suppressed serum TSH but normal concentrations of T3 and T4. Subclinical hyperthyroidism is present in about 0.5–3.0% of the population and rises in prevalence with age. Most patients are asymptomatic and revert to normal thyroid status over time. However, a small proportion of patients (1–5% per annum) will progress to overt hyperthyroidism (suppressed TSH and elevated T3 and T4). Patients with a fully suppressed TSH concentration (<0.01 mU/L) are more likely to progress to overt hyperthyroidism than those with partial TSH suppression (TSH 0.1–0.4 mU/L). Patients with subclinical hyperthyroidism are at increased risk of atrial fibrillation and osteoporosis and, once persistent abnormal thyroid function over a period of six months is confirmed, treatment may be indicated to prevent these complications. Other indications for treatment are listed in [Box 19.3](#). Radioiodine is generally used as the underlying aetiology is almost always nodular thyroid disease, although this form of treatment is contraindicated in pregnancy.

Hyperthyroidism or non-thyroidal illness?

It may be difficult to determine whether the finding of suppressed serum TSH and raised free T4 are due to non-thyroidal illness (NTI) or hyperthyroidism, especially if the serum T3 concentration is in the upper part of its reference range. A raised total T4 is uncommon in NTI. Furthermore, features such as ophthalmopathy, goitre or unexplained atrial fibrillation will favour hyperthyroidism. In the absence of these clinical signs, measurement of the TSH receptor antibody and isotope imaging may be helpful in detecting Graves disease and nodular goitre. If there still remains doubt, repeat thyroid function testing after 3–6 months is indicated.

HYPOTHYROIDISM

Clinical features

The clinical features seen as a consequence of low circulating concentrations of thyroid hormone are summarized in [Table 19.6](#).

TABLE 19.6 The symptoms and signs of hypothyroidism

	Common	Uncommon
Symptoms	Lethargy Skin dry and coarse Slow speech and mentation Facial puffiness (oedema) Cold intolerance Pallor Hoarse voice Constipation Weight gain Hair dry and falling out Weakness/stiffness Breathlessness	Anorexia Irritability Menorrhagia Angina Deafness Poor coordination
Signs	Periorbital/facial oedema Pale, dry skin Goitre Obtunded mental state Cool peripheries Diffuse alopecia Bradycardia Median nerve compression Delayed relaxation phase of reflexes	Psychosis Pleural/pericardial effusions Ascites Cerebellar ataxia Galactorrhoea Hydrocoele (males)

Cardiovascular system

A reduction in resting cardiac output occurs. Cool peripheries are characteristic, owing to a reduction in cutaneous blood flow, which contributes to the intolerance to cold that is so often present. In the thorax, cardiac dilatation may be seen on chest X-ray and occurs in association with pericardial effusion, which occasionally leads to compromised myocardial function. Ischaemic chest pain is uncommon, more frequently being seen in hypothyroid patients with coincidental ischaemic heart disease when they first receive thyroid hormone replacement therapy. The cardiac changes reverse with appropriate thyroid replacement therapy.

Gastrointestinal system

Most individuals show a moderate weight gain despite reduced appetite, due primarily to fluid retention. Intestinal absorption of nutrients may be affected both by reduced absorption rates and increased intestinal transit time, but net absorption may actually be reduced, normal or even increased. Results of biochemical liver function tests are usually normal.

Central and peripheral nervous system

Deficiency of thyroid hormones in fetal or early neonatal life, if not promptly treated, results in irreversible damage to the CNS, with structural abnormalities evident on histological examination. The classic picture of congenital hypothyroidism is fortunately only rarely seen now,

due largely to the introduction of neonatal screening for hypothyroidism and the efficacy of therapy, if introduced sufficiently early in life.

In adult life, neurological defects resulting from hypothyroidism are usually reversible. The characteristic features are of generalized slowing in intellectual function, with inanition, slow mentation, somnolence, and occasionally, a frankly psychotic state. Speech becomes slow and the voice coarse and gruff in nature, the latter in part due to oedema within the vocal apparatus. Cerebellar ataxia may be seen with prolonged hypothyroidism and may become irreversible with delay in treatment. Seizures may also occur in severe cases. Peripheral nervous system manifestations are also common, with compression of the median nerve at the wrist being perhaps the best known (carpal tunnel syndrome). Relaxation of the tendon jerks is characteristically delayed.

Locomotor system

Muscular stiffness is a particularly common complaint in hypothyroidism and relates to reduced relaxation rate. The muscles show abnormal structure on microscopy, with loss of striations, oedema, swelling of fibres and relative deficiency of type II fibres. Muscular weakness is often evident clinically and plasma activities of muscle enzymes such as creatine kinase may be raised.

Respiratory system

Similar changes to those described above may occur in the respiratory muscles, with abnormal muscle function leading, in patients with pre-existing lung disease, to exacerbation of any carbon dioxide retention and sleep apnoea. Chest X-ray may show pleural effusions, though these are seldom large.

Skin and hair

Increased water binding occurs as a result of deposition of mucopolysaccharides in the skin, in common with the other tissues. The indurated oedema that results gives rise to the 'myxoedematous' appearance of the typical hypothyroid patient. Associated anaemia and hypercarotenaemia through impaired conversion of β -carotene into retinol may render the skin pale or yellow, respectively. Body hair tends to be easily lost, though the classic description of loss of the outer-third of the eyebrows is rarely seen today.

The skeleton

Thyroid hormone deficiency in early life leads to abnormalities of the epiphyses with marked reduction in linear growth and stunted final height. Short stature may be an apparently isolated presentation of hypothyroidism in childhood. In common with all systemic illnesses, prolonged hypothyroidism in childhood leads to retardation of bone age compared with chronological age. Rates of bone turnover are reduced, leading to a reduction in the pool of exchangeable calcium. Plasma

concentrations of calcium and phosphate remain normal. Alkaline phosphatase activity tends to be low in children with hypothyroidism.

The kidneys: mineral and water balance

Renal blood flow and glomerular filtration are both decreased, but total body water has been shown to increase with hypothyroidism, owing to impaired renal excretion of water that itself results from a reduction in delivery to the distal tubule and abnormal osmoregulatory function in the hypothalamus and posterior pituitary. Although exchangeable body sodium is increased, the dilutional effect typically leads to a mild hyponatraemia. Plasma creatinine and urea concentrations remain normal.

Reproductive system

In adults of both sexes, hypothyroidism leads to a reduction in libido and subfertility. Menorrhagia due to failed progesterone secretion with anovulatory cycles is common in the female, as is oligospermia in the male. These changes may be related to impaired luteinizing hormone secretion, particularly in longstanding cases. Basal gonadotrophin concentrations are, however, typically within the normal range, unless pituitary disease is responsible for the hypothyroid state. A reduction in sex hormone binding globulin concentration leads to an elevation in free sex hormone concentrations, with a reduction in total concentrations of both oestrogen and testosterone following from both this and alterations in sex steroid synthesis.

Other systems

Cortisol turnover is often reduced and, in some patients, the cortisol response to hypoglycaemia is blunted, although response to exogenously administered ACTH is normal. Hyperprolactinaemia is a common finding, resulting from increased TRH release. The hyperprolactinaemia correlates with the degree of elevation of TSH, although frank galactorrhoea is only relatively infrequently found.

A normochromic anaemia, which may be either normo- or macrocytic in nature, is often seen and is likely to reflect diminished production of erythropoietin, with low red cell mass. Macrocytosis is frequently ascribed to coincidental occurrence of vitamin B₁₂ deficiency due to autoimmune pernicious anaemia, but a deficiency in the response to available B₁₂ and concurrent malabsorption of folate from the gut may contribute. If menorrhagia has been prolonged or severe, microcytosis, rather than macrocytosis, may be present as part of an iron deficiency state. Plasma concentrations of clotting factors VIII and IX may be reduced in hypothyroidism and platelet adhesiveness reduced, causing a mild bleeding tendency that may exacerbate the existing risk of anaemia. The effects of thyroid hormones on lipids have been outlined earlier in this chapter. Glucose absorption from the gut and uptake by the tissues from plasma are both delayed, but in patients with established diabetes, a characteristic increase in sensitivity to exogenous insulin is seen, probably due to decreased clearance of insulin.

Causes of hypothyroidism

Causes of hypothyroidism are listed in [Table 19.7](#).

Measurement of plasma TSH concentrations provides the cornerstone of the biochemical evaluation of hypothyroidism. As circulating concentrations of thyroid hormone fall, TSH secretion increases and is used to monitor thyroid status. Secretion of T3 is preferentially maintained in the presence of the high TSH concentrations that accompany declining thyroid function. T3/T4 ratios, therefore, rise and plasma T4 concentrations correlate better with thyroid activity than do plasma T3 concentrations. Replacement therapy for primary hypothyroidism can be monitored using plasma TSH concentrations. The particular problems resulting from pituitary failure are described below. Hashimoto disease and other forms of thyroiditis are described in the following section on thyroiditis. It should be noted that not all raised concentrations of TSH equate to hypothyroidism: of possible sources of error clinically, the most important is hypoadrenalism, which results in a mild to moderately raised TSH (with completely normal free T4) but treatment with thyroxine (rather than steroids) will increase metabolism of any remaining cortisol and precipitate a potentially fatal hypoadrenal crisis.

Primary myxoedema

In a large proportion of patients with primary hypothyroidism, no goitre, or history of goitre, will be present. These individuals will have high plasma TSH concentrations with low total and free T4 concentrations, and the majority will have anti-peroxidase and/or anti-thyroglobulin antibodies. Thyroid growth blocking antibodies have also been described in these patients. While the majority of patients may represent end-stage Hashimoto thyroiditis with lack of clinical recognition of the early phases of the disease, clearly other immunological processes may be responsible for some of them.

Post-surgery or post-radioiodine

Although the hypothyroidism developing after surgery or ¹³¹I therapy for Graves disease is usually permanent, it may be temporary, especially in the first 3–4 months. If symptomatic at this early stage, patients should be treated with a relatively small dose of thyroxine (50–75 µg daily) and the need for continued treatment assessed at six months. If serum TSH remains elevated, thyroxine therapy will be required lifelong and the dose needs to be increased. If at that stage serum TSH is normal or undetectable, stopping the thyroxine for four weeks and re-testing thyroid function would be the appropriate action.

Congenital hypothyroidism

Causes of congenital hypothyroidism are listed in [Box 19.4](#). Clinical detection of hypothyroidism in the neonate may be difficult. In many developed countries, screening programmes measuring TSH or T4 on dried bloodspots from heel-prick blood samples (taken at six days when phenylketonuria screening is performed) have been operating for some years with considerable success. Abnormal thyroid development is responsible for most congenital hypothyroidism. Scintiscanning may be used in order to help to clarify the diagnosis.

Inability to organify trapped thyroidal iodide can be recognized by an abnormal perchlorate discharge test and is usually associated with goitre. Patients with mild forms of this type of defect may also have deafness (Pendred syndrome), but are in this case not often hypothyroid. Ineffective transport of iodide into the thyroid gland can produce both goitre and hypothyroidism and will be found in individuals with abnormally low radioiodine uptake. The block to transport can, in some cases, be overcome by treating patients with high doses of oral iodide, reducing goitre and restoring normal thyroid function.

Deficiency of iodotyrosine dehalogenase produces impaired deiodination of iodotyrosine, such that large

TABLE 19.7 Causes of hypothyroidism

	Disease	Pathogenesis
Primary (due to disease of the thyroid gland)	Thyroiditis: Hashimoto; postpartum; de Quervain (rarely); Riedel (rarely)	Autoimmune destruction of the gland Prolonged inflammatory damage Gland becomes fibrosed
	Primary myxoedema	Gland atrophy; post-autoimmune in many cases
	Ablative	Post-radioiodine or surgery; gland bulk reduced
	Athyreosis	Abnormal or absent thyroid tissue
	Dyshormonogenesis	Abnormal synthesis of thyroid hormones
	Drugs	Inhibition of thyroid hormone synthesis or induction of thyroid autoimmunity
	Iodine deficiency	Lowered gland iodine; impaired hormone synthesis
	Acute iodine excess	Transient inhibition of hormone synthesis may become permanent in the presence of coexisting thyroid destructive autoimmune activity
Secondary (due to extrathyroidal disease)	Anterior pituitary failure: tumours; granulomatous deposits; Sheehan syndrome; post pituitary destructive therapy; developmental abnormalities; post-head injury	Loss of TSH stimulation of thyroid
	Hypothalamic dysfunction	Loss of TRH stimulation of anterior pituitary

BOX 19.4 Causes of congenital hypothyroidism

- Structural abnormalities
 - Absent gland
 - Ectopic site
- Enzyme defects (dyshormonogenesis)
 - Iodide transport
 - Iodide organification
 - Iodotyrosine dehalogenase
- Defective iodoprotein secretion
- Mutation in MCT8 gene (T3 transporter)
- Maternal antibodies (transient)

amounts of mono- and di-iodotyrosines appear in the blood, and iodine deficiency can result from the urinary loss of large quantities of deaminated metabolites of these molecules. Again, large doses of iodine may reduce the severity of the hypothyroidism and the accompanying goitre. Biochemically, parenteral administration of mono- and di-iodotyrosines will be followed by their rapid urinary excretion and this can be used as a diagnostic test for the condition.

Diversion of thyroidal iodine into metabolically inactive or less active iodoproteins, rather than thyroid hormones, can lead to hypothyroidism. Radioactive iodine uptake will be high, due to high TSH drive to synthetic activity within the gland, and the abnormal quantities of iodinated products of the gland can be measured in serum. Thyroid hormone replacement therapy is required.

Maternal TSH receptor-blocking antibodies can cross the placenta to produce transient hypothyroidism in the fetus, which resolves within a few weeks after birth. In these patients, bloodspot TSH values are usually only modestly raised. Testing for TSH receptor antibodies would distinguish these infants from those requiring T4 replacement therapy.

Lithium treatment

Lithium therapy may lead to reduced thyroid hormone synthesis in a similar manner to the acute effects of iodine, but more commonly aggravates any underlying autoimmune disease. Female patients are more often affected and thyroid autoantibodies are often present. Lithium can, therefore, cause hypothyroidism (in approximately 14% of women and 5% of men taking lithium) but also, less commonly, induces hyperthyroidism. Patients taking lithium should have their thyroid function tests measured every six months. Patients on lithium who have positive TPO antibodies are at increased risk of developing thyroid dysfunction. Lithium itself has been used as a treatment for hyperthyroidism and as an adjunct to radioiodine treatment (as it enhances radioiodine uptake) but because of the potential for toxicity, this approach has not entered routine practice.

Cytokine therapy

Treatment with a variety of cytokines (see Table 19.1) can result in hypothyroidism that is more common in patients with underlying autoimmune thyroid disease. This

is most commonly observed in patients being treated with interferon therapy for viral hepatitis. It is usually self-limiting once cytokine therapy ceases, but may need temporary treatment with thyroxine.

Iodine

Both excess and deficiency of dietary iodine may result in hypothyroidism.

Although oral use of large doses of iodine would normally lead to transient suppression of thyroid hormone synthesis, iodine can rarely produce more lasting hypothyroidism, particularly in individuals with Hashimoto disease.

Environmental iodine deficiency remains a major cause, worldwide, of goitre and hypothyroidism. Clinical euthyroidism is often maintained by preferential production of T3 and compensatory thyroid hyperfunction, leading to large goitre formation.

Secondary hypothyroidism

Loss of TSH drive to thyroid function may result from any of the causes of pituitary gland hypofunction. Recognition of the aetiology of this type of hypothyroidism is critical and is usually made by observing a low T4 accompanied by an inappropriately 'normal' TSH concentration. In some cases of secondary hypothyroidism, TSH may be slightly increased. Increased T3:T4 ratios are not seen in this type of hypothyroidism as TSH drive is absent.

Treatment of hypothyroidism

Myxoedema coma

Profound hypothyroidism may produce the state known as myxoedema coma. This is a relatively uncommon endocrine emergency that may be triggered by factors such as infection, cold exposure, the use of sedative medications or non-compliance with treatment. The classic presentation is that of decompensated hypothyroidism with altered sensorium, marked bradycardia, hypothermia and circulatory collapse. Patients should be admitted to an intensive care unit where possible. Therapy is supportive with thyroid hormone replacement using nasogastric T4 or parenteral T3 therapy. Replacement doses of glucocorticoids should be given until coincidental adrenal insufficiency has been excluded, infections should be treated aggressively and further heat loss prevented to allow progressive rewarming to occur. Despite appropriate therapy, the mortality from this condition remains high, often with arrhythmias in the first 24 h after commencing therapy, and early recognition and careful management in a critical care setting offers the best chance of recovery.

Thyroid hormone replacement therapy

Treatment of primary or secondary hypothyroidism is with oral synthetic levothyroxine. The usual replacement dose is 1.6 µg/kg per day, which equates to about 100–125 µg daily. Patients are customarily advised to take levothyroxine 30–60 min before breakfast since food and caffeine interfere with its absorption. Bed time administration is

equally effective and may be suited to patients who take a number of other medications. Treatment can usually be initiated at full replacement doses except in elderly individuals and patients with cardiac disease who will require more cautious starting doses. Serum T4 and TSH should be checked 6–8 weeks after initiation, making any minor adjustment to the dose necessary to restore TSH to normal. In the elderly and in patients with established ischaemic heart disease, levothyroxine replacement should begin with 25 µg daily, increasing by 25 µg increments every 4–6 weeks. In patients with hypopituitarism, with both secondary adrenal and thyroid failure, it is important that levothyroxine is not started before hydrocortisone replacement, as this might precipitate adrenal crisis by increasing the metabolic rate in a patient unable to secrete cortisol.

The objective of treatment is to achieve clinical well-being and restore biochemical euthyroidism, i.e. a serum TSH within the laboratory reference range. Patients who remain symptomatic despite full replacement doses may benefit from additional dose increases to keep TSH concentration in the lower half of the reference range. Lowering TSH to below the reference range is not advisable as there is evidence that such individuals with exogenous hyperthyroidism have an increased risk of atrial fibrillation and osteoporosis. The response to treatment in patients with secondary hypothyroidism should be based on FT4 measurements since TSH secretion is deficient in pituitary disease. The therapeutic goal in such cases would be a FT4 in the upper-third of the reference range.

Although thyroid hormone replacement with synthetic levothyroxine is effective in most cases, a significant proportion of patients report that they remain symptomatic. The management of such patients can be challenging and factors that may predispose to inadequate thyroid hormone replacement include poor patient compliance, inadequate dosage and administration, concurrent use of medications which interfere with levothyroxine availability and the presence of comorbidities which impair levothyroxine absorption. The combination of a raised serum T4 and TSH is suggestive of poor compliance, the patient having been over zealous in the few days prior to thyroid function testing in an attempt to compensate for missing doses earlier. Some individuals may remain symptomatic even after normalization of thyroid function. Although some of such patients may benefit from further dose titrations to attain a low normal TSH, it is important to consider alternative causes of persistent symptoms such as diabetes mellitus, obesity, Addison disease, anaemia, depression, coeliac disease, obstructive sleep apnoea and post-viral syndromes. In practice, such investigations are frequently negative and whether some individuals with persistent symptoms will benefit from combined treatment with T4 and T3 remains contentious. The use of T3 in replacement is much harder to titrate and monitor, is not recommended by professional bodies and should not be conducted away from specialist centres with programmes of long-term follow-up for these individuals. Recent delineations of common genetic variations in the deiodinase and thyroid hormone transport proteins suggest that such polymorphisms may account for some of the variability in the response to thyroid hormone treatment.

BOX 19.5 Indications for treatment in patients with subclinical hypothyroidism

- Increased TPO antibody concentration
- TSH >10.0 mU/L
- Goitre
- Pregnancy
- Infertility
- Hypothyroid symptoms^a
- Diabetes mellitus^b
- Cardiac disease^b
- Dyslipidaemia^b

^aSome practitioners advocate treatment of subclinical hypothyroidism if there are classic hypothyroidism symptoms, but this is controversial and the evidence base is lacking.

^bConsider treatment because of increased cardiovascular disease risk.

Subclinical hypothyroidism

This is the term used to describe patients who are clinically euthyroid with normal serum T4 concentration but raised TSH, usually <10 mU/L. There may be mild non-specific symptoms, such as tiredness, weight gain and depression. Now viewed as the mildest form of thyroid failure, it is common practice to treat with thyroxine if antibodies are positive and/or serum TSH is >10 mU/L in order to 'nip things in the bud' before the progression to overt thyroid failure (5% per year), and the possibility of loss to follow-up and later presentation with severe hypothyroidism. Other potential indications for treatment in patients with subclinical hypothyroidism are shown in Box 19.5. Recovery from non-thyroidal illness should be excluded before a diagnosis of subclinical hypothyroidism is made, emphasizing that in all cases thyroid function tests should be repeated and confirmed as remaining abnormal before initiating therapy.

THYROIDITIS

Inflammation of the thyroid gland (thyroiditis) can result in both overactivity and underactivity of the gland.

Thyroiditis producing hyperthyroidism

Autoimmune thyroiditis (typified by Hashimoto disease) is a common cause of hypothyroidism and, as such, will be reviewed in detail below. However, in the early phase of autoimmune damage to the gland, release of stored thyroid hormone may lead to transient hyperthyroidism in some patients. This usually lasts about 6–8 weeks, followed by mild and equally transient hypothyroidism and then recovery, although, in the long term, permanent hypothyroidism is common. Known as silent thyroiditis, the biochemical pattern is similar to that observed in postpartum thyroiditis and in de Quervain thyroiditis.

Diagnosis and treatment

Depending on the phase of the illness, thyroid function may show hyperthyroidism, euthyroidism or hypothyroidism. Radioactive iodine scans in the hyperthyroid phase of the illness will typically show reduced isotope

uptake since the hyperthyroidism is not due to excessive synthesis of thyroid hormones but to the release of pre-formed hormones. For the same reason, treatment with antithyroid drugs is ineffective, although a β -blocker may help to alleviate symptoms of hyperthyroidism.

Hypothyroidism resulting from Hashimoto thyroiditis

In Hashimoto disease, the commonest form of autoimmune hypothyroidism, destructive thyroiditis results from both a cell-mediated and humoral attack on the thyroid tissue. Females are affected with greater frequency than males. The gland is typically enlarged but small and firm in early cases, with a palpable pyramidal lobe. At this stage, hyperthyroidism may transiently occur, but further gland damage rapidly leads to permanent hypothyroidism, at which stage goitre regresses and the gland remnant is composed of fibrous tissue.

Diagnosis

Thyroid-directed autoantibodies (described earlier) are almost invariably present in the early phase of the disease, though they may ultimately become undetectable over a period of years. In about half of patients with Hashimoto thyroiditis, serum TSH is elevated and T4 normal (sub-clinical hypothyroidism), the other patients having overt thyroid failure.

Immunological and biochemical evidence of other organ-specific autoimmune diseases such as diabetes, pernicious anaemia, Addison disease and hypoparathyroidism may also be found.

Other forms of thyroiditis

De Quervain thyroiditis is an unusual condition, which often follows a viral illness. Patients typically present with pain in the thyroid and neck region with fever and malaise. Thyroid function tests may transiently become hyperthyroid, then hypothyroid, before returning to normal. Rarely, permanent hypothyroidism may follow repeated episodes. Riedel thyroiditis is a condition of unknown aetiology. Extensive replacement of the thyroid with fibrous tissue causes the gland to become stony hard. Hypothyroidism is a rare complication.

Hypothyroidism and the postpartum period

Postpartum thyroiditis, due to autoimmune thyroid disease, may develop during the early postpartum period, and is typically histologically and biochemically identical with Hashimoto disease. The classic presentation is of a transient hyperthyroid phase which is followed by a hypothyroid phase. Published series suggest that the overall incidence of the condition is between 5% and 9% and that 40% of patients have failed to recover euthyroid function by one year post-delivery. Of those who do recover normal thyroid function, a further 20–30% will have become hypothyroid within 3–4 years. After the initial episode, the future risk of developing the syndrome increases in successive pregnancies.

Although the presence of antithyroid antibodies during pregnancy is a risk factor for postpartum thyroid disease, at most only half of these women will go on to develop frank thyroid dysfunction. Swings in thyroid function may contribute to the aetiology of postnatal depression and thyroid function should be tested in all such patients.

NEOPLASIA

Thyroid neoplasia forms a small but clearly important proportion of all thyroid disease. Thyroid cancer is the most common endocrine malignancy and accounts for more mortality than all the other endocrine cancers combined. The types of primary and secondary thyroid neoplasm are summarized in [Box 19.6](#). The differentiated thyroid cancers (DTC), papillary and follicular thyroid cancer, are the most common histological types. Papillary thyroid cancer is most frequent in iodine sufficient parts of the world and is associated with a favourable prognosis. Papillary microcarcinomas (diameter <1 cm), are now increasingly detected owing to the growing use of imaging techniques such as ultrasound, computerized tomography or positron emission tomography scans. Anaplastic thyroid cancer is relatively uncommon and typically follows an aggressive course with rapid thyroid enlargement and poor prognosis. Primary thyroid lymphomas almost always arise on a background of Hashimoto thyroiditis and also present with rapid gland enlargement.

Diagnosis

The usual presentation is with a solitary nodule in the thyroid. Although thyroid nodules are common in the general population, only about 5% of such nodules are malignant. Malignancy is suspected in patients with thyroid nodules if there is a history of rapid enlargement, a family history of thyroid cancer or a past medical history of head and neck irradiation as therapy for another disease ([Box 19.7](#)). Clinical suspicion of the diagnosis is further raised by the finding of a nonfunctioning solitary nodule on thyroid scintiscanning ([Fig. 19.9D](#)) that is shown on ultrasound examination to be solid (although cystic lesions may also be malignant). The diagnosis of thyroid carcinoma ultimately depends on histological examination of the gland following an excision biopsy or a fine needle aspirate of the nodule. Biochemical assessment (other than establishing the usually euthyroid status of the patient and excluding evidence of autoimmune processes) plays little part in making the diagnosis. Measurement of

BOX 19.6 Typical thyroid malignancies

Primary neoplasms

- Papillary carcinoma
- Follicular carcinoma
- Anaplastic carcinoma
- Medullary carcinoma (calcitonin secreting; may form part of the syndromes of multiple endocrine neoplasia)
- Lymphoma

Other neoplasms

- Secondary deposits from extrathyroidal tumours

BOX 19.7 Clinical features suggestive of malignancy in patients with thyroid nodules

- Age <20 years or >80 years
- Hoarseness or voice change
- Breathlessness or stridor from upper airway obstruction
- Rapid enlargement of nodule
- Cervical lymphadenopathy
- Family history of thyroid cancer
- History of radiation exposure
- Smoking history

plasma thyroglobulin is of no diagnostic value, but is essential for long-term monitoring for recurrence.

Treatment

The management of thyroid cancer should be undertaken in a multidisciplinary care setting comprising health professionals with expertise in the field including oncologists, surgeons, endocrinologists, pathologists and radiologists. For papillary and follicular carcinoma, treatment is by total thyroidectomy and, unless the carcinoma is small (<1 cm in diameter), in which case the prognosis is excellent, adjunctive treatment is given with ablative doses of ^{131}I . In order to maximize the effect of the radioiodine, the patient should stop any thyroxine for four weeks beforehand to achieve a serum TSH of >25 mU/L. Alternatively, symptomatic hypothyroidism can be avoided by increasing the serum TSH with the use of recombinant human TSH (rhTSH), thus allowing levothyroxine therapy to continue uninterrupted. Whole body scanning, taking advantage of the therapeutic ^{131}I , will identify any metastatic disease at this stage. Thereafter, thyroxine should be given either in suppressive or replacement doses depending on individual patient risk (Box 19.8). The differentiated thyroid carcinomas are TSH dependent and suppression of TSH has been shown to improve outcomes in patients with high risk disease. Thus, full suppression (TSH <0.1 mU/L) is recommended for patients with persistent disease, while partial suppression (TSH 0.1–0.5 mU/L) is advised in disease-free high-risk patients. TSH suppression is not required in patients with low or very low risk (Box 19.8). Patients on suppressive therapy should undergo periodic cardiovascular and bone mineral density evaluation because of the risk of osteoporosis and atrial fibrillation. Further evaluation should be undertaken six months after initial treatment and should comprise a neck examination, cervical ultrasound and rhTSH-stimulated Tg measurement. Patients without clinical or ultrasound evidence of disease who have normal stimulated Tg concentrations (<1.0 ng/mL) are considered to be in remission and will then require long-term surveillance with annual neck examinations and basal Tg measurements.

Tumour markers

Following total thyroidectomy and ^{131}I ablation, there should be no normal thyroid tissue remaining, and any

BOX 19.8 Target ranges for serum TSH concentration in the follow-up of patients with differentiated thyroid cancer

1. Patients with persistent disease: TSH suppression to <0.1 mU/L
2. Disease-free high-risk patients^a: TSH suppression to 0.1–0.5 mU/L for 5 years
3. Disease-free low-risk patients^a: TSH in low normal range, 0.3–1 mU/L
4. Disease-free very-low-risk patients^a: TSH in normal range, 1–2 mU/L

^aHigh risk: any T3, any T4, any T with N1 or any M1; Low risk: T1–T2, N0, M0 or multifocal T1, N0, M0; Very low risk: unifocal, T1 (<1 cm), N0, M0. T1: tumour <2 cm; T2: tumour 2–4 cm; T3: tumour >4 cm; T4 tumour extending beyond the thyroid capsule or anaplastic histology.

N0: no regional lymph node involvement; N1: regional lymph node involvement; M0: no distant metastasis; M1: distant metastasis.

Modified from Cooper et al. 2009 Revised American Thyroid Association management guidelines for patients with thyroid nodules and differentiated thyroid cancer. *Thyroid* 19:1167–21, and Pacini F et al. 2010 ESMO Guidelines Working Group. Thyroid cancer: ESMO Clinical Practice Guidelines for diagnosis, treatment and follow-up. *Annals of Oncology* 21(Suppl 5):v214–9.

thyroglobulin detected in the serum must arise from the current tumour or from metastases. The sensitivity of the current thyroglobulin assays is poor and the most meaningful results are obtained following TSH stimulation, either as a result of thyroxine withdrawal or by rhTSH stimulation. An undetectable serum thyroglobulin, which fails to increase following TSH stimulation, is indicative of cure and a reason for less intensive follow-up. Response to treatment of recurrent disease or metastases can be monitored by measuring the serum thyroglobulin concentration. The utility of thyroglobulin measurements is limited in the presence of thyroglobulin antibodies, as these antibodies interfere with the thyroglobulin assays. Tests of thyroglobulin recovery have been used in a bid to overcome this problem, but these tests are not entirely reliable and the clinician must be aware of the limitations of thyroglobulin assays in monitoring patients with differentiated thyroid cancer.

Medullary carcinoma of the thyroid secretes calcitonin, which may therefore, be used as a tumour marker. The tumour occurs in both sporadic and familial forms, and because of the association with syndromes of multiple endocrine neoplastic (MEN) disease, patients should be screened for the other manifestations of MEN (e.g. hyperparathyroidism and pheochromocytoma). If the diagnosis of MEN is confirmed, first-degree relatives of the index patient should also be screened for these diseases. Multiple endocrine neoplasia is discussed in detail in Chapter 41.

SYNDROMES OF RESISTANCE TO THYROID HORMONES

These occur most commonly due to a mutation in the nuclear T3 receptor (TR β). The mutation may be inherited (usually autosomal dominant) or occur de novo. Thyroid hormone resistance has been detected in approximately

TABLE 19.8 Overview of factors that enable thyroid hormone resistance to be distinguished from TSH secreting adenomas

Factor	Thyroid hormone resistance	TSH-secreting adenoma
Thyroid status	Usually clinically euthyroid	Usually clinically thyrotoxic
Serum α TSH subunit	Normal	Elevated
Serum SHBG	Often high (85%)	Normal
TSH response to TRH stimulation	Rise in TSH	No response
MRI pituitary	No tumour visualized	Primary tumour visualized (However, incidentaloma detected in 10% of normal subjects)
Genetic analysis of thyroid hormone receptor B gene	Mutation confirmed	No mutation

in 1 in 50 000 live births and affects males and females equally. The condition is characterized by elevated concentrations of total and free thyroid hormones, normal or slightly increased plasma TSH, normal or exaggerated response to TRH and absence of the usual symptoms and metabolic consequences of thyroid hormone excess. Goitre is often present. It is important to distinguish these patients from those with a pituitary TSHoma (Table 19.8). The SHBG concentration is often normal in patients with thyroid hormone resistance, but is increased in TSHoma. Suppression of TSH secretion by high doses of T3 is suggestive of thyroid hormone resistance rather than a TSHoma. A useful pointer to thyroid hormone resistance is to obtain thyroid function test results in first-degree relatives. DNA analysis to demonstrate the mutation in the *TR β* gene should be performed to confirm the diagnosis. Some patients appear to have a relatively selective pituitary resistance and present with hyperthyroid-type symptoms. Management is complex and should be reserved for specialist centres. In many cases no treatment is required.

SCREENING

Is screening for thyroid disease justified? There are undoubtedly some groups of patients in whom thyroid function testing is justified, even if there is no clinical evidence of thyroid disease. The question of screening in neonates has already been discussed. Screening is warranted in all patients with a personal history of previous thyroid disease or neck irradiation, ophthalmic Graves disease, atrial tachyarrhythmias or a history of goitre or previous thyroiditis. In view of the increased prevalence of long-term thyroid dysfunction in patients who have previously received antithyroid drugs, this group of individuals should also be offered regular thyroid function testing. Screening patients with a personal or family

history of autoimmune disorders such as type 1 diabetes, pernicious anaemia, coeliac disease, Addison disease and rheumatological disorders will also yield a significant proportion of patients with undiagnosed thyroid disorders. Thyroid screening is also indicated in patients receiving medications which affect thyroid function such as amiodarone, lithium, tyrosine kinase inhibitors, α -interferon, Campath[®] and antiretroviral agents. Screening patients who have hyperlipidaemia (who have a higher prevalence of hypothyroidism than the normal population) is also justified. The situation is far less clear in the case of screening larger sections of the general population, such as the elderly female population or the hospital in-patient population. In the former example, the cost of such a screening programme has to be balanced against the likely pick-up rate, and in the latter, the confounding influence of non-thyroidal illness is likely to reduce the value of screening in this circumstance. Screening programmes should probably be targeted on otherwise well but 'at-risk' individuals in the community, rather than on the hospital population at large.

The value of thyroid screening in all pregnant women is contentious. Most international endocrine associations do not recommend universal thyroid screening but propose screening only in pregnant patients at risk of thyroid disease, e.g. women with a personal or family history of thyroid disease, co-existent autoimmune disease, goitre, thyroid antibodies, history of head and neck irradiation, or history of poor obstetric outcomes. However, such a targeted case finding approach would miss a third of pregnant women with thyroid disease. A randomized controlled trial of a thyroid screening strategy in early pregnancy showed no beneficial effect on childhood neurointellectual development at three years.

ACKNOWLEDGEMENT

We would like to thank Geoffrey J. Beckett and Anthony D. Toft who wrote the chapter in the previous edition of this book.

CONCLUSION 411

INTRODUCTION

Stress can be defined as any influence, arising either internally or externally to the body, that threatens to disrupt normal structure, function or behaviour. Not surprisingly, complex mechanisms have evolved to protect the body against such threats, whether physical or psychological. It may be surmised that during man's evolution, the most important stresses were external, e.g. attack and lack of food, water or shelter. For many people, such factors are now of little or no relevance, but others, for example psychological stresses, have become more prevalent; stressors such as trauma and infection remain universal.

The body's response to stress tends to be qualitatively similar whatever the stress, although the severity of the stress affects the response quantitatively, albeit with considerable intra- and interindividual variation.

It is reasonable to suppose that the development of the metabolic response to stress was subject to evolutionary pressures, and that the response is potentially beneficial. For some aspects this clearly is the case, but, as will become apparent, some aspects of the response to severe stressors, particularly sepsis, appear potentially harmful to the body as a whole. One can only speculate how this might have come about. The metabolic response to stress is complex, and includes processes that act to propagate the response as well as to curtail it and thereby limit its extent, both physiologically and anatomically.

Conventionally, stressors are divided into four categories:

1. physical, e.g. heat, cold, immobilization and pain
2. psychological, e.g. anxiety and fear
3. social, e.g. bereavement, marital breakdown
4. cardiovascular and metabolic, e.g. exercise, haemorrhage and infection.

While this system helps categorize the nature of the stimulus, multiple stressors can be applied to an individual at any one time and these, in turn, can be either acute or chronic in nature. Stress responses are intended to be short lived and self-limiting, but are proportional to the intensity of the stimulus and, consequently, can range from simple localized reactions to complex processes. Systemic responses involve vascular, endocrine and metabolic changes orchestrated by the hypothalamo–pituitary axis and sympathetic nervous systems. Centrally, there is facilitation of arousal, inhibition of vegetative functions (feeding and reproduction) and activation of counter-regulatory feedback loops. Respiratory and heart rates increase and there is an increase in vascular tone, resulting in a rise in blood pressure and hence oxygen and nutrient supply to the brain, heart and skeletal muscles.

The intensity of stress may be gauged by peak concentrations of stress hormones and neurotransmitters, by physiological changes, such as increases in heart rate and blood pressure, and by the length of time for which these changes persist during stress and following the cessation of stress. Whilst intended to confer a survival advantage, the stress response can become part of the pathological process. In severe stress, responses that appear potentially advantageous if limited in extent (e.g. mobilization of muscle protein to provide glucose as an energy source) become harmful.

THE RESPONSE TO STRESS

Initiation of the stress response

Figure 20.1 summarizes the complexity of the systemic responses to potential stimuli. Stimulation of the

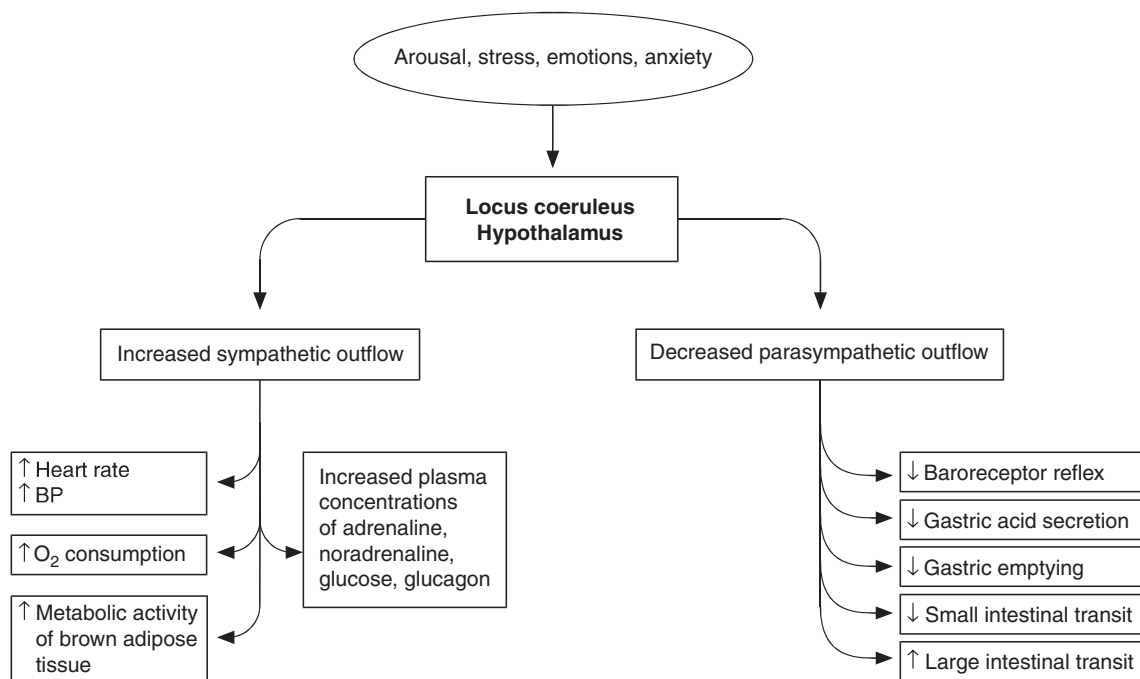

FIGURE 20.1 ■ The systemic response to stress.

hypothalamus and locus coeruleus leads to the release of pituitary hormones and activation of the sympathetic nervous system. The locus coeruleus, hypothalamus and brainstem are closely linked, both anatomically and functionally. The locus coeruleus and hypothalamus mutually innervate and stimulate each other. This positive feedback system allows for activation of the systemic stress response by any stimulus that initiates either side of this loop. The locus coeruleus is located in the lateral floor of the fourth ventricle, and represents the major pool of noradrenaline (norepinephrine) secreting neurons in the brain. It receives afferents from many areas, including the hypothalamus, the cerebellum, prefrontal cortex and the hypoglossi. The cingulate gyrus and amygdala also innervate the locus coeruleus, transmitting emotional and pain stressors. Nerve fibres from this nucleus innervate the spinal cord, brainstem, thalamic relay nuclei, cerebellum and hypothalamus and are predominantly excitatory in action. Adrenaline (epinephrine) secreting nerve terminals are also found within the locus coeruleus and are thought to represent part of the medullary regulatory circuit.

At the centre of the limbic system, the hypothalamus controls most of the vegetative (homeostatic) and endocrine functions of the body. Combined with the locus coeruleus, it is the major effector of the stress response.

The efferent neuronal pathways from the hypothalamus can be classified into two groups: direct monosynaptic projections to pre-ganglionic neurons in the lower brainstem and spinal cord projections to brainstem catecholaminergic neurons in the medulla that innervate neurons in the thoracic spinal cord.

Additionally, hypothalamic nuclei participate in other regulatory pathways, such as temperature control, energy homeostasis and body fluid composition.

Hypothalamo–pituitary–adrenal axis

Stimulation of the paraventricular nucleus by afferent fibres from the limbic system and lower brainstem results in the secretion of corticotrophin-releasing hormone (CRH), into the primary capillary plexus of the hypophyseal portal system, from where it is transported to the anterior pituitary gland.

The hypothalamus also secretes the polypeptide arginine vasopressin (AVP), which is transported along nerve tracts to the posterior pituitary. Under resting conditions, CRH and AVP are secreted in a circadian and highly concordant pulsatile fashion: stressors promote a surge in AVP secretion. Vasopressin increases water retention in the kidneys, is a potent vasoconstrictor, acts as a neurotransmitter and has the ability to modulate a number of physiological processes including gluconeogenesis, platelet aggregation and inflammation.

Corticotrophin-releasing hormone and AVP act synergistically on the anterior pituitary to induce synthesis of the large prohormone, proopiomelanocortin (POMC). The POMC molecule is processed to form a series of smaller peptides, the nature of which is dependent on the enzyme systems present within the tissue type. Anterior pituitary corticotrophin cells express prohormone convertase 1 (PC1), which cleaves POMC into ACTH, N-terminal peptide, joining peptide and β -lipotropin. In the hypothalamus the enzyme PC2 cleaves POMC to α -, β - and γ -melanocyte stimulating hormones and β -endorphin.

α -Melanocyte stimulating hormone acts on melanocortin receptors in the paraventricular nucleus of the hypothalamus, stimulating the sympathetic nervous system. Adrenocorticotrophic hormone and the other peptide cleavage products of POMC have a negative feedback effect on the hypothalamus to limit CRH release.

While CRH and AVP act synergistically on the anterior pituitary, only small amounts of ACTH are secreted in the absence of CRH, which is pivotal to an integrated stress response.

Cortisol

Following stimulation by ACTH, cortisol is the principle glucocorticoid produced by the adrenal cortex, accounting for 95% of glucocorticoid activity. Approximately 90% of circulating cortisol is protein bound; some is attached non-specifically to albumin, but the majority binds with high affinity to cortisol-binding globulin (CBG); only free cortisol is biologically active. Cortisol-binding globulin is an α_2 -globulin, produced in the liver, which behaves as a negative acute phase protein. The concentration of CBG falls in response to some inflammatory stimuli, increasing the bioavailability of cortisol.

Cortisol is a major effector of the metabolic response to stress. It is lipid soluble and readily crosses cell membranes, its activity being mediated via the glucocorticoid receptor (GR). Two isoforms of GR have been isolated, GR α , which binds cortisol and the GR β , which does not bind cortisol and may act to inhibit the effect of endogenous glucocorticoid action. The hormone receptor complex is translocated to the nucleus where it interacts with glucocorticoid response elements and, following recruitment of co-activators, leads to increased gene transcription. Other actions are DNA independent and involve direct interactions with transcription factors, such as nuclear factor- κ B (NF- κ B). This is important in the modulation of the stress response, since NF- κ B activates the expression of interleukin-1 (IL-1), IL-6 and tumour necrosis factor α (TNF α), all of which are key components of the inflammatory response and interact with the hypothalamo-pituitary-adrenal axis (HPAA).

Cortisol exerts a negative feedback effect on CRH and ACTH release, affects carbohydrate, protein and fat metabolism, and modulates the immune response. Cortisol limits glucose utilization in cellular respiration, perhaps by reducing the oxidation of NADH to NAD⁺ in the tricarboxylic acid cycle. High concentrations of cortisol reduce the sensitivity of peripheral tissues to insulin. This anti-insulin effect is particularly marked in skeletal muscle and adipose tissue, reducing glucose uptake and metabolism.

In extra-hepatic tissues, there is increased protein catabolism and decreased protein synthesis through reduced RNA formation and amino acid uptake. Within the liver, however, this metabolic picture is reversed, with increased amino acid uptake and the synthesis of acute phase proteins. Additionally, cortisol enhances the mobilization of fatty acids from adipose tissue, shifting oxidative metabolism to favour energy generation from glucose to fatty acids.

Thyroid hormones

Major disturbances of thyroid hormone metabolism and plasma concentration occur during the metabolic response to stress, typically with falls in the concentrations

of tri-iodothyronine and often of thyroxine and, sometimes, in the critically ill, a fall in the concentration of thyroid stimulating hormone. (These changes are discussed further in Chapter 19.)

Sex hormones

The effects of trauma and sepsis on sex hormones are complex and dependent on the type of injury. Plasma concentrations of free testosterone may fall without any consistent change in the concentration of luteinizing hormone (LH), suggesting a change in the sensitivity of Leydig cells to LH or a disturbance of normal feedback regulation. The effects tend to be more marked in women, with reduced activity of the entire hypothalamo-pituitary-gonadal axis. Corticotrophin releasing hormone is known to have inhibitory effects at various levels in this axis, including antagonizing the effects of LH on Leydig cells. Chronic activation of the hypothalamo-pituitary-gonadal axis, such as has been demonstrated in long distance runners and ballet dancers, causes suppression of gonadal function in males and females.

Growth hormone

The anterior pituitary secretes growth hormone, stimulated by growth hormone releasing hormone, produced by the ventral medial nucleus of the hypothalamus. Growth hormone is a small protein that is active in most cells of the body, where it enhances amino acid uptake and protein synthesis. Under the influence of growth hormone, free fatty acids are used as an energy source in preference to carbohydrates and proteins. Growth hormone reduces glucose uptake by skeletal muscle and fat cells, promotes gluconeogenesis by the liver and consequently increases insulin secretion by the pancreas.

Adrenal medulla

Activation of the locus coeruleus by stressors causes the release of noradrenaline and increased sympathetic discharge via the brainstem and spinal cord. Pre-ganglionic sympathetic nerves pass through the sympathetic chain to innervate modified neuronal cells in the adrenal medulla. These cells secrete noradrenaline and adrenaline into the circulation. Catecholamine synthesis is an energy-dependent process with many mitochondria packing the terminal varicosities containing the secretory vesicles. Tyrosine is converted to L-DOPA and then to dopamine, which is transported into the secretory vesicles where a hydroxylation reaction converts it into noradrenaline. The majority of noradrenaline is then metabolized to adrenaline. The sympathetic nerve impulse to the adrenal medulla results in the influx of intracellular calcium and the discharge of the catecholamine secretory vesicles (in the ratio of 80:20, adrenaline:noradrenaline) directly into the circulation. The combined effect of this circulating adrenaline and noradrenaline is identical to that caused by direct sympathetic nervous system stimulation, but has a longer duration and can reach all cells of the body irrespective of their autonomic innervation.

STRESS AND THE KIDNEYS

Fluid conservation occurs as part of the stress response, often resulting in low urine outputs despite euvoelaemia. Increased sympathetic nervous system activity, combined with raised concentrations of circulating catecholamines, reduces renal blood flow. This initiates the metabolism of prorenin to renin in the juxtaglomerular cells of the kidneys. Renin is released into the blood where it acts on angiotensinogen to form angiotensin I. Under the influence of angiotensin-converting-enzyme, predominantly in the lung, angiotensin I is converted to angiotensin II, a potent vasoconstrictor. Angiotensin II stimulates AVP release from the hypothalamus, as well as having a direct affect on the kidney to increase salt and water retention. Furthermore, under the influence of angiotensin II, the mineralocorticoid aldosterone is synthesized in the zona glomerulosa of the adrenal cortex, by metabolism of corticosterone by the enzyme aldosterone synthase. Whilst ACTH has a permissive role in aldosterone synthesis, it does not control the rate of release. Aldosterone acts on the cortical collecting tubules where it stimulates a Na^+, K^+ -ATPase, leading to the retention of sodium and water. (Salt and water balance is considered further in Chapter 4 and renal function in Chapter 7.)

CYTOKINES

Cytokines are peptides secreted by many cell types including mast cells, macrophages and endothelial cells. They are released into the extracellular fluid and can function as autocrine, paracrine or endocrine hormones and they trigger the acute phase response.

Major changes in the plasma concentrations of cytokines occur during trauma and sepsis: they are also released during psychological stress. Cytokines are produced by activated cells of the immune system and mediate communication between the immune, endocrine and central nervous systems. Cytokines are classified into three groups dependent on their function. Group 1 (IL-2, IL-3, IL-4, IL-7, IL-10, IL-11, IL-12 and granulocyte-macrophage colony stimulating factor) act on a variety of cell types as positive or negative growth factors, whilst group 2 (TNF α / β , IL-1 α / β , IL-6, IFN- α / γ , IL-8 and macrophage inhibitory protein-1) have proinflammatory properties. Group 2 cytokines are responsible for the induction of fever, muscle catabolism, activation of white blood cell precursors and growth of inflammatory fibroblasts and macrophages. Group 3 contains cytokines with anti-inflammatory activity (IL-1 receptor antagonists, soluble IL-1 receptors, TNF α binding protein and IL-1 binding protein). Endothelial cells and macrophages are major producers of IL-1, IL-6 and TNF α , but virtually all nucleated cells have the ability to synthesize them.

Physical damage to cells results in the release of cytokines, some of which are chemotactic (e.g. IL-8), attracting large numbers of macrophages and neutrophils to the site of injury, where they are activated by TNF α , IL-1 and IL-6 to phagocytose dead tissue and bacteria.

Whether cytokines have localized (paracrine) or generalized (endocrine) effects is an important determinant of

the extent of the inflammatory response. Cytokines having local actions are also released into the circulation where they initiate some of the systemic features of the metabolic response, such as fever (IL-1) and stimulation of hepatic protein synthesis to produce acute phase proteins (IL-6): IL-6 is also a potent stimulator of ACTH (and hence cortisol) secretion, which amplifies the stress response.

Interleukin-1, IL-6 and TNF α are particularly important cytokines. Interleukin-1 is produced by activated macrophages and mediates the inflammatory response, stimulates the HPA and potentiates amino acid flux in skeletal muscle. Tumour necrosis factor- α , produced by macrophages and lymphocytes has similar properties to IL-1, and acts synergistically with it. Tumour necrosis factor- α stimulates inducible nitric oxide synthase, causing vasodilatation whilst also stimulating the production of cyclooxygenase, which in turn facilitates prostaglandin and thromboxane synthesis. Prostaglandin E_2 acts on the hypothalamic thermoregulatory centre to cause fever and is also immunosuppressive; other prostaglandins excite A and C pain fibres. Thromboxanes stimulate platelet function and are procoagulant. Interleukin-6 may also contribute to the activation of the HPA and to insulin resistance. Tumour necrosis factor- α , IL-1 β and IFN- γ are crucial for the induction of other cytokines (e.g. IL-6 and IL-8), platelet activating factor, prostaglandins, leukotrienes and nitric oxide.

STRESS AND INFLAMMATION

Stress and glucocorticoid hormones can either enhance or suppress immune function, depending on the following factors:

- the duration of the stress
- changes in leukocyte distribution and the compartments involved
- the concentration, duration and nature of the glucocorticoid exposure
- the timing of stress or stress hormone exposure relative to the stage of an immune response.

The stress response promotes a physiological synchronization of cardiovascular, musculoskeletal and neuroendocrine systems to confer a survival advantage. Despite the known anti-inflammatory effects of glucocorticoids, the body is unlikely to suppress immune function when the host is liable to wounding and infection. Indeed it is more likely that acute stress may serve to enhance the immune response.

Tissue injury (trauma, infection, hypoxia) causes the release of proinflammatory mediators such as heat shock proteins, adenosine and high mobility group box protein 1 in a characteristic damage-associated molecular pattern, and they are known collectively as 'alarmins'. Effective immunoprotection requires rapid recruitment of leukocytes to the site of damage, which is facilitated by the binding of alarmins to endogenous receptors on neutrophils and macrophages. Subsequently, the activation of NK- κ β leads to the transcription of proinflammatory proteins, including the cytokines IL-1, IL-6 and TNF α . Following release, these cytokines further activate inflammatory cells and the vascular system leading to a systemic response.

Cortisol and adrenaline act synergistically to induce rapid changes in leukocyte distribution and to enhance cell mediated and contact hypersensitivity immunity. Stress-induced changes include a reduction in the numbers of lymphocytes and monocytes but an increase in the number of neutrophils. These changes are rapidly reversed upon cessation of the stress.

Glucocorticoids act synergistically with cytokines to enhance specific immune reactions, by inducing their release and potentiating their actions. Synergistic interactions between glucocorticoids and cytokines may be mediated by glucocorticoid induced upregulation of cytokine receptors on target cells as determined by increased cytokine binding or cytokine receptor mRNA expression. For example, glucocorticoid-induced TNF receptors have been shown to promote survival and serve as a stimulatory receptor for T cells. Furthermore, glucocorticoids increase IL-1 binding to human peripheral blood B cells.

Acute psychological stress is known to increase circulating TNF α , IL-1 β and IL-10, with glucocorticoids also enhancing the biological activity of IL-2, interferon γ (IFN- γ) and granulocyte colony stimulating factor. Acute stress responses may induce a biphasic shift in leukocyte numbers. Initially, catecholamine hormones and neurotransmitters induce leukocytes to exit the spleen and bone marrow and to enter blood vessels and lymphatics. Consequently, there is an increase in blood leukocytes, predominantly natural killer (NK) cells and granulocytes. As the stress response evolves, glucocorticoid hormones initiate migration of lymphocytes to sites of infection. This redistribution leads to a reduction in the numbers of circulating lymphocytes, but is not an anti-inflammatory effect.

In contrast to acute stress, chronic stress has been shown to dysregulate immune responses by altering the cytokine balance from type 1 to type 2. Immunosenescence is accelerated and immunity decreased owing to a reduced number of circulating protective cells and increased populations of suppressor T lymphocytes.

To limit potential tissue damage after activation of the immune system, a counter-regulatory response is simultaneously triggered by inflammation and hypoxia. An important physiological role of endogenous glucocorticoids might be to suppress an ongoing immune response. Studies have demonstrated the existence of a negative feedback loop between the immune system and HPA axis such that proinflammatory mediators arising from ongoing immune reactions stimulate the axis, which in turn results in the secretion of cortisol, which suppresses the immune response and prevents it from potentially damaging the host.

Cortisol exerts its anti-inflammatory effects through a number of mechanisms. By stabilizing lysosomal membranes, cortisol reduces the release of proinflammatory proteolytic enzymes and reduces damage to the vascular endothelium, thereby decreasing capillary leak. Cortisol is thought to have an anti-inflammatory action through the non-genomic binding of the GR-cortisol complex to the transcriptase NK-k β , reducing the formation of prostaglandins and cytokines that would act as positive chemotactic agents for phagocytic white blood cells. Cortisol

inhibits the production of IL-2, which stimulates the proliferation of T cells. It also induces the synthesis of lipocortin, an inhibitor of phospholipase A2, which is required for the synthesis of prostaglandins and leukotrienes. Concurrently, there is secretion of IL-6 an anti-inflammatory cytokine that inhibits the production of IL-1 and TNF α and thus provides negative feedback for the inflammatory cascade.

Cortisol can promote increased transcription of anti-inflammatory genes. Mitogen activated protein kinases (MAPKs) form intracellular signalling pathways that result in the production and post-transcriptional modification of proinflammatory mediators. MAPK phosphatases dephosphorylate MAPKs rendering them inactive; glucocorticoids increase the expression of MAPK phosphatases and thus can down regulate the inflammatory response.

Cells that surround the inflamed tissues express specific tissue protective receptors (TPR) that bind the type 1 cytokine erythropoietin. Binding of this ligand inhibits pro-inflammatory cytokine production, inhibits macrophage activity and delimits the volume of injury by countering apoptosis. Activation of TPRs also acts to recruit vascular and tissue specific stem cells and enhances tissue repair.

Catecholamines

Noradrenaline is released mainly from the postganglionic nerve endings, while the adrenal medulla is the major source of adrenaline in the circulation.

Stimulation of the sympathetic nerves to the adrenal medulla results in large quantities of adrenaline and noradrenaline being released into the circulation. The action of these catecholamines is mediated via cell surface adrenergic receptors, which are themselves bound to protein molecules that traverse the cell membrane. Binding to these receptors causes a conformational change in the protein, resulting in the opening of an ion channel or the stimulation of a second messenger enzyme system. There are two major groups of adrenergic receptors, α and β , which are further divided into subgroups (α_{1-2} , β_{1-3}). Noradrenaline preferentially excites α receptors in addition to having some β activity, whilst adrenaline is equally effective across both receptor groups. Sympathetic stimulation is excitatory in some tissues and inhibitory in others and similarly α and β receptors may be excitatory or inhibitory.

Circulating catecholamines enhance the sympathetic nervous system's stimulation of the cardiovascular system. This results in arteriolar and venous constriction and increased heart rate and force of myocardial contraction. The net result is raised ventricular blood volume causing increased muscle fibre stretching, improving cardiac output and raising blood pressure.

During stress, noradrenaline and adrenaline both cause hyperpolarization of gut smooth muscle and decreased bowel motility. Circulating adrenaline stimulates the phosphorylase enzyme via cAMP, causing rapid glycogenolysis especially in the liver and skeletal muscle. Combined with the anti-insulin effects of cortisol, adrenaline and noradrenaline activate triglyceride lipase in fat cells, causing the rapid mobilization of fatty acids, shifting energy metabolism away from glucose.

Brain catecholaminergic systems utilize noradrenaline, adrenaline, dopamine and L-DOPA. Stressful stimuli accelerate both the synthesis and release of brain catecholamines, with adrenergic and noradrenergic neurons involved in the central processing of the stress response. The effect of these neurotransmitters is dependent on which receptors and transporters are expressed on target cells. Adrenaline binds to the same receptors as noradrenaline and adrenergic neurons may use noradrenaline transporters for reuptake from synaptic clefts.

Acute stress leads to transient alterations in brain catecholamine systems with transient activation of the HPA. After a short period of time and depending on the nature of the stressor, the activity of these catecholaminergic neurons can return to baseline. Chronic, long-term or repeated stressors may induce permanent changes and keep catecholamine producing neurons chronically active.

In response to the majority of stressors, brainstem noradrenaline producing neurons stimulate the HPA non-specifically via adrenergic receptors. In contrast, stimulation of the paraventricular nucleus of the hypothalamus is stressor specific.

Acute phase proteins

Hepatic protein synthesis shifts from constitutive proteins (e.g. albumin and transferrin), to acute phase proteins (e.g. C-reactive protein (CRP) and fibrinogen), following activation of the systemic stress response. This causes increased plasma concentrations of CRP, coagulation proteins, protease inhibitors and complement proteins. These acute phase proteins are arbitrarily divided into type I, e.g. haptoglobin and α_2 -acid glycoprotein that are mediated by IL-1 and TNF-like cytokines, and type II acute phase proteins mediated by IL-6-like cytokines. Since the synthesis of this group of proteins increases under stress, they are referred to as positive acute phase proteins. In contrast, constitutive proteins such as albumin and the hormone binding proteins are downregulated and classified as negative acute phase proteins. Under stress conditions, the amino acids required for this protein synthesis are derived from extrahepatic tissues, where proteolysis and reduced amino acid uptake occur, secondary to the influence of cortisol and the catecholamines.

Positive acute phase proteins have diverse functions in opsonization and trapping of microorganisms, activating complement, binding cellular remnants, neutralizing enzymes, scavenging free radicals and in modulating the host's immune response.

C-reactive protein is a ring-shaped protein that binds to phosphocholine on the surface of dead cells and some bacteria where it acts as an opsonin, activating complement by the classical pathway. Haptoglobin binds free haemoglobin, inhibiting its oxidative activity and has anti-inflammatory capabilities, binding to major receptors on the cell membranes of leukocytes. It is removed from the circulation, along with any bound molecules, by the reticuloendothelial system. Fibrinogen (factor 1) is a high molecular weight glycoprotein involved in the clotting cascade and inflammation. It is converted by the enzyme thrombin into fibrin monomers that automatically

polymerize to form fibrin fibres as part of clot formation. Fibrinogen and fibrin contribute to inflammation by inducing leukocyte migration and by modulating the inflammatory response of leukocytes and endothelial cells via an increased responsiveness to cytokines and chemokines.

Coagulation factors

Coagulation may be enhanced during the stress response to infection, with the inflammatory and clotting cascades being closely linked. Endothelial cell injury activates the clotting cascade through binding of factor VIIa to tissue factor, leading to the generation of thrombin. This catalyses the formation of fibrin and activates platelets, resulting in the formation of a clot. During stress, there are increased concentrations of circulating procoagulants such as fibrinogen and the cytokine IL-6, which stimulate the expression of tissue factor. Concurrently, platelets are activated by proinflammatory cytokines and adrenaline. There is downregulation of physiological anticoagulant mechanisms such as proteins C and S (negative acute phase proteins) and inhibition of fibrinolysis. Consequently, inflammation-induced coagulation is characterized by widespread intravascular fibrin deposition. Impairment of thrombolysis occurs because of high circulating concentrations of plasminogen activator inhibitor type 1.

By binding to protease activated receptors (PARs), thrombin induces leukocyte migration to the surface of the endothelium and by induction of the expression of cytokines and chemokines by leukocytes. The four isoforms of PARs (PAR 1–4) belong to a family of G-coupled receptors activated by proteolytic cleavage.

Procoagulant activity is regulated by three important anticoagulant pathways: antithrombin, the protein C system and tissue factor pathway inhibitor. During inflammation-induced coagulation, the function of all three pathways can be impaired.

The serine protease inhibitor antithrombin is the main inhibitor of thrombin. During severe inflammatory responses, antithrombin concentrations are markedly decreased owing to impaired synthesis (negative acute phase response), degradation by elastase from activated neutrophils and consumption by ongoing thrombin generation.

Antithrombin has an anti-inflammatory effect, by stimulating prostacyclin release from endothelium. The anti-inflammatory effects of cytokines are the result of blockade of both cytokine production by neutrophils and their tethering to vascular endothelium. Antithrombin also binds to specific receptors on neutrophils, monocytes and lymphocytes, blocking their interactions with the endothelium.

In severe inflammation, plasma concentrations of protein C are low due to impaired synthesis, consumption and degradation by proteolytic enzymes such as neutrophil elastase. There is also a significant downregulation of thrombomodulin, a protein cofactor expressed on the surface of endothelial cells. Under normal conditions, the thrombin–thrombomodulin complex activates protein C, but in severe inflammation the expression of this protein is inhibited by the inflammatory cytokines TNF α and IL-6. Low plasma concentrations of free protein S may compromise the function of the protein C system.

In plasma, 60% of the cofactor protein S is bound to complement regulatory protein C4b binding protein (C4bBP). Increased plasma concentrations of C4bBP, as a consequence of the acute phase response, result in a relative protein S deficiency. In sepsis, the endothelial protein C receptor is downregulated, further impeding the function of this anticoagulant.

SHOCK

Shock can be classified according to its aetiology: cardiac dysfunction (either primary or secondary); loss of circulating volume (fluid loss or redistribution), or failure to maintain systemic vascular resistance. These may occur in combination, particularly when entering the final common pathway of refractory shock. If untreated, the end result, whatever the cause, is tissue hypoperfusion and impairment of cellular metabolism.

The amount of oxygen delivered to tissues is a function of the cardiac output and arterial oxygen content. In haemorrhagic shock, cardiac output falls because of reductions in preload, force of contraction and stroke volume. These changes promote compensatory sympathetic responses inducing tachycardia, peripheral vasoconstriction, tachypnoea and the activation of neurohumoral mechanisms. The adrenal glands secrete adrenaline, noradrenaline and cortisol, whilst renal hypoperfusion activates the renin–angiotensin system. Angiotensin II, a vasoconstrictor, stimulates the release of vasopressin and aldosterone. Vasopressin, a pressor agent, increases the permeability of the renal collecting ducts to water, resulting in water retention, whilst aldosterone acts at the distal renal tubule to promote sodium retention.

If the stress response is inadequate for the metabolic challenge imposed upon the body, endothelial cells switch to anaerobic metabolism, absorb interstitial fluid and swell. This causes narrowing of the lumen of arterioles, further restricting the oxygen supply. Ischaemic cells accumulate lactic acid and free radical species, which are directly cytotoxic, prompting the release of inflammatory mediators and the adhesion of neutrophil leukocytes cells. As the inflammatory cascade is propagated, the cumulative anaerobic metabolites become negatively inotropic, and energy-dependent potassium channels fail, causing arterioles to dilate, heralding the onset of refractory shock.

CARE OF THE SHOCKED PATIENT

The response to stress is typically well regulated but homeostatic control can be lost in the presence of powerful stimuli or if a second insult occurs, for example an infection or a need for surgery after trauma.

Definitions

Patients are admitted to critical care units because of various underlying disorders, yet may display similar clinical manifestations regardless of the clinical insult. This observation led to the introduction of the term 'systemic inflammatory response syndrome' (SIRS) and

BOX 20.1 Definitions used in critically ill patients

Infection: a microbial phenomenon characterised by an inflammatory response to the presence of micro-organisms or the invasion of normally sterile host tissues or fluids by these organisms

Systemic inflammatory response syndrome (SIRS): two or more of the following:

- temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$
- heart rate >90 beats/minute
- respiratory rate >20 breaths/minute or $\text{PaCO}_2 <4.3\text{kPa}$
- white cell count $>12 \times 10^9$ or $<4 \times 10^9$ or $>10\%$ immature forms

Severe sepsis: infections causing SIRS with associated organ failure, hypoperfusion or hypotension (systolic BP <90 mmHg)

Septic shock: severe sepsis with arterial hypotension refractory to fluid replacement

to attempts to define shock in order to establish a consistent basis to assist diagnosis and treatment (Box 20.1). Such a classification also facilitates design of clinical trials and incorporation of their results into routine clinical practice. The term multi-organ dysfunction syndrome (MODS) is now preferred to the previously used term 'multi-organ failure'. Multi-organ dysfunction syndrome is defined by organ specific criteria, involving clinical and investigation findings. It is now preferred as a concept as it is acknowledged that it may be appropriate to offer organ support before the function of individual organs has deteriorated to a life-threatening extent. Signs of organ system dysfunction are shown in Box 20.2.

BOX 20.2 Signs of organ system dysfunction

Neurological dysfunction: altered mental status (reduced Glasgow Coma Scale)

Respiratory dysfunction: arterial hypoxaemia ($\text{PaO}_2 <10\text{kPa}$) and/or hypercapnia ($\text{PaCO}_2 >6.5\text{kPa}$); the presence of infiltrates radiologically and the requirement for respiratory support

Cardiovascular dysfunction: ischaemia, tachydysrhythmias, systolic hypotension (<90 mmHg) and a requirement for vasopressor and/or inotropic support. Increased capillary refill times and hyperlactataemia (>2 mmol/L)

Renal dysfunction: acute oliguria (urine output <0.5 mL/kg/hr) with increased serum creatinine concentration, acid base and electrolyte disturbances

Hepatic dysfunction: elevated liver enzymes, hyperbilirubinaemia and coagulopathy; hypoglycaemia in severe cases

Gastrointestinal dysfunction: intolerance of enteral feeding, ileus, gastrointestinal bleeding and ischaemia

Haematological dysfunction: leukocytosis or leukopenia, thrombocytopenia and platelet dysfunction, disseminated intravascular coagulation

Endocrine dysfunction: hypothalamo–pituitary–adrenal axis failure; hyperglycaemia, hypertriglyceridaemia

Immunological dysfunction: hospital-acquired infection

Multi Organ Dysfunction Syndrome (MODS): when two or more organs are involved

Management

The mortality and morbidity of critically ill patients has been much improved by the Surviving Sepsis Campaign (SSC), an international forum launched in 2004 to improve the management of sepsis. Since the majority of patients with SIRS, shock and MODS have infection as a contributory factor, appropriate management of sepsis is essential.

Immediate care

Immediate measures include removing the source of infection (if practicable), collection of tissues and fluids for microbiology and the commencement of antimicrobials. Targets in this phase of management include a heart rate <90 bpm, systolic BP >90 mmHg (MAP >65 mmHg), a urine output >0.5 ml/kg/min and normalisation of serum lactate concentration (if previously raised).

Initial antimicrobial therapy must be empirical, on the basis of the likely causative organisms until the results of culture and sensitivity are known. Factors to consider include the site of the infection, knowledge of the patient's pre-morbid condition, previous antibiotic exposure and local prescribing guidelines. In the case of antibiotics, broad-spectrum agents can often be replaced with a tailored regimen once sensitivities are known. This approach reduces the risk of promoting multi-drug resistance in pathogenic bacteria. Gram staining of specimens may reveal bacteria and recently the application of PCR (polymerase chain reaction) technology has led to rapid diagnostics in some infections.

Organ support

Balanced salt solutions (e.g. Hartmann's, lactated Ringer's) are the fluids of choice in the resuscitation of septic shock. Norepinephrine (noradrenaline) is typically the favoured vasopressor (because of its predominant α -adrenergic effects), often in combination with the vasodilating inotrope, dobutamine. In cases of refractory shock, vasopressin is a valuable and potent pressor agent, usually used in combination with noradrenaline and intravenous steroids. Frequently, the use of vasopressin will allow a reduction in the dose of noradrenaline, potentially limiting some of its deleterious effects. Glucocorticoids enhance vascular responsiveness to catecholamines by mechanisms that may include adrenoceptor function and prostaglandin action. Hydrocortisone is prescribed at a dose of 200 mg daily in divided aliquots or as a continuous infusion. Whilst it is not necessary to perform a tetracosactide test to identify adrenal suppression, hydrocortisone should not be commenced in septic patients who are not shocked, because of its immunosuppressive effects.

Respiratory support should be given as required. Patients receiving mechanical ventilation should undergo intermittent interruptions to assess the need for ongoing assistance. If their underlying condition permits, they should also be nursed with the head of the bed elevated to 30–45° as this has been shown to limit aspiration and reduce the risk of pneumonia.

Red cell transfusion should generally be reserved for patients whose haemoglobin concentration falls to <70 g/L, once tissue hypoperfusion has resolved, except in particular circumstances such as acute haemorrhage or myocardial ischaemia. Platelet transfusion should be administered prophylactically in severe sepsis when platelet counts are <10 × 10⁹/L, in the absence of severe bleeding and 50 × 10⁹/L in the context of active bleeding, surgery or invasive procedures. Intravenous immunoglobulins are not recommended in severe sepsis or septic shock.

Continuous renal replacement therapy and intermittent haemodialysis have been shown to be of equal benefit in patients with severe sepsis. However, continuous therapies facilitate fluid balance in patients who are haemodynamically unstable.

In the first 48 h after a diagnosis of severe sepsis or septic shock, it is preferable to administer nutrition enterally, as tolerated, rather than to fast the patient or to provide only intravenous glucose. Current evidence suggests that intravenous glucose and low dose enteral feeding, increased as tolerated, is preferable to parenteral feeding in the first week of illness. Various immunomodulating agents have been used in nutritional formulations but none is currently recommended for use in patients with sepsis. The reduction in the availability of arginine in sepsis has the potential to lower nitric oxide synthesis and increase production of superoxide and peroxynitrite. Conversely, arginine supplementation has the potential to cause vasodilatation and hypotension and studies of its use in nutritional preparations have had conflicting results. Plasma glutamine concentration is reduced during severe illness. A previous meta-analysis showed a reduction in mortality associated with its use but this has not been reflected in other studies. Whilst there do not appear to be adverse effects of glutamine supplementation, a large trial (the REDOXS study) is currently in progress to investigate its use. There is some initial evidence that the administration of selenium may have a beneficial effect in SIRS and shock by providing an antioxidant defence. Further studies are required before its administration can be recommended for this specific purpose, but its use as part of standard trace element supplementation is endorsed.

There should be protocols in place for the management of blood glucose. Initially, blood glucose should be monitored every 1–2 h and insulin infusion begun if two consecutive concentrations are >10 mmol/L. Once glucose concentrations and insulin infusion rates are stable, the frequency of monitoring may be reduced to every four hours. The upper acceptable limit for blood glucose should be 10 mmol/L in this group of patient; the stricter target of 6.1 mmol/L advocated previously was not associated with reduced mortality, but predisposed to hypoglycaemia.

Patients with severe sepsis should receive mechanical prophylaxis against venous thromboembolism using graduated compression stockings or mechanical compression devices. In addition, they should receive pharmacoprophylaxis with low molecular weight heparin unless contraindicated, e.g. thrombocytopenia, active bleeding, recent intracerebral haemorrhage.

Patients with severe sepsis and risk factors for bleeding (e.g. coagulopathy, mechanical ventilation for at least 48 h and possibly hypotension) are at risk of stress ulceration and should be given prophylaxis using proton pump inhibitors in preference to H₂ receptor blockers.

Immunomodulation

The body has a non-specific, or innate, immune response provided by mechanical barriers such as the skin and gastric acid secretion, and a more specific acquired immune response. Both may be altered by treatment, either directly or as a secondary effect, e.g. proton pump inhibitors given for stress ulceration reduce gastric acidity (potentially compromising innate immunity) and nutritional support may have a beneficial effect on the immune response.

As the pathogenesis of SIRS, shock and MODS involves immune mediators, it is logical to attempt to treat the conditions by their specific modulation. Various agents have been tried for this purpose.

The use of glucocorticoids for their vasopressor effect in shock has been described above. Their effect on the immune response is via a reduction in the production of proinflammatory cytokines, particularly TNF α and IL-6, although trials of the use of glucocorticoids for immunomodulation have not shown great benefit. Similarly, trials of anti-cytokine therapies, such as monoclonal antibodies to TNF β and recombinant IL-1 receptor antagonist, have not proven their efficacy.

Inflammatory and procoagulant responses are intimately linked and may lead to widespread injury to vascular endothelium, contributing to MODS. Protein C acts to promote fibrinolysis and has inhibitory actions on thrombosis and inflammatory responses which make it a potential therapeutic target. Activated protein C has been used in the treatment of severe sepsis but has now been withdrawn due to lack of evidence of benefit on 28-day mortality.

Some agents used routinely in the critically ill, e.g. sedatives such as propofol and benzodiazepines, and non-steroidal anti-inflammatory agents, have been shown, particularly in animal studies, to modify the immune response, although a precise clinical role is unclear. Recent evidence suggests that statins may modify the immune response but the results of clinical trials to evaluate this further are awaited.

One explanation for the lack of clinical benefit from immunomodulating therapies may be the redundancy of action that exists between the cytokines; blocking of one pathway still allows for activation and release of mediators by an overlapping route. A further reason could be that the timing of the administration of the immunomodulating agent may be of critical importance for the success of a response.

CONCLUSION

The body's response to stress tends to be qualitatively similar whatever the stress, although the severity of the stress affects the response quantitatively. In severe stress, responses that appear potentially advantageous if limited in extent become harmful. There have been improvements in the survival of critically ill patients as a result of better organ support and more effective treatment of infection, but attempts at specific immunomodulation of the inflammatory response have been disappointing.

INTRODUCTION

The clinician is most commonly faced with the investigation and management of abnormal sexual development at two age periods: birth and puberty. Abnormal sexual development at birth is the result of a disorder of sex development (DSD) presenting with genitalia that are either atypical for sex or ambiguous. Disorders of sex development can also present at adolescence as abnormalities of pubertal development. However, in most cases, abnormal pubertal development is due to an alteration in the regulation of puberty in an individual without a DSD. To understand these disorders there is a need to understand the normal processes of sex and pubertal development.

NORMAL SEX DEVELOPMENT

Male or female sex development is programmed at fertilization, depending on whether the zygote is heterogametic (46XY) or homogametic (46XX). A scheme summarizing the embryology and genetic control of sex

development in the male and female fetus is shown in [Figure 21.1](#). The indifferent, or primitive, gonad develops from a thickened ridge of coelomic epithelium that arises from the intermediate mesoderm. Cell precursors from this region give rise to the kidneys, adrenals and gonads. The adrenogenital primordium comprises a single population of steroidogenic factor-1 (SF-1) immunoreactive cells. The gonadal ridge becomes populated with primordial germ cells that have migrated from the wall of the yolk sac.

The first histological expression of fetal testicular development is the appearance of seminiferous or sex cords at between six and seven weeks of gestation. Surrounding the sex cords is the interstitial region, which contains the precursors of Leydig cells and also the peritubular myoid cells. Primitive interstitial cells differentiate later into Leydig cells, an event that coincides with the onset of testosterone synthesis by the fetal testis. Steroidogenesis is placental human chorionic gonadotrophin (hCG)-dependent and results in the production of fetal testosterone concentrations within the normal adult male range. The pivotal role for the Y chromosome in male sex differentiation has been recognized for more than

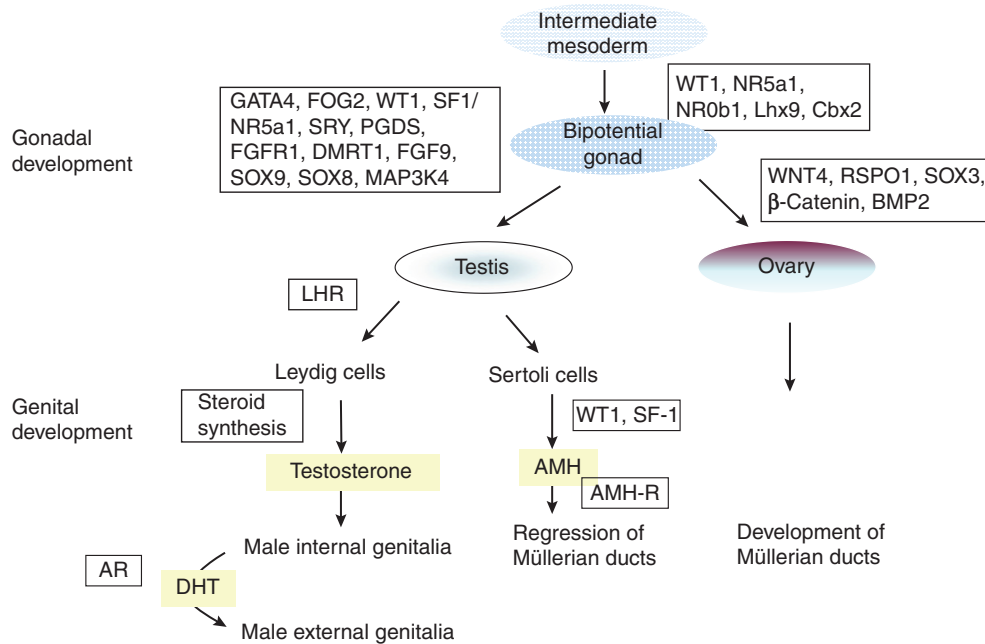

FIGURE 21.1 ■ Embryology and genetic control of fetal sex development. LHR, LH receptor; AR, androgen receptor; DHT, dihydrotestosterone; AMH-R, anti-Müllerian hormone-receptor.

40 years, based on the phenotype of individuals with sex chromosome aneuploidies such as XXY and XO. The study of sex-reversed XX males and XY females led to the identification of the *SRY* gene (sex-determining region Y) on the short arm of the Y chromosome. That this is the prime testis-determining gene is illustrated by the introduction of the *Sry* homologue into a transgenic XX mouse and a resulting male phenotype. The majority of XX males are positive for the *SRY* gene, as a result of terminal exchange between the X and Y chromosomes during paternal meiosis. In the case of XY females, mutations have been identified that disrupt the function of the *SRY* protein, which acts as a transcription factor. However, these are found in only 15–20% of patients, indicating there are other genes also involved in testis determination. *SRY* acts to up-regulate the transcription of the related gene, *Sox9* in the Sertoli cell lineage. High concentrations of *SOX9* protein are maintained in these cells through a positive interaction with the secreted molecules fibroblast growth factor 9 (FGF9) and prostaglandin D2 (PGD2). These molecules are important in securing two other necessary steps in testis development: the recruitment of other somatic cells to differentiate into the Sertoli cell lineage and, in the case of FGF9, spread of the initial central testis-determining signal to the anterior and posterior poles of the gonad. Not only does *SOX9* promote testis development, but it also antagonizes the Wnt signalling pathway and *FOXL2*, both of which are crucial for ovarian development and which can, themselves, antagonize *SOX9* action.

With the committed development of the gonad as a testis, two trophic factors produced by the testis control subsequent differentiation of internal and external genitalia in the male. Anti-Müllerian hormone (AMH) is produced by the Sertoli cells and signals through two trans-membrane receptors expressed in the mesenchyme that gives rise to

the Müllerian ducts. Anti-Müllerian hormone acts ipsilaterally to cause regression of the Müllerian ducts, the anlage (rudimentary precursor) of the uterus, fallopian tubes and upper two-thirds of the vagina. Circulating concentrations of AMH in males are high in early infancy and fall gradually throughout childhood, until they become undetectable after puberty; its measurement is useful for detecting testicular tissue, especially in early childhood. Testosterone is the other key trophic factor produced by the early developing testis. There is indirect evidence, based on luteinizing hormone (LH) receptor mouse knockout models and human LH β -chain mutations, that production is initially autonomous, but, thereafter, is under the control of hCG and then fetal pituitary gonadotrophin secretion. High local concentrations of testosterone stabilize Wolffian duct development in the male to differentiate into the vas deferens, epididymis and seminal vesicles. The external genitalia in both sexes develop from a common anlage, comprising the urogenital sinus, genital tubercle and swellings and urethral folds. In the male, androgens, again, play the key role in differentiation of these primordial structures, to develop as the penis, scrotum and opening of the urethra on the glans. Dihydrotestosterone (DHT) is necessary to provide an amplification of the androgenic effect. The evidence for DHT dependency is illustrated by the predominantly female external genital phenotype in 5 α -reductase deficiency.

In the absence of the testis-determining factors, testosterone and AMH, and in the presence of the trophic proteins necessary for ovarian development, the gonad associated with the 46XX karyotype develops as an ovary and the Müllerian ducts differentiate normally into female internal genital ducts. The external genital anlage, in the absence of androgens, remains underdeveloped with respect to growth of the genital tubercle and the absence of midline fusion of the labioscrotal folds and swellings.

The development of the lower part of the vagina from canalization of the vaginal plate is incompletely understood, but the process is probably influenced by oestrogens. Virilization of the female external genitalia from an extraneous source of androgens leaves the development of the female internal genitalia intact.

NORMAL PUBERTAL DEVELOPMENT

Endocrinology of normal puberty

The precise trigger that initiates the onset of puberty in the human remains an enigma. There is activation of pituitary gonadotrophin secretion both in early fetal life and, again, after birth for several months. During this latter period, plasma concentrations of gonadotrophins and sex steroids may reach values normally observed at puberty. Throughout later infancy and childhood, gonadotrophin concentrations remain low, although evidence of pulsatile LH secretion using more sensitive immunoassays can be detected in some children. Consequently, puberty represents the reactivation of gonadotrophin secretion that has been restrained during childhood.

The initial endocrine event at puberty is an increase in nocturnal pulsatile LH secretion in response to gonadotrophin releasing hormone (GnRH) released into the pituitary portal system. The neurons that release GnRH migrate to the hypothalamus, from the medial olfactory placode, during fetal development. A failure of such migration is considered to be the cause of some inherited forms of hypogonadotrophic hypogonadism that are associated with anosmia (Kallman syndrome). A GnRH pulse generator controls the onset of puberty by causing a progressive increase in amplitude and frequency of LH pulses, which occurs about one year before the onset of physical signs of puberty. The neuroendocrine mechanisms that cause activation of the GnRH generator at the appropriate age are extremely complex, but appear to involve excitatory amino acids, catecholamines, neuropeptide Y, leptin and acetylcholine, as well as external influences such as nutritional intake. Furthermore, an additional factor discovered as a result of studies in patients with hypogonadotrophic hypogonadism, is the kisspeptin/GPR54 system, which appears to be a gatekeeper of reproductive development. GPR54 is a G-protein-coupled receptor whose endogenous ligand is a 54-amino acid peptide, cleaved from the parent 145-amino acid peptide encoded by the *KISS-1* gene. GPR54-deficient mice are infertile and have low circulating gonadotrophin concentrations. Mutations in the *GPR54* gene cause hypogonadotrophic hypogonadism in humans. It appears that GPR54 is one of the key factors in the control of puberty. Administration of kisspeptin stimulates LH and follicle stimulating hormone (FSH) secretion, which can be blocked by GnRH antagonists, indicating that the kisspeptin/GPR54 system effect on the hypothalamic-pituitary-gonadal axis is mediated via GnRH release.

Increased gonadotrophin secretion leads to a gradual increase in the secretion of gonadal steroids, principally testosterone in males and oestradiol in females. Random, daytime sex steroid measurements are seldom predictive

of pubertal events in an individual, although early morning testosterone concentration as a reflection of nocturnal secretion is more useful. Inhibin B, a marker of Sertoli cell function, increases early in puberty and reaches adult concentrations by mid-puberty. Spermatogenesis starts between 11 and 15 years of age and sperm can be detected in early morning urine specimens by 13 years of age.

The attainment of reproductive capacity in the female is dependent on cyclical gonadotrophin secretion to ensure ovulation. Follicle stimulating hormone-induced oestrogen secretion, by developing ovarian follicles, leads to a positive feedback on LH secretion and a mid-cycle surge that induces rupture of the mature follicle. After ovulation, the luteinized follicle secretes progesterone while oestradiol concentrations fall. Inhibin B secretion predominates during the follicular phase, while inhibin A secretion is dominant during the luteal phase. All these events are coordinated by pulsatile release of GnRH secretion and modulation of gonadotrophin and sex steroid production, by both negative and positive feedback loops. It is not surprising that there is generally a 1–2-year interval after menarche before the majority of girls are ovulating regularly. Ultrasonography can be used to assess the development of reproductive function in girls. Enlargement of the uterus and endometrial thickening are evident after birth because of the effect of maternally derived oestrogens. Multiple ovarian follicular cysts are often seen on ultrasound at this time. The effect of increasing secretion of oestradiol during puberty can be observed by appropriate morphological changes in the appearance of the uterus. The prepubertal uterus starts to increase in size from seven years of age onwards.

The onset of increased production of dehydroepiandrosterone (DHEA) and its sulphate (DHEAS) by the zona reticularis of the adrenals, between six and eight years of age, defines the phenomenon of adrenarche. Concentrations of DHEAS thereafter increase throughout puberty into early adult life in micromolar amounts and then start to decline gradually in older age (adrenopause). There is no concomitant increase in adrenal glucocorticoid and mineralocorticoid secretion, so ACTH is not the primary trophic factor controlling DHEA production. Intra-adrenal modulation of steroidogenesis, by post-translational regulation of the 17-hydroxylase enzyme (by phosphorylation on serine/threonine residues, and electron transfer by the P450-oxidoreductase enzyme), is the key factor in the production of C19 steroids such as DHEA. There is also a relative underexpression of the enzyme 3 β -hydroxysteroid dehydrogenase enzyme in the zona reticularis that contributes to a preponderance of Δ^5 steroids. Extra-adrenal factors postulated to play a role in adrenarche include prolactin, oestrogens, growth factors and cytokines. There is an association between leptin concentration and the timing of adrenarche in obese children.

Physical signs of normal puberty

Puberty is the transitional period between childhood and adulthood that spans adolescence and leads to the acquisition of reproductive capacity. The time span for

the physical changes to take place is generally 4–5 years, but individual variations can result in a time interval of 2–6 years. This is referred to as the tempo of puberty. The age of onset of puberty also varies considerably, with epidemiological evidence suggesting that puberty may now be starting earlier.

The first sign of puberty in girls is breast development, starting, on average, at 11 years with an age range of 8–13 years (see Fig. 21.2A). This is termed ‘thelarche’ and starts as a small mound of tissue beneath the nipple manifest as a breast ‘bud’, which is usually distinguishable, on palpation, by its firmness compared with the softer and more diffuse texture of subcutaneous fat. Further development of the nipple, areola and underlying breast tissue takes place over the ensuing four years

or so (Tanner stages B2–B5). Epidemiological studies conducted in the USA indicate that 25% of girls may have already started thelarche by eight years of age. However, it is unclear whether misinterpretation of adipose tissue as breast development may have skewed the data.

Coincident with breast development is the onset of growth of pubic hair which may precede thelarche in 10% of girls. Hair growth usually starts on the labia before spreading over the mons pubis and is quantified as Tanner stages PH2–5. Sometimes there may be further growth on the upper medial aspects of the thighs and along the linea alba (PH6). Axillary hair starts to appear at about 12.5 years of age and takes a further 18 months to reach adult distribution.

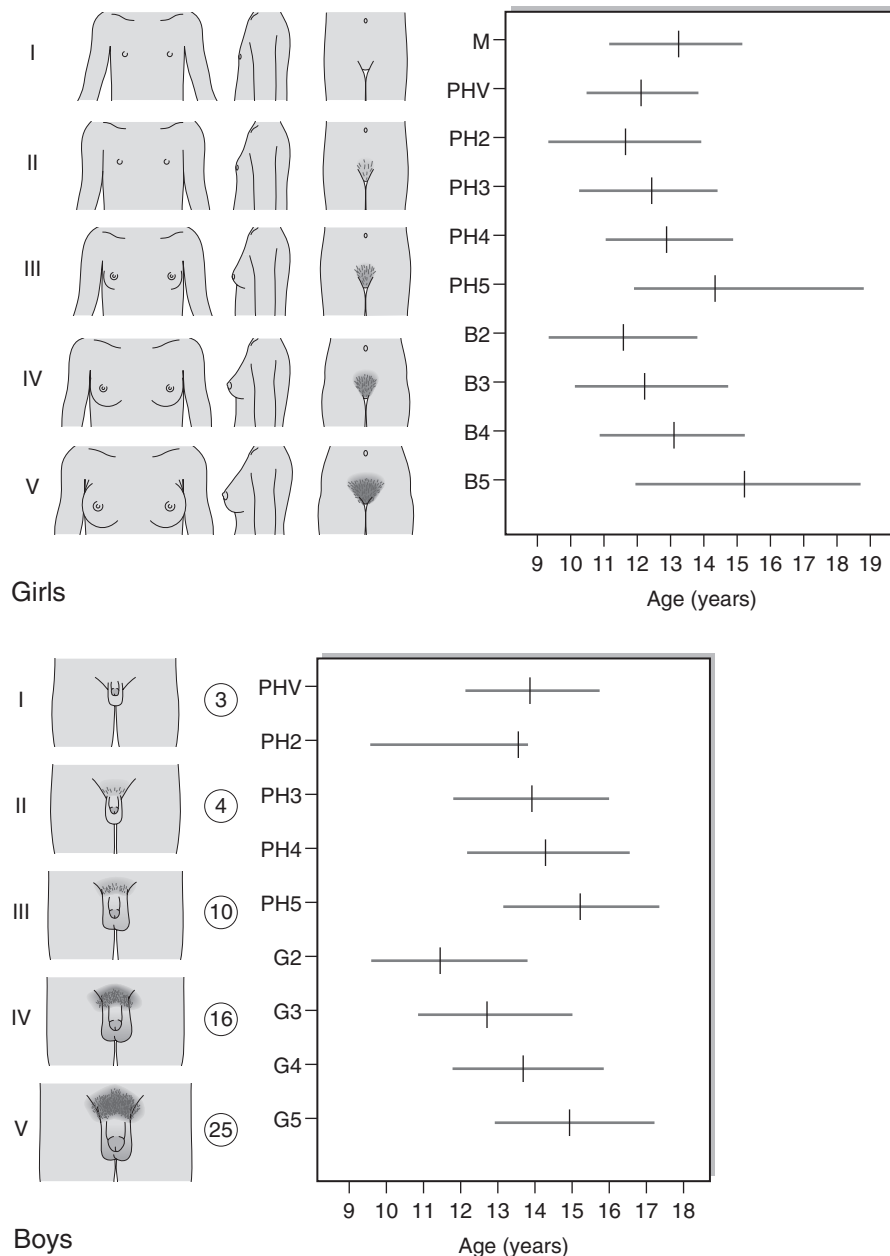

FIGURE 21.2 ■ Tanner staging of physical development, based on external primary and secondary sexual characteristics in children, adolescence and adults. M, menarche; Circled figures, testicular volume (mL); PHV, peak height velocity; PH, B, G, see text.

Menarche, the onset of menses, is a relatively late event in the pubertal process and occurs at around 12.5–13 years of age. This coincides with breast stage B4. A trend in the lowering of the age of menarche has occurred in the past, but the reduction has only been by a few months during the past 30 years. There are racial differences as well as geographical variations. The age of menarche tends to be slightly higher in Northern than Southern Europe.

Increased growth velocity is a measurable, indirect sign of puberty. In girls, peak height velocity (defined as the maximum rate of growth achieved during puberty, which is usually ~10 cm/year) is achieved relatively early in puberty (during breast stages B2–3) and before the onset of menarche. By the time of menarche, the majority of adult height has been achieved. Changes in body composition also occur, particularly with respect to fat distribution.

The first sign of puberty in boys is an increase in testis size (see Fig. 21.2B). Testicular size can be assessed clinically by the use of a series of standard ovoids (the Prader orchidometer). Testicular volume remains between 2–3 mL throughout infancy and childhood, an increase to 4 mL heralds the onset of puberty that occurs, on average, at 11.5 years with an age range of 9–14 years. Progressive enlargement of the testes takes place over three years with testicular volumes reaching up to 25 mL in adult life. Leydig cells constitute only a small part of testicular volume, the majority being the result of an increase in Sertoli cell and seminiferous tubule number and size.

Pubic hair growth, which may start as a few scrotal hairs, follows closely on testicular development and is quantified as Tanner stages PH2–5. Spread of hair up the abdominal wall is characteristic in many men and is classified as stage PH6. Growth of the penis, first in length and then in breadth, occurs concomitantly and is rated G1–G5. Growth of axillary and facial hair, are both later events in puberty, ranging in age from 14 to 16 years. ‘Breaking’ of the voice is due to enlargement of the larynx and elongation of the vocal cords and does not occur until stages G3–G4.

Peak height velocity in boys corresponds with stages G4 and PH4 and testicular volumes of 12–15 mL. This occurs, on average, at a chronological age of 14 years, as opposed to 12 years in girls. The adult male is, on average, taller than the adult female by 13 cm. This is partly due to the fact that boys start the growth spurt later and are, therefore, taller at its onset. In addition, the magnitude of growth achieved during the growth spurt is greater in boys (28 cm in males and 20 cm in females). Body composition alters in favour of increased muscle bulk and relatively less subcutaneous fat.

DISORDERS OF SEX DEVELOPMENT

Terminology of disorders of sex development

It is important to define terms used in relation to the investigation and management of disorders of sex

development that present at birth or in childhood. *Sex assignment* (often used interchangeably with *gender assignment*), is the sexing of an infant at birth as being male or female. This is straightforward in the vast majority; indeed, sex assignment is increasingly an activity that occurs before birth. *Gender identity* refers to how individuals perceive themselves as being male or female, while *gender role* describes characteristics that are sexually dimorphic within a normal population. In childhood, for example, male-typical behaviour is attributed to toy preferences being vehicles and soldiers as opposed to playing with dolls, generally preferred by girls. This rather simplistic illustration of sexual dimorphism has some physiological underpinning from observations of girls’ play behaviour following exposure to androgens in utero. Thus, gender role is more male-typical in girls with congenital adrenal hyperplasia. There is less convincing evidence that prenatal hormones affect gender identity. *Sexual orientation* refers to the subject of erotic arousal, which may be heterosexual, homosexual or bisexual. *Gender dysphoria* or *gender identity disorder* are terms that describe gender dissatisfaction. The phenomenon appears to be more common in individuals with disorders of sex development than in the general population, but it is difficult to identify predisposing factors related to the specific disorder.

The use of terminology that is clear and easy to use and understand by all health professionals, patients and their families is fundamental to the understanding, investigation and management of affected newborns and children. In addition, terminology should respect the individual and avoid terms that might cause offence. The term ‘intersex’ has had variable connotations even among professionals; some employed it as a term that covered all affected newborns while at the other end of the spectrum, some believed that the term should only apply to those where there is complete mismatch between chromosomal and anatomic sex. The consensus reached in Chicago in 2005 on the management of these patients, stressed the importance of terminology and recommended a substitution for the term ‘intersex’ for ‘disorder of sex development (DSD)’, which is defined as any congenital condition in which development of chromosomal, gonadal or anatomic sex is atypical. It also recommended the abandonment of terms such as ‘pseudohermaphroditism’ and ‘true hermaphroditism’. While this new nomenclature (Table 21.1) is easier to use and understand, it will nevertheless evolve over time as our understanding of long-term outcome and molecular aetiology improves. Given that genital anomalies may occur as commonly as 1 in 300 births and may not always be associated with a functional abnormality, some have advocated the use of ‘differences’ in preference to the term ‘disorder’. The strength of the abbreviation ‘DSD’ is that it can be used to cover both differences and disorders of sex development. However, the likelihood of this difference existing as a disorder will depend on the functional implications of the condition, which may be heavily influenced by the social and cultural framework within which the child exists.

TABLE 21.1 Old and new terminologies for abnormal sex development

<i>Previous</i>	<i>Proposed</i>
Intersex	Disorders of sex development (DSD)
Male pseudohermaphrodite. Undervirilization of an XY male, undermasculinization of an XY male	46XY DSD
Female pseudohermaphrodite. Overvirilization of an XX female, masculinization of an XX female	46XX DSD
True hermaphrodite	Ovotesticular DSD
XX male or XX sex reversal	46XX testicular DSD
XY sex reversal	46XY complete gonadal dysgenesis

General principles of management

The management of a child with an abnormality of genital development can often be difficult, particularly in patients for whom the sex of rearing is uncertain. The initial contact with the parents of a child with a DSD is important as first impressions from these encounters often persist. A key point to emphasize is that a child with a DSD has the potential to become a well-adjusted, functional member of society. Establishing a dialogue and building rapport with the affected child and the parents, evaluating the child and then developing a logical, as well as pragmatic, plan for investigations are central to the initial approach and ongoing management. It is paramount that any child or adolescent with a suspected DSD is assessed by an expert with adequate knowledge about the range of variation in the physical appearance of genitalia. If there is any doubt, the patient should be discussed with the regional team. For most patients, particularly in the case of the newborn, the paediatric endocrinologist within the regional DSD team acts as the first point of contact. The underlying pathophysiology of DSD and the strengths and weaknesses of the tests that can be performed, should be discussed with the parents and child, as appropriate, and tests undertaken in a timely fashion. With babies in whom there is true genital ambiguity, it should be explained to the parents that the best course of action may not initially be clear, but the healthcare team will work with the family to reach the best possible set of decisions in the circumstances. Finally, in the field of rare conditions, it is imperative that the clinician shares the experience with others through national and international clinical and research collaboration.

General examination of a newborn with suspected DSD

The physical examination should determine whether there are any dysmorphic features and the general health of the baby. Affected infants, particularly those who have XY DSD, are more likely to be small for gestational age and may display other developmental abnormalities. In

addition, the affected infant should be examined for mid-line defects which may point towards an abnormality of the hypothalamo-pituitary axis. The state of hydration and blood pressure should be assessed, as adrenal steroid biosynthetic defects can be associated with a variable extent of salt loss, masculinization and hypertension. In congenital adrenal hyperplasia (CAH), cardiovascular collapse with salt loss and hyperkalaemia does not usually occur until the second week of life (with salt loss usually evident from day four) and so will not be apparent at birth in the well neonate, but should be anticipated if the diagnosis is suspected. Jaundice (both conjugated and unconjugated) may be observed in babies with hypopituitarism or cortisol deficiency. Urine should be checked for protein as a screen for any associated renal anomaly (e.g. Denys-Drash or Frasier syndromes) and a pre-feed blood glucose concentration should be measured to exclude hypoglycaemia (suggestive of hypopituitarism, or occasionally CAH, e.g. 3β -hydroxysteroid dehydrogenase deficiency). Renal tract anomalies, such as ureteropelvic junction obstruction, vesicoureteric reflux, pelvic or horse-shoe kidney, crossed renal ectopia and renal agenesis, are reported to be more common in children with DSD.

Evaluation of the external genitalia

If the appearance of the external genitalia is sufficiently ambiguous to render sex assignment impossible, or the phenotype is not consistent with prenatal genetic tests, then investigations are clearly required. However, the ability to evaluate external genitalia fully may depend on the expertise of the observer and, before presentation to a specialist, the label of ambiguous genitalia has often already been assigned to newborns where the most appropriate sex of rearing was not clear to those present at the child's birth. The birth prevalence of genital anomalies may be as high as 1 in 300 births but the birth prevalence of complex anomalies that may lead to true genital ambiguity on expert examination may be as low as 1 in 5000 births.

Apart from those whose genitalia are truly ambiguous, infants can often be divided into those who overall seem to have largely male or female genitalia but with some unusual features. However, it is very important to bear in mind that a 46XX newborn infant with congenital adrenal hyperplasia can either present as a girl with clitoromegaly or as a boy with bilateral undescended testes. When evaluating these infants, the clinical features of the external genitalia that require examination include the presence of gonads in the labioscrotal folds, the fusion of the labioscrotal folds, the size of the phallus and the site of the urinary meatus on the phallus, although the real site of the urinary meatus may, sometimes, only become clear on surgical exploration. These external features can be individually scored to provide an aggregate score, the external masculinization score (EMS) (see Fig. 21.3A), or they can be graded according to their overall description as classically described by Prader staging (see Fig. 21.3B).

Infants with suspected DSD who require further clinical evaluation and need to be considered for

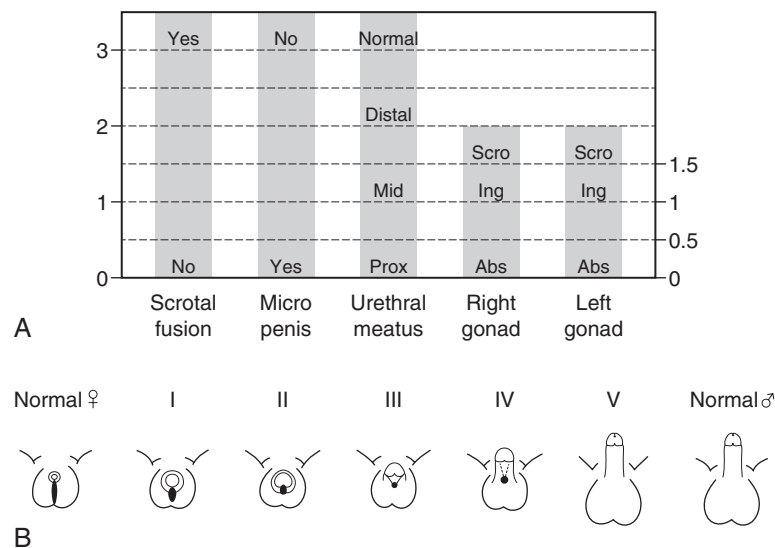

FIGURE 21.3 ■ (A) External Masculinization Score. Each individual feature of the genitalia (phallus size, labioscrotal fusion, site of the gonads and location of urethral meatus) can be individually scored to provide a score out of 12. Microphallus refers to a phallus smaller than normal for age. Scro, scrotal; Ing, inguinal; Abs, abdominal or absent on examination. (B) Differential virilization of the external genitalia using the staging system of Prader from normal female (left) to normal male (right).

investigation by a specialist, should include those with isolated perineal hypospadias, isolated micropenis, isolated clitoromegaly, any form of familial hypospadias and those who have a combination of genital anomalies with an EMS of less than 11. This will avoid unnecessary detailed investigations of boys with isolated glandular or mid-shaft hypospadias and boys with unilateral inguinal testis. The coexistence of a systemic metabolic disorder, associated malformations or dysmorphic features would lower the threshold for investigation as would a family history of consanguinity, stillbirths, multiple miscarriages, fertility problems, genital abnormalities, hernias, delayed puberty, genital surgery, unexplained deaths and the need for steroid replacement. In addition, maternal health and drug exposure during pregnancy, and the pregnancy history itself, may hold key information.

Evaluation of the internal anatomy

Examination and assessment by a paediatric surgeon with experience of DSD is critically important for defining the internal and the external anatomy in the affected patient. Combining examination with endoscopic visualization and radiological assessment can provide information on the location and state of the gonads, the urogenital sinus and Müllerian structures. Ultrasonography is the first-line imaging modality but the reliability is child and operator dependent. In the neonate the uterus, ovaries and adrenals should be identifiable. In the adolescent, it is sometimes difficult to confirm the presence of a prepubertal uterus by ultrasonography and there may be a place for repeat imaging after a six-month course of oestrogen. Magnetic resonance imaging (MRI) may be reserved for patients where ultrasonography has failed to delineate the relationship of the Müllerian structures and where there are abnormalities of the urinary tract. In adolescents, MRI can delineate structural anomalies

such as hydrometrocolpos or hydronephrosis and identify secretory tumours. Nowadays, the 'genitogram' has been superseded by endoscopic examination of the genital tract (genitoscopy), which provides a more detailed and thorough assessment. Laparoscopy is a very effective method of visualizing the internal sex organs and facilitates direct inspection, biopsy or excision of intra-abdominal gonads. In 46XY DSD, laparoscopy is clearly indicated in all children with impalpable testes as the gonads need to be identified and brought down to the scrotum if possible.

Investigating the newborn with DSD

In all infants with ambiguous genitalia and/or bilateral impalpable gonads, a first tier of investigations should be undertaken to define the sex chromosomes, delineate the internal genitalia by pelvic ultrasound and to exclude life-threatening congenital adrenal hyperplasia (CAH) – the commonest cause of ambiguous genitalia of the newborn. This first tier should, therefore, also include plasma glucose, 17OH-progesterone (17OHP), and measurement of sodium and potassium. 17OH-Progesterone measurement is usually unreliable before the age of 36 h and in the salt losing form of CAH, electrolytes usually do not become abnormal before day four of life. The results of FISH (fluorescence in situ hybridization) analysis using Y- and X-specific probes should be available within one working day and the 17OHP results should be available within a maximum of two working days in all specialist DSD centres. In situations where the level of suspicion of CAH is very high and the infant needs immediate steroid replacement therapy, samples should be collected and stored before starting therapy. These should be of a sufficient volume to assess 17OHP, testosterone, androstenedione and, possibly, renin, in that order of priority. At least one spot or 24-h urine sample for a urine steroid profile should be collected before starting therapy. The

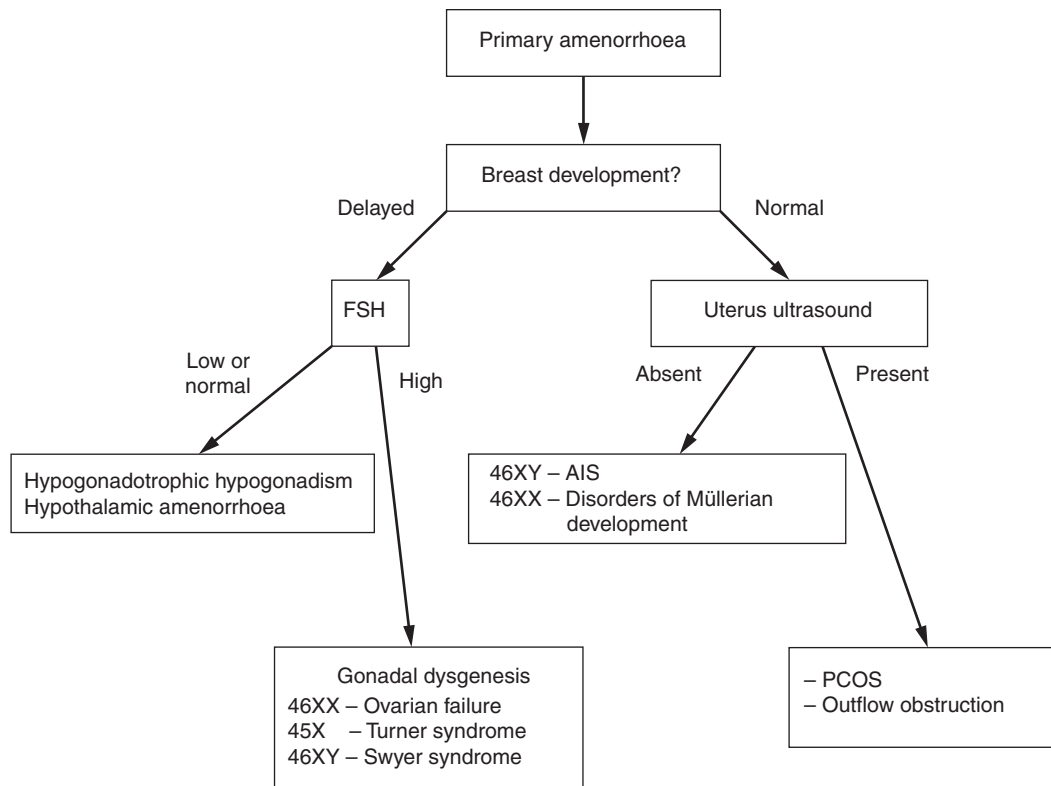

FIGURE 21.4 ■ Approach to investigating adolescent girls with primary amenorrhoea. AIS, androgen insensitivity syndrome; PCOS, polycystic ovary syndrome.

results of these initial investigations will often dictate the second tier of investigations.

In an infant with impalpable gonads, a karyotype of 46XX, a significantly elevated plasma 17OHP concentration and the presence of a uterus, CAH due to 21-hydroxylase deficiency is the most likely diagnosis. A urine steroid profile can confirm this diagnosis and identify other rarer forms of CAH, which may also be associated with a raised 17OHP concentration in the newborn. In infants with sex chromosomes other than 46XX, a second tier of investigations is necessary to determine the presence of testes and the adequacy of androgen production and action. These tests include measurement of AMH, an hCG stimulation test, further imaging and laparoscopy. Confirmation of a specific diagnosis will often require biochemical identification of a defect in the androgen biosynthesis pathway and detailed genetic analysis.

Investigating the adolescent with DSD

Adolescents typically present with a suspected DSD in three ways – as a girl with primary amenorrhoea (with or without breast development), as a girl who virilizes at puberty, or, as a boy with pubertal delay (see Fig. 21.4). The potential psychological impact of a thorough physical examination and medical photography on an adolescent should be carefully considered and, in some circumstances may be appropriate only under an anaesthetic. In girls with primary amenorrhoea, investigations should be considered at the age of 14 years if there is no pubertal development and at 16 years if

other aspects of puberty, particularly breast development, have progressed normally. History should include a family history and an assessment of coexisting chronic disease, exercise and weight changes. Physical examination should include measurement of blood pressure, height and weight and assessment of secondary sexual characteristics including clitoral enlargement. Vaginal examination to assess vaginal length is rarely indicated if imaging is informative and, if carried out, should be clearly explained and performed by a gynaecologist. An initial investigation screen should comprise measurements of LH, FSH, prolactin, thyroid stimulating hormone (TSH), free thyroxine (FT4), sex hormone binding globulin (SHBG), androstenedione, oestradiol and testosterone, and transabdominal pelvic ultrasound, performed by a sonographer with experience of adolescent appearances. Raised gonadotrophins, or an absent uterus in the presence of normal breast development, are indications for karyotyping.

The appearance of clitoromegaly and hirsutism at puberty, in the presence of primary amenorrhoea, is a classical presentation of two 46XY DSDs: 17 β -hydroxysteroid dehydrogenase type 3 deficiency and 5 α -reductase type 2 deficiency. It is less typical of partial androgen insensitivity syndrome (PAIS), which is usually associated with ambiguous genitalia at birth. Müllerian structures will not be detectable in any of these conditions. In partial gonadal dysgenesis and ovotesticular DSD, mild clitoromegaly that may have been present at birth but may have been overlooked, becomes a more prominent feature at adolescence. The differential diagnosis would also

include CAH and androgen-secreting tumours of the ovary or adrenal gland, but in these conditions Müllerian structures are present. Investigations include measurement of LH, FSH, DHEAS, SHBG, androstenedione, testosterone, dihydrotestosterone (DHT) and 17OHP. A 24h urine collection for urinary steroid profiling will confirm 5 α -reductase type 2 deficiency, CAH or adrenocortical tumour. A pelvic ultrasound will assess the presence of a uterus and determine the need for a karyotype.

Although the commonest cause of delayed puberty is constitutional delay, all boys with delayed puberty who are over the age of 14 years should be assessed. Overweight boys need careful examination so that a buried penis is not mistaken for micropenis. Rarely, PAIS, a disorder of testosterone biosynthesis or mild forms of testicular dysgenesis can present in this age group; often there is a history of hypospadias repair or orchidopexy. Investigations include a bone age and measurements of LH, FSH, testosterone and prolactin. For those with raised gonadotrophins, karyotype should be performed to exclude disorders such as Klinefelter syndrome (47XXY and variants) or 45XO/46XY mosaicism.

Steroid measurement and its interpretation

Steroid hormone analysis is a vital component of the biochemical evaluation of the child with DSD but the method of analysis can have a significant impact on the result. Analysis is most often performed by non-extraction (direct) immunoassays on automated platforms and these are subject to concerns of analytical specificity and variability between manufacturers. Liquid chromatography linked with tandem mass spectrometry (LC-MS/MS) allows multiple analyte analysis from a single sample whilst maintaining analytical specificity. Thus, in patients with DSD steroid measurement by either LC-MS/MS or immunoassay after organic solvent extraction is preferred. As these methods tend to be labour intensive, close communication between the clinical and laboratory personnel within the DSD team is vital to ensure timely availability of results.

Urinary steroid profile (USP) analysis by gas chromatography mass spectrometry (GC-MS) provides qualitative and quantitative data on excretion of steroid metabolites (see Fig. 21.5). It is ideal for detecting altered steroid metabolites, especially in patients with CAH, where the activity of a combination of steroidogenic enzymes can produce unusual metabolites which can cross-react in traditional direct serum assays. The diagnosis of rarer forms of CAH such as P450 oxidoreductase deficiency (ORD) is best established using urinary GC-MS analysis as it allows for concurrent determination of all adrenal-derived steroid metabolites. As concentrations of gonadotrophins, androgens and precursors fluctuate markedly over the first few months of life it may be appropriate to consider an early neonatal collection as well as further samples at a later stage. A urine sample can be frozen and stored for many years and may help with a review of the diagnosis at a later stage. Urinary steroid profiling is not appropriate for suspected cases of 5 α -reductase type 2 deficiency until after three months of age as diagnostic ratios of 5 β to 5 α reduced metabolites are not detectable

before then. Infants, particularly boys, normally have significant changes in steroid and other endocrine hormone concentrations during the first 100 days of life. In boys, serum testosterone and DHT may initially be high at birth but decline to <1 nmol/L and undetectable, respectively by around day 30. Concentrations then rise to peak at day 70 before declining to normal prepubertal values. These normal variations may influence the interpretation of sex steroid and gonadotrophin measurements as well as the results of an hCG stimulation test (see p. 422). Furthermore, the actual value for the hormone concentration will vary depending on the assay methodology; it is therefore essential that age and method-related reference ranges are available to facilitate appropriate interpretation of results.

Anti-Müllerian hormone

Anti-Müllerian hormone, also known as Müllerian inhibiting substance, is strongly expressed in Sertoli cells from the time of testicular differentiation to puberty and to a much lesser degree in granulosa cells from birth to menopause. Measurement of AMH concentration in the adult female is used to assess ovarian reserve. Published information on circulating AMH concentrations have to be interpreted with caution owing to differences in primary antibody, standard calibration and units used for measurement in individual immunoassays. In boys, AMH is detectable at birth at much higher circulating concentrations than in girls and these concentrations rise during infancy before gradually declining at puberty. Therefore, it may be helpful to repeat AMH measurement later in infancy if a newborn boy is found to have a low concentration. As summarized in Table 21.2, measurement of AMH is a powerful tool to assess Sertoli cell activity in children with suspected DSD and may also have diagnostic utility in conditions associated with androgen deficiency or insensitivity.

Insulin-like factor 3

Insulin-like factor 3 (INSL3) is one of the hormones secreted by the Leydig cells in the testis, and plays a pivotal role in testicular descent during fetal development. In males, circulating INSL3 concentrations display a characteristic pattern with a transient perinatal increase, low concentrations during childhood, increasing during puberty with highest concentrations found in adulthood when it is expressed constitutively. Insulin-like factor 3 is increasingly being recognized as a more sensitive marker of current Leydig cell differentiation and function than testosterone and, thus, has potential clinical value when used as an adjunct to standard investigations for DSD and may avoid reliance on hCG stimulation tests to assess testicular function adequately. In females, INSL3 is produced by theca cells and the corpus luteum, therefore concentrations are undetectable until puberty, when active ovarian cycling occurs. Circulating INSL3 concentrations are significantly lower in females than males. Lack of age-appropriate reference values, robust, sensitive commercial immunoassays and larger-scale studies are major barriers to the use of INSL3 in routine practice.

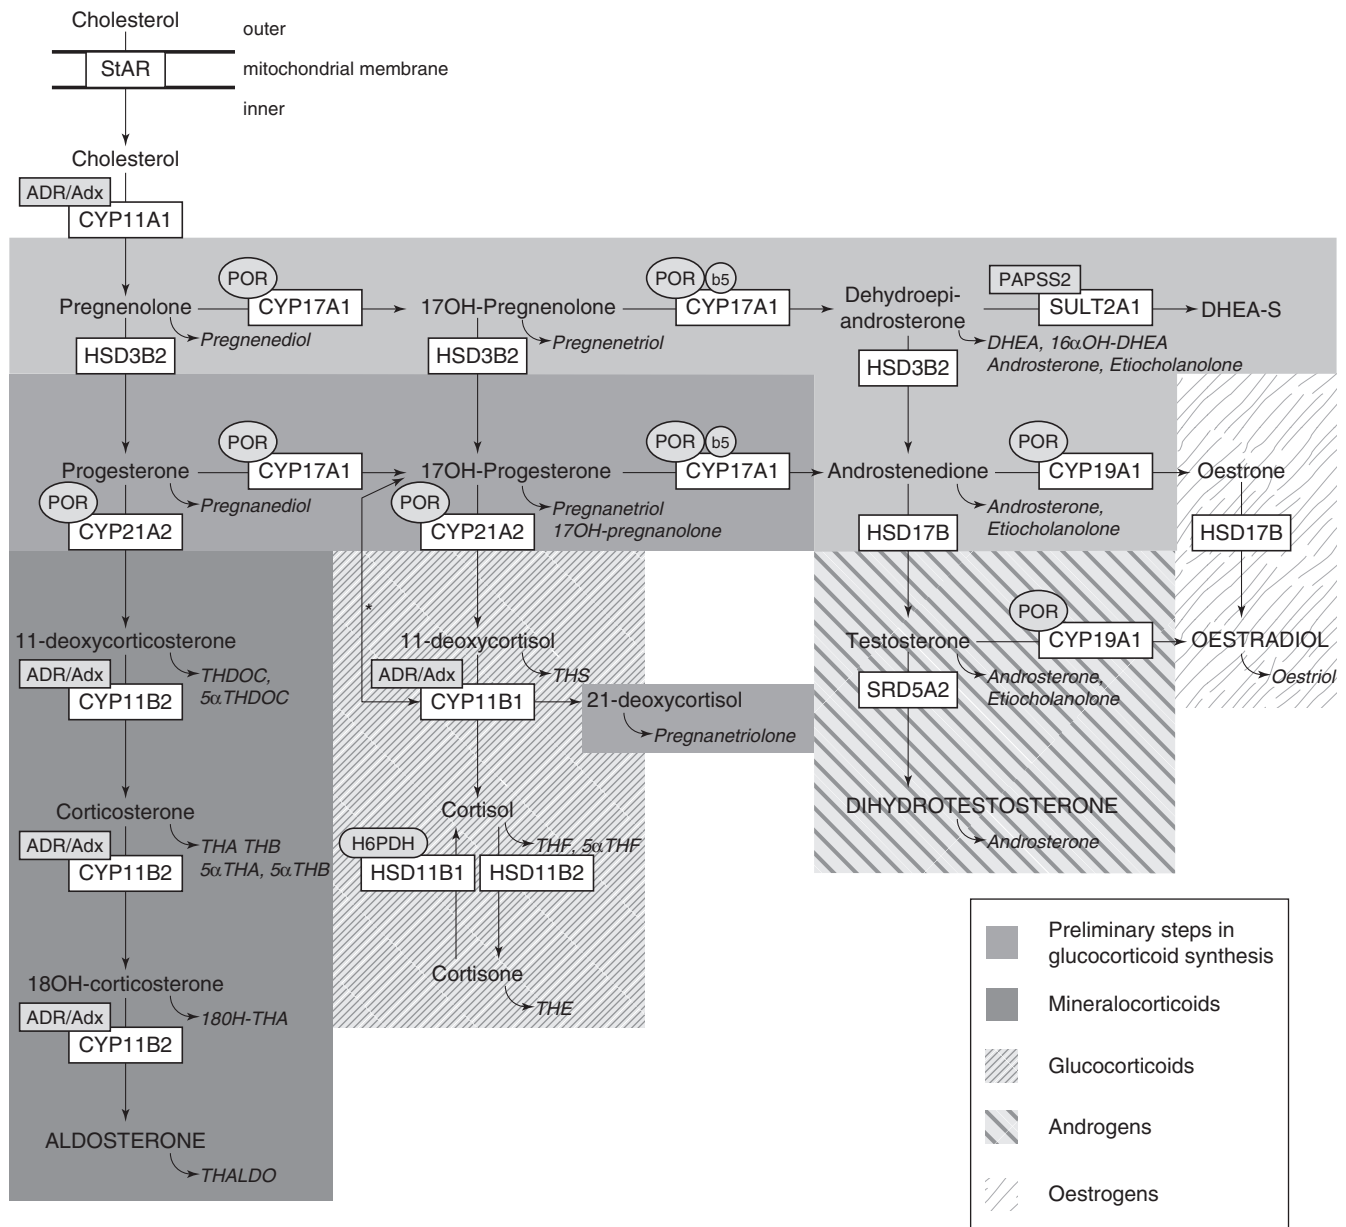

FIGURE 21.5 ■ Synthesis and metabolism of hormonal steroids. This figure illustrates the formation of the major hormone classes from cholesterol. Steroid names in conventional script are steroid hormones and precursors; those in *italics* are urinary metabolites of the aforementioned. The major transformative enzymes are in rectangular boxes, the cofactor ('facilitator') enzymes in ovals. Mitochondrial CYP type I enzymes requiring electron transfer via adrenodoxin reductase (ADR) and adrenodoxin (Adx) CYP11A1, CYP11B1, CYP11B2, are marked with a labelled box ADR/Adx. Microsomal CYP type II enzymes receive electrons from P450 oxidoreductase (POR), CYP17A1, CYP21A2, CYP19A1, are marked by circled POR. The 17,20-lyase reaction catalyzed by CYP17A1 requires in addition to POR also cytochrome b5 indicated by a circled b5. Similarly, hexose-6-phosphate dehydrogenase (H6PDH) is the cofactor-generating enzyme for 11 β -HSD1. The asterisk (*) indicates the 11-hydroxylation of 17OHP to 21-deoxycortisol in 21-hydroxylase deficiency. The conversion of androstenedione to testosterone is catalysed by HSD17B3 in the gonad and AKR1C3 (HSD17B5) in the adrenal. StAR, steroidogenic acute regulatory protein; CYP11A1, P450 side-chain cleavage enzyme; HSD3B2, 3 β -hydroxysteroid dehydrogenase type 2; CYP17A1, 17 α -hydroxylase; CYP21A2, 21-hydroxylase; CYP11B1, 11 β -hydroxylase; CYP11B2, aldosterone synthase; HSD17B, 17 β -hydroxysteroid dehydrogenase; CYP19A1, P450 aromatase; SRD5A2, 5 α -reductase type 2; SULF2A1, sulfotransferase 2A1; PAPSS2, 3'-phosphoadenosine 5'-phosphosulfate synthase 2; TH, tetrahydro. Inhibins

Inhibins, produced by granulosa and theca cells of the ovary and Sertoli cells of the testes, play an important role in the negative feedback control of pituitary gonadotrophin secretion. The two major isoforms present in circulation are inhibin A and B. In human males, inhibin B,

a marker of Sertoli cell function, is the only biologically active form present. After an initial rise in concentration shortly after birth, inhibin B remains low until the onset of puberty, when increasing concentrations denote Sertoli cell maturation and accurately reflect spermatogenesis. In females, both inhibin A and B are produced. Inhibin B concentrations show a biphasic pattern with a

TABLE 21.2 Interpretation of serum Anti-Müllerian hormone concentrations in DSD

Serum AMH	Testicular tissue	Interpretation
Undetectable	Absent	46XX,CAH Complete gonadal dysgenesis PMDS due to AMH gene defect

Above male age-related reference range	Present	AIS especially complete androgen insensitivity syndrome 5 α -reductase deficiency Testosterone biosynthetic defect Leydig cell hypoplasia

PMDS, Persistent Müllerian duct syndrome; AIS, androgen insensitivity syndrome; CAH, congenital adrenal hyperplasia.

peak at around three months, a pre-pubertal quiescent phase and a gradual rise several years prior to the onset of puberty, suggesting pre-pubertal increase in follicular activity. Inhibin A becomes detectable only in the latter stages of puberty. During the menstrual cycle, inhibin B predominates during the follicular phase reflecting recruitment of pre-antral follicles, whereas inhibin A is the major isoform produced during the luteal phase, being secreted by dominant follicles and the corpus luteum.

Original radioimmunoassays for inhibins were not able to distinguish between non-biologically active free alpha inhibin and biologically active inhibin A or B. Therefore, it was not until the development of sensitive and specific immunoassays for inhibin A and B that their potential diagnostic utility in various fields of reproductive endocrinology was truly recognized. When used in combination with standard baseline investigations of reproductive function, inhibin B has considerable potential in aiding diagnoses of disorders of pubertal development, (delay and precocity) and premature ovarian and testicular failure.

The human chorionic gonadotrophin (hCG) stimulation test

Stimulation with hCG allows the identification of functioning testicular tissue, as well as biosynthetic defects in testosterone synthesis (see Fig. 21.6). However, it is an invasive test which should only be performed as a second-line investigation after discussion with the paediatric endocrinologist in the regional DSD team. Most protocols for hCG stimulation in the UK use intramuscular hCG 1000–1500 units on three consecutive days. This can be followed by further hCG stimulation with 1500 units on two days a week for the following two weeks. In young infants and older children, three days of hCG stimulation may be sufficient. In the very young infant with an intrinsically active gonadal axis, an hCG stimulation test may not be necessary if serial blood samples show raised serum testosterone concentrations. A testosterone response to hCG may be labelled as normal if absolute testosterone

concentrations reach a level that is above the upper limit of the normal prepubertal range, or rise by more than twice the baseline value. As a minimum, other androgens that should be assessed include dihydrotestosterone (DHT) and androstenedione. For these two metabolites, the post-hCG, day four sample is more important than the pre-hCG sample. Following prolonged hCG stimulation there is no additional benefit of analysing a sample for these two metabolites on day 22. However, a day 22 sample collected for testosterone measurement can be stored and used to measure DHT or androstenedione if analysis was not achieved on day four. In the presence of a poor testosterone response following hCG stimulation, assessment of adrenal function by a standard short tetra-cosactide stimulation test should be considered. There is currently insufficient evidence to recommend that every child with XY DSD should have a tetra-cosactide stimulation test, but clinicians should be aware of the clear association between some forms of DSD and primary adrenal insufficiency. They should consider thorough assessment of adrenal function in children with diagnoses where an association has already been described and in children with any clinical suspicion of adrenal insufficiency, especially those with low steroid precursors on USP.

The role of the clinical geneticist

Establishing a specific molecular diagnosis is helpful in the clinical management of patients and in offering accurate genetic counselling for the family. However, the number of diagnostic gene tests that are available in clinically accredited DNA laboratories in the UK, or internationally, is limited and testing is costly. As developments in DNA and chromosomal analysis accelerate biomedical research, many techniques such as multiplex ligation-dependent probe amplification (MLPA) and comparative genomic hybridization (CGH) have the potential to become routine in clinical practice. Next generation DNA sequencing platforms will allow whole genome sequencing for rare diseases to become a reality at a realistic price. The clinical geneticist at the specialist DSD centre is correctly placed

TABLE 21.3 A classification system for DSD

Sex chromosome DSD	46XY DSD	46XX DSD
A: 45XO (Turner syndrome and variants)	A: Disorders of gonadal (testicular) development 1. Complete gonadal dysgenesis (Swyer syndrome) 2. Partial gonadal dysgenesis	A: Disorders of gonadal (ovarian) development 1. Ovotesticular DSD 2. Testicular DSD (e.g. SRY+, dup SOX9)
B: 47XXY (Klinefelter syndrome and variants)	B: Disorders in androgen synthesis or action 1. Androgen biosynthesis defect (e.g. 17-hydroxysteroid dehydrogenase deficiency, 5 α -reductase deficiency, StAR mutations) 2. Defect in androgen action (e.g. CAIS, PAIS)	B: Androgen excess 1. Fetal (e.g. 21-hydroxylase deficiency, 11-hydroxylase deficiency) 2. Fetoplacental (aromatase deficiency, POR deficiency)
C: 45XO/46XY (mixed gonadal dysgenesis, ovotesticular DSD)	C: Other (e.g. severe hypospadias, cloacal exstrophy)	C: Other (e.g. cloacal exstrophy, vaginal atresia, MURCS, other syndromes)
D: 46XX/46XY (chimeric, ovotesticular DSD)		

CAIS, complete androgen insensitivity syndrome; MURCS, Müllerian duct aplasia, renal aplasia, cervicothoracic somite dysplasia; PAIS, partial androgen insensitivity syndrome; POR, P450-oxidoreductase deficiency; StAR, steroidogenic acute regulatory protein.

TABLE 21.4 Characteristics of 46XX disorders of sex development due to androgen excess

	Inheritance and gene	Genitalia	Wolffian duct deriv.	Müllerian duct deriv.	Gonads	Typical signs and symptoms	Hormone profile
21-hydroxylase deficiency	Autosomal recessive, <i>CYP21A2</i>	Ambiguous	Absent	Normal	Ovary	Severe adrenal insufficiency in infancy \pm salt loss; moderate to severe androgenization at birth; \pm pigmentation	Decreased cortisol and/or mineralocorticoids Increased 17-hydroxyprogesterone, 21-deoxycortisol, androstenedione, testosterone, and/or plasma renin (activity/concentration)
11 β -hydroxylase deficiency	Autosomal recessive, <i>CYP11B1</i>	Ambiguous	Absent	Normal	Ovary	Adrenal insufficiency in infancy; moderate to severe androgenization at birth; arterial hypertension often developing at different ages	Decreased cortisol, corticosterone, aldosterone, and/or plasma renin (activity/concentration) Increased 11-deoxycortisol, 11-deoxycorticosterone, androstenedione, testosterone
3 β -hydroxysteroid dehydrogenase II deficiency	Autosomal recessive, <i>HSD3B2</i>	Commonly clitoromegaly or mild virilization, also normal	Absent	Normal	Ovary	Severe adrenal insufficiency in infancy \pm salt loss, androgenization during childhood and puberty, premature pubarche	Increased concentrations of Δ^5 C ₂₁ - and C ₁₉ -steroids, 17-hydroxypregnenolone and DHEA suppressible by dexamethasone
P450 oxidoreductase deficiency	Autosomal recessive, <i>POR</i>	Ambiguous or normal female	Absent	Normal	Ovary	Variable androgenization at birth and puberty, glucocorticoid deficiency, features of skeletal malformations. Maternal androgenization during pregnancy onset second trimester possible	Combined P450c17 and P450c21 insufficient, normal or low cortisol with poor response to ACTH stimulation, elevated 17-hydroxyprogesterone, testosterone, progesterone and corticosterone; low oestradiol
P450 aromatase deficiency	Autosomal recessive, <i>CYP19A1</i>	Ambiguous	Absent	Normal	Ovary	Delayed bone age, development of ovarian cysts during infancy, childhood and puberty. Maternal androgenization during pregnancy	High androgens in cord blood, androgens may stay elevated or normalize soon after birth

Adapted from DSD Guidelines Clinical Endocrinology 2011; 75:12–26.

the ipsilateral gonad. The minority of infants raised as girls have breast development at puberty and may also menstruate. Fertility has been reported in some cases. In contrast, individuals with 46XX testicular DSD usually have a normal male phenotype and absent Müllerian structures and are often diagnosed after karyotype analysis during investigation for infertility. In 46XX testicular DSD, about 80–90% of patients will have Y chromosomal material including a translocated *SRY* gene, which is only rarely detected in 46XX ovotesticular DSD. In other patients with 46XX testicular DSD, duplications of the *SOX9* gene and mutations of the *RSOP1* gene have been described. In patients with the suspicion of 46XX ovotesticular DSD, there is a need to assess the functional potential of testicular and ovarian tissue by a combination of biochemical testing, imaging and surgical exploration.

Disorders of Müllerian development are another group of 46XX DSD and in these patients ovarian function is usually normal but often associated with cloacal anomalies and other characteristic malformations. Although most cases of Müllerian development disorders are not associated with androgen excess, the presence of the latter, particularly in the adolescent, should alert the clinician to a possible abnormality of the *WNT4* gene.

XY DSD with low testosterone and low precursor concentrations

The differential diagnosis of 46XY DSD associated with low testosterone and precursor concentrations includes: defects occurring early in steroid synthesis (steroidogenic acute regulatory (StAR) protein, P450 side-chain cleavage (scC) enzyme/*CYP11A1*, sometimes Smith–Lemli–Optiz/*DHCR7*); LH receptor defects (*LHCGR*), and partial and complete forms of gonadal (testicular) dysgenesis (Table 21.5).

Of note, complete or partial combined 17 α -hydroxylase/17,20-lyase deficiency (*CYP17A1*) may also present with ‘low testosterone and precursor’ concentrations if DHEAS and androstenedione are the only intermediates measured. The actual diagnosis can be reached by assessment of adrenal function by measuring ACTH, tetraacetate-stimulated cortisol, plasma renin activity (PRA), 11-deoxycorticosterone (DOC), aldosterone, Δ^5 -(pregnenolone, 17OHPreg) and Δ^4 -(progesterone, 17OHP) precursors or by urine steroid analysis. Isolated 17,20-lyase deficiency and ORD might also be diagnosed by this approach. Proximal blocks (StAR, P450scC) in the pathway affect steroidogenesis in the adrenal gland as well as the developing gonad.

LH receptor defects (‘Leydig cell hypoplasia’) typically result in elevated basal LH concentrations, hyper-responsive LH to GnRH stimulation, low testosterone and precursor concentrations and impaired androgen response to hCG stimulation. No Müllerian structures will be present and adrenal function is normal. A spectrum of phenotypes has been reported including ambiguous genitalia and micropenis. In some patients, basal LH may not be elevated when the hypothalamo–pituitary–gonadal axis is quiescent (six months to late childhood).

In complete gonadal dysgenesis (Swyer syndrome), children will usually have a female phenotype with

intra-abdominal streak gonads. In some situations, ovaries or even ovaries may be found. Müllerian structures are usually present owing to impaired AMH secretion in early fetal life. Androgens and their precursor concentrations will be low, LH elevated, depending on age, and a poor or absent testosterone response to hCG stimulation is seen. Anti-Müllerian hormone concentrations will be low or undetectable. Adrenal function is usually normal, unless the underlying defect is in steroidogenic factor-1 (*SF-1*) or related adrenal or gonadal factors.

Partial gonadal (testicular) dysgenesis can present with a spectrum of phenotypes ranging from clitoromegaly, to ambiguous genitalia or severe hypospadias. Müllerian structures may or may not be present and testes of variable size and architecture are present along the path of descent. The biochemical profile is similar to complete gonadal dysgenesis, but generally less severe. If mild degrees of clitoromegaly in infancy are overlooked, a 46XY child with partial gonadal dysgenesis may first present at puberty with progressive androgenization. Genetic analysis and associated features may be useful in defining the molecular aetiology of some forms of gonadal dysgenesis.

Frasier syndrome is a rare form of gonadal dysgenesis in which there is also chronic kidney disease and a risk of gonadoblastoma arising in the streak gonads. The syndrome is caused by mutation in the *WT1* gene, located on chromosome 11p13, which encodes a zinc finger protein that functions as a transcription factor.

XY DSD with low testosterone and high steroid precursor concentrations

46XY DSD with low testosterone and increased precursor concentrations can be caused by several variants of CAH, namely 17 α -hydroxylase (*CYP17A1*) deficiency, ORD and 3 β -hydroxysteroid dehydrogenase type 2 (3 β HSD2) deficiency, caused by inactivating mutations in the corresponding genes *CYP17A1*, *POR* and *HSD3B2*. In addition, 46XY DSD with low testosterone and increased precursor concentrations, can typically be found in individuals affected by 17 β -hydroxysteroid dehydrogenase type 3 (17 β HSD3) deficiency, caused by *HSD17B3* mutations (see Table 21.5).

About 1% of patients with 46XY DSD have deficiency of *CYP17A1*. Characteristically, affected individuals present with female genitalia and low DHEA, androstenedione and testosterone concentrations. In ORD, sex steroid concentrations are characteristically low, sometimes low normal, while pregnenolone and progesterone and their metabolites accumulate, because of the combined block of *CYP21A2* and *CYP17A1* activities. There is often a relative preponderance of mineralocorticoid over glucocorticoid metabolites in affected patients but hypertension manifests only in adolescence, or later. Although baseline glucocorticoid secretion is usually sufficient, in the majority of patients, the stress response to ACTH is significantly impaired, requiring hydrocortisone cover at least in times of stress or permanent glucocorticoid replacement. 3 β -hydroxysteroid dehydrogenase type 2 deficiency (also termed Δ^4 – Δ^5 isomerase deficiency) invariably leads to glucocorticoid deficiency, as well as a variable degree of mineralocorticoid deficiency; its characteristic features are

TABLE 21.5 Characteristics of 46XY disorders of sex development due to androgen deficiency or resistance

	Inheritance and gene	Genitalia	Wolffian duct derivatives	Müllerian duct derivatives	Gonads	Typical features	Hormone profile
Leydig cell hypoplasia	Autosomal recessive, <i>LH/HCGR</i>	Female, hypospadias or micropenis	Hypoplastic	Absent	Testes	Under androgenization with variable failure of sex hormone production at puberty	Low T and DHT, elevated LH and FSH, exaggerated LH response to LHRH, poor T and DHT response to hCG stimulation
Lipoid CAH	Autosomal recessive, <i>StAR</i>	Female, rarely ambiguous or male	Hypoplastic or normal	Absent	Testes	Severe adrenal insufficiency in infancy with salt loss, failure of pubertal development, rare cases associated with isolated glucocorticoid deficiency	Usually deficient of glucocorticoids, mineralocorticoids and sex steroids
P450SCC deficiency	Autosomal recessive, <i>CYP11A1</i>	Female, rarely ambiguous or hypospadias	Hypoplastic or normal	Absent	Testes	Severe adrenal insufficiency in infancy with salt loss ranging to milder adrenal insufficiency with onset in childhood	Usually deficient of glucocorticoids, mineralocorticoids and sex steroids
3 β -hydroxysteroid dehydrogenase II deficiency	Autosomal recessive, <i>HSD3B2</i>	Ambiguous, hypospadias	Normal	Absent	Testes	Severe adrenal insufficiency in infancy \pm salt loss, poor androgenization at puberty with gynaecomastia	Increased concentrations of Δ^5 C ₂₁ - and C ₁₉ -steroids, 17-hydroxypregnenolone and DHEA suppressible by dexamethasone
Combined 17 α -hydroxylase/17,20-lyase deficiency	Autosomal recessive, <i>CYP17A1</i>	Female, ambiguous, hypospadias or micropenis	Absent or hypoplastic	Absent	Testes	Absent or poor virilization at puberty, gynaecomastia, hypertension	Decreased T, increased LH and FSH, increased plasma deoxycorticosterone, corticosterone and progesterone, decreased plasma renin activity/concentration, low renin hypertension with hypokalaemic alkalosis
Isolated 17,20-lyase deficiency	Autosomal recessive, <i>CYP17A1</i> , usually affecting key redox domains, alternatively caused by cytochrome b5 mutations (<i>CYB5</i>)	Female, ambiguous or hypospadias	Absent or hypoplastic	Absent	Testes	Absent or poor androgenization at puberty, gynaecomastia	Decreased T, DHEA, androstenedione and oestradiol, abnormal increase in plasma 17-hydroxyprogesterone and 17-hydroxypregnenolone, increased LH and FSH, increased ratio of C ₂₁ -deoxysteroids to C ₁₉ -steroids after hCG stimulation
True isolated 17,20-lyase deficiency (Cytochrome b5 deficiency)	Autosomal Recessive, <i>CYP17A1</i> , caused by missense mutations in cytochrome b5 (<i>CYB5</i>)	Female, ambiguous or hypospadias	Normal	Absent	Testes	Absent or poor androgenization at puberty	Decreased T, DHEA, normal cortisol response to ACTH stim, increased 17-OHP metabolites excretion, normal mineralocorticoid and glucocorticoid metabolites excretion. Increased methaemoglobin
P450 oxidoreductase deficiency	Autosomal recessive, <i>POR</i>	Ambiguous, hypospadias or normal male	Absent or hypoplastic	Absent	Testes	Variable androgenization at birth and puberty, glucocorticoid deficiency, features of skeletal malformations. Maternal androgenization during pregnancy onset second trimester possible	Combined P450c17 and P450c21 insufficient, normal or low cortisol with poor response to ACTH stim, elevated 17-hydroxyprogesterone, T low

TABLE 21.5 Characteristics of 46XY disorders of sex development due to androgen deficiency or resistance (Continued)

	Inheritance and gene	Genitalia	Wolffian duct derivatives	Müllerian duct derivatives	Gonads	Typical features	Hormone profile
17 β -hydroxysteroid dehydrogenase type 3 deficiency	Autosomal recessive <i>HSD17B3</i>	Female, ambiguous, blind vaginal pouch	Present	Absent	Testes	Androgenization at puberty, gynaecomastia variable	Increased plasma estrone, decreased ratio of testosterone/androstenedione and oestradiol after hCG stimulation, increased FSH and LH
5 α -reductase-2 deficiency	Autosomal recessive <i>SRD5A2</i>	Ambiguous, micropenis, hypospadias, blind vaginal pouch	Normal	Absent	Testes	Decreased facial and body hair, no temporal hair recession, prostate not palpable	Decreased ratio of 5 α :5 β C ₂₁ - and C ₁₉ -steroids in urine, increased T/DHT ratio before and after hCG stimulation, modest increase in LH, decreased conversion of T to DHT in vitro
CAIS	X-linked recessive <i>AR</i>	Female with blind vaginal pouch	Often present depending on mutation type	Absent or vestigial	Testes	Scant or absent pubic and axillary hair, breast development and female body habitus at puberty, primary amenorrhoea	Increased LH and T, increased oestradiol, FSH levels normal or slightly increased, resistance to androgenic and metabolic effects of T (may be normal in some cases)
PAIS	X-linked recessive <i>AR</i>	Ambiguous with blind vaginal pouch, isolated hypospadias, normal male with infertility (mild)	Often normal	Absent	Testes	Decreased to normal axillary and pubic hair, beard growth and body hair, gynaecomastia common at puberty	Increased LH and T, increased oestradiol, FSH levels may be normal or slightly increased, partial resistance to androgenic and metabolic effects of T

DHT, dihydrotestosterone; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotrophin; LH, luteinizing hormone; T, testosterone; DHEA, dehydroepiandrosterone; ACTH, adrenocorticotropic hormone, 17-OHP, pregnanetriol; AR, androgen receptor; CAIS, complete androgen insensitivity syndrome; PAIS, partial androgen insensitivity syndrome.
Adapted from DSD Guidelines Clinical Endocrinology 2011; 75:12–26.

outlined in Table 21.5. 17 β -hydroxysteroid dehydrogenase type 3 is responsible for the conversion of androstenedione to testosterone in the gonad and deficiency has no effect on adrenal steroidogenesis. Characteristically, androstenedione concentration is increased while that of testosterone is low, particularly after hCG stimulation. However, a low testosterone to androstenedione ratio may also occur in patients with gonadal dysgenesis and the reliability of a low ratio in identifying 17 β -HSD3 deficiency is unclear. In urine, the typical finding is an increase in the androgen and androstenedione metabolites, androsterone and etiocholanolone, but it is unclear whether this applies across all age groups.

XY DSD with normal testosterone, normal precursor and low DHT concentrations

The 5 α -reductase type 2 (*SRD5A2*) isoenzyme is highly expressed in androgen sensitive tissues and converts testosterone to the more potent androgen, dihydrotestosterone (DHT) required for the development of external male genitalia. At birth, the external appearance of the genitalia of a child with *SRD5A2* deficiency can range from a completely female phenotype, through hypospadias of varying severity, to isolated micropenis. A positive family history is often present in this autosomal recessive condition. In serum, the testosterone:DHT ratio following hCG stimulation usually exceeds 30:1. In infants

over 3–6 months, the defect should be easily identifiable on a urine sample which shows a decreased ratio of 5 α :5 β -reduced C₂₁ and C₁₉ steroids and the diagnosis can therefore be made in situations where a child has had early gonadectomy. Early diagnosis of this condition is important as the affected infant may need sex reassignment if initially raised as a girl. In the child raised as a boy, application of topical DHT cream may be a way of assessing the potential of the genitalia to virilize over the longer term.

XY DSD with normal testosterone, normal precursor and normal DHT concentrations

A defect in androgen signalling is most likely to be due to dysfunction of the androgen receptor (*AR*) and mutations resulting in a complete lack of function of the *AR* cause complete androgen insensitivity syndrome (CAIS). This presents in the newborn infant as a discordance between a female phenotype and a prenatal karyotype of 46XY, as inguinal swellings in an otherwise normal girl or during a postnatal check because of a positive family history. Complete androgen insensitivity syndrome usually presents in adolescence as primary amenorrhoea with normal breast development. The presence of pubic hair is often reported in CAIS and should not be used to exclude the diagnosis. Mutations which result in some residual *AR*

function and varying degrees of androgenization cause partial androgen insensitivity syndrome (PAIS). Although children with PAIS typically have a normal testosterone and DHT response to hCG stimulation and a normal urinary steroid profile, some demonstrate a poor response to hCG stimulation. The serum AMH concentration is normal or may even be elevated. Luteinizing hormone concentrations are increased in the face of normal or elevated serum testosterone, reflecting a state of androgen resistance. A family history of X-linked inheritance is informative, although one-third of cases are the result of spontaneous new mutations.

A functional assessment of androgen sensitivity may include the clinical effect of a short course of testosterone applied to the phallus, or the effect of systemic testosterone following hCG stimulation. However, there is no consensus on the choice of androgen, dosage, method of administration, timing or duration of treatment or on the definition of a satisfactory response in the growth of the phallus. Androgen sensitivity can also be assessed by measuring the change in SHBG, an androgen-responsive protein which normally decreases in concentration following androgen exposure. This fall in SHBG is absent in CAIS, variable in PAIS and difficult to interpret in young infants who have highly variable circulating SHBG concentrations. Androgen receptor analysis may reveal a mutation in over 80% of patients with a CAIS phenotype and 30% of patients with a PAIS phenotype and androgen receptor binding studies are not necessary for routine diagnosis of AIS. A number of patients with XY DSD are loosely labelled as 'PAIS' when no conclusive biochemical or genetic abnormalities are identified in gonadal function, androgen synthesis or androgen action. The term PAIS should be reserved for those children who have XY DSD and a pathogenetic mutation in *AR*.

DISORDERS OF PUBERTY

Precocious puberty

Signs of puberty that occur before the ages of eight years in girls and nine years in boys are generally considered to indicate abnormally early puberty. The problem is more common in girls, in whom a cause is not often found. The earlier occurrence of puberty in the population has been attributed to the effects of xenoestrogenic chemicals in the environment and perhaps also to the increasing incidence of obesity. Adipocytes are a source of oestrogens through peripheral aromatization. Precocious puberty is increasingly seen in girls migrating from deprived environments for adoption in the developed world. Previous exposure to chemicals such as pesticides coupled with refeeding and catch-up growth in the new environment may be the trigger for early puberty. [Box 21.1](#) lists some of the known causes of precocious puberty in both sexes. Structural lesions in the hypothalamic-pituitary region are increasingly recognized through sensitive imaging techniques. Severe head trauma may be followed quite abruptly by the onset of puberty. It is presumed that premature activation of the GnRH pulse generator has occurred. Similar mechanisms may operate in hydrocephalus, cerebral palsy, spina bifida and intracranial infections.

BOX 21.1 Some causes of precocious puberty

Gonadotrophin dependent (central causes)

- Idiopathic (particularly girls)
- Intracranial tumours (hypothalamic hamartoma)
- Raised intracranial pressure (trauma, hydrocephalus)
- Cerebral palsy
- Cranial irradiation

Gonadotrophin independent

- McCune–Albright syndrome
- Increased peripheral sex steroids (CAH)
- Gonadal tumours
 - Male: Leydig cell adenoma, adrenal tumour
 - Female: juvenile granulosa cell tumour, ovarian cyst
- Activating LH receptor mutation (male limited)

Puberty variants

- Premature adrenarche
- Premature thelarche (female limited)
- Exposure to environmental oestrogens
- Pubertal gynecomastia

Gonadotrophin dependent puberty (central causes)

Although the cause of precocious puberty in a large majority of children remains unknown (idiopathic), some children may require a thorough endocrine evaluation of the pubertal axis as listed in [Table 21.6](#). Important causes outlined below should be considered if clinically appropriate.

Tumours in the region of the hypothalamus known to be associated with precocious puberty include hamartoma, astrocytoma, neurofibroma and, occasionally, craniopharyngioma. While the prevalence of such tumours causing precocious puberty is the same in boys and girls, a tumour is more likely to be the cause of precocious puberty in a boy. Hypothalamic-pituitary damage from irradiation to intracranial tumours causes pituitary deficiency of growth hormone and thyrotrophin releasing hormone (TRH) but, paradoxically, premature reactivation of the GnRH pulse generator and precocious puberty.

The McCune–Albright syndrome comprises the triad of café-au-lait skin pigmentation, fibrous dysplasia of bone (affecting particularly long bones and the base of

TABLE 21.6 Basic endocrine investigation of disorders of puberty

Precocious puberty	Delayed puberty
Basal LH, FSH, testosterone or oestradiol	Basal LH, FSH, testosterone or oestradiol
Acute GnRH stimulation test	Acute GnRH stimulation test
Thyroid hormone profile (TSH & FT4)	Thyroid function tests (TSH & FT4)
Prolactin	Peripheral karyotype (females)
β-hCG	Possibly hCG stimulation test (males)
Skeletal age (bone age)	Skeletal age (bone age)

the skull) and precocious puberty. In girls, the latter is typically gonadotrophin independent, as shown by a prepubertal LH and FSH response to acute GnRH stimulation. Autonomously functioning multiple ovarian cysts occur, as well as evidence of dysfunction in other endocrine glands such as the thyroid (thyrotoxicosis), adrenal (Cushing syndrome), pituitary (gigantism and hyperprolactinaemia) and parathyroid (hyperparathyroidism). The condition may present in early childhood and progress to gonadotrophin-dependent ovarian hyperfunction and the consequent problems of menses in a young child. The McCune–Albright syndrome is less common in boys and may manifest with asymmetrical enlargement of the testes as well as the development of secondary sexual characteristics. Somatic activating mutations of the G-protein α subunit ($GS\alpha$) component of the guanine nucleotide binding protein, alpha stimulating (GNAS) complex that couples seven transmembrane receptors to the cAMP signal transduction pathway, cause the widespread distribution of tissue abnormalities in the syndrome. The predominant mutation is substitution of an arginine at codon 201 in the $GS\alpha$ gene. Heterozygous inactivating $GS\alpha$ mutations cause Albright hereditary osteodystrophy, a syndrome characterized by short stature, obesity, short metacarpals, subcutaneous calcification and behavioural problems.

Autonomously hyperfunctioning testes, independent of gonadotrophic stimulation, also cause precocious puberty in males, owing to Leydig cell hyperplasia. Familial forms are recognized that present with signs of virilization, but with testes inappropriately small for the advanced stage of puberty. The onset of precocious puberty often occurs in early childhood and may even occur in infancy. Testosterone concentrations are increased, while basal and GnRH-stimulated concentrations of gonadotrophins are suppressed. Histological examination of the testes shows Leydig cell hyperplasia and spermatogenesis. This form of familial, male-limited precocious puberty is autosomal dominant and is caused by an activating mutation in the G-protein-LH-coupled receptor. Somatic LH receptor mutations are also found in males with Leydig cell adenomas without a history of precocious puberty, but a Leydig cell adenoma rarely occurs in the precocious puberty phenotype. This is at variance with the phenotype associated with activating mutations in the TSH receptor where nodular thyroid hyperplasia is often an associated histological feature of this form of hyperthyroidism. Treatment for male-limited, familial precocious puberty comprises an anti-androgen agent, such as spironolactone, together with an aromatase enzyme inhibitor such as testolactone or anastrozole, but the long-term therapeutic benefits of this approach are unclear. Use of a GnRH analogue is not appropriate initially as gonadotrophin concentrations are already suppressed. However, the precocious puberty may become gonadotrophic dependent at a later stage, when a long-acting GnRH analogue can be added to the treatment regimen.

Variants of early puberty

The most frequent variant of early puberty is premature thelarche, or isolated early breast development. The usual age of onset is 1–3 years and occasionally breast

development may have persisted from the neonatal period. The breast enlargement may be unilateral or bilateral and typically tends to wax and wane over time. No other signs of puberty occur and the rate of linear growth is normal for chronological age. Serum oestradiol and gonadotrophin concentrations remain prepubertal, although most immunoassays are insufficiently sensitive to detect fluctuations in oestradiol concentrations in prepubertal girls. It has been proposed that breast enlargement is the result of enhanced tissue responsiveness to a transient increase in circulating oestradiol. Increased concentrations of SHBG have been detected in some girls with premature thelarche, thereby resulting in an increase in the ratio of free oestradiol to testosterone concentrations. This may explain the breast development, even though total oestradiol concentration is not increased. The source of oestrogen is ovarian, and cysts of the ovary are sometimes detected on ultrasound. While population studies imply the possibility of exposure to chemicals in the environment acting as xenoestrogens, it is difficult to prove such exposure in individual patients. The natural history of premature thelarche is the onset of puberty and menarche at a normal age, as well as normal reproductive potential. A form of thelarche variant is also recognized that is associated with some increase in growth rate and skeletal maturation and a slightly exaggerated LH and FSH response to acute GnRH stimulation.

Isolated recurrent vaginal bleeding can sometimes occur in girls before puberty. It is important to exclude local lesions of the genital tract, self-harm by the child or child abuse. Generally, it is associated with increased FSH concentrations that produce sufficient oestradiol to stimulate the endometrium and induce a subsequent withdrawal bleed. Sometimes, ovarian cysts are found on ultrasound. This form of premature isolated menarche is generally self-limiting and has no adverse consequences for subsequent puberty and reproductive capacity.

Premature adrenarche is the term applied to the early development of pubic hair without any other signs of puberty. It is more common in girls, occurring usually between six and eight years of age. The cause is an increase in adrenal androgen production associated with elevated concentrations of DHEA and its sulphate, as well as androstenedione. It is partly explained by a change in steroidogenesis regulated by the orphan nuclear receptor, NGF1B. Premature adrenarche is generally followed by a normal progression through puberty. There is some evidence that girls with premature adrenarche have a higher risk of later developing polycystic ovarian syndrome.

Delayed puberty

The wide range for the age of onset of puberty in normal children has previously been emphasized. Puberty is regarded as delayed if physical signs have not started by 13 years in girls and 14 years in boys. [Box 21.2](#) lists some of the causes of delayed puberty in both sexes. The list is not an exhaustive one but encompasses the majority of important causes. During the clinical assessment it is important to exclude a chronic disease that may manifest solely as slow growth and delayed puberty, examples include cystic fibrosis, inflammatory bowel disease and anorexia nervosa.

BOX 21.2 Some causes of delayed puberty

- Constitutional delay in development
- Hypogonadotrophic hypogonadism
 - CNS tumours (craniopharyngioma, germinoma)
 - Kallmann syndrome
 - Prader–Willi syndrome
 - *GPR54* mutation
 - Inactivating GnRH receptor mutation
 - Congenital adrenal hypoplasia (associated with *DAX1* mutation)
 - Leptin deficiency
- Hypothyroidism
- Cushing disease
- Hyperprolactinaemia
 - Primary gonadal failure
 - Turner syndrome
 - Gonadal dysgenesis (XX and XY)
 - Chemotherapy (e.g. cyclophosphamide)
 - Radiation therapy
- Chronic systemic dysfunction
 - Inflammatory bowel disease
 - Coeliac disease
 - Chronic kidney disease
 - Psychosocial deprivation
 - Anorexia nervosa
 - Intense exercise

Delayed growth and puberty

Delayed puberty presents as a clinical problem far more often in boys than in girls. This may be an ascertainment bias, perhaps because of the greater social pressures of delayed puberty (and hence short stature) in a boy than a girl. Most delayed puberty just represents the extreme lower end of the physiological range for pubertal events. Since it is inevitably accompanied by short stature due to the delayed appearance of the pubertal growth spurt, this common cause is called constitutional delay in growth and development. There is often a family history of delayed puberty. The natural outcome is for puberty to develop spontaneously (according to skeletal maturation as assessed by bone age examination rather than chronological age) and lead to normal, albeit delayed, final height according to genetic potential. Sometimes, low-dose sex steroids are given to prime the pubertal growth spurt. Final height may be increased in boys with constitutional delay by treatment with aromatase inhibitors during adolescence, but there are concerns that such treatment may have undesired effects on bone health at this critical period of skeletal development.

Delayed puberty is a disturbance in the tempo of growth and pubertal maturation associated with a delay in activation of the hypothalamic GnRH pulse generator. Random and GnRH-stimulated plasma gonadotrophin concentrations are low and appropriate for physiological development, as are those of gonadal steroids. A similar endocrine profile is found in delayed puberty secondary to hypogonadotrophic hypogonadism in which spontaneous onset of puberty does not occur. It can be difficult to distinguish these two variants, even when short-term pulsatile GnRH therapy is used in the prepubertal state. Spontaneous onset of puberty is the ultimate decider.

Familial clustering may suggest rare causes such as mutations affecting the GnRH receptor gene or the *GPR54* gene. No mutation has yet been found involving the *GnRH* gene and delayed puberty. Short stature in delayed puberty is partly the result of an insufficient production of growth hormone (GH) reflected in decreased pulse amplitude. This, in turn, results in less generation of insulin-like growth factor 1, which may be relevant for gonadal function. Puberty is a complex interplay of sex hormones, GH and growth factors activated as a result of polygenic and environmental factors. While the discovery of *GPR54* has provided a molecular explanation for a rare form of hypogonadotrophic hypogonadism, no *GPR54* mutations have been reported in constitutional delayed puberty.

Organic causes affecting the hypothalamic-pituitary area result in hypogonadotrophic hypogonadism and delayed puberty. Numerous examples exist such as craniopharyngioma, optic glioma, germinoma, astrocytoma, head trauma (which may also lead to early puberty), effects of irradiation, infiltrative diseases and post-infectious lesions. An organic cause should be considered when puberty has started, but then becomes arrested in progress.

Hypogonadotrophic hypogonadism

Syndromes associated with gonadotrophin deficiency include Prader–Willi, Lawrence–Moon–Biedl and Kallman syndromes. Failure of migration of the GnRH neurons from the olfactory placode to the medial basal hypothalamus causes Kallman syndrome and explains the association with anosmia. An X-linked form of Kallman syndrome is caused by mutations in the *KALI* gene, which encodes for the anosmin-1 protein. An autosomal dominant form is caused by heterozygous mutations in the *FGFR1* gene (fibroblast growth factor receptor-1). Inactivating mutations in the *GPR54* gene cause isolated hypogonadotrophic hypogonadism.

Isolated gonadotrophin deficiency may occur in association with congenital adrenal *hypoplasia*. Affected individuals present in infancy with a salt-losing crisis and masquerade as if the diagnosis were congenital adrenal *hyperplasia*. However, adrenal steroid concentrations are low and unresponsive to ACTH stimulation. The diagnosis may be suspected before birth because of low maternal oestriol excretion resulting from decreased steroid substrates from the affected fetal adrenals. The disorder is X-linked; affected boys fail to enter puberty spontaneously because of an associated gonadotrophin deficiency. Adult males have azoospermia and a poor response to pulsatile GnRH treatment. Mutations in *DAX-1*, a gene on Xp21.3–21.2 that encodes an orphan nuclear hormone receptor, are described in patients with X-linked congenital adrenal hypoplasia and hypogonadotrophic hypogonadism. A variant of the syndrome may present for the first time in adulthood with mild adrenal insufficiency and partial hypogonadism. Another orphan nuclear receptor involved in both adrenal and hypothalamic development is steroidogenic factor-1 (SF-1). Rare mutations cause adrenal failure and generally XY sex reversal.

Primary hypogonadism

The other major groups of disorders that manifest with delayed puberty are those associated with primary hypogonadism. In these, gonadotrophin concentrations are elevated. The chromosome aneuploidies, Klinefelter syndrome (47XXY) and Turner syndrome (45XO and variants), are important causes of delayed puberty. Turner syndrome has an incidence of about 1 in 2000 live-born girls. It is estimated that 1–2% of conceptuses have the syndrome with only 1% of these not aborted spontaneously. Two constant clinical features of this syndrome are short stature and failure to enter puberty spontaneously because of premature ovarian failure. The former feature dictates that a peripheral karyotype should be performed on any short girl in whom there is no readily apparent cause for the growth failure.

The typical physical features of Turner syndrome may not always be present. They include a short, broad neck which may be webbed, a low hairline, low-set ears, high-arched palate, ptosis, hypoplastic nails, short metacarpals, cubitus valgus (increased carrying angle), pigmented naevi and cardiovascular anomalies. Affected girls are often small at birth and have peripheral lymphoedema. This usually is an alert to making the diagnosis. The results of a pilot study using FSH measurement in blood spots for newborn screening were not sufficiently specific. Pyrosequencing assays for quantitative genotyping of informative single nucleotide polymorphism (SNP) markers spanning the X chromosome in a newborn screening programme reliably detect complete or partial X deletions and mosaicisms. Growth failure is invariably present by 2–3 years of age. Ovarian failure is a progressive process starting in late gestation and appears to be an acceleration of the diminution in the number of primary oocytes that occurs between fetal and postnatal life in the normal female. Generally, streak gonads are the only remnants of ovaries, although 5–10% of Turner syndrome girls do have spontaneous puberty and menstruate. A small number are able to become pregnant, but this is associated with a high rate of miscarriage, stillbirths and congenital malformations. Management of Turner patients requires oestrogen replacement at the time of expected puberty and the early use of GH to enhance adult height. Numerous studies confirm that GH can significantly increase final height. Chromosomal mosaicism in the form of 45XO/46XY may show some features of the Turner phenotype, such as short stature, but the presentation may be at birth because of abnormal genitalia. Adult patients with Turner syndrome need regular surveillance of cardiovascular parameters, metabolic abnormalities such as insulin resistance, renal disorders and sensorineural hearing deficits. Turner syndrome represents one example of spontaneous premature ovarian failure. In addition, there are other causes of acquired as well as genetic causes of ovarian failure.

Klinefelter syndrome affects about 1 in 1000 males and is characterized by tall stature, small firm testes, gynaecomastia and infertility in adults. These men are also hypogonadal and, although they enter puberty normally, they undergo pubertal arrest and progress through puberty does not occur as expected. Serum

testosterone concentrations increase appropriately according to the stages of puberty, while a characteristic elevation of gonadotrophin concentrations is displayed from the age of 13 years. Fertility may be achievable using testicular extraction for intracytoplasmic sperm injection. Other causes of primary hypogonadism in the male include testosterone biosynthetic defects and the effects of chemotherapy in conditions such as leukaemia. Anorchia (absence of both testes at birth) is relatively common and is sometimes referred to as the vanishing testis syndrome. Genital development in affected boys is otherwise normal, which implies that testicular function (including testosterone and AMH production) was also normal in early gestation. The cause of testicular regression is not known but is postulated to be the result of intrauterine testicular torsion. The presence or absence of testicular tissue after birth can be assessed by a prolonged hCG stimulation test to determine any response in serum testosterone. Serum AMH is also a useful marker that avoids the necessity of undertaking an hCG stimulation test. At the expected age of puberty, there is an increase in plasma gonadotrophins.

APPENDIX 450

INTRODUCTION

In both normal males and females, the gonads produce steroid hormones that affect secondary sexual characteristics, the functioning of the reproductive tract and sexual behaviour. Production of gametes and hormones by the gonads is under the control of pituitary glycoprotein hormones. The hypothalamo–pituitary–gonadal axis appears to be universal throughout the vertebrates: small amounts of releasing factors from the hypothalamus elicit the release of larger amounts of glycoprotein gonadotrophins and yet larger increases in gonadal steroids. These steroids in turn influence the rate at which they themselves are produced (feedback control).

PHYSIOLOGY

The ovaries

The human ovaries produce female gametes and steroid sex hormones. Both functions depend largely on the monthly growth and rupture of (usually) a single ovarian follicle.

At birth, some 10^6 immature germ cells are present in the ovaries as primary oocytes, arrested between prophase and metaphase of the first meiotic division. Each primary oocyte is surrounded by a layer of epithelial cells, the whole being known as a primordial follicle (Fig. 22.1). Primary oocytes do not complete meiosis during childhood: in fact the majority of them degenerate.

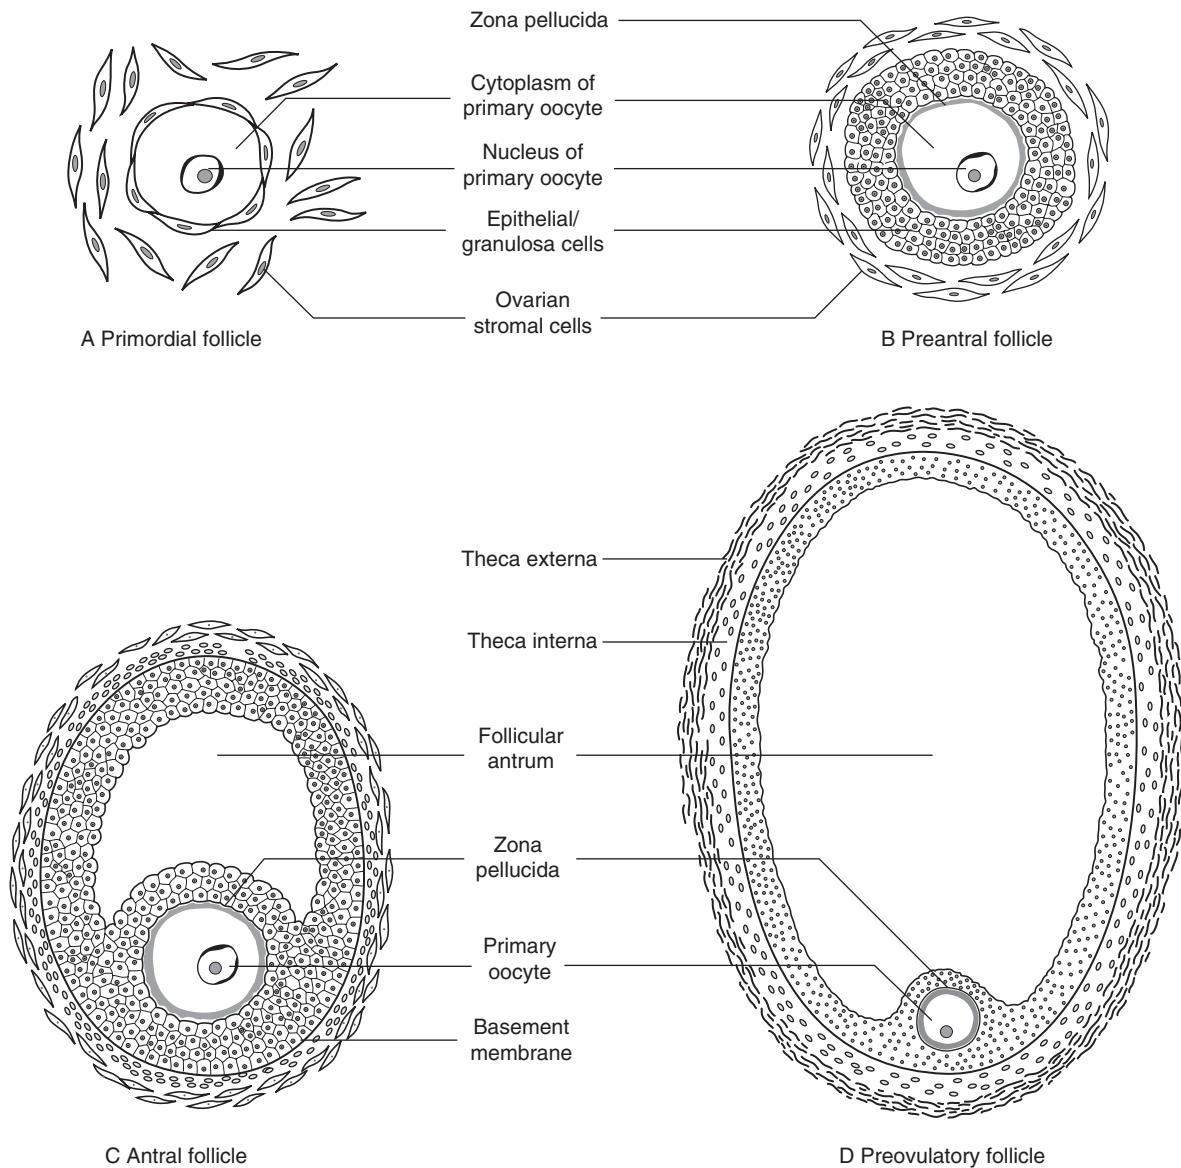

FIGURE 22.1 ■ Maturation of ovarian follicles.

During childhood, the ovaries remain inactive, but at puberty, a monthly ovarian cycle is established through the interaction of the hypothalamus and pituitary with ovarian follicles and manifests itself by the onset of menstruation.

At puberty, the pulsatile release of gonadotrophin-releasing hormone (GnRH) from the hypothalamus stimulates the pituitary production of gonadotrophins. Growth hormone (GH) pulses released by the pituitary also increase in amplitude. This amplification of GH secretion may be regulated by the pubertal increase in the production of androgenic and oestrogenic hormones. These sex steroids stimulate skeletal growth and sexual maturation, augmenting the role of GH in promoting somatic growth and development.

The human menstrual cycle is 23–39 days long. By definition, day 1 of the cycle is the first day of menstrual bleeding. The cycle is divided into follicular (or proliferative) and luteal (or secretory) phases by the event of

ovulation. In cycles of different length, it is the duration of the follicular phase that varies; the length of the luteal phase is remarkably constant at 13–15 days.

On day one of the cycle, several antral follicles, which are 2–9 mm in diameter, are present in both ovaries. These consist largely of a fluid-filled antrum and can be visualized by ultrasonography (Fig. 22.2A). Each antral follicle has developed from a primordial follicle by proliferation of the epithelial granulosa cells and by the appearance and coalescence of fluid-filled spaces among them (see Fig. 22.1). The earlier stages of follicle development do not require gonadotrophin stimulation, but the 'recruitment' of antral follicles from the preantral pool appears to be follicle stimulating hormone (FSH) and anti-Müllerian hormone (AMH) dependent.

Anti-Müllerian hormone is now considered to be the main regulator of early follicular recruitment from the primordial pool. It is produced by small enlarging follicles rather than the primordial follicles themselves. Plasma

FIGURE 22.2 ■ Vaginal ultrasonographic images of the ovary. (A) Polycystic ovary showing multiple antral type peripheral follicles; (B) Pre-ovulatory follicle 20 mm; (C) Corpus luteum with Doppler showing surrounding neovascularity. Vessels show as prominent echoes below the darker collapsed follicle.

concentrations of AMH do, however, appear to reflect primordial follicle numbers in humans and rodents.

Through a poorly understood process of selection, one of the apparently identical antral follicles present on day 1 becomes dominant, while the others degenerate. The dominant follicle grows rapidly in the late follicular phase, reaching a maximum diameter of approximately 20 mm (Fig. 22.2B). Outside the basement membrane of the granulosa cell layer, the wall of the dominant follicle consists of the theca interna and theca externa, which have developed from ovarian stromal cells. At ovulation, the follicle collapses, releasing its fluid and the oocyte, which by now has completed the first meiotic division. The follicle subsequently refills with fluid, and blood vessels penetrate the basement membrane and vascularize the granulosa cells for the first time; further proliferation of the granulosa cells transforms what was the follicle into the corpus luteum (Fig. 22.2C). The corpus luteum has a limited life span: in the absence of conception it involutes, another dominant follicle develops and the cycle repeats itself.

Insulin-like growth factor-1 has actions that regulate sex steroids through the control of the plasma concentration of sex hormone binding globulin (SHBG). Although the precise mechanism is unclear, increasing concentrations of GH are believed to exert some effects on circulating insulin concentrations. Growth hormone induces peripheral insulin resistance which leads to compensatory increases in insulin secretion and protein anabolism. Insulin regulates hepatic insulin-like growth factor 1 (IGF-1) through its effects on insulin-like binding protein 1 (IGFBP-1).

Obesity is associated with increased plasma concentrations of insulin. Therefore, if excessive nutrition intake persists during childhood, it is possible that hyperinsulinaemia may lead to lower concentrations of IGFBP-1 and reduced plasma SHBG concentrations, enhancing IGF-1 and sex steroid bioavailability.

Plasma concentrations of reproductive hormones

Figure 22.3 illustrates the fluctuations in plasma concentrations of reproductive hormones through a typical menstrual cycle. Changes in the pulsatile release of gonadotrophins in the late luteal phase and early follicular phase

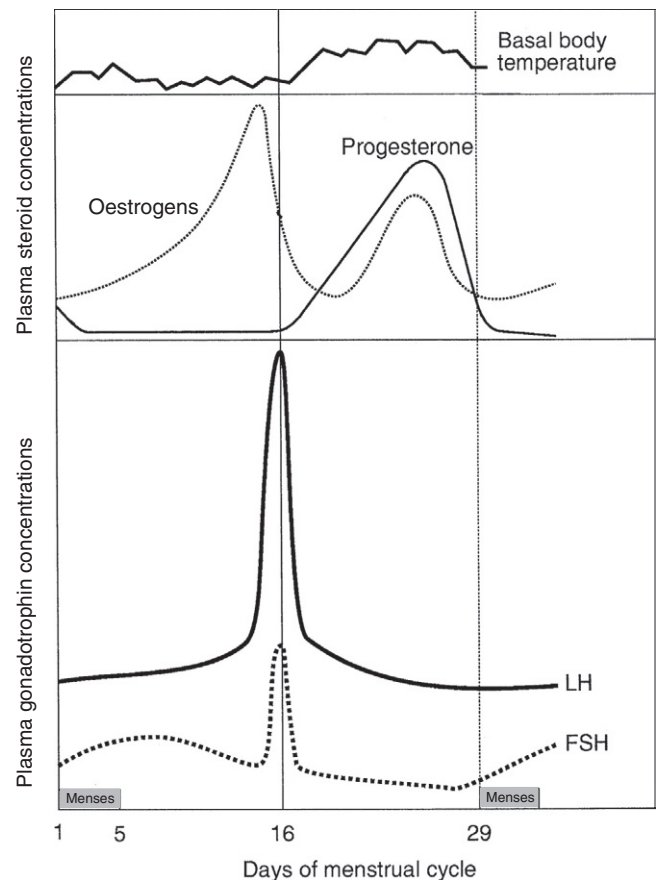

FIGURE 22.3 ■ Hormone fluctuations during the human menstrual cycle.

appear to bring about the growth of a group of antral follicles, one of which (the dominant follicle) enlarges greatly and secretes increasing amounts of oestrogens (mainly 17 β -oestradiol). Although oestrogens generally exert a negative feedback effect on gonadotrophin concentrations, high, rising oestrogen concentrations in the late follicular phase feed back positively on the hypothalamic–pituitary axis, causing a massive release of luteinizing hormone (LH) (the LH ‘surge’) and a smaller release of FSH. The LH surge triggers the resumption of meiosis and follicle rupture with oocyte release. Oestrogen concentrations fall transiently prior to ovulation. The corpus luteum secretes

both oestrogens and progesterone; plasma concentrations of both hormones peak in the mid-luteal phase falling in the late luteal phase as, in the absence of conception, the corpus luteum involutes. It is likely that ovarian proteins such as inhibin and activin also play a role in regulating follicle development and steroid synthesis. These proteins and other structurally similar 'growth factors' may exert important paracrine effects within the ovary.

Uterine changes

Rising oestrogen concentrations in the follicular phase induce proliferative changes in the endometrium, causing it to thicken. Oestrogens and progesterone (from the corpus luteum) induce secretory changes in the endometrium, preparing it for pregnancy. Once deprived of hormonal support from the corpus luteum, the endometrium is shed and another cycle begins.

Conception

Fertilization usually takes place in the ampullary part of the Fallopian tube, close to the ovary. Implantation occurs 6–7 days after fertilization. Human chorionic gonadotrophin (hCG) production from the conceptus acts to prolong the life of the corpus luteum so that it continues to produce progesterone, thus maintaining the endometrium.

HORMONES REGULATING REPRODUCTIVE FUNCTION

Gonadotrophin releasing hormone is a decapeptide secreted by neurons in the median eminence of the hypothalamus. It is carried in the portal hypophysial vessels from the hypothalamus to the pituitary, where it stimulates the release of LH and FSH. Concentrations of GnRH in the general circulation are very low but are assumed to be reflected by LH concentrations. The release of LH and FSH are pulsatile: the inter-pulse interval decreases from 90 to 60 min during the follicular phase until ovulation, then lengthens to once or twice a day in the late-luteal phase.

Pulsatile secretion of GnRH is essential to maintain normal function, as continuous infusion causes downregulation of receptors and amenorrhoea. Administration of GnRH, modified to prolong its action, is used to induce therapeutic hypogonadism.

Follicle stimulating hormone, LH and hCG are structurally similar glycoproteins. Each consists of an α - and a β -subunit, which are associated by non-covalent interactions. The α -subunits of FSH, LH and hCG (and of thyroid stimulating hormone, TSH) are identical, while the β -subunits differ, conferring hormonal specificity. The α -subunit consists of 92 amino acids. Gonadotrophins are largely metabolized in the liver; 10–15% is excreted unchanged in the urine.

Follicle stimulating hormone

The β -subunit of FSH contains 118 amino acids. Carbohydrate constitutes 22–25% of the dry weight of

FSH and there are four branched, mannose-rich oligosaccharide side chains covalently bound to asparagine residues, two on the α -subunit and two on the β -subunit. The biological role of the carbohydrate is partly to protect the hormone against degradation. Follicle stimulating hormone is synthesized and secreted by gonadotrophic cells of the anterior pituitary, which also synthesize LH.

The primary target of FSH is the granulosa cell of the ovarian follicle. Follicle stimulating hormone stimulates differentiation of immature granulosa cells, induces cytochrome P450-dependent aromatase, induces LH receptors on granulosa cells and increases the binding of FSH by granulosa cells. The circulating half-life of FSH is ~4h. Oestradiol amplifies the actions of FSH on granulosa cells.

Luteinizing hormone

The β -subunit of LH consists of 92 amino acids. Luteinizing hormone has three carbohydrate side chains, carbohydrate accounting for approximately 15% of the dry weight of the hormone. The circulatory half-life of LH is short (20 min), contributing to the pronounced pulsatility of plasma LH concentrations.

Ovarian LH receptors are found on theca cells and on mature granulosa cells. Luteinizing hormone stimulates production of androgens by the theca cells, and of oestradiol and progesterone by mature granulosa cells and corpus luteal cells. Luteinizing hormone regulates steroid biosynthesis by influencing uptake and side chain cleavage of cholesterol.

Human chorionic gonadotrophin

The β -subunit of hCG consists of 145 amino acids. The hormone is synthesized by the syncytiotrophoblastic cells of the placenta. It has a relatively long plasma half-life (24–36 h).

Human chorionic gonadotrophin interacts with the same receptors on luteal cells as does LH. It acts in the first trimester of pregnancy to maintain the corpus luteum and its ability to secrete progesterone, which supports the endometrium. After the first trimester, the placenta takes over the synthesis of progesterone from the corpus luteum. Human chorionic gonadotrophin is detectable in plasma eight days after conception and its concentration peaks around the tenth week of pregnancy.

Human chorionic gonadotrophin also stimulates testosterone synthesis in the testes of male fetuses, providing stimulation for male sexual differentiation.

Inhibin and activin

Inhibin is a glycoprotein that has been isolated from follicular fluid in two forms comprising a common α -subunit and one of two β -subunits, β_A (in inhibin A) and β_B (in inhibin B). Follicular fluid also contains two dimers of the inhibin β -subunit, which are called activin: activin A is the homodimer of the β_A -subunit, activin A-B is the $\beta_A\beta_B$ heterodimer.

Inhibin A and inhibin B have different patterns of circulation during the two phases of the ovarian cycle and play different physiological roles during follicular recruitment, maturation and ovulation. In the luteal phase,

inhibin A suppresses FSH secretion. The concentration of inhibin A then decreases significantly as the corpus luteum involutes.

Development of the dominant follicle is characterized by secretion of increasingly large amounts of oestradiol and inhibin A into the circulation. There is evidence that the maintenance of the follicle is affected by intraovarian signalling, with inhibins and activins acting as important paracrine messengers.

During the menstrual cycle, plasma activin A concentrations vary in a biphasic manner, with the highest values occurring at mid-cycle during the luteo-follicular transition and nadirs occurring in the mid-follicular and mid-luteal phases.

Prolactin

Prolactin is a single chain polypeptide comprising 199 amino acids. It shares a high degree of homology with growth hormone and placental lactogen. Its most potent biological form (80–90%) is monomeric; 8–20% is dimeric and 1–5% is macroprolactin. The latter is a complex of monomeric prolactin and IgG and is immunoreactive (i.e. detected in most assay systems) but biologically relatively inactive.

Prolactin is synthesized by lactotroph cells of the anterior pituitary. Dopamine is the principal negative modulator of prolactin secretion; oestrogens and thyroid hormone releasing hormone increase prolactin release.

Prolactin has a variety of actions in vertebrates, playing roles in processes as diverse as osmoregulation and metamorphosis. It also has a direct but variable effect on follicular development and function. Prolactin is luteotrophic in some mammals but not in man. The only definite role of prolactin in women is the postpartum initiation and maintenance of milk production.

Macroprolactinaemia is a relatively common phenomenon in patients with hyperprolactinaemia in clinical practice; to ensure appropriate detection and management, all patients found to have significant hyperprolactinaemia should be screened for macroprolactinaemia (see Chapter 18).

Anti-Müllerian hormone

Anti-Müllerian hormone is a glycoprotein also known as Müllerian inhibitory factor (MIF) (see Chapter 21 for its role in normal and disordered sex development). It belongs to the transforming growth factor b family and is encoded on the short arm of chromosome 19. It acts through two receptors (AMHR1 and 2), which are present on the target organs in the gonads and Müllerian ducts.

Measurement of AMH is used clinically for assessment of 'ovarian reserve' and likely response to ovarian stimulation for subfertility. It has largely superseded measurement of basal FSH and inhibin B as a marker of follicular potential, particularly as the concentrations do not change with the menstrual cycle. It can also be used as a tumour marker for granulosa cell malignancies and appears to be an excellent marker for polycystic ovarian syndrome as these patients have significantly elevated concentrations.

REPRODUCTIVE STEROID HORMONES

Structure

Ovarian steroid hormones are derivatives of cholesterol and contain the cyclopentanoperhydrophenanthrene nucleus (Fig. 22.4). Oestrogens (C-18 steroids), androgens (C-19 steroids) and progestogens (C-21 steroids) contain 18, 19 and 21 carbon atoms, respectively. These compounds and the pathways involved in their biosynthesis are illustrated in Figure 22.5.

Biosynthetic enzymes

The numbers below refer to the enzymes and pathways labelled in Figure 22.5.

1. *Cholesterol side chain cleavage*. Three separate reactions are involved: 20 α -hydroxylation, 22-hydroxylation and splitting of the C20–22 carbon bond. This is the point where LH primarily regulates ovarian steroidogenesis. The product of the process, which occurs in a mitochondrial complex containing the cytochrome P450 system, is pregnenolone.
2. *3 β -Hydroxysteroid dehydrogenase $\Delta^{4,5}$ isomerase*. This catalyses both the 3 β -hydroxysteroid dehydrogenation and isomerization of the double bond from ring B to ring A. Pregnenolone is thereby converted to progesterone.
- 3/4. *17 α -Hydroxylase/17,20-desmolase*. This catalyses the 17 α -hydroxylation of pregnenolone and progesterone. The desmolase reaction involves the formation of a peroxide at C-20, epoxidation of the C-17 and C-20 carbons and side chain cleavage to form the C-17 oxosteroids dehydroepiandrosterone (from pregnenolone) and androstenedione (from progesterone). Both reactions are catalysed by the same enzyme.

The cyclopentanoperhydrophenanthrene nucleus

Cholesterol

FIGURE 22.4 ■ Structural basis of steroid hormones.

FIGURE 22.5 ■ Ovarian steroid biosynthetic pathways. The numbered arrows correspond to the description of biosynthetic enzymes in the text.

The intermediates are 17 α -hydroxypregnenolone and 17 α -hydroxyprogesterone, respectively.

5. *17-Oxosteroid reductase*. This catalyses the conversion of a 17-oxosteroid to a 17 β -hydroxysteroid and vice versa. Androstenedione and oestrone are converted to testosterone and oestradiol, respectively.
6. *Aromatase*. This converts C-19 $\Delta^{4,3}$ oxosteroids to oestrogens by hydroxylation of the C-19 angular methyl group, oxidation and cleavage of the C-19 methyl group as formaldehyde, dehydrogenation of the A ring, and finally conversion of the 3-oxo group to a 3 β -hydroxy group. The activity of this enzyme in granulosa cells is regulated by FSH.

Oestrogens are synthesized from androstenedione, the major pathway being through oestrone. Pregnenolone is converted to androstenedione either by the Δ^4 pathway (through progesterone) or by the Δ^5 pathway (through dehydroepiandrosterone).

The Δ^4 pathway is favoured in granulosa/corpus luteal cells, while the Δ^5 is favoured in theca cells.

The major secreted oestrogen is 17 β -oestradiol; it is in equilibrium with oestrone in the circulation. Oestrone is further metabolized to oestriol, probably mostly in the

liver. Oestradiol is the most potent oestrogen of the three and oestriol the least.

Steroid secretion through the menstrual cycle

Before ovulation the granulosa cells are not vascularized. The theca cells produce large quantities of androgens, which diffuse into the granulosa cells and are converted to oestrogens. This concept of cooperation between cell types is called the two-cell theory. Vascularization of the granulosa cells leads to increased progesterone secretion in the luteal phase. The stromal cells of the ovaries secrete small amounts of androgens. This secretion becomes more significant after the menopause when it adds to oestrogen concentrations through peripheral conversion in adipose tissue.

Steroid hormone transport and metabolism

Most of the circulating oestrogens and progesterone is protein bound, loosely to albumin and strongly to globulins: oestrogens are carried by SHBG and progesterone

by cortisol-binding globulin. Degradation of both C-18 and C-21 steroids occurs in the liver and involves hydroxylation and water solubilization by conversion to glucuronide and sulphate conjugates. Water-soluble metabolites are excreted in urine and in bile. Quantitative urinary tests were used in the past to assess concentrations of oestrogens and progestogens, but have been superseded by rapid, sensitive and specific serum immunoassays. The major excreted oestrogen and progestogen are oestradiol and pregnanediol, respectively.

Actions of gonadal steroid hormones

Oestrogens

Oestrogens broadly maintain the functions of the reproductive tract, are responsible for the development of secondary sexual characteristics and affect sexual behaviour. Oestrogens cause myometrial hypertrophy, cause the endometrium to thicken in the follicular phase, promote secretion of large amounts of watery cervical mucus around the time of ovulation and maintain vaginal function; after bilateral oophorectomy or the menopause, the uterus and vagina shrink in size.

Oestrogens produce duct growth in the breasts and are responsible for breast enlargement at puberty. Oestrogens, like androgens, increase libido in humans, apparently by a direct action on hypothalamic neurons. In general, oestrogens reduce secretion of LH and FSH (negative feedback) but, in mid-cycle, oestrogens increase LH secretion (positive feedback). In addition to their reproductive role, oestrogens have important systemic effects: they maintain bone density and skin thickness and protect against atheromatous arterial disease in premenopausal females.

Synthetic oestrogen derivatives with agonist actions are used in contraceptive and hormone replacement preparations. Ethinylloestradiol is the most commonly used, particularly in contraceptives; it is potent and, unlike naturally occurring oestrogens, is active when given by mouth.

Anti-oestrogen preparations are also available: clomifene citrate and tamoxifen are non-steroidal triphenylethylene derivatives with mixed oestrogen agonist and antagonist actions. Clomifene citrate is used to induce ovulation, and tamoxifen to treat oestrogen-dependent breast cancers.

Progestogens

Progesterone causes secretory changes in endometrium already primed by oestrogen. It promotes the secretion of smaller amounts of thicker cervical mucus. It is essential for the maintenance of early pregnancy.

Synthetic steroids with progesterone agonist properties are used in contraception and hormone replacement therapy. Those commonly used tend to be derivatives either of 17 α -hydroxyprogesterone or of 19-nortestosterone. Both types of derivative are used in combined oral contraceptive preparations: along with ethinylloestradiol, they prevent follicle growth, promote an endometrial reaction unfavourable to implantation and render cervical mucus thick and impenetrable to sperm.

Mifepristone is a derivative of norethisterone that blocks the actions of progesterone peripherally. It induces

menstruation when given in the late luteal phase and induces abortion when given in pregnancy.

Androgens

The two main androgens in the female are testosterone and androstenedione. Dehydroepiandrosterone (DHEA) and its sulphate (DHEAS) are less important androgens. During the reproductive years, 90% of DHEA and DHEAS is synthesized by the adrenals and 10% by the ovaries. Androstenedione is derived equally from the ovaries and adrenals. Only 50% of testosterone production is glandular (roughly equal contributions from adrenals and ovaries), the remainder resulting from peripheral metabolism of weaker androgens, mostly in adipose tissue. A total of 99% of testosterone is bound and 1% is free: the great majority (78%) is bound to SHBG. This is a glycoprotein synthesized in the liver, with a carbohydrate content of 34%. It is a high-affinity, low-capacity binding protein. Plasma SHBG concentrations are raised when oestrogen concentrations are high (as in pregnancy) and in hyperthyroidism; concentrations are low in women treated with testosterone. Because SHBG-bound testosterone is relatively inert biologically, it may be useful for laboratories to measure both testosterone and SHBG, to give an indication of how much testosterone is not bound to SHBG ('free androgen index').

OLIGO- AND AMENORRHOEA

Oligomenorrhoea is defined as a menstrual cycle length of greater than six weeks but less than six months. Amenorrhoea is complete absence of menstruation or cycle length greater than six months. In these conditions, ovulation does not occur or is very infrequent. Women with oligo- or amenorrhoea may seek medical assistance because their bleeding pattern is abnormal, because of infertility, because of hirsutism/virilism or with a combination of these complaints.

The majority of patients with oligomenorrhoea have the polycystic ovary syndrome. The classic 'polycystic ovary syndrome' (PCOS) was described by Stein and Leventhal in 1935; they described an association between polycystic ovaries and oligo- and amenorrhoea in a small series of patients, most of whom were infertile or hirsute. It later became apparent that plasma concentrations of LH and/or androgens are elevated in many, but not all, women with polycystic ovaries; FSH concentrations are normal. However, it should be noted that around a quarter of women who have no gynaecological symptoms have also been found to have polycystic ovaries.

Polycystic ovary syndrome is a syndrome of ovarian dysfunction. It seems most likely that changes in the pattern of gonadotrophin secretion are responsible for the failure of antral follicles to grow and for a dominant follicle to emerge and ovulate (Fig. 22.2A). It is possible to induce follicular growth in patients with PCOS by therapeutic administration of FSH. It is important to recognize that polycystic ovaries and PCOS can occasionally occur as a secondary phenomenon in patients with other endocrine disorders. These include conditions such as

congenital adrenal hyperplasia and Cushing syndrome, hyperprolactinaemia and acromegaly.

The revised diagnostic criteria of PCOS require any two of the following to be present:

- oligo- or anovulation
- clinical and/or biochemical evidence of hyperandrogenism
- polycystic ovaries

and exclusion of other aetiologies (e.g. congenital adrenal hyperplasia, androgen-secreting tumours, Cushing syndrome).

The primary clinical indicator of androgen excess is the presence of hirsutism or acne. The sole presence of androgenic alopecia as an indicator of hyperandrogenism has been less well studied.

Few data are available on the value of routinely measuring androstenedione in hyperandrogenic patients, although it may be somewhat more elevated in patients with non-classic 21-hydroxylase deficiency congenital adrenal hyperplasia than in PCOS. Nonetheless, at present, the paucity of clinical data with androstenedione precludes its recommendation for the routine assessment of hyperandrogenism.

Weight loss can help to regularize menstrual periods with resumption of natural ovulation. If weight loss fails, clomifene, tamoxifen or gonadotrophins may be used to induce ovulation. Metformin may also improve ovulation rates when used with clomifene in patients resistant to clomifene alone.

Cyproterone acetate (an anti-androgenic progestogen) reduces hirsutism and is usually given as part of a combined oral contraceptive pill. The oestrogen component increases the plasma concentration of SHBG, which is often low in women with PCOS. The result is a decrease in the concentration of free testosterone, which also contributes to the reduction in hirsutism and acne. The treatment adopted depends on the desired outcome, for example whether this is to control acne, regularize menstruation or to achieve pregnancy.

Polycystic ovary syndrome is frequently associated with the metabolic syndrome of insulin resistance, hyperinsulinaemia and dyslipidaemia. This topic is discussed in detail in Chapter 15.

Hyperprolactinaemia is another important cause of oligo/amenorrhoea and acts by suppressing LH secretion and inhibiting ovulation. The normal range for plasma prolactin concentration in women is approximately 300–700 mIU/L, although this is dependent on the assay used. It is difficult to define a precise upper limit, but significant disease is unlikely unless the prolactin concentration is >1000 mIU/L. The possibility that hyperprolactinaemia is secondary to drugs (e.g. opiates, methyl dopa, antipsychotics, oestrogens and metoclopramide) must be excluded. Thyrotropin-releasing hormone (TRH) stimulates prolactin secretion, and therefore primary hypothyroidism can cause oligomenorrhoea. Patients found to have unexplained significant hyperprolactinaemia should have pituitary imaging to exclude a macroprolactinoma (a prolactin-secreting adenoma) or a non-functioning tumour (interfering with the normal dopamine suppression of prolactin secretion); the most frequent diagnoses resulting are idiopathic

disease (no scan abnormality) or a microadenoma. (See Chapter 18 for further details.)

The medical management of hyperprolactinaemia is with a dopamine agonist. Bromocriptine has been used widely, but cabergoline, a longer acting preparation, is now usually preferred. It is better tolerated and more efficacious than bromocriptine but is associated with psychiatric adverse effects. Quinagolide is another longer acting preparation, and an alternative to cabergoline. This topic is discussed further in Chapter 18. Trans-sphenoidal surgery is an option for some patients.

Primary ovarian failure also causes amenorrhoea. It is diagnosed by the finding of a raised plasma FSH concentration (>40 IU/L) and is irreversible. Other causes of oligomenorrhoea include androgen-secreting tumours and late onset congenital adrenal hyperplasia: these conditions are discussed later in this chapter, in the account of hirsutism and virilism.

INFERTILITY

Infertility is defined as failure to conceive after 12 months of regular sexual intercourse without contraception. The partner's semen should be analysed to exclude male subfertility, but the results are often inconclusive; insemination of mature oocytes in vitro establishes the fertilizing capacity of semen more reliably.

Imaging techniques are of considerable importance in the investigation of infertility. Laparoscopy with hydrotubation, hysterosalpingography and hysterocontrast sonography all assess patency of the fallopian tubes, using direct vision, radiography and sonography respectively; intraperitoneal spillage of fluid injected through the cervix excludes tubal blockage. Transvaginal ultrasonography is used to assess ovarian morphology and to monitor ovulation.

Tests to predict ovulation are required in women who have long cycles (>35 days). The LH surge that precedes follicle rupture can be detected by qualitative urine tests based on monoclonal antibodies. Commercially available point-of-care tests are very sensitive and are increasingly being used. Measuring serum progesterone concentration in the mid-luteal phase (i.e. seven days after time of expected ovulation) is a well-established method for assessing ovulation. Values in conception cycles have been found to range between 28 and 53 nmol/L; 30 nmol/L is generally taken as the lower limit of normal for mid-luteal phase progesterone. Blood sampling before or after the mid-luteal peak can give misleadingly low values. Sampling can be timed correctly by taking serial specimens and identifying the mid-luteal phase specimen retrospectively. It is the specimen taken seven days before the first day of the next menstrual period. (The classic day 21 sample will only be the mid-luteal phase if the woman has a regular 28-day cycle.) Progesterone is secreted in a pulsatile fashion during the luteal phase, concentrations varying by as much as a factor of three; when sampling coincides with a trough, the plasma progesterone concentration may appear abnormally low.

Basal plasma concentrations of FSH and LH are measured routinely in infertile women. A single specimen is

usually taken during the early follicular phase on day 1–3 of the cycle. Interpretation of apparently abnormal early follicular phase gonadotrophin concentrations must take into account the pulsatile nature of release of both hormones. For LH, the pulse interval in the early follicular phase is 65–90 min, with peak and trough concentrations varying by as much as a factor of five. Plasma FSH concentrations do not fluctuate so widely – by a factor of two at the most. Elevated FSH concentrations in women with normal-length menstrual cycles indicate diminished fertility and possibly incipient ovarian failure. In patients undergoing assisted conception, early follicular phase plasma FSH concentrations are inversely related to the number of oocytes obtained and to the probability of conception. Measurement of AMH, however, is now preferred, as it gives a more accurate reflection of ovarian reserve and likely response to ovarian stimulation, and is not dependent on the day of the cycle. Measurement of early follicular phase LH is of less certain diagnostic value; concentrations tend to be abnormally high in patients with PCOS. Misleadingly high values are obtained when sampling coincides with a pulse peak. Basal concentrations of prolactin and thyroid hormones are unlikely to be of diagnostic value unless the length of the menstrual cycle is abnormal.

Increasingly, subfertility, whatever its cause, is treated using assisted conception techniques. Modern superovulation regimens promote the development of more than one follicle and include the use of gonadotrophin releasing hormone analogues, follicle stimulating hormone and human chorionic gonadotrophins.

Oocytes are collected by ultrasound-directed follicle aspiration. They are then either incubated with sperm (in vitro fertilization, IVF) or directly injected (intracytoplasmic sperm injection, ICSI). The resulting embryos are then transferred to the uterine cavity.

The major risk of superovulation regimens is ovarian hyperstimulation syndrome (OHSS). This generally occurs in the luteal phase or during early pregnancy and is triggered by either exogenous or endogenous hCG. Patients with polycystic ovaries, more than 20–25 follicles in both ovaries or with a high (>6000 pmol/L) or rapidly rising oestradiol (doubling on consecutive days) prior to hCG administration are most at risk. Mild OHSS is common (20–30% of stimulated cycles) and leads to abdominal distension, enlarged ovaries, nausea and vomiting and is treated conservatively. Severe OHSS (<2%), caused by increased vascular permeability and fluid shift out of the intravascular space, presents with ascites, increased blood viscosity, oliguria, thromboembolism and respiratory problems and can result in multi-organ failure. Biochemical changes include hyponatraemia from hypersecretion of antidiuretic hormone, hyperkalaemia, hypoalbuminaemia, abnormal liver enzymes and high plasma creatinine.

HIRSUTISM AND VIRILISM

Hirsutism means excessive hair growth in sites usually associated with male sexual maturity, that is, the face, lower abdomen (giving the appearance of a male escutcheon),

anterior thigh, mid-chest and periareolar region. It can be associated with acne and oily skin. Virilism refers to more extreme manifestations of androgen exposure, including temporal hair recession, clitoromegaly, increased muscle mass, breast atrophy and deepening of the voice.

Dihydrotestosterone derived from testosterone acts on hair follicles to stimulate growth of terminal hair (long, coarse and pigmented) rather than vellus hair (short, fine and poorly pigmented). Once stimulated, the hair follicle remains responsive to low-dose weak androgen exposure because it has attained the ability to convert weak androgens to testosterone.

Polycystic ovary syndrome is responsible for hirsutism in a substantial proportion of patients. Rarer causes are discussed below. In many cases, however, no cause can be diagnosed; such hirsutism is termed idiopathic.

In idiopathic hirsutism, total plasma testosterone concentrations are normal, but subtle androgen disorders can generally be identified. Plasma androstenedione concentrations may be elevated and SHBG reduced; free testosterone concentration may be raised even though total testosterone is within normal limits.

The investigation of hirsutism should determine whether androgen concentrations are indeed elevated and to what degree, and rule out serious disease (particularly malignancy) of the ovaries or adrenals. Grossly elevated testosterone concentrations (>5 nmol/L) and hirsutism of sudden onset (especially if accompanied by virilism) suggest malignancy.

Computed axial tomography (CT) or magnetic resonance imaging (MRI) is used to visualize adrenal tumours. Laboratory investigations used to evaluate hirsutism include measurements of serum cortisol and 17 α -hydroxyprogesterone, in addition to testosterone, androstenedione and SHBG; steroid hormone concentrations following overnight dexamethasone suppression or ACTH stimulation may also be useful. Congenital adrenal hyperplasia is a recognized cause of hirsutism. The most frequent type is 21-hydroxylase deficiency, which results in elevated plasma concentrations of 17 α -hydroxyprogesterone and increased synthesis of adrenal androgens. Testosterone concentrations are significantly elevated and ACTH stimulation is followed by an excessive increase in 17 α -hydroxyprogesterone (see [Appendix 22.1](#), below, for protocol). In Cushing syndrome, there is typically loss of the normal diurnal rhythm in plasma cortisol concentrations and failure of suppression in the overnight dexamethasone suppression test.

Although 90% of DHEAS is normally of adrenal origin, elevated DHEAS concentrations in hirsutism do not confirm an adrenal source of the excess: elevated DHEAS concentrations may also be found in polycystic ovary syndrome. However, a DHEAS concentration of more than twice the upper limit of normal does suggest the possibility of an adrenal tumour. Suppression of elevated androgen concentrations in hirsutism by dexamethasone might be expected to confirm an adrenal source; however, selective venous catheterization studies have demonstrated that elevated ovarian androgens can also be suppressed by dexamethasone in patients with hirsutism.

Once the rarer causes of hirsutism ([Box 22.1](#)) have been excluded, treatment consists of medication to suppress

BOX 22.1 Some rare causes of hirsutism

- Congenital adrenal hyperplasia (adult onset)
- Cushing syndrome
- Ovarian tumours
- Adrenal tumours
- Self-administration of androgens

androgen secretion or counter its effects. Combined oral contraceptives and the anti-androgen cyproterone acetate are widely used. Medical treatment can be supplemented by cosmetic techniques such as shaving, waxing and electrolysis.

PREGNANCY**Introduction**

Pregnancy is associated with marked hormonal changes in the maternal circulation that facilitate the metabolic, vascular and immunological adjustments necessary for the fetus to thrive. Abnormal concentrations of these hormones, or of other plasma constituents of fetoplacental origin, may indicate gestational pathology. The metabolic changes associated with pregnancy are relatively short lived and thus are rarely harmful to the healthy mother.

Prior to the widespread availability of high-resolution ultrasound scanning, the diagnosis of early pregnancy failure (such as spontaneous abortion and ectopic pregnancy), fetal malformation and fetal growth disturbances relied solely on clinical evaluation backed by tests on maternal blood. Although these indirect and often inaccurate methods have largely been replaced by ultrasound technology, biochemical assays still form an important part of the screening of many pregnancies.

Biochemical diagnosis of pregnancy**Human chorionic gonadotrophin**

Human chorionic gonadotrophin (hCG) can be detected in maternal blood 7–9 days after conception (i.e. 22–24 days after the last menstrual period in women with regular 28-day cycles) and in urine 1–2 days later. The biochemical diagnosis of pregnancy is routinely made by a monoclonal antibody enzyme immunoassay that detects urinary hCG concentrations as low as 25 IU/L. The plasma concentration of hCG in normal pregnancy rises steeply to a peak at ten weeks of gestation and then falls and remains at a lower concentration for the remainder of pregnancy. This fall at the end of the first trimester is peculiar to hCG, as concentrations of the other chemical products of the fetoplacental unit rise with increasing length of gestation.

High sensitivity assays have shown that hCG is present in the plasma at low concentrations (<5 IU/L) prior to conception. The biochemical diagnosis of pregnancy should only be made when plasma hCG concentration exceeds 25 IU/L or if a lower concentration doubles within two days. In cases where exogenous hCG has been given

to induce ovulation, hCG estimations should be delayed by up to 14 days to allow clearance of the administered hCG.

The use of quantitative serum hCG estimations in the diagnosis of ectopic pregnancy is discussed below.

Apart from its place in the diagnosis of pregnancy, other well-established roles for hCG estimation are in the diagnosis and monitoring of gestational trophoblastic disease and as a marker for some tumours (see Chapter 42). The diagnosis of gestational trophoblastic disease is usually made ultrasonographically or histologically after an episode of vaginal bleeding in early pregnancy, though the condition may present after a term pregnancy when persistently high concentrations of hCG may help in making the diagnosis. After the uterus has been surgically evacuated, persistence or recurrence of the condition is monitored by serial quantitative hCG assays. The response of gestational trophoblastic disease to chemotherapy can be monitored in a similar fashion.

Human chorionic gonadotrophin measurement also plays a part in screening for Down syndrome. This topic is discussed on p. 443.

Diagnosis of ectopic pregnancy

Ectopic pregnancy poses a considerable hazard to the mother (95% are tubal: a ruptured tubal pregnancy can cause severe intra-abdominal bleeding), so that accurate diagnosis of this condition is essential. The symptoms and signs are notoriously variable and definitive diagnosis frequently depends on laparoscopy. However, use of additional investigations, such as measurement of hCG concentration, may help to reduce the number of ‘unnecessary’ laparoscopies and allow medical or conservative treatment.

Transvaginal ultrasound enables the diagnosis of intrauterine pregnancy at a time when the plasma hCG concentration is around 1000 IU/L. The absence of a visible embryonic sac within the uterus in these circumstances makes an ectopic pregnancy the likely diagnosis. The rate of increase in plasma hCG concentrations may provide useful additional information. Early in a normal pregnancy, these usually double every two days, while the rise in ectopic pregnancy is, in general, less. Progesterone measurements have also been used in the investigation of possible ectopic pregnancy. A plasma progesterone concentration of >25 nmol/L is suggestive of a viable intrauterine pregnancy; however, recent guidelines from the National Institute for Health and Care Excellence (NICE) in the UK suggest that progesterone measurement should no longer be used in this context. Low or falling concentrations of progesterone and hCG may allow expectant management if symptoms are minimal, as this suggests that the pregnancy is failing and will resolve spontaneously. Surgery can also be avoided in patients with hCG <5000 IU/L and minimal symptoms, as they can be treated with the folate antagonist, methotrexate, as long as hCG monitoring is available. Pain and haemodynamic instability are indications for laparoscopy.

In clinical practice, the diagnosis of ectopic pregnancy depends on a high index of suspicion, measurement of serum hCG concentration, pelvic ultrasound and, when indicated, laparoscopy.

Biochemical monitoring of pregnancy

Spontaneous abortion

Many studies have reported low concentrations of various hormones and placental proteins in patients with early spontaneous abortion. However, these studies have often been performed after the onset of bleeding and their findings may have been the result, rather than the cause, of the pregnancy failure. Plasma progesterone concentrations have, for example, been reported to be low in these circumstances, but administration of progestogens to women with threatened abortions has not been shown to prevent pregnancy loss.

Screening for fetal malformation

Prior to the widespread availability of high-resolution ultrasound scanners, the antenatal detection of fetal malformation was based on maternal biochemical screening. To some extent, ultrasound has made this screening less important, but these tests may focus attention on the high-risk pregnancy so that an appropriate diagnostic procedure can be performed.

Biochemical screening. Screening for Down syndrome (trisomy 21) in the past has depended entirely on maternal age and past history of chromosomal abnormalities in offspring and has resulted in some form of invasive tissue sampling (chorionic villus sampling or amniocentesis) being offered to essentially all pregnant women over a locally agreed age, usually 35 years. (The risk of a Down syndrome pregnancy is 1:1528 at maternal age 20, 1:1351 at 25, 1:909 at 30, 1:384 at 35 and 1:112 at age 40.) This approach was unsatisfactory because, although the risk of trisomy 21 increases with maternal age, 70% of Down infants are born to women below the age of 35. In addition, many women over 35 decline the offer of invasive tissue sampling because of the risk of miscarriage.

The observation in 1984 that maternal plasma α -fetoprotein (AFP) concentrations were lower in the presence of fetal Down syndrome than in unaffected pregnancies, led to its use in screening for this condition. Subsequently, maternal plasma concentrations of hCG were found to be elevated and concentrations of unconjugated oestriol decreased when the fetus had Down syndrome. The assay of these substances in maternal plasma at around 16 weeks of gestation has become known as the 'triple test' and, in combination with maternal age and weight, gives a risk score of the fetus having Down syndrome.

The chosen cut-off for a 'positive' screen will govern the detection and false positive rates. A commonly chosen cut-off is a triple test result representing a risk of 1 in 250 or higher, corresponding approximately with the risk for a maternal age of 35 years alone. At this cut-off, there is a detection rate of 61% and a false positive rate of 5%.

Maternal biochemical screening for Down syndrome is not diagnostic of the condition, but allows a better selection of a high-risk group (to whom diagnostic amniocentesis may be offered) than use of maternal age alone. However, screening does not detect other, more serious trisomies, for which older women are also at increased

risk. The detection and analysis of free fetal DNA in the maternal plasma may, in future, obviate the need for invasive testing and reduce the risk of fetal loss.

α -Fetoprotein is one of the two major proteins in the fetal circulation. The AFP concentration in fetal plasma greatly exceeds that in amniotic fluid and maternal plasma. Thus, even minor leakages from the conceptus result in readily detectable rises in maternal plasma AFP concentrations. This formed the basis of maternal screening in the second trimester for a range of fetal malformations, e.g. neural tube defects, but these are now reliably diagnosed by ultrasound. Several situations can give rise to false positive results, the most important of which is an incorrect estimation of gestational age, as maternal plasma AFP rises steeply at 16–20 weeks (Fig. 22.6). Multiple pregnancies are also associated with higher concentrations.

Ultrasound. While ultrasound examination allows the diagnosis of the majority of significant structural fetal anomalies, most genetic disorders cannot be diagnosed by this means and require tissue sampling techniques to identify an affected fetus. The majority of these procedures are performed for fetal karyotyping, but despite the increasing use of tissue sampling techniques such as amniocentesis and chorionic villus sampling (CVS) over the last 20–30 years, there has not been a significant reduction in the birth incidence of infants with abnormal karyotypes.

Current screening practice. An important advance in the antenatal diagnosis of Down syndrome was the recognition of the nuchal translucency (NT) sign. This is the appearance on ultrasound of increased fluid at the back of the fetal neck in affected fetuses and can be detected late in the first trimester. Its specificity and sensitivity are enhanced if it is combined with other investigations such as measurement of hCG and pregnancy-associated plasma protein A (PAPP-A; the 'combined test'). Pregnancy-associated plasma protein A is a zinc metalloproteinase that acts on insulin-like growth factor binding protein 4, decreasing its affinity for IGF-1 and IGF-2, and thus regulating IGF activity in certain tissues. The combined test

FIGURE 22.6 ■ Changes in α -fetoprotein (AFP) concentration with gestation in maternal and fetal plasma and amniotic fluid liquor.

BOX 22.2 Screening for Down syndrome

- From 11 to 14 weeks:
 - Nuchal translucency (NT)
 - The combined test (NT, hCG and PAPP-A)
- From 14 to 20 weeks:
 - The triple test (hCG, AFP, OE3 (oestriol))
 - The quadruple test (HCG, AFP, OE3 and inhibin A)
- From 11 to 14 *and* 14 to 20 weeks:
 - The integrated test (NT, PAPP-A+hCG, AFP, OE3, inhibin A)
 - The serum integrated test (PAPP-A+hCG, AFP, OE3, inhibin A)

Abbreviations are explained in the text.

detects 90% of affected pregnancies with a screen positive rate of 2%, if a cut-off risk of 1:150 is chosen.

For women presenting only in the second trimester, the recommended screening tests are either the 'triple test', involving measurement of hCG, AFP and oestriol or the 'quadruple test' – the triple test with the addition of inhibin A. Other available tests are: the 'integrated test' (NT and serum measurements) or, if NT is not available, measurements on maternal serum alone ('the serum integrated test') (see [Box 22.2](#)). The integrated test (if good quality NT measurement is available) performs better than the combined test but is more difficult to administer. The serum integrated test performs less well.

Women undergoing screening should appreciate that positive tests require confirmation (diagnosis) by an invasive procedure: before 12 weeks of gestation, this is by chorionic villus sampling, thereafter by amniocentesis.

Fetal tissue sampling techniques

The prenatal diagnosis of many chromosomal and genetic abnormalities requires tissue sampling. Various techniques are available (see [Table 22.1](#) and [Fig. 22.7](#)) but, with few exceptions, if a diagnostic test is available for the condition under investigation, any of the methods of sampling may be employed. The differences between the techniques are primarily the gestation at which the test may be performed and the delay between sampling and the result. The list of inherited disorders that can be diagnosed by DNA studies is growing rapidly. However,

TABLE 22.1 Techniques for assessment of the fetus

Procedure	Gestation	Delay in result	
		PCR	Culture
Preimplantation diagnosis	3 day embryo	See text	–
Chorionic villus sampling	10+ weeks	2 days	2 weeks
Amniocentesis	15+ weeks	3 days	3 weeks
Cordocentesis	19+ weeks	–	1 week
Fetoscopy (anatomy/sample)	15–20 weeks	–	1 week

FIGURE 22.7 ■ Ultrasound-guided tissue sampling sites used during pregnancy.

in many cases, these conditions are not due to single gene abnormalities, or disease-specific gene probes are not available, and family studies may be necessary to evaluate individual cases to assess their suitability for prenatal diagnosis. In vitro fertilization has also opened up the possibility of preimplantation genetic diagnosis from one or two cell biopsy of the embryo, using comparative genomic hybridization or single nucleotide polymorphism arrays. It is beyond the scope of this book to discuss fetal tissue sampling techniques in detail, and this section only summarizes the essential features.

Chorionic villus sampling

As the fetus and the placenta both develop from the same early blastocyst, their genetic make-up is identical in the vast majority of cases. Thus, chromosomal and DNA analysis of the placenta (chorionic villi) will provide information about the fetus. The post-procedure spontaneous miscarriage rates for transabdominal and transcervical CVS are comparable at approximately 2.5%, not significantly different from the background rate of loss. Potential sources of diagnostic inaccuracy from CVS are maternal cell contamination and placental mosaicism.

Amniocentesis

Traditionally, amniocentesis was usually performed at 15–16 weeks of gestation, but it can be performed earlier. Results of cell culture become available 2–4 weeks later (though a preliminary result may be available within hours from direct examination); the associated fetal loss rate is approximately 1%. Amniocentesis can be used for biochemical assessment of the liquor for fetal lung maturity (now rarely used in the UK). The production of the

surfactants lecithin and sphingomyelin by the fetal lung are almost equal until ~32 weeks of gestation, after which the lecithin concentration increases more rapidly than that of sphingomyelin. A lecithin–sphingomyelin ratio of >2 indicates a low risk of the baby developing respiratory distress syndrome after birth. Amniocentesis can also be used for the monitoring of haemolytic disease of the fetus by determining the Rhesus genotype on uncultured amniocytes and measuring the optical density of the liquor at 450 nm as an indication of bilirubin concentration.

Cordocentesis

Fetal blood can be obtained from 19 weeks of gestation by cordocentesis, an outpatient procedure that does not require maternal sedation or the use of fetal paralysis. After visualization of the insertion of the umbilical cord into the placenta by real-time ultrasound, a needle is passed into the umbilical cord through the (locally anaesthetized) maternal abdomen. The fetal loss rate after cordocentesis is approximately 1%.

Monitoring of maternal and fetal well-being

The increased accuracy and availability of ultrasound-based biophysical tests of fetal well-being has resulted in a marked decline in the use of biochemical tests, except for a few clinical situations, for example serum uric acid measurements in a patient with pre-eclampsia, and 'liver function' tests and serum bile acid measurements in women with obstetric cholestasis.

Pre-eclampsia is the occurrence of proteinuria and hypertension in pregnancy; peripheral oedema is often present. Untreated, it may progress to life-threatening severe hypertension, renal failure and convulsions (eclampsia) or be complicated by the haemolysis, elevated liver enzymes and low platelets (HELLP) syndrome. An early biochemical feature of pre-eclampsia is an increase in plasma urate concentrations, as a result of increased renal tubular reabsorption of urate secondary to decreased renal perfusion. However, this is an unreliable indicator, as urate concentrations rise in the last trimester of normal pregnancies.

Cholestasis of pregnancy is discussed in more detail in Chapter 14. The term includes acute fatty liver of pregnancy (of which hyperuricaemia is also a feature) and HELLP syndrome.

Intrapartum fetal monitoring

The widespread use of fetal heart rate (FHR) monitoring in labour resulted in an increase in the number of operative deliveries, frequently delivering a neonate without any sign of asphyxia. As a result, fetal scalp blood sampling was introduced in order to improve the specificity of FHR monitoring alone. A variety of studies have demonstrated that, when interpreting FHR patterns, variability and accelerations are the features that correlate most closely with fetal scalp pH or lactate concentration. The presence of normal variability or accelerations is indicative of normal oxygenation, whereas the presence of reduced variability or decelerations makes poor oxygenation and

hence acidosis, more likely. Although there is good evidence that continuous FHR monitoring can detect a low fetal pH, acidosis, especially in well-grown term fetuses, does not correlate well with fetal death or cerebral injury. Indeed, a number of studies suggest that only 8–15% of cases of cerebral palsy are associated with events occurring during labour and, even in these, the link is not proven as causal.

Biochemical changes during pregnancy

Pregnancy is a major endocrine event in the female lifespan, involving wide-ranging and often considerable changes in the metabolism of various hormones. Concentrations of oestrogens, progesterone, testosterone and prolactin all increase steadily through gestation, while those of LH and FSH decrease. Sharp increases in the concentrations of hormone-binding globulins such as SHBG are seen, reaching a plateau by the end of the first trimester. In addition, placental hormones such as hCG and human placental lactogen (hPL) appear in the maternal circulation within the first few weeks following conception. Pregnancy does not usually alter thyroid function to a significant extent, but changes in individual indices of thyroid function are often seen, such as increases in plasma concentrations of total thyroxine (T4) secondary to an increase in thyroxine binding globulin. Free T4 and free tri-iodothyronine (fT3) concentrations may rise slightly in early pregnancy (as a result of the thyrotrophic action of hCG), but later fall to within, or just below, the non-pregnant reference ranges. Thyroid stimulating hormone concentrations tend to fall in early pregnancy (sometimes to undetectable concentrations), but later return to normal.

Associated with the changes in gonadotrophins and steroid hormones, pregnancy affects several metabolic processes in various tissues and organs, in turn altering the concentrations of many maternal plasma constituents. In some instances, these changes are apparently unrelated to the needs of mother or fetus. Because the use of standard reference ranges is often inappropriate during pregnancy, an appreciation of the metabolic effects of pregnancy is desirable.

An important consideration when interpreting the effects of pregnancy on blood components is the associated change in plasma volume. Total body water increases by about 7 L during pregnancy, with an increase in extracellular fluid being responsible for at least half of this increase. Marked alterations in renal haemodynamics accompany this increase in extracellular fluid. Both glomerular filtration rate (GFR) and renal plasma flow increase by up to 50% above pre-pregnancy values, changes that are compensated for by changes in tubular reabsorption. Plasma creatinine and urea concentrations decrease during pregnancy, and increases in creatinine clearance (paralleling the increase in GFR) become apparent four weeks after conception, peaking 9–11 weeks later. Renal function may deteriorate markedly during pregnancy in women with pre-existing renal disease or a history of pre-eclampsia in a previous pregnancy, and monitoring of plasma urate and creatinine concentrations is advisable.

Plasma proteins

Pregnancy induces widespread changes in plasma protein concentrations, owing both to the effect of changes in plasma volume and to specific hormone-induced changes in protein synthesis and degradation. In general, total protein concentrations are slightly reduced, with those of albumin falling by approximately 15% and those of globulins (especially acute phase proteins) often increasing. Two to three-fold increases in the concentrations of α_1 -antitrypsin, fibrinogen and caeruloplasmin are often seen during the later stages of gestation. Prealbumin is a notable exception as plasma concentrations fall during pregnancy. Plasma immunoglobulin concentrations are rarely affected by pregnancy.

Pregnancy may induce slight increases in the plasma activity of aminotransferases such as aspartate aminotransferase. Substantial increases in alkaline phosphatase activities occur, reaching a peak of 2–3 times normal adult values during the third trimester. This increase is largely due to the presence of the placental isoenzyme in maternal plasma. Although changes in the fetal isoenzyme have been related to problems of fetal development, this has proved of little diagnostic use owing to the wide range of isoenzyme activities seen in normal pregnancy.

Plasma lipids and lipoproteins

The hyperlipidaemia of pregnancy is well recognized. By the third trimester, fasting plasma triglyceride concentrations are increased 2–3 times, with lesser increases being seen in total cholesterol, phospholipids and non-esterified fatty acids. These increases result from a complicated sequence of changes in the major plasma lipoprotein classes, low density lipoproteins (LDL) and high density lipoproteins (HDL). LDL concentrations rise steadily, but level off during the last ten weeks of pregnancy, whereas those of HDL initially increase, but level off (and may even fall) approximately half way through pregnancy; this may be a result of the onset of the insulin resistance that is typical of pregnancy. Serial measurement of hormones during gestation indicates that the hyperlipidaemia of pregnancy is influenced not only by oestradiol and progesterone, but also by insulin and hPL.

Glucose tolerance

Fasting plasma glucose concentrations usually fall slightly during pregnancy, whereas postprandial concentrations increase. Pregnancy may lead to a deterioration in glucose tolerance, which is subtle in the majority of women, probably due to insulin resistance induced by elevated concentrations of sex hormones. In patients with pre-existing type 1 diabetes mellitus, this may result in an increased requirement for exogenous insulin. The insulin requirement should thus be monitored closely (by regular measurements of blood glucose and glycated haemoglobin) in order to reduce the incidence of fetal malformation, macrosomia and intrauterine death, conditions that are all associated with poor glycaemic control.

The precise nature of the defect in gestational glucose intolerance remains controversial. Patients who are initially free from diabetes but develop gestational diabetes may

either revert to normal glucose tolerance after pregnancy (in which case they remain at risk of developing diabetes in the future) or remain frankly diabetic. Although screening for gestational diabetes has been advocated (based on factors such as obesity, strong family history of diabetes mellitus or previous delivery of a baby weighing 4 kg or more), most 'at-risk' patients do not develop glucose intolerance and those that do often have low risk factor scores. The presence of glycosuria is similarly of little use, as the majority of pregnant women will have glycosuria at some stage of their pregnancy owing to their lowered renal threshold, rather than glucose intolerance per se.

Consequently, routine measurement of blood glucose has been advocated in *all* pregnancies. While this will indeed detect patients with gestational glucose intolerance, controversy exists concerning the indications for subsequent formal glucose tolerance testing, as well as the stage of gestation at which such testing should take place. In addition, there is no agreement as to what constitutes an abnormal tolerance test profile, as the World Health Organization (WHO) criteria are based on non-pregnant individuals and other criteria are purely statistical (e.g. values more than two standard deviations above the mean), rather than relating to the outcome of pregnancy. In the UK, the National Institute for Health and Care Excellence (NICE) has produced guidelines, including for the selection of patients for formal glucose tolerance testing. Gestational diabetes, and the management of maternal diabetes during pregnancy are discussed in Chapters 15 and 16.

Other changes

Mild proteinuria may accompany the changes in plasma protein concentrations seen during pregnancy. However, this may be an early warning of a threat to mother and fetus if it develops into pre-eclampsia or eclampsia, where increasing proteinuria is associated with maternal hypertension. In the past, serial quantitative assessments of proteinuria using dipsticks were used. Detection of significant proteinuria is now more usually carried out by measuring a protein to creatinine ratio in a random urine sample. A value of <30 g/mol helps to rule out significant proteinuria in hypertensive pregnant women. However, severity of the disease is not always related to absolute values.

Labour

The factors that lead to the onset of labour in humans appear to be complex, with a combination of biochemical and physical changes such as uterine stretch. In the first trimester, progesterone from the corpus luteum maintains uterine quiescence until the placenta takes over. In many species, it is falling concentrations of progesterone that initiate labour. This is not the case in humans, although inhibiting progesterone action does increase uterine activity and ripens the cervix. The uterus is primed for activity by a gradual rise in plasma oestrogen concentration and corticotrophin-releasing hormone (CRH) over a period of many weeks. The uterus then becomes sensitive to stimulants including oxytocics, prostaglandins and CRH. These appear to create a biochemical inflammatory-like reaction in the uterus.

Prostaglandins and oxytocin play central roles in human labour by stimulating myometrial contractility. Arachidonic acid is found in amniotic fluid and fetal membranes. This is converted by cyclooxygenase to prostaglandins. Clinical use of this process is seen with digital 'sweeping of the membranes' to enhance enzyme activity prior to therapeutic induction of labour, for which slow-release prostaglandin formulations are commonly used.

Oxytocin is a nonapeptide secreted by the posterior pituitary. Administration of oxytocin in pregnancy provokes uterine contractions and is used in the induction and acceleration of labour. Its exact role in the initiation and maintenance of normal human labour is not fully understood, particularly since normal parturition has occurred in women with oxytocin deficiency secondary to pituitary disease.

Corticotrophin-releasing hormone is a 41 amino acid peptide produced in the hypothalamus but in pregnancy it is also synthesized in the placenta and membranes. The concentration of free CRH rises markedly in the last three weeks of pregnancy. It promotes fetal cortisol production and prostaglandin production in the fetal membranes.

Pre-term labour (onset prior to 37 completed weeks of pregnancy) is the commonest cause of later disability and perinatal death. A major contributor to neonatal morbidity is lung dysfunction owing to lack of alveolar surfactant. Corticosteroid administration to the mother at least 24 h before delivery substantially improves outcome. Diagnosis of the onset of pre-term labour can be difficult but important, as tocolytics may delay delivery long enough for steroids to have an effect. An adjunct to assessing the likelihood of the onset of labour is the use of fetal fibronectin measurement. Fibronectins are large (450 kD) glycoproteins found in the cervical tissue, membranes and amniotic fluid. They act as an adhesive between the cells of the membranes and uterine lining and 'leak' out into the vagina if this is disrupted, as happens in pre-term labour. A bedside monoclonal antibody swab

test for fibronectin is now available, which is poor at predicting the onset of labour but has a negative predictive value of 99% that delivery will not occur within 14 days. Its use substantially reduces the need and cost for treatment or transfer of patients.

ORAL CONTRACEPTION AND HORMONE REPLACEMENT THERAPY

Introduction

Worldwide, many women are taking gonadal steroids (oestrogens and progestogens) as oral contraceptives (OCs) or sex hormone replacement therapy (HRT). Gonadal steroids have the potential to influence many metabolic systems and hence biochemical variables in the blood.

Methods for contraception can be divided into hormonal and non-hormonal methods. The latter include sterilization, barrier methods, the use of spermicides and natural methods. These do not have metabolic effects (although development of antisperm antibodies can affect the success of vasectomy reversal). Hormonal methods involve treatment of the woman (usually) with hormones to prevent conception, and have the potential to cause secondary metabolic disturbances.

Hormonal methods of contraception are summarized in Table 22.2. The most widely used are combined oral preparations of oestrogen and progestogen. Both components can have metabolic effects, in particular affecting lipid and glucose metabolism. Older combined oral contraceptives used relatively high doses of oestrogen, which could increase the concentration of thyroxine binding globulin, and hence increase total T4 (but not free T4) concentrations, but this is not a significant problem with modern combined oral contraceptives, in which lower doses of oestrogens are used.

There is an important difference between the oestrogen used in OCs and that used in HRT. If suppression

TABLE 22.2 Hormonal methods of contraception

Type	Components	Principle mode of action	Comments
Combined oral contraceptive pill	Oestrogen and progestogen	Inhibition of ovulation; also effects on cervical mucus and changes to endometrium	Typically taken for 21 days, followed by 7-day pill-free break
Combined contraceptive patch	Oestrogen and progestogen	As above	One patch worn for a week for three weeks, followed by one week with no patch
Combined contraceptive vaginal ring	Oestrogen and progestogen	As above	Worn for three weeks, followed by one week with no ring
Combined injectable contraceptive	Oestrogen and progestogen	As above	Monthly injections; not available in UK
Progestogen-only contraceptive pill	Progestogen	Multiple effects, including alteration of cervical mucus, suppression of ovulation and changes to endometrium	Taken daily with no breaks
Progestogen-only injectable contraceptive	Progestogen	As above	Injections at 2–3 monthly intervals according to product
Other progestogen-only devices	Progestogen	As above	Implants and intrauterine systems
Emergency contraception	Progestogen (levonorgestrel)	Probably prevents or delays ovulation	High dose of progestogen (50× that used in pill) but single dose and no metabolic sequelae

of ovulation is required, a synthetic oestrogen (almost always ethinyloestradiol) is necessary. In contrast, HRT requires lower doses of oestrogen, as the objective is to reverse the adverse effects of oestrogen deficiency. For this purpose, 'natural' (non-alkylated) oestrogens such as 17 β -oestradiol, oestradiol valerate and conjugated equine oestrogens have proved adequate, despite their ineffectiveness as contraceptive agents.

Contraceptive progestogens are used in order to increase contraceptive efficacy in combined regimens, on their own in the 'mini-pill' or to control menstrual bleeding. In contrast, HRT progestogens are used to prevent endometrial proliferation, hyperplasia and neoplasia. Again, the net dose of progestogen used in HRT is lower than that required for OC. Because natural progesterone is poorly absorbed when given orally, various synthetic progestogens have been developed. In the UK, the progestogens most commonly used in OC are levonorgestrel, norethisterone, gestodene and desogestrel, the latter two being novel derivatives chosen for their relatively low androgenicity. For postmenopausal HRT, levonorgestrel and norethisterone are most commonly used.

The majority of oral gonadal steroid therapies in current use combine an oestrogen with a progestogen. Progestogen-only oral contraceptives use very low doses of steroids and have comparatively little effect on plasma components.

Metabolic effects of oestrogens

Oestrogens suppress the secretion of FSH by the pituitary and hence suppress follicular maturation. The oestrogen in most combined oral contraceptives is ethinyloestradiol, at a daily dose between 15 and 50 μ g, but typically 30–35 μ g. Oestrogens tend to increase plasma triglyceride concentrations, reduce LDL-cholesterol and increase HDL-cholesterol concentrations. Oestrogens are prothrombotic, but their net effects on lipid metabolism tend to be anti-atherogenic. They have a negligible effect on glucose tolerance.

Metabolic effects of progestogens

The contraceptive effect of progestogens is related to suppression of LH secretion (tending to suppress ovulation) and to effects on cervical mucus that make it hostile to sperm, and on the endometrium that reduces the likelihood of successful implantation. Several different progestogens are used in combined oral contraceptives; they all lack the 19-methyl group that is present in progesterone and differ mainly (but not exclusively) in their C-17 substituents, whether or not they have a C-21 carbon and in the presence or absence of a methyl or ethyl group in the C-18 position. They include norethindrone, one of the first to become available for this purpose; norgestrel and levonorgestrel ('second-generation' progestogens), and the 'third generation' progestogens, desogestrel, gestodene and norgestimate. The metabolic effects of progestogens are largely dependent on their androgenicity. Levonorgestrel, gestodene, norgestimate and desogestrel (all 19-nor compounds, that is, lacking a 19-methyl group) have androgenic as well

as progestogenic activity, and tend to increase plasma LDL-cholesterol and reduce HDL-cholesterol concentrations. The effects of progestogens on glucose tolerance are considered below.

Metabolic effects of contraceptives

Effects of hormonal contraceptives on lipid metabolism and risk of vascular disease

The overall effect of combined oral contraceptives on lipid metabolism depends on the type and dose of oestrogen and progestogen and on the presence of any genetic tendency to hyperlipidaemia. In general, the effects of the oestrogen and progestogen tend to cancel each other out, though most modern agents tend slightly to reduce plasma LDL-cholesterol and increase HDL-cholesterol concentrations. They may also slightly increase triglyceride concentrations. Although it is not necessary to monitor plasma lipid concentrations in most women, this may be appropriate if there is known hyperlipidaemia, especially hypertriglyceridaemia.

It is noteworthy that in women who do not smoke cigarettes and who are normotensive, there is no evidence of an increase in the relative risk of cardiovascular disease associated with long-term use of combined oral contraceptives. Even in women who smoke or are hypertensive, the absolute risk, though higher, remains very low. The relative risk of ischaemic stroke is slightly increased, but the absolute risk remains very low. The risk of haemorrhagic stroke is unaffected in women below the age of 35, but slightly increased in older women.

The relative risk of venous thromboembolic disease is increased in users of combined oral contraceptives, although the absolute risk remains very low, and is certainly lower than that associated with pregnancy. The mechanisms involved are complex, but appear primarily to be the result of prothrombotic effects on the coagulation mechanism.

Contraindications to the use of the combined oral contraceptives include a personal history of stroke, myocardial infarction or venous thromboembolism, severe hypertension and heavy cigarette smoking.

There is no evidence of increased risk of venous thrombosis, cardiovascular or cerebrovascular disease in women using progestogen-only contraceptives.

Effects of oral contraceptives on glucose homoeostasis and diabetes

Any adverse effect of oral contraceptives on glucose tolerance appears to be related to the progestogen component. Progestogens antagonize the effects of insulin and increase the area under the curve of insulin response to oral glucose tolerance tests, but the effects on glucose tolerance, though statistically significant, are not clinically so.

There is no need to avoid combined preparations in patients with uncomplicated diabetes. Progestogen-only oral contraceptives are safe in patients with type 1 diabetes and can be recommended in many patients for whom combined products are contraindicated (e.g. heavy

smokers, severe hypertension). However, longer-acting progestogens, such as levonorgestrel, should be avoided in patients with type 2 diabetes.

Other metabolic effects of oral contraceptives

Hypertension may be exacerbated in OC users owing to an increase in the synthesis of angiotensinogen. However, most oral contraceptive users adapt their vasoactive controls and aldosterone production to compensate for the increase in blood pressure, and there is a poor correlation between the metabolic changes and actual changes in blood pressure.

Metabolic effects of injectable contraceptives

The metabolic effects of combined oral contraceptives in which the hormones are delivered other than orally are broadly similar to those seen with oral agents.

The metabolic effects of injectable progestogen contraceptives are minimal, with the exception that there is concern that depot medroxyprogesterone acetate may have an adverse effect on bone mineral density, probably related to a reduction in plasma oestradiol concentrations. The decrease in density appears reversible but whether there is still a later increased risk of osteoporosis is unknown and thus prolonged use, or use in women with other risk factors for osteoporosis, should be avoided. There is no evidence of significant adverse metabolic effects with progestogen-only implants or intrauterine delivery devices.

Although emergency contraceptives contain high doses of progestogens, exposure to the agent (levonorgestrel) is short-lived and has no adverse metabolic consequences.

Hormone replacement therapy

The primary aim of hormone replacement therapy in postmenopausal women is usually to reduce the clinical features of oestrogen deficiency, which include hot flushes, depression, vaginal dryness and consequent dyspareunia. Particularly in women who undergo a premature menopause, a secondary aim may be to reduce the risk of long-term consequences of oestrogen deficiency, particularly osteoporosis. In seeking to achieve these aims, it is clearly also important to avoid potentially harmful consequences.

Although menopausal symptoms are caused by oestrogen deficiency, oestrogen replacement should be accompanied by cyclical or continuous progestogen replacement in order to prevent endometrial hyperplasia: there is a clear association between the use of unopposed oestrogen treatment and the development of endometrial carcinoma. Women who have undergone hysterectomy can safely be treated with oestrogen alone.

Metabolic effects of the menopause

The onset of the menopause is accompanied by an increase in the plasma concentrations of LDL-cholesterol and triglycerides; HDL concentrations fall slightly, but with a rise in the HDL₃ fraction and a fall in the anti-atherogenic HDL₂ fraction. These changes are all

pro-atherogenic and are thought to be important factors in the increase in the prevalence of cardiovascular disease that occurs following the menopause.

Pancreatic insulin secretion tends to decline and, although there may be an increase in the half-life of insulin in the plasma, insulin sensitivity, and hence glucose tolerance, tend to decline. The distribution of body fat tends towards android rather than gynoid. Increases occur in the plasma concentrations of proteins involved in blood coagulation, including fibrinogen and antithrombin III, and there is a reduction in fibrinolytic activity. All these factors are likely to contribute to the increased risk of cardiovascular disease against a background of the increasing risk associated with advancing age.

Metabolic effects of HRT

The metabolic effects of HRT depend upon the steroids used, their doses and the route of administration, but in summary, oestrogen replacement tends to reduce LDL-cholesterol concentrations. Oestrogens also increase the clearance of remnant particles and reduce the concentration of lipoprotein(a). Although, when used alone, oestrogen replacement may increase HDL concentration, the effects of progestogens may counter this, depending on the androgenicity of the progestogen used. Non-androgenic agents may have little effect or even contribute to an increase in HDL-cholesterol. Conjugated equine oestrogens tend to increase plasma triglyceride concentrations, but oral oestradiol has a lesser effect and transdermal oestradiol reduces triglycerides.

Adverse consequences of hormone replacement therapy

Cyclical, combined oestrogen and progestogen replacement restores cyclical bleeding in the majority of women and is a common cause for them to abandon HRT. However, there are also possible long-term consequences. The most important of these include a small but significant increase in the risk of venous thromboembolism. There is no increase in the risk of endometrial cancer or ovarian cancer. The risk of breast cancer does increase in women who use combined HRT for more than five years, although only very slightly, but the effect declines after cessation of HRT and almost disappears after a further five years.

Hormone replacement therapy and heart disease

The increase in the risk of coronary heart disease following the menopause, together with the metabolic effects of HRT described above, suggested that HRT might be beneficial in the prevention of coronary disease. A major problem in adducing evidence to support this notion is the relatively small number of women who develop coronary disease in the years immediately following the menopause, necessitating the recruitment of large numbers of women into trials to provide the necessary statistical power. Although early epidemiological studies suggested that HRT reduces the risk of coronary disease,

meta-analyses of primary prevention trials suggest that HRT confers either no, or only a very small, degree of protection against cardiovascular death in younger women, and none in older women. The results of a large secondary prevention study showed no benefit. Indeed, one trial has indicated that HRT may cause an increase in cardiovascular events in older women in the first few years after starting treatment. The results of clinical trials thus appear to conflict with those of observational studies, and the reason for this remains uncertain. Thus HRT is not recommended for use solely for the primary or secondary prevention of coronary heart disease.

Hormone replacement therapy and osteoporosis

The increased rate of bone loss associated with oestrogen deficiency is a major cause of morbidity and mortality in older women (see Chapter 31); this is mainly due to the increased risk of hip fracture. Evidence from numerous trials is that HRT, whether with oestrogen alone or combined oestrogen and progestogen, increases bone mineral density and reduces the risk of hip fracture. However, although significant, the effect is small, and, except in women who sustain a premature menopause, HRT is not recommended solely for the prevention of fractures. Tibolone, a synthetic steroid with androgenic, oestrogenic and progestogenic properties, has also been shown to increase bone mineral density in postmenopausal women with osteoporosis.

APPENDIX 22.1 ACTH STIMULATION TEST FOR THE DIAGNOSIS OF CONGENITAL ADRENAL HYPERPLASIA

Perinatal diagnosis of congenital adrenal hyperplasia can be confirmed by a single assay of 17 α -hydroxyprogesterone (17-OHP) in a capillary blood sample. In less clear-cut cases, it may be necessary to measure concentrations of 17-OHP before and following stimulation. Consequently, 17-OHP concentrations are measured before and 60 min after an intravenous injection of 0.25 mg ACTH. The expected values 1 h after ACTH are as follows:

- unaffected adults 3–30 nmol/L
- heterozygotes for 21-hydroxylase deficiency 6–44 nmol/L
- patients with mild 21-hydroxylase deficiency 63–470 nmol/L

For further details of the diagnosis of heterozygotes and the late onset form of 21-hydroxylase deficiency, see New et al. (1983, below). A test assessing the ACTH and 17-OHP responses to corticotrophin releasing hormone (CRH) has been described that appears to distinguish classic from late onset congenital adrenal hyperplasia.

APPENDIX 460

INTRODUCTION

Normal male reproductive function – the manufacturing of semen, the ability to create and sustain penile erection and to ejaculate – is dependent on the physiological integration of the hypothalamo–pituitary–testicular axis. Production of androgens, normal responses in the tissues on which these hormones act and intact neurological pathways required for ejaculation are crucial for full operation of this system, to make human reproduction possible.

THE TESTES

The testes have two distinct roles: androgen production and spermatogenesis. These are achieved by two main units – the interstitial cells and the seminiferous tubules – under the control of the hypothalamo–pituitary axis.

Production and actions of testosterone

Testosterone is the major androgen produced in the interstitial cells of the testes. Also known as Leydig cells, these are found in clumps between the seminiferous tubules, and their mass correlates positively with androgen production. Sertoli cells, along with germ cells, form the seminiferous tubules (Fig. 23.1) and secrete

hormones that control embryological sexual differentiation. In addition, they support spermatogenesis by regulating the composition of the seminiferous tubular fluid, thereby providing an environment for meiotic germ cell development.

At week eight of gestation, a human fetus has both Müllerian and Wolffian ducts, with the potential to develop into female and male genital tracts, respectively, and differing only by its sex chromosomes. The Y chromosome is a powerful sex determinant – it confers maleness to the extent that even XXXXY fetuses are phenotypically male at birth. (This topic is covered in more detail in Chapter 21.)

Normal male sexual differentiation in utero depends on the presence of testosterone and other hormones produced by these embryological gonads. Leydig cells are stimulated by placental human chorionic gonadotrophin (hCG) to secrete testosterone from the ninth week of gestation, leading to development of the Wolffian ducts. Sertoli cells secrete anti-Müllerian hormone (AMH), which causes regression of the Müllerian ducts and oögonia (the precursors of primary oocytes). In the absence of AMH and testosterone, the Müllerian ducts differentiate into female internal genitalia. Lower concentrations of testosterone are maintained during late gestation by secretion of luteinizing hormone (LH) from the fetal pituitary. The presence of 5 α -reductase, and the subsequent production of dihydrotestosterone (DHT) from testosterone,

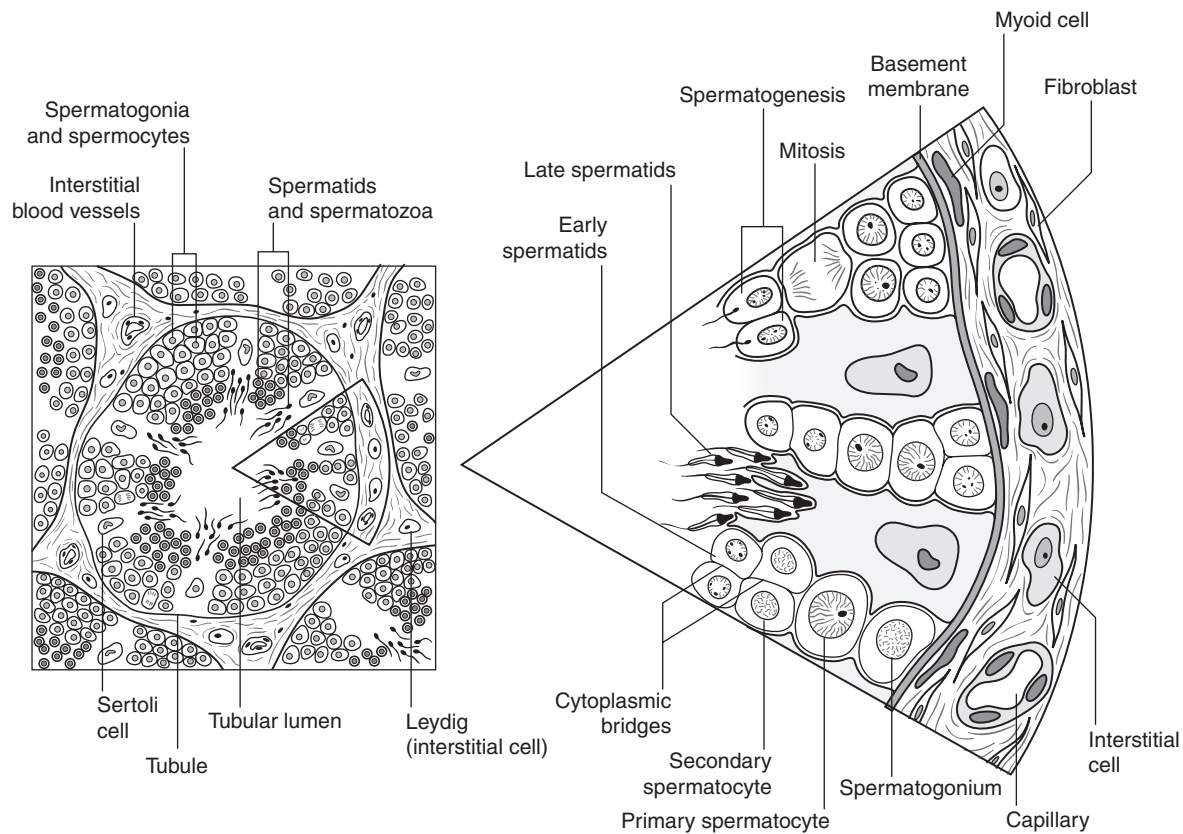

FIGURE 23.1 ■ The seminiferous tubules.

is required for development of the urogenital sinus. Testosterone secretion may continue for many months post partum before declining until the onset of puberty, when it will again be essential for sexual development.

Testosterone secretion from Leydig cells follows stimulation by LH, which binds to specific membrane receptors. Luteinizing hormone activates adenylyl cyclase, resulting in formation of cAMP, which binds to protein kinase and in turn activates the enzyme 20,22-desmolase, which is responsible for conversion of cholesterol to pregnenolone (see Fig. 22.5, p. 438). The synthesis of testosterone is completed by four other enzymes (3β -hydroxysteroid dehydrogenase, 17α -hydroxylase, $17,20$ -desmolase and 17β -hydroxysteroid dehydrogenase). At the target organ, testosterone is transported to the nucleus, and gene activation results in the formation of specific messenger RNAs and proteins. Testosterone is usually converted to the active metabolite DHT by the enzyme 5α -reductase. In the adult, there is circadian variation in testosterone secretion with a peak in the early morning and a trough at about 18.00 h, and therefore blood samples for testosterone measurement should ideally be taken at 09.00 h. The biological actions of testosterone and DHT are summarized in Table 23.1.

Hypothalamo–pituitary control of testicular function

Gonadotrophin releasing hormone (GnRH) is secreted from the hypothalamus in a pulsatile fashion, with peaks

TABLE 23.1 Biological actions of testosterone and dihydrotestosterone

	Testosterone	Dihydrotestosterone
Fetus	Wolffian stimulation	Differentiation of external genitalia Growth of phallus

occurring approximately every 90 min. It regulates the release of LH, which is crucial for the regulation of Leydig cell number and function, and hence production of testosterone, and follicle stimulating hormone (FSH), which stimulates Sertoli cell division and growth and is therefore responsible for testicular enlargement at puberty. Faster pulse frequencies favour LH release and slower ones, FSH. The pulsatility of GnRH secretion is important in the regulation of gonadotrophin secretion, as continuous exposure results in down-regulation of the GnRH receptor. Luteinizing hormone secretion is also highly pulsatile, which is reflected in measured

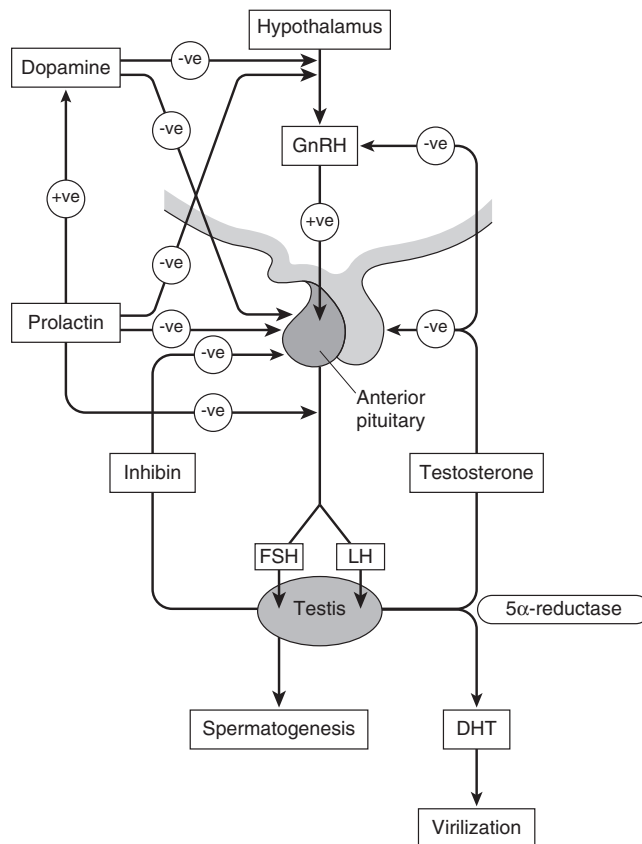

FIGURE 23.2 ■ Hypothalamo-pituitary control of testicular function.

plasma concentrations. Plasma concentrations of FSH are less variable, presumably as a result of slower metabolic clearance.

The gonadotrophins are, in turn, regulated by a series of feedback mechanisms (Fig. 23.2). Testosterone inhibits LH and, to a lesser extent, FSH secretion from the anterior pituitary. Oestradiol, which is formed in the male through metabolism of androgens by aromatase found in adipose tissue, skin, kidneys and brain, in addition to Leydig cells, also inhibits gonadotrophin secretion by the pituitary. Opioids and prolactin reduce the pulsatile activity of GnRH and thus decrease FSH and LH secretion; prolactin also inhibits the direct action of gonadotrophins on the testes.

Follicle stimulating hormone is also regulated by inhibin B, which is produced by Sertoli cells and inhibits FSH production to regulate spermatogenesis. Conversely, activin works to enhance FSH action in the gonads, increasing spermatogenesis. Both are secreted in the seminal fluid and are thought to work locally in addition to centrally on the pituitary. Inhibin B can be used as a marker for male factor infertility as concentrations directly reflect the function of the Sertoli cells: plasma inhibin B concentrations are significantly higher in fertile men than in infertile men.

Gonadotrophin secretion is affected by a diverse range of regulators, including stress and nutritional status. Recent studies have shown that low concentrations of leptin, an adipose-derived hormone, or decreased

sensitivity to leptin, such as occurs in obese individuals, are associated with decreased gonadotrophin concentrations and decreased fertility. This is mediated via hypothalamic kisspeptin neurons rather than directly via GnRH neurons. Kisspeptin is a neurohormone thought to have a key role in puberty, although this is yet to be clearly defined. Patients with mutations in the kisspeptin gene fail to go through puberty owing to hypogonadotropic hypogonadism. In animal models, treatment with kisspeptin can restore GnRH pulsatility and gonadotrophin secretion.

Testicular malignancy

Testicular cancer is the commonest malignancy of men aged 20–39. Histologically, it is commonly a germ cell malignancy – either a seminoma or, more often, a teratoma. Patients are likely to present with a testicular mass, and as this cancer is relatively easily detectable with regular self-inspection/examination, and has a high cure rate if detected prior to metastatic spread, there have been several public campaigns to raise awareness amongst young men.

Approximately 80% of testicular teratomas produce hCG or α -fetoprotein (AFP) (see Chapter 42). Human chorionic gonadotrophin is very similar to LH in structure. It stimulates the LH receptor in the testis eventually resulting in increased secretion of oestradiol, and hence gynaecomastia. Some rarer testicular malignancies, such as Sertoli cell tumours, can also secrete oestradiol directly. Human chorionic gonadotrophin can interact with the thyroid hormone axis as an agonist of the thyroid stimulating hormone (TSH) receptor, to cause hyperthyroidism.

Endocrine disrupting chemicals

Endocrine disruptors are environmental substances that interfere with normal hormonal systems. They are very diverse and can be plastics, chemicals, pesticides and fungicides. They are often able to interact with steroid hormone receptors and can act as androgens and anti-androgens. Exposure may be occupational, but also through water supply, soil and food. There may be a lag between exposure and clinical presentation and there may be trans-generational effects if mutations or modifications of gene expression occur. The developmental stage at which a person is exposed may be crucial. The observations of a declining sperm count, and increasing rates of testicular cancer throughout the last century prompted researchers to ask if these epidemiological trends could be explained by endocrine disruptors. In animal models, exposure to phthalates is significantly related to oligospermia, and epidemiological evidence suggests this may be the case for humans. Endocrine disruptors have also been linked to cryptorchidism, hypospadias, early or delayed puberty and prostatic hyperplasia. More detail on this topic is beyond the scope of this chapter, but the interested reader will find more material in the further reading section, below.

EVALUATION OF TESTICULAR FUNCTION

The laboratory evaluation of testicular function may be conveniently divided into assessment of spermatogenesis and assessment of endocrine gonadal function.

Semen analysis

Semen analysis is used both in the evaluation of male fertility and the follow-up of treatment regimens for male subfertility. It must be noted that there is wide inter-laboratory variation in the results, although this has been reduced in recent years by automated systems using electro-optics or computer-assisted analysis. Furthermore, there is marked variation in sperm output on a day-to-day basis. It is often more useful in clinical practice to assess the actual fertilization capacity of sperm *in vitro*.

A semen sample is collected by masturbation and should ideally be analysed within 1 h. Basic semen analysis measures the number of spermatozoa (per unit volume and per ejaculate), motility and morphology. These are assessed according to World Health Organization (WHO) criteria, updated in 2010, although it should be noted that individual laboratories will also have developed their own reference ranges. The WHO reference ranges were determined by the analysis of semen from fertile men whose partners became pregnant within one year of trying to conceive. Average sperm count is >60 million/mL and a count of <15 million/mL is considered subfertile. There should be >39 million sperm in a given ejaculate and semen volume should be 1.5 mL or greater.

Motility is defined as the percentage of moving sperm and is subdivided into the following categories:

- progressive motility (PR): spermatozoa moving actively, either linearly or in a large circle, regardless of speed
- non-progressive motility (NP): all other patterns of motility with an absence of progression
- immotility (IM): no movement.

The WHO reference values state that $\geq 40\%$ of the sperm should exhibit either PR or NP motility and $\geq 32\%$ should exhibit PR motility. At least 58% of sperm should be alive – this is especially important for samples with a PR motility of <40% and must be assessed within 1 h of ejaculation.

Morphology, describing defects in the appearance of spermatozoa, is most commonly assessed according to the WHO morphology standards. The WHO lower reference limit for normal morphology is 4%. Few samples exhibit >25% normal spermatozoa.

Other parameters measured include volume, pH, white blood cell count, antisperm antibodies, colour, viscosity, agglutination, aggregation and time until liquefaction. Reference ranges for semen analysis are shown in [Table 23.2](#).

Endocrine evaluation: hypothalamo–pituitary–gonadal axis

Determination of basal plasma LH and FSH concentrations is a routine part of the assessment of the hypothalamo–pituitary–gonadal axis. As LH and, to a

TABLE 23.2 Reference ranges for semen variables^a

Variable	Reference range
Volume	>1.5 mL
pH	>7.2
Sperm concentration	>15 × 10 ⁶ sperm/mL
Total count	>39 × 10 ⁶ sperm/ejaculate

	32% or more with PR motility
Vitality	58% or more alive
White blood cells	<1 × 10 ⁶ cells/ejaculate
Fructose	>13 μmol/ejaculate

^aWHO classification described in text. PR, progressive motility; NP, non-progressive motility.

lesser extent, FSH are secreted in a pulsatile fashion, more accurate interpretation may be possible if serial samples are taken over a period of time. However, in routine clinical practice, the measurement of basal plasma concentrations of LH and FSH with testosterone provides most of the information required.

Elevated LH and FSH in the presence of low testosterone concentrations suggest primary testicular failure; low or normal LH and FSH associated with low testosterone concentrations suggest a hypothalamo–pituitary disorder. It is important to recognize that the latter may be caused by any acute illness. Rarely, LH alone may be elevated with a low testosterone (the Sertoli-only syndrome) and, in patients with abnormal spermatogenesis, FSH may be raised with a normal testosterone. It should be remembered that pituitary and gonadal dysfunction may coexist, as in haemochromatosis. In this situation, LH, FSH and testosterone concentrations are low.

The GnRH test ([Appendix 23.1i](#)) has been used to assess pituitary reserve of LH and FSH and overall hypothalamo–pituitary function. This test is now used relatively infrequently, as it rarely provides extra information beyond that from basal LH and FSH concentrations.

The clomifene stimulation test ([Appendix 23.1ii](#)) can be used to assess the hypothalamo–pituitary axis with respect to gonadotrophin secretion. Clomifene competitively inhibits hypothalamo–pituitary androgen binding. The normal response is a doubling of LH and FSH by day 10 after administration. A low response, however, does not distinguish between abnormalities at the pituitary or hypothalamic level.

Plasma testosterone concentrations exhibit diurnal variation throughout the day – some studies suggesting a variation of as much as 30% between a sample taken at 08.00 h and one at 16.00 h. Consequently, and by convention, testosterone is usually determined on a sample taken before 09.00 h. Analysis of serum testosterone concentrations must take into account sex hormone-binding globulin (SHBG), as 50% of circulating testosterone is bound to SHBG. Low testosterone concentrations are seen both in primary testicular disease, indicating poor Leydig cell function, and hypothalamo–pituitary disorders with

depressed gonadotrophin secretion. Elevated concentrations are seen in patients with gonadotrophin- or androgen-secreting tumours (e.g. Leydig cell tumours), in whom gonadotrophin concentrations will be low.

The hCG stimulation test (Appendix 23.1iii) can be helpful in differentiating primary testicular failure from gonadotrophin deficiency. Failure of testosterone to rise after administration of hCG suggests inadequate Leydig cell function. An exaggerated response suggests secondary hypogonadism. The test is also useful in confirming the presence of testicular tissue in cryptorchidism and in conditions in which there may be combined pituitary and testicular dysfunction, for example as a result of iron deposition in haemochromatosis or treated thalassaemia.

MALE HYPOGONADISM

Male hypogonadism may result from either primary testicular failure, in which the testes fail to develop properly or are injured by disease or medical manipulation, or secondary testicular failure owing to hypothalamic or pituitary lesions (hypogonadotrophic hypogonadism). The latter may result from developmental or acquired pituitary disease or a failure of hypothalamic GnRH secretion. Other syndromes resulting in hypogonadism include enzyme defects in which hormonal synthesis is interrupted despite an intact hypothalamo-pituitary-testicular axis.

Clinical features

The physiological effects of testosterone are listed in Table 23.1. Prepubertal testicular failure results in lack of sexual maturation with persistent infantile genitalia and absence of pubic and axillary hair growth. Delayed epiphyseal closure leads to the development of a eunuchoid habitus with increased arm span (>5 cm greater than height) and increased lower body height (sole-to-pubic symphysis length >5 cm greater than pubic symphysis-to-head length). The reduction in testosterone is also associated with diminished anabolism and a decrease in normal male muscular development.

Postpubertal onset of androgen deficiency is less obvious and usually presents with decreased libido, impotence and infertility. There may be an associated decrease in growth of facial, pubic and axillary hair and a diminution in skeletal musculature. Gynaecomastia may occur as a result of an increase in the oestradiol:testosterone ratio (see below). Despite some reduction in testicular volume, the penis and prostate do not shrink and erections and orgasms may continue. Nevertheless, spermatogenesis requires testosterone and, even when able to ejaculate, severely hypogonadal males are azoospermic.

Primary hypogonadism

This implies primary testicular failure and is characterized by low plasma testosterone and elevated LH and FSH concentrations. The chief causes can be divided into genetic abnormalities and cryptorchidism. Other causes are

orchitis, chronic illness, drugs (including excess alcohol), chemo- and radiotherapy and, rarely, testicular trauma.

Genetic causes

In the male, the most common of these is Klinefelter syndrome, thought to occur in 1 in 500 live births. This was described in 1942 by Klinefelter, Reifenstein and Albright, and comprises eunuchoid stature, gynaecomastia, small testes and infertility. It is caused by non-disjunction of the sex chromosomes during meiosis, the most common resulting abnormality being 46XXY but occasionally other X states or mosaicism (e.g. 48XXXY/46XY) are seen. All these cause Leydig cell abnormalities, resulting in impaired testosterone secretion and seminiferous tubular function, and decreased inhibin secretion. Other genetic causes of primary hypogonadism include XX males, Noonan syndrome, XY/XO gonadal dysgenesis and deletion of the Y chromosome in part or entirety.

Cryptorchidism

In 1–2% of male neonates, the testes fail to descend bilaterally from the abdominal cavity and do not produce adequate concentrations of testosterone. In addition, there is an increased risk of testicular malignancy. Surgery to position the testes in the scrotum, particularly if carried out in early childhood, reduces the risk of later malignancy, and facilitates surveillance. For this reason, it is important to distinguish this condition from anorchia, complete absence of testes in a 46XY male. The presence or absence of gonadal tissue can be assessed using ultrasound or magnetic resonance imaging scanning. If functional testicular tissue is present, there will be an increase in testosterone during an hCG stimulation test.

Secondary hypogonadism

This is hypogonadism caused by hypothalamic or pituitary dysfunction, resulting in deficient gonadotrophin secretion and leading to a low testosterone concentration. The causes may be divided into congenital and acquired disorders.

Congenital causes

The most common of these is Kallmann syndrome. Mutations or deletions of the *KAL1* gene, which encodes anosmin-1, result in the X-linked form, leading to an abnormal migration of GnRH-producing neurons to the hypothalamus and failure of episodic GnRH secretion. The syndrome manifests as scant secondary sexual development and eunuchoid habitus in association with anosmia and, occasionally, other craniofacial abnormalities such as cleft lip and palate.

Congenital adrenal hypoplasia presents with primary adrenal failure in association with inadequate GnRH secretion. It is caused by a mutation of the *DAX-1* gene on the X chromosome. The fertile eunuch syndrome is a selective LH deficiency leading to partial virilization with normal Sertoli cell function. This can be treated with testosterone replacement or hCG.

Homozygous mutations of the leptin gene and receptor have been found to be associated with idiopathic hypogonadotrophic hypogonadism (IHH) and severe obesity as a result of impaired GnRH release. Idiopathic hypogonadotrophic hypogonadism has also been associated with mutations of the FSH β -subunit, LH β -subunit, *PC1* (prohormone convertase 1) and *GPR54* (part of the kisspeptin pathway) genes. Other rare congenital causes of hypogonadotrophic hypogonadism include Prader–Willi syndrome and Laurence–Moon–Biedl syndrome. Haemochromatosis is another inherited condition sometimes associated with the development of secondary hypogonadotrophic hypogonadism, although the presentation of this complication is usually rather later in life.

Acquired causes

There are a number of acquired conditions leading to reduced gonadotrophin secretion (Box 23.1). These include excessive exercise or weight loss, physical or psychological stress and systemic illness. Direct damage to the hypothalamus or pituitary, such as from head trauma, radiotherapy, surgery, pituitary tumours and infiltrative disorders (e.g. sarcoidosis) can also be a cause, in addition to prescribed medications causing hyperprolactinaemia and illicit drugs such as cocaine, anabolic steroids and opioids.

Defective hormone synthesis and hormone receptor defects

These conditions lead to ambiguous external genitalia with a 46XY genotype. There are rudimentary or absent Wolffian duct derivatives (seminal vesicles and ductus deferens), but because of the presence of AMH, the uterus and fallopian tubes do not develop either. In addition to this there is usually cryptorchidism.

Five enzymes are responsible for the conversion of cholesterol to testosterone; defects in each of these enzymes have been reported (see Chapter 21). Plasma testosterone concentrations are low and hCG stimulation results in elevated concentrations of precursors proximal to the enzyme block. Defects in androgen receptor

proteins can also lead to hypogonadism, but with normal testosterone concentrations.

5 α -Reductase deficiency

5 α -Reductase converts testosterone to dihydrotestosterone (DHT). Dihydrotestosterone is responsible for masculinization, and normal plasma concentrations are a prerequisite for the full development of the phallus, scrotum and prostate. In 5 α -reductase deficiency, external genitalia at birth are ambiguous with a urogenital sinus, clitoromegaly, bifid scrotum, blind vaginal pouch and inguinal or labial testes. Wolffian duct derivatives are present, as they develop under the influence of testosterone rather than DHT. The deficiency is caused by a mutation in the 5 α -reductase type 2 gene, which is inherited in an autosomal recessive fashion.

At puberty, patients undergo virilization with some phallic enlargement, development of male habitus and psychosexual orientation and descent of the testes, occasionally with spermatogenesis. This occurs either as a result of a massive increase in testosterone secretion at puberty or by conversion of some testosterone to DHT if the enzyme deficiency is incomplete. Patients may respond to very high doses of testosterone or to DHT (the latter can be applied locally as a 2% cream with some beneficial effects on penile length). If peripubertal virilization is minimal, patients may be raised as infertile females after removal of the cryptorchid testes.

Androgen insensitivity syndromes

These are caused by absence or deficiency of the DHT receptor protein. The complete form results in an apparently normal female phenotype with absent pubic and axillary hair and is transmitted as an X-linked recessive trait. Administration of testosterone has no effect on the generation of secondary sexual hair. As patients usually have normal female psychosexual orientation, treatment involves removal of cryptorchid testes and subsequent oestrogen replacement. Normal female sexual activity is possible, although, of course, the patients remain infertile.

In partial androgen insensitivity syndrome, presentation varies according to the degree of DHT receptor deficiency. It ranges from apparent clitoromegaly in a phenotypically female neonate at birth, to infertility in an apparently normal adult male. Diagnosis is confirmed by identification of the androgen receptor gene mutation. The management of these patients depends on age at diagnosis and the response to treatment with exogenous testosterone.

Treatment of hypogonadism

Testosterone replacement remains the mainstay of treatment. Traditionally, this has been administered by implantation of subcutaneous pellets or by long-acting mixtures of testosterone esters (e.g. Sustanon[®]). The latter are given by deep intramuscular injection every 2–4 weeks. More recently, patches have been used, although there have been problems with varying degrees of absorption resulting in unpredictable plasma testosterone concentrations,

BOX 23.1 Acquired causes of hypogonadotrophic hypogonadism

- Malnutrition and weight loss
- Excessive exercise
- Stress
- Chronic illness
- Suprasellar tumours
 - Craniopharyngiomas
 - Pinealomas
- Destructive pituitary disease
 - Pituitary adenomas
 - Trauma, surgery or radiotherapy
 - Empty sella syndrome
- Sarcoidosis
- Prolactinomas
- Iron overload
 - Frequent blood transfusion, haemochromatosis
- Oestrogen-secreting adrenal tumours
- Drugs

and also problems with adhesion and hypersensitivity at the site of application. Gel and buccal mucoadhesive preparations are now available and are widely used. These are more convenient and result in much more even plasma concentrations, although a disadvantage of gel preparations is inadvertent transfer of gel to women or children. Oral preparations have been used but are poorly absorbed. As the prostate and seminal vesicles are androgen sensitive, there is a risk of stimulating growth of a prostatic carcinoma and therefore plasma prostate specific antigen concentrations should be monitored. (Treatment regimens are discussed in more detail in Chapter 21.)

Testosterone replacement will not achieve fertility in primary testicular failure. Only in secondary hypogonadism can infertility be treated. Treatment in hypogonadotropic hypogonadism is with intramuscular hCG with the addition of human menopausal gonadotrophin to supply FSH activity as necessary. This will usually induce a good quality ejaculate, which is potentially capable of resulting in conception despite a relatively low sperm count (1–20 million/mL). An alternative treatment is with small pulses of GnRH delivered by a programmed pump, mimicking physiological GnRH pulsatility. These are not long-term treatment options, partly because hCG, whether endogenous or exogenous, causes gynaecomastia. When the need for fertility is over, patients should resume treatment with testosterone.

Fertility can also be achieved using assisted reproduction techniques; in male infertility these include intrauterine insemination and intracytoplasmic sperm injection (ICSI). In ICSI, spermatozoa are injected directly into an oocyte and the fertilized embryo is then inserted into the uterus. ICSI can be appropriate where there is a very low sperm count, poor morphology or motility of sperm. It is also useful where there is an interruption in the pathway from testes to urethra such as occurs post-vasectomy or with an absent vas deferens in patients with cystic fibrosis. Abnormal sperm morphology does not appear to have a negative effect on blastocyst formation and birth defect rates are not significantly different from those conceived using conventional in vitro fertilization. However, as there is some evidence of an increased number of chromosomal abnormalities in children conceived using ICSI, concerns remain regarding health and fertility later in life.

Plasma testosterone concentrations gradually decline with age after the third decade, as a result of a number of factors including decreased GnRH release, increased sensitivity to the negative feedback of testosterone and reduced responsiveness of Leydig cells. Symptoms associated with testosterone deficiency, such as reduced exercise tolerance and increased body fat, overlap with changes linked to the natural process of ageing and hence there is an unavoidable implication that testosterone replacement in the elderly will be beneficial. Positive effects of replacement include increased bone density, increased lean body mass, improvement of lipid profile and stimulation of red blood cell production. There is a concern that such replacement may be associated with an increased risk of prostatic carcinoma, but this has not been proven.

Although testosterone replacement may be indicated in elderly patients with clear testosterone deficiency and no contraindications to treatment, the approach to marginally low concentrations is controversial. Initiation of treatment

should always be preceded by evaluation to rule out pre-existing contraindications, for example prostatic carcinoma or polycythaemia, and followed by regular monitoring.

GYNAECOMASTIA

Excessive development of the male mammary glands with increases in both stromal and glandular tissue (gynaecomastia) accounts for ~70% of male breast disorders. In the male, breast development may vary from a small subareolar button of tissue to florid breast development with feminization of the nipples and associated breast tenderness.

Gynaecomastia may occur in neonatal life, when it is usually transient and caused by transplacental transfer of maternal oestrogens into the fetal bloodstream. During puberty, gynaecomastia of some degree occurs in up to 60% of adolescent boys: this may reflect normal physiological development and is typically followed by spontaneous regression after 12–18 months.

Causes of gynaecomastia

Physiological gynaecomastia during puberty probably occurs as a result of the relative changes in oestradiol and testosterone concentrations – in normal early puberty, oestradiol concentrations are high in comparison with those of testosterone and this increased oestradiol:testosterone ratio can induce breast development.

Indeed, pathological causes are invariably related to imbalances between testosterone and oestrogen synthesis and action, and can be broadly divided into hypogonadism, other endocrine disorders, tumour related, systemic disease (Box 23.2) and drugs (Table 23.3).

BOX 23.2 Causes of gynaecomastia

Hypogonadism

- Primary
 - Castration
 - Orchitis
 - Klinefelter syndrome
 - Cryptorchidism
- Secondary
 - Prolactinoma (effect of tumour expansion or prolactin)

Other endocrine disorders

- Thyrotoxicosis
- Cushing syndrome
- Congenital adrenal hyperplasia
- Androgen insensitivity

Tumours

- Testicular (Leydig cell, Sertoli cell, choriocarcinoma)
- Adrenal (adenoma and carcinoma)
- Bronchogenic carcinoma
- Hepatocellular carcinoma
- Others – gastric, renal, haematological

Systemic disease

- Chronic kidney disease
- Liver failure
- Haemochromatosis

TABLE 23.3 Drugs implicated in the pathogenesis of gynaecomastia

Drug	Mechanism
Oestrogens	Direct stimulation, inhibition of androgen production
Androgens	Aromatized to oestrogens
Digitalis	Binding to oestrogen receptors
Tetrahydrocannabinol	Binding to oestrogen receptors
Griseofulvin	Binding to oestrogen receptors
Ketoconazole	Increase in oestradiol:testosterone ratio
Spirololactone	Anti-androgen
Cimetidine	Anti-androgen
Cyproterone	Anti-androgen
Methadone	Mechanism unknown
Phenothiazines	
Reserpine	
Isoniazid	

Investigation

A full drug history and a careful physical examination are essential, with particular reference to the testes, thyroid, liver and lungs.

A suggested schedule for the investigation of symptomatic gynaecomastia is illustrated in [Figure 23.3](#) and the interpretation of endocrine tests in [Table 23.4](#).

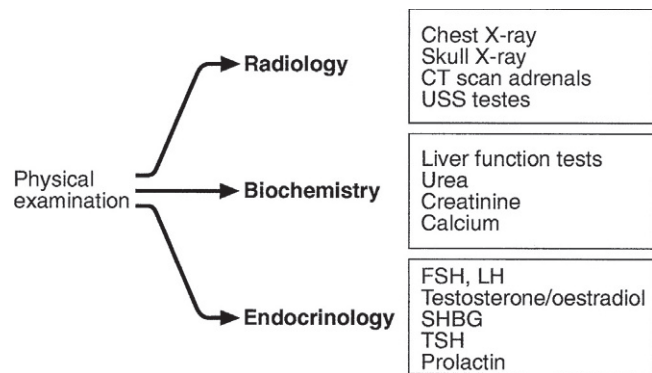

IMPOTENCE

Erectile impotence is defined as the inability to achieve and maintain a penile erection of sufficient quality to permit penetrative intercourse. In practice, the commonest physical cause of impotence is diabetes mellitus – some 50% of diabetic males will become impotent after the age of 50. Both autonomic neuropathy and vascular insufficiency may contribute to this. Other endocrine causes include hypogonadism (primary or secondary), hyperprolactinaemia and thyroid disease. Other causes are summarized in [Box 23.3](#).

A psychogenic aetiology is suggested by a history of early morning or sleep erections or full erection on masturbation or with other partners. Treatment with certain drugs can result in impotence – these are summarized in [Box 23.4](#).

Investigation

The initial history and examination is of great importance. Reduced frequency of shaving, reduced libido,

BOX 23.3 Causes of erectile impotence

- Diabetes mellitus
- Psychogenic
 - Depression
 - Anxiety
- Endocrine
 - Hyperprolactinaemia
 - Thyroid disease (hyper- and hypothyroidism)
 - Hypogonadism
- Peyronie disease
- Alcohol abuse
- Spinal cord damage (neurogenic)
 - Multiple sclerosis
 - Surgery
 - Trauma
- Vascular disease
- Chronic systemic disease
 - Chronic kidney disease
 - Disseminated malignancy
 - Liver disease
- Drugs – see [Box 23.4](#)

small testes and regression or lack of secondary sexual characteristics suggests hypogonadism. Testicular tumours may be palpable and visual field assessment and imaging of the brain and skull should be carried out if there is a possibility of pituitary tumour. A full neurological and cardiovascular examination is essential. The relevant basic biochemical investigations are listed in [Box 23.5](#).

TABLE 23.4 Interpretation of endocrine tests in the investigation of gynaecomastia (only those changes important in diagnosis are shown)

Condition	Hormone						
	Testosterone	LH	FSH	SHBG	Oestradiol	TSH	hCG
Primary testicular failure	↓	↑	↑				
Secondary testicular failure	↓	↓	↓				
Primary oestrogen-secreting tumour	↓	↓			↑		
hCG-secreting tumour		↑ ^a			↑		↑
Chronic liver disease	↓	↓	↓	↑			
Thyrotoxicosis	↑	↑	↑	↑		↓	

^aDepends on the specificity of the LH assay; modern assays show very little cross-reactivity with hCG.

BOX 23.4 Substances causing erectile impotence

- Oestrogens
- Cyproterone
- Dopamine antagonists
- Cimetidine
- Spironolactone
- Alcohol
- Cigarette smoke
- Guanethidine
- Methyldopa
- Clonidine
- Thiazide diuretics
- β -Blockers
- Disopyramide

BOX 23.5 Investigation of erectile impotence**Biochemical tests**

- Serum glucose and lipids
- Renal function
- Testosterone
- Thyroid function
- LH, FSH
- Prolactin
- Others as indicated clinically

Tests for vascular causes

- Duplex ultrasonography
- Papaverine test
- Pudendal arteriography
- Nocturnal tumescence testing
- Penile brachial index

Tests for neurogenic causes

- Pudendal nerve-evoked potentials
- Biothesiometry

Previously, treatment options were invasive and hence thorough justification by extensive investigation was necessary. Following a dramatic improvement in the treatment options in the last two decades, owing mainly to the availability of phosphodiesterase (PDE)-5 inhibitors, more extensive specialist evaluation of vascular and neurological causes (Box 23.5) is now reserved for a limited subset of patients.

For example, penile arterial blood pressure may be investigated. Penile systolic blood pressure is measured with a Doppler stethoscope and recorded as a ratio to that of the brachial artery. Low penile:brachial ratios (<0.6) suggest an arterial cause for impotence. Continuous arterial blood pressure recordings can be achieved using a small cuff around the base of the penis attached via a transducer to a recorder. If the arterial supply is impaired, the recording will show small amplitude pulses with abnormal waveforms.

Normal men experience nocturnal erections during rapid eye movement (REM) sleep and their absence suggests an organic cause for impotence. Nocturnal tumescence testing is ideally carried out in a sleep laboratory and should be repeated on three or more occasions to maximize

diagnostic accuracy. Other techniques include pudendal arteriography and duplex ultrasonography, but a detailed discussion of these is beyond the scope of this book.

Techniques for the investigation of neurological causes include biothesiometry, which is a simple test of afferent sensory function. An electromagnetic test probe is placed on the penile skin in various sites and the intensity of vibration increased until it is perceived by the patient. The degree of vibration required for perception can be compared with other sites on the patient's body.

Treatment of erectile impotence

Treatment options for erectile impotence include oral therapy in the form of PDE-5 inhibitors (sildenafil, vardenafil, and tadalafil), intraurethral alprostadil, intracavernosal injection of vasodilators, vacuum devices and surgery (bypass and implants).

The advent of the PDE-5 inhibitors has greatly simplified the treatment of impotence. The available agents have similar efficacy, with sildenafil and vardenafil possessing similar pharmacokinetic profiles and tadalafil exhibiting a longer duration of action. Phosphodiesterase-5 inhibitors should be avoided in patients using, or likely to use, nitrates because of potentiation of their hypotensive effect.

Intracavernosal injection of vasodilatory agents such as alprostadil and papaverine, and intraurethral alprostadil are useful second-line treatment options, local penile pain being the limiting side-effect of the latter. Self-injection can result in successful erections in patients without a vascular cause of impotence. The injection method needs to be adequately taught and should not be used more than once a week to reduce the risk of potential side-effects, such as corporeal fibrosis and priapism.

Variable results have been seen with vacuum devices, which act by increasing corporeal blood flow and are used in conjunction with a penile ring.

Penile prostheses, either semi-rigid or malleable rods inserted into the corpora, or self-inflatable prosthetic devices have been used with varying degrees of success. Mechanical failure, the need for manual inflation from an internal fluid reservoir and the length of waiting lists for the procedure in the UK have resulted in diminished use of this treatment option.

APPENDIX 23.1: PROTOCOLS FOR ENDOCRINE INVESTIGATIONS

(i) Gonadotrophin releasing hormone stimulation test

In the investigation of gonadotrophin deficiency, assessment of the responses to exogenous GnRH may be useful. There is no need for the patient to fast unless the test is being combined with assessment of other anterior pituitary hormone responses to insulin-induced hypoglycaemia.

Gonadotrophin releasing hormone (100 µg) is given intravenously at time 0 and samples taken at 0, 20 and 60 min. Normally, LH and FSH concentrations both rise, though the degree of increase is dependent on the method used for measurement. The peak response may be seen at either 20 or 60 min.

The interpretation of the GnRH test is largely based on the basal values. In a patient with delayed puberty, a normal response or a response in which the LH peak is greater than that of FSH, suggests that the patient is

about to go into puberty. The response to GnRH may be suppressed by intervening illness.

Besser GM, Ross RJM. Are hypothalamic releasing hormones useful in the diagnosis of endocrine disorders? In: Edwards IR, Lincoln CRW, editors. *Recent advances in endocrinology and metabolism*. Edinburgh: Churchill Livingstone; 1989, pp. 135–158.

(ii) Clomifene test

The clomifene test may be helpful in distinguishing gonadotrophin deficiency from weight-related hypogonadism and idiopathic delayed puberty. Side-effects include visual disturbances, symptoms of oestrogen deficiency and depression, which may be severe enough to warrant discontinuation of the test.

Clomifene 50 mg is given daily for 5 days. Serum LH and FSH are measured on days 0 and 7; in addition, in females, progesterone concentration is measured on day 21 to confirm ovulation. In a normal response, LH and FSH concentrations rise to outside the reference ranges or to double the basal values. A lack of response suggests gonadotrophin deficiency due to pituitary or hypothalamic disease. Patients with anorexia nervosa may show no response. Prepubertal children show no response and children in early puberty may actually show a reduction in gonadotrophin concentrations during the test.

Andersen DC, Marshall JC, Young JL et al. Stimulation tests of pituitary–Leydig cell function in normal male subjects and hypogonadal men. *Clinical Endocrinology* 1972; 1:127–40.

(iii) Human chorionic gonadotrophin stimulation test

In the differential diagnosis of male hypogonadism, a stimulation test with hCG may be useful. There are no specific precautions and the test does not have to be carried out after fasting.

Human chorionic gonadotrophin is injected i.m. in a dose of 2000 IU on days 0 and 2 and serum testosterone measured on days 0, 2 and 4. A normal response is defined as a rise in serum testosterone to within the reference range. A failure of any rise in testosterone suggests an absence of functioning testicular tissue. If the testes are not palpable in the scrotum or inguinal canals, a rise in testosterone suggests the presence of intra-abdominal testes. In gonadotrophin deficiency with normal testes, the low basal testosterone concentration should triple after hCG.

CONCLUSION 483

INTRODUCTION

Inherited metabolic diseases (IMDs), also known as in-born errors of metabolism, are inherited conditions that develop as a result of mutations that affect the function of proteins. The majority of IMDs are monogenic conditions and the mutant proteins are enzymes, but others involve structural proteins, receptors, hormones or transport proteins. Although they are inherited, not all IMDs present in the newborn period: some present later in childhood or not until adult life.

Inherited metabolic diseases are individually rare. Of those that present in childhood, the commonest, such as phenylketonuria (PKU) and medium chain acyl-CoA dehydrogenase deficiency (MCADD), have an incidence of 1 in 10 000. However, collectively, the IMDs that present in childhood are thought to occur with an incidence of 1 in 750 live births, although the true incidence is unknown, as no newborn screening programme is comprehensive, and many of these conditions go undiagnosed. More diagnoses are being secured with advancing diagnostic techniques, such as tandem mass spectrometry, and the growing awareness of these disorders by clinicians. Similarly, the therapeutic options are continuing

to expand, increasing the pressure to detect cases at an earlier stage. Importantly, improving treatments leads to longer survival that, in turn, may present new clinical challenges such as the management of pregnancy in an affected mother. Altering the natural history of a condition may also reveal previously unknown long-term complications.

If IMDs that present in adult life (e.g. familial hypercholesterolaemia, genetic haemochromatosis) are included, at least 1 in 100 individuals has one of these conditions. If disorders such as the haemoglobinopathies are included (see Chapter 28), the prevalence is greater still.

CLINICAL PRESENTATION AND PATHOPHYSIOLOGY

Inherited metabolic diseases may present at any age. However, there are key times when presentation is more common, either owing to the individual having to survive biochemically without the support of the mother's placenta, or to additional metabolic stresses at that particular time.

Neonatal presentation

Many IMDs present in the neonatal period. They may be considered in four broad categories: problems of synthesis and breakdown of complex molecules; intoxications; energy deficiency states, and seizure disorders.

Defects in synthesis and breakdown

Many complex molecules are integral to cell-to-cell communication and ordered patterning within the developing embryo. Failure to make these complex molecules can, therefore, result in disordered embryogenesis, presenting as a dysmorphic neonate at birth. An example is Zellweger syndrome, the most severe of the peroxisomal biogenesis defects. Affected neonates have a typical appearance, with a large fontanelle, prominent forehead and hypertelorism, hypotonia, hepatomegaly and calcific stippling, particularly of the knees and shoulders, on X-rays. The principle defect in peroxisomal disorders lies within the *PEX* genes, which encode the peroxin proteins critical for the targeting and importing of peroxisomal enzymes and proteins into peroxisomes, resulting in multiple enzyme deficiencies. This group of disorders is diagnosed by the analysis of very long chain fatty acids (VLCFAs), which are elevated in plasma owing to the block in their oxidation, which is a peroxisomal process. Management remains supportive, rather than curative.

Smith–Lemli–Opitz syndrome is another example of a synthetic defect. It results from a block in the penultimate step in cholesterol synthesis, 3β -hydroxysterol- $\Delta 7$ -reductase. The production of cholesterol, an essential component of cell membranes, is decreased with marked elevation of its precursor 7-dehydrocholesterol (7-DHC) in body fluids and tissues. The characteristic dysmorphism includes anteverted nares, low-set ears, micrognathia, ptosis and microcephaly. Other features include syndactyly of the 2nd and 3rd toes, present in 98% of patients, genital and renal anomalies, learning difficulties and severe failure to thrive. Dietary cholesterol replacement and statin treatment have been used with the aim of inhibiting cholesterol synthesis and reducing accumulation of 7-DHC; no convincing effects have been seen with either approach, but this may be because the phenotype is determined by the in utero availability of cholesterol.

Problems with the breakdown of complex molecules result in storage disorders. These tend not to be apparent at birth, but rather become so with time as the substance(s) stored in excess begins to affect structure and function. For example, affected children with Hurler syndrome (mucopolysaccharidosis type I, MPSI) appear normal at birth, but the gradual accumulation of glycosaminoglycans over time produces the typical coarsening of the features, corneal clouding, organomegaly and dysostosis multiplex (distortion of the normal bony architecture secondary to storage material) that are characteristic of the condition. However, it is parental concerns about delayed development, rather than the coarse features, that usually bring these patients to medical attention. Storage disorders in which dysmorphism and organomegaly are

often present in the first month of life include I-cell disease, infantile sialic acid storage disease and early infantile GM1 gangliosidosis.

Intoxications

Intoxication is the classic presentation of inherited metabolic disorders. An unremarkable period immediately after birth is followed by increasing clinical abnormality as the baby feeds, and toxic metabolites, which cannot be broken down because of the metabolic block, accumulate. Prior to birth, these toxic metabolites are cleared via the placenta. Typically, clinical features develop within 48–72 h after birth, but can take considerably longer. Phenylketonuria (phenylalanine hydroxylase deficiency) is an intoxication, but the first signs of the condition do not usually develop until 6–12 months after birth when motor developmental milestones are not met. Phenylketonuria (PKU) also illustrates two other features of inherited metabolic diseases affecting enzymes: accumulation of the substrate of the defective enzyme may lead to increased metabolism via alternative, normally minor, pathways by a mass action effect (phenylalanine is transaminated to phenylpyruvate and phenylketones), and there may be deficiency of the normal product of the enzyme (in this case, tyrosine). Both of these may contribute to the clinical presentation.

Urea cycle defects typically present with encephalopathy in the first days of life. As milk feeds are established, the block in the conversion of waste nitrogen, derived from the amine groups of amino acids, to urea produces hyperammonaemia and increases glutamine formation. Ammonia interferes with neurotransmission causing astrocyte swelling, and glutamine increases the risk of cerebral oedema, owing to the osmotic load as it accumulates in the brain. Ammonia is also a respiratory stimulant, acting on the respiratory centre in the brain stem to produce a respiratory alkalosis, which is an unusual finding in a sick neonate. Diagnosis relies on measuring plasma ammonia concentration in conjunction with plasma amino acids and urinary orotic acid to determine the location of the block (Fig. 24.1). Immediate management depends on attempting to increase the clearance of ammonia and supplementation of arginine, usually a non-essential amino acid, synthesized in the urea cycle, which becomes an essential amino acid in many of the urea cycle defects. Low arginine also contributes to neurotoxicity by reducing nitric oxide and creatine synthesis.

Galactosaemia (galactose 1-phosphate uridylyltransferase deficiency) usually presents a little later, at the end of the first week of life, with jaundice due to conjugated bilirubinaemia, hepatomegaly, coagulopathy and characteristic ‘oil drop’ cataracts. The diagnosis is made by measuring the enzyme activity in red cells. The exact pathogenesis is not fully elucidated, but restriction of galactose and lactose (a disaccharide of glucose and galactose) is effective in reversing the liver toxicity. However, the diet does not prevent all adverse effects of the disease and it is clear that endogenous galactose production is significant. As with many IMDs, some infants present

Enzyme	Disorder	Amino acids	Orotic acid
1 N-acetylglutamate synthetase (NAGS)	NAGS deficiency	↑glutamine	Normal
2 Carbamoylphosphate synthetase (CPS)	CPS deficiency	↑glutamine ↓arginine	Normal
3 Ornithine transcarbamoylase (OTC)	OTC deficiency	↑glutamine ↓arginine	↑↑
4 Argininosuccinate synthetase	Citrullinaemia	↑↑citrulline ↓arginine	↑
5 Argininosuccinate lyase	Argininosuccinic aciduria	↑↑citrulline ↑↑argininosuccinic acid ↓arginine	↑
6 Arginase	Hyperargininaemia	↑arginine	↑

FIGURE 24.1 ■ The urea cycle. The numbers refer to the enzymes listed in the table, deficiencies of which cause changes in the plasma concentrations of amino acids and increased urinary excretion of orotic acid as indicated.

later than the neonatal period, with the renal effects of galactosaemia, namely proximal tubulopathy and rickets, rather than the hepatic consequences. A similar difference in presentation is seen in tyrosinaemia type 1, with an early hepatotoxic picture not unlike galactosaemia and a later Fanconi-type presentation due to nephrotoxicity. The key diagnostic marker in tyrosinaemia type 1 is the detection of succinylacetone on urinary organic acid analysis.

Energy deficiency disorders

Energy deficiency disorders are the result of either a fundamental block in energy production, as seen in the congenital lactic acidoses, or a failure of adequate energy production in the absence of a regular food supply. The congenital lactic acidoses have a number of causes (Box 24.1), with a definitive diagnosis being made in only approximately half of the patients. Clinical features develop early, but significant problems due to metabolic decompensation may take longer to develop, in comparison with intoxications.

BOX 24.1 Some inherited metabolic disorders causing lactic acidosis

Primary lactic acidosis

- Respiratory chain disorders
- Pyruvate dehydrogenase deficiency
- Disorders of gluconeogenesis (e.g. fructose 1,6-bisphosphatase deficiency)

Secondary lactic acidosis

- Organic acidurias
- Urea cycle disorders
- Fatty acid oxidation disorders
- Glycogen storage disease type I

The key diagnostic marker is a raised plasma lactate concentration but, in practice, secondary hyperlactataemia (due, e.g. to hypoxia, hypovolaemia, hypotension etc.) is more common. The distinguishing diagnostic clue is the absence of ketones in the secondary elevations. Spurious elevation may result from squeezing the arm to elevate the vein prior to venepuncture. A free-flowing sample is required and an arterial stab should be used if a free-flowing sample cannot be obtained otherwise. Further evidence may be gleaned from measuring lactate in the cerebrospinal fluid (CSF), which reflects brain lactate over days rather than at that specific time. Secondary elevations of CSF lactate are seen in primary brain infections such as encephalitis and meningitis, and following seizures.

In certain disorders, energy deficiency only becomes apparent when feeding is interrupted. Neonates with fatty acid oxidation defects remain asymptomatic while fed, but can develop hypoketotic hypoglycaemia during prolonged fasting or intercurrent infections. The commonest fat oxidation defect, MCADD, usually presents much later, at around the age of one year, but a subgroup present in the first few days of life, before feeding becomes established, most commonly if they are breast fed. Neonatal glycogen stores are more rapidly exhausted than those in older infants and adults, requiring mobilization of fat stores for energy. Fats cannot be directly utilized by the brain, requiring conversion in the liver to ketones, which can be. Failure to produce ketones results in encephalopathy as a result of a combination of hypoglycaemia and the accumulation of acylcarnitines. Clinically evident hypoglycaemia is a late feature: treatment, either with oral glucose polymer or intravenous 10% dextrose, should be started before it occurs.

Seizure disorders

Inherited metabolic diseases are a rare cause of neonatal seizures compared with birth asphyxia and infections, and are usually a late, non-specific feature of blocks in intermediary metabolism. There are, however, a number of IMDs that typically present with seizures at this time that will not be detected on routine investigation and so need to be specifically excluded if no other cause is apparent (Table 24.1). Seizures may have been present in the antenatal period and been interpreted as the

TABLE 24.1 Inherited metabolic disorders presenting with neonatal seizures and their diagnostic investigations

Disorder	Investigation
Biotinidase deficiency	Plasma biotinidase Urine organic acids CSF:plasma glycine ratio
Non-ketotic hyperglycinaemia (NKH)	
3-Phosphoglycerate dehydrogenase deficiency	CSF serine
Pyridoxine 5' phosphate oxidase deficiency	CSF neurotransmitters Urine organic acids Trial of pyridoxal phosphate PNPO genotyping
Pyridoxine-dependent seizures	Trial of pyridoxine Plasma α -amino adipic semialdehyde Antiquitin genotyping
Purine disorders	Urinary purine studies
Sulfite oxidase/molybdenum cofactor deficiency	Dip-stick test for sulphite on fresh urine Urinary purine studies
Peroxisomal disorders	Plasma very long chain fatty acids

baby being particularly active because of increased fetal movements. Some mothers do note the rhythmic nature of these movements.

Presentation at weaning

Weaning is a time when new dietary components may first be encountered, and if any one of their metabolic pathways is blocked, clinical features may develop. Weaning may also result in greater intake of the particular substrate whose metabolism is compromised, e.g. protein. If the relevant metabolic pathway is unable to cope with the increased load, the threshold for the development of clinical features may be breached. An example of the latter is a partial urea cycle defect. Prior to weaning, protein intake may have been within the tolerance of the compromised pathway, but with the addition of solids, greater quantities of protein can be ingested. If, as a result, the pathway's capacity is exceeded, hyperammonaemia will ensue. A similar effect is seen in children with hyperphenylalaninaemia detected on newborn screening. A decision is usually made to monitor concentrations to see if the phenylalanine increases with greater food intake, particularly around the time of weaning.

Hereditary fructose intolerance (aldolase B deficiency) does not present until an infant is exposed to fructose, which typically occurs around the time of weaning when pureed fruit is introduced; the sucrose in fruit is broken down to fructose and glucose. There is no fructose or sucrose in breast milk or formula milk. In the affected patient, fructose 1-phosphate accumulates, inhibiting glucose production, promoting hypoglycaemia and depleting inorganic phosphate, thereby reducing ATP production. Clinically, the first features are nausea and vomiting with postprandial

hypoglycaemia. If the condition is not recognized, and fructose ingestion persists, the infant will fail to thrive and may develop liver and kidney failure. Confirmatory enzymology requires liver biopsy; however, in some patients a clinical diagnosis can be made on the basis of a history of exposure to fructose and reversal of symptoms after elimination of sources of fructose from the diet. The diagnosis may then be confirmed by genotyping.

Presentation in later infancy

Infancy is a time when there is a considerable risk of infections, as the body is exposed to numerous infectious agents for the first time and the immune system is still developing. Infection causes increased metabolic stress; patients with known IMDs may decompensate and others may present for the first time. Some IMDs show seasonal variation in presentation: for example, MCADD presents more frequently in the autumn and winter months, because of the increase in infections at this time of year.

Glutaric aciduria type I (GA-I) is an autosomal recessive defect in lysine catabolism. Affected infants may have large heads but minimal neurological signs prior to catastrophic metabolic decompensation around the end of the first year, usually precipitated by an infection. Such decompensation causes damage to the basal ganglia, with resultant irreversible dystonia and movement disorder. In presymptomatic siblings, prospective early aggressive management of intercurrent illnesses with antibiotics, protein (lysine) restriction, carnitine supplements and hyperalimination with glucose polymer or intravenous dextrose, can reduce the incidence of decompensation and subsequent neurological sequelae. Measurement of urinary organic acids shows elevated glutarate and 3-hydroxyglutarate in this condition. Occasional patients have been described with classic histories and abnormal enzymology in fibroblast studies without the typical urine abnormalities; plasma acylcarnitine analysis may show reduced free carnitine and a glutaryl carnitine peak, but may be normal in such patients.

Infants may present with IMDs towards the end of the first year, when growth slows. On average, a baby will put on just under 7 kg in weight in the first year of life, compared with 2 kg each subsequent year during childhood. This means that for the same protein intake, more will need to be catabolized, as less is needed for growth. This increased pressure on an affected metabolic pathway may result in decompensation.

Presentation at puberty

Puberty is recognized as a difficult time for teenagers and rebellion affects all areas of life, including caring for their health. Patients with significant IMDs may break their diets or fail to take their medication in an attempt to be 'normal'. Both can precipitate decompensation. However, new presentations are also seen at this time, probably as a result of changes in growth and the hormonal milieu. For girls with urea cycle defects, it is well recognized that following menarche, symptoms may

fluctuate in time with the menstrual cycle, being worse in the few days leading up to, and including, the start of the period. The use of hormonal therapy to suppress ovulation and menstruation has proven helpful in some patients.

Presentation during adulthood

Inherited metabolic diseases are often considered to be paediatric conditions, but it must be remembered that they can present at any age. This may be owing to the defect being less severe so that an individual's metabolism has not previously been sufficiently stressed to provoke decompensation. Patients with partial ornithine transcarbamoylase (OTC) deficiency, the commonest of the urea cycle defects, may remain asymptomatic throughout childhood and only present in adult life. Some adults may not have been exposed previously to sufficient quantities of metabolites they cannot deal with. Some adults with hereditary fructose intolerance will have learned at an early age that sweet, sugary foods make them feel unwell and will subconsciously avoid them. Many patients with this condition have perfect dentition owing to their self-imposed diet.

For some IMDs, presentation differs between adults and children. The severe form of X-linked adrenoleukodystrophy (ALD) usually presents at 5–10 years with progressive neurological deterioration, ultimately leading to spastic quadriplegia, seizures, vegetative state and death. More than 90% of affected boys have adrenal insufficiency. However, adrenal involvement may precede, or follow, neurological symptoms by years. There is wide phenotypic variability within families, and another family member may not present until adulthood. The cerebral form in adults is extremely rare, accounting for <5% of all cases. The commoner adult presentation is adrenomyeloneuropathy (AMN), with a slowly progressive neurological picture mimicking spinal cord syndrome, with spastic gait and difficulty voiding urine. Some 10% of patients have only adrenal involvement, and 10% remain asymptomatic. Adrenoleukodystrophy is the commonest peroxisomal disorder. The defective adrenoleukodystrophy protein (ALDP) is thought to play a role in the uptake of VLCFAs across the peroxisomal membrane, but the exact pathophysiology is not completely understood. The use of Lorenzo's oil (a 4:1 mixture of glyceryl trioleate and glyceryl trierucate) reduces the accumulation of the VLCFAs, but fails to prevent neurological decline in symptomatic patients. It appears to have a role in asymptomatic boys reducing the risk of developing abnormalities apparent on magnetic resonance imaging. Bone marrow transplantation can be performed to stabilize cerebral ALD in the very early stages of demyelination. The varied phenotype is not explained by differences in genotype, as family members with different manifestations of the condition will usually have the same mutation.

Adrenoleukodystrophy also demonstrates another variation in adult presentation, that of the manifesting heterozygote. This is seen in some X-linked conditions where a carrier female develops symptoms. Two-thirds of females carrying an ALD gene mutation have some

degree of neurological involvement, ranging from brisk reflexes and mild abnormalities on clinical examination to a full-blown AMN-like picture. This may be misdiagnosed as multiple sclerosis.

A similar phenomenon is seen in Fabry disease (α -galactosidase deficiency). Deposition of glycosphingolipids in blood vessel walls, heart, kidneys, skin and autonomic ganglia produces cerebrovascular disease, cardiac disease, nephropathy, angiokeratoma, corneal dystrophy and acroparaesthesia (severe pain in the extremities). It was believed that the majority of female carriers were entirely asymptomatic throughout life, but it is now clear that one-third of female carriers have significant symptoms, which may be so severe as to warrant treatment. One explanation for the spectrum of severity is the random inactivation of the X chromosome in cells – lyonization. If sufficient numbers of the unaffected X chromosomes are suppressed, a significant number of cells will have a functioning, affected X chromosome. The resulting enzyme function may be low enough for symptoms to develop.

A significant number of IMDs present for the first time in adulthood. The classic mitochondrial syndromes that led to the recognition of mitochondrial DNA (mtDNA) mutations and their role in pathology are all primarily adult presentations: an example is Leber hereditary optic neuroretinopathy, presenting most commonly in the third decade of life with bilateral, painless central vision loss.

The IMDs that typically present only in adult life usually involve the accumulation of a toxic substance that, although it begins at birth, takes many years to become manifest. Important examples include heterozygous familial hypercholesterolaemia (homozygotes usually present with xanthomata or coronary disease in the second decade), familial combined hyperlipidaemia and primary (genetic) haemochromatosis (excepting the rare neonatal variant). All these conditions are discussed elsewhere in this book.

Presentation during pregnancy

The physiological stresses of pregnancy may precipitate crises in women with IMDs so meticulous care is required to ensure the best outcome for the mother and baby. Some women develop symptoms in pregnancy because they carry an affected child, although they do not have the condition themselves. The classic examples of this are the long chain fatty acid oxidation defects, long chain hydroxyl-acyl-CoA dehydrogenase deficiency (LCHADD) and very long chain acyl-CoA dehydrogenase deficiency (VLCADD). These conditions are recessively inherited and the mother, therefore, is an obligate carrier with 50% enzyme activity, which is compatible with normal life and function. Clinical manifestation of most IMDs only occurs if activity is <5%. However, the mother also has to combat the metabolic stresses of pregnancy, which increase the load on the pathway. If the fetus is affected, she will also have to break down the long chain acylcarnitines that the fetus is producing owing to the block in its metabolism. Such women do not present with the typical hypoketotic hypoglycaemia seen in

affected infants, but liver function is impaired, precipitating HELLP (hepatomegaly, elevated liver enzymes and low platelets) syndrome or the rarer, more severe acute fatty liver of pregnancy (AFLP). This may require intensive care and early delivery of the fetus. Only a small number of women with HELLP and AFLP carry affected fetuses, but it is imperative that their newborn infants are screened by measurement of plasma acylcarnitines to exclude a fat oxidation defect. Screening only for the associated dicarboxylic aciduria, using urinary organic acid analysis, is not sensitive enough and has led to the diagnosis being overlooked.

Presentation postpartum

Women with partial OTC deficiency may present for the first time a few days after delivery. They are able to withstand the increased metabolic stress of pregnancy and delivery, but the massive protein load presented by the involution of the uterus precipitates hyperammonaemia. Many of these women have never had previous symptoms that might alert their obstetrician to the cause of their illness, although some have an aversion to high protein diets.

Clinical abnormalities in the infant may also reveal an undetected IMD in the mother. Maternal PKU syndrome is a description of the clinical consequences to the fetus of in utero exposure to elevated plasma phenylalanine resulting from PKU in the mother. A mother not known to have PKU, usually because she was born in an area without a neonatal screening programme, may have had hyperphenylalaninaemia that was sufficiently mild for her not to have come to medical attention, but significant enough to affect the fetus. Typical features are low birth weight, microcephaly, cardiac abnormalities and developmental delay. The infant does not have PKU or hyperphenylalaninaemia, and therefore does not require dietary restriction. The diagnosis is usually made when the infant is investigated for microcephaly or developmental delay. Plasma phenylalanine needs to be measured in the mother for diagnosis; urinary amino acids may not be sufficiently sensitive and diagnoses have been missed when only this investigation has been used.

NEWBORN SCREENING

Newborn screening is used to detect conditions that have a presymptomatic period during which treatment can dramatically improve outcome. In the UK, conditions screened for at this time include congenital hypothyroidism (see below), PKU, MCADD, cystic fibrosis and sickle cell disorders. A pilot study is underway in the UK to examine an expanded neonatal screening programme including maple syrup urine disease, glutaric aciduria type 1, isovaleric acidaemia, LCHADD and pyridoxine unresponsive homocystinuria. This is modest compared to some countries, e.g. the USA where newborns are screened for over 30 conditions. However, for many of these conditions the natural history is not fully understood, treatments are only partially effective and

infants may present and die prior to the screening result being available. The detection of infants who will never develop symptomatic disease remains a real concern. During the development of MCADD screening, mutations were identified in infants with raised octanoylcarnitine that have never been associated with clinical abnormalities.

Screening is also used to detect IMDs in populations with higher frequencies of a particular condition, usually secondary to a founder effect (a mutation occurring early in the settlement of a geographically isolated area or within a limited gene pool so that it occurs with high frequency), for example Tay–Sachs disease in the Ashkenazi Jewish population.

Newborn screening is widely practised for congenital hypothyroidism, but while some of these infants have inherited disorders of thyroid hormone synthesis, some have thyroidal agenesis or dysgenesis (that is, failure of development of the gland), for which a genetic basis has not been defined.

INHERITANCE

The molecular bases of IMDs are mutations in genes that adversely affect the functions of specific proteins. The patterns of inheritance vary, but the majority of these conditions are autosomal recessive.

Autosomal recessive inheritance

Autosomal recessive inheritance requires both parents to carry a mutation affecting the same gene. It is estimated that we each carry 250–300 loss of function mutations in our genes, but, as we also have a normal copy of the gene, the resultant 50% activity is more than sufficient for normal function: as a result, carriers of autosomal recessive conditions are generally not clinically affected (patients with IMDs typically have <5% activity). Even if the parents are carriers for the same condition, both faulty copies of the gene need to be passed on to the embryo, resulting in a 1 in 4 risk of the infant being affected in each pregnancy (Fig. 24.2A). There is also a 1 in 4 chance that neither faulty gene will be inherited and a 2 in 4 (1 in 2) chance that the embryo will be a carrier.

If the frequency of the gene defect in the general population is known, the incidence can be calculated: for example the carrier frequency for PKU is 1 in 50, so the incidence equals $(1/50 \times 1/50)$ (the chance of two carriers having children together) multiplied by 1/4 (the chance of them having an affected child), that is, 1/10000. If a certain condition is known to exist in a family, genetic counsellors can use calculations of this sort to inform individual couples of their risk of having an affected child. For example, if the sister of an individual PKU were to have a child with an unrelated man, the risk of the baby having the condition would be 1 in 300, which is considered negligible. (She is not affected: she has a 2 in 3 chance of being a carrier and 1 in 3 of being homozygous normal – the denominator is three rather than four because she is unaffected). The man's chance of being

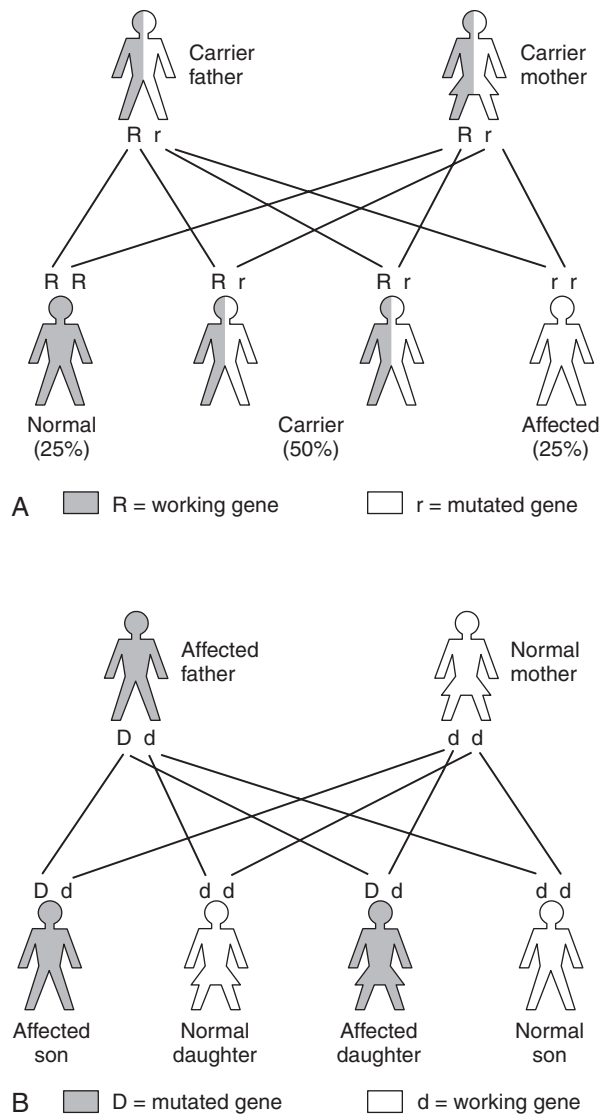

FIGURE 24.2 ■ (A) Autosomal recessive inheritance. (B) Autosomal dominant inheritance.

a carrier is 1 in 50 (the carrier frequency in the general population), so the risk of two faulty genes being passed to an embryo is $\frac{2}{3} \times \frac{1}{50} \times \frac{1}{4} = \frac{1}{300}$.)

Consanguinity within a family increases the risk of autosomal recessive conditions and there are some disorders with a high frequency within particular populations. There may be a founder effect within certain populations, for example the Pennsylvania Mennonites, in whom the severe form of maple syrup urine disease has an incidence of 1:176. In these kindred, lineage can be traced to one couple who emigrated from Europe in the eighteenth century. The tradition of first cousin marriages in some immigrant groups is increasing the incidence of IMDs in some areas of the UK.

It should be noted that, although affected individuals with autosomal recessive IMDs are often classified as homozygotes, the existence of multiple mutations affecting individual genes means that some are, strictly speaking, compound heterozygotes.

Autosomal dominant inheritance

Autosomal dominant inheritance is rare in IMDs with the exception of some of the porphyrias, for example acute intermittent porphyria, hereditary coproporphyria and porphyria variegata (see Chapter 28). The risk of transmission in autosomal dominant disorders is 1 in 2, as only one faulty copy of the gene is required to cause disease (Fig. 24.2B), although variable penetrance and other factors may influence the degree to which the offspring are affected. Dominant inheritance is less common than recessive, as severe disease may result in death prior to an individual reaching reproductive maturity and so the defective gene fails to pass on to the next generation. However, in some cases, the mutation may have occurred *de novo* in the embryo. For some dominantly inherited conditions, the condition may provide some protection against another serious condition (e.g. the sickle haemoglobin trait provides protection against *P. falciparum* malaria, see Chapter 29).

X-linked inheritance

X-linked recessive inheritance occurs with a variety of IMDs, for example: OTC deficiency; pyruvate dehydrogenase complex deficiency; Hunter syndrome (mucopolysaccharidosis type II); Lesch–Nyhan syndrome (a purine disorder); Fabry disease (sphingolipidosis), and ALD. This pattern of inheritance is characterized by carrier females (unaffected, as they have a normal copy of the gene on their other X chromosome) passing the gene to their affected sons (the Y chromosome does not carry the gene so there is no normal copy) (Fig. 24.3A). The chance of a son being affected is 1 in 2 in each pregnancy, the same as the risk of a daughter being a carrier. As the affected gene lies on the X chromosome, affected fathers can only pass it to their daughters, who will be obligate carriers.

Unlike autosomal recessive conditions, in X-linked disorders carriers may manifest the disorder clinically, for example in OTC deficiency. As discussed previously, in carrier females the variation in the degree of symptoms is due to lyonization, the random inactivation of one of the two X chromosomes in all cells, including hepatocytes. The severity of disease depends on the percentage of hepatocytes expressing the normal gene. This can lead to a varied clinical presentation within families, with some female carriers presenting with severe hyperammonaemia in the neonatal period and others being apparently unaffected.

X-linked dominant conditions require only one copy of the gene to be inherited to express the condition, hence males and females are equally affected, for example vitamin D-resistant rickets (Fig. 24.3B).

Mitochondrial inheritance

Mitochondria are unique intracellular organelles, in that they have their own genes. However, a fully functional mitochondrion is the product of both the nuclear and mitochondrial genomes with the vast majority of genes, in the order of 1300, being encoded in the nucleus.

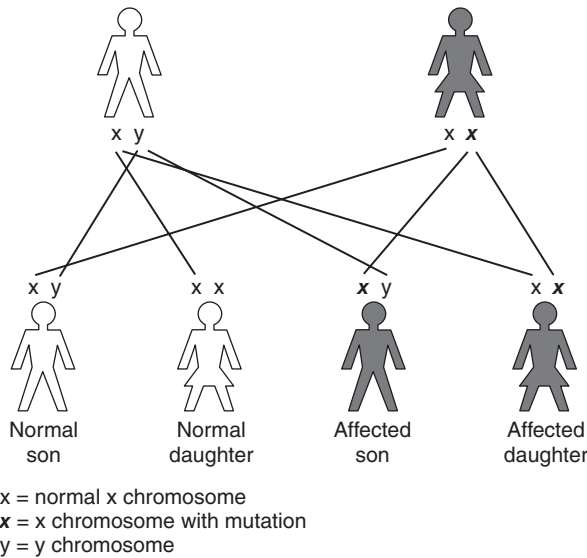

FIGURE 24.3 ■ (A) X-linked recessive inheritance. (B) X-linked dominant inheritance.

If disease-causing mutations arise in the nucleus, these can be inherited in the usual way, for example as autosomal recessive or dominant, or X-linked traits. Mitochondrial DNA (mtDNA) is inherited in a matrilineal fashion; that is, mtDNA is inherited exclusively from the mother. Paternal mitochondrial DNA is present in the mitochondria in the sperm's tail to provide ATP for propulsion. On fertilization, the tail of the sperm is left outside and hence no paternal mtDNA enters the zygote. Mitochondrial DNA mutations can therefore be inherited only from females, but can affect males or females. Point mutations inherited in this fashion include those for: myoclonic epilepsy, ragged red fibres (MERRF); mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) and Leber hereditary optic neuropathy.

The degree to which the offspring will be affected in these conditions is influenced by the mutant load, in that each cell has many mitochondria and each mitochondrion has multiple copies of mtDNA, a mix of

FIGURE 24.4 ■ Mitochondrial DNA replication. Mitochondria randomly segregate to daughter cells following replication. Each cell may contain mitochondria with both mutant and wild-type DNA (heteroplasmy). Daughter cells may drift towards homoplasmy for either wild-type or mutant mtDNA. As the percentage mutant mtDNA load increases, the chance of developing clinical features increases.

normal (wild type) and mutant. The presence of normal and mutant mtDNA within the same cell is called heteroplasmy. During cell division, the mtDNA becomes randomly divided between the daughter cells (Fig. 24.4). The proportion of mutant mtDNA may drift towards homoplasmy of either normal or mutant mtDNA. When the proportion of mutant mtDNA reaches a certain threshold within an individual cell, cellular function is compromised and, if sufficient cells are similarly affected, clinical features will develop. The distribution of the affected mitochondria within the body will determine the presentation. Mitochondrial disorders typically present with multiorgan involvement; however, the high energy-requiring organs are more frequently involved, especially brain, muscle, liver, heart, kidneys and eyes. Cells that divide rapidly may clear the mutant mtDNA because cells with normal function have reproductive advantage, e.g. refractory anaemias and enteropathy can resolve as the marrow or gastrointestinal tract recover, whereas brain and muscle involvement tend to be progressive.

Rearrangements (deletions/duplications) within the mitochondrial genome are usually sporadic and therefore the risk of recurrence is small. Examples include Kearns–Sayre syndrome (external ophthalmoplegia, pigmentary retinopathy, heart block) and Pearson syndrome (anaemia and pancreatic dysfunction, both endocrine and exocrine).

DIAGNOSTIC STRATEGIES

Close collaboration between the clinician and the metabolic laboratory is essential to establish the diagnosis of an IMD promptly. Links should be established between referring centres and specialist metabolic units, so that urgent cases can be discussed, investigations planned and a structured approach taken to the use of small samples.

Details of the patient's drug and feeding history, as well as transfusion status, will be needed for a full interpretation of results. Ideally, in the specialist unit, the clinical and laboratory services should be integrated with a multidisciplinary approach to the investigation and interpretation of results. This should lead to rapid diagnosis and initiation of appropriate treatment.

Essential laboratory investigations

When the suspicion of an IMD is raised, there are a number of basic laboratory investigations that can be performed immediately in the local hospital. These analyses will include full blood count and serum electrolytes as well as the more specific investigations discussed below. Their results may provide clues to the diagnosis and suggest further investigations.

Blood gas analysis

Blood gas analysis is a key investigation in a patient with a suspected IMD, particularly during acute episodes of illness. The most common acid–base imbalance seen in the paediatric population is a metabolic acidosis, secondary to infections, catabolic states or severe dehydration. The difficulty in interpretation in these circumstances is that these conditions are often the triggers of acute decompensation in patients with IMD. Calculation of the anion gap may assist in interpretation of the blood gas analysis: metabolic acidosis with an increased anion gap (>16 mmol/L) is observed in many IMDs, whereas metabolic acidosis with a normal anion gap is more likely to be due to diarrhoea or renal tubular acidosis.

In patients with a metabolic acidosis and suspected IMD it is important to test the urine for ketones. Point-of-care testing for urine and blood ketones, using simple stick technology, is readily available in most neonatal and paediatric units and provides a rapid indication of the ketotic status of the patient. Ketosis is a physiological response to fasting, and is often seen in normoglycaemic children with severe nausea and vomiting. However, during the neonatal period, metabolic acidosis with ketonuria is nearly always pathological and should prompt consideration of branched chain amino acid disorders: propionic acidaemia, methylmalonic acidaemia, isovaleric acidaemia and maple syrup urine disease, as possible diagnoses. Urinary organic acids, blood acylcarnitine and amino acid analysis should be undertaken urgently to elucidate the underlying defect.

The detection of urine ketones, in addition to blood lactate and glucose measurement, provides the basis for the differential diagnosis of metabolic acidosis in the context of IMD (Box 24.2). Although diabetes mellitus is not an IMD, it is the most important diagnosis to consider when ketoacidosis is found associated with hyperglycaemia. In ketotic patients with hypoglycaemia, the gluconeogenic and glycolytic defects should be considered first. The most suggestive features in this group are hepatomegaly and lactic acidaemia, although neither is consistently present. If the ketosis is sustained, the rare ketolysis defects (succinyl-CoA:3-oxoacid-CoA

BOX 24.2 Differential diagnosis of metabolic acidosis

Acquired causes

- Circulatory failure (cardiac abnormalities, hypovolaemia, sepsis)
- Renal failure
- Hypoxaemia

Inherited causes

- Organic acidaemias
- Lactic acidaemias (see Box 24.1)
- Renal tubular acidosis
- Some amino acidaemias

transferase deficiency and 3-oxothiolase deficiency) should be considered, as these can be easily missed. Urine organic acid profiling followed by enzyme and mutation analysis will be needed to confirm a diagnosis of these rare conditions.

It will be apparent from Box 24.2 that the predominant causes of metabolic acidosis in IMDs are ketosis and lactic acidosis. Lactic acidosis is frequently present in the acutely ill, when circulatory collapse results in tissue hypoxia. It is also frequently associated with organic acid disorders, such as propionic acidaemia and methylmalonic aciduria, as a result of secondary interference with the metabolism of coenzyme A. Ketone analysis, again, provides clues to the differential diagnosis, since, although ketosis is a consistent finding in many IMDs, it is generally absent in lactic acidosis secondary to hypoxia. Secondary causes of lactate accumulation should be excluded before an inherited disease of lactate/pyruvate metabolism is sought.

Respiratory alkalosis is a far less frequent finding in IMDs and when it is present, plasma ammonia should be measured urgently. Ammonia stimulates the respiratory centre, causing hyperventilation, resulting in a decrease in $p\text{CO}_2$. The finding of acute encephalopathy with respiratory alkalosis should raise the suspicion of hyperammonaemia that, if confirmed, should prompt immediate investigations to exclude urea cycle disorders. In hyperammonaemia due to organic acid disorders, the acid–base disturbance is typically a metabolic acidosis.

Blood glucose

Hypoglycaemia is a presenting feature of many IMDs, such as those in which there is a primary block in glucose metabolism, for example glycogen storage diseases, or those in which glucose metabolism is affected secondarily, for example tyrosinaemia type I. Further investigations to identify the underlying cause should ideally be carried out when the child is hypoglycaemic. If this window of opportunity is missed, it is often difficult to make the diagnosis, since biochemical abnormalities may not be present during normoglycaemia; the child may then have to be subjected to a controlled fast with all the risks associated with this procedure. It is best practice for any hospital with a paediatric workload to

have an agreed protocol for the investigation of hypoglycaemia. This protocol should be instituted if a child has a laboratory blood glucose of <2.6 mmol/L (or point-of-care testing glucose <3 mmol/L). Best practice guidelines are available from the MetBioNet website: www.metbio.net

Plasma ammonia

It is essential to measure plasma ammonia in all children with acute or chronic encephalopathy, recurrent vomiting or hyperventilation. Suspicion of an IMD should be raised in an infant who is well at birth, with abnormal clinical features developing only after the first 24 h once feeds have been established. Clues may be gleaned from the family history: for example, where a background of early male deaths or females with episodic illness would suggest X-linked OTC deficiency.

Hyperammonaemia is often missed, particularly in the neonatal period, when the clinical presentation is non-specific and can mimic sepsis. All centres with neonatal and paediatric units should therefore be able to provide rapid analysis of plasma ammonia. Care should be taken in the sample handling, with ammonia-free tubes used for collection of blood and the separation of plasma from cells within 15 min.

Overwhelming hyperammonaemia in the neonatal period is usually due either to a urea cycle disorder (approximately 70%) or to an organic acid disorder (approximately 30%). The hyperammonaemia in organic acid disorders is a result of a deficiency in acetyl-CoA required for the synthesis of N-acetylglutamate, a preliminary step in urea synthesis. The finding of a metabolic acidosis in a patient with hyperammonaemia is suggestive of an organic acid disorder. Since the severity of hyperammonaemia does not allow a distinction between the causes, and treatment will differ depending on the underlying defect, rapid biochemical follow-up with second-line investigations is required. Analysis of urinary organic acids and orotic acid, in conjunction with plasma amino acids and acylcarnitines, is essential; results can usually be available the same day after discussion with the regional metabolic laboratory. [Figure 24.5](#) provides a flowchart for the investigation and diagnosis of neonatal hyperammonaemia.

In older children and adults, plasma ammonia should be measured in those with unexplained encephalopathy (progressive or chronic relapsing), vomiting or drowsiness, Reye-like syndrome (hyperammonaemia, hypoglycaemia and raised amino-transferases), neurological dysfunction or ataxia. Clinical illness is often episodic in the late onset group, presentation being associated with catabolism such as occurs during infections. If a complete dietary history is taken clues, such as self-selection of a low protein diet, may be revealed. In those patients with a Reye-like presentation, the possibility of a fatty acid oxidation disorder should be considered.

Liver function tests

Jaundice, accompanied by other features of liver dysfunction, is one of the most frequent presenting features of IMDs. This is not surprising, given the central role of

the liver in metabolism. Liver function tests are therefore essential first-line investigations in suspected IMDs. They should comprise measurement of bilirubin (total and conjugated), aminotransferases, alkaline phosphatase and the prothrombin time (or international normalized ratio).

Many IMDs present with liver failure, often in the neonatal period. The liver function test findings are characterized by a severe conjugated hyperbilirubinaemia and raised serum aminotransferases. The most striking of this group of disorders is classic galactosaemia (galactose 1-phosphate uridyl transferase deficiency), which typically presents after introduction of milk feeding. The principal IMDs causing neonatal liver disease are listed in [Box 24.3](#). This box does not include the inherited hyperbilirubinaemias, which are not associated with other features of hepatic dysfunction.

Measurement of ketones

Ketosis is a normal response to fasting and, when not associated with either acidosis or hypoglycaemia, should, in infancy and childhood, be considered as physiological. However, as previously mentioned, the presence of ketones in a neonate is abnormal and requires urgent follow-up. Although ketosis is a physiological response, it is likely to be of clinical significance when it is associated with acidosis. The detection of urine ketones, using a simple point-of-care testing device, is therefore the starting point for the investigation of metabolic acidosis (see [Box 24.2](#)).

The absence of ketones can also give a clue to the underlying IMD, the most classic example of which is hypoketonaemia with hypoglycaemia due to a fatty acid oxidation defect such as MCADD. Patients with this group of disorders are able to mobilize fat stores during periods of fasting or catabolic stress but, owing to enzyme deficiencies, are unable to oxidize the fatty acids completely, leading to a relative deficiency of acyl-CoA required for ketogenesis. Although classically considered to lead to a complete absence of ketone production, it is more common to see some ketones present but at an inappropriately low concentration. The presence of ketonuria in hypoglycaemia should therefore not preclude investigation for fatty acid oxidation defects.

Urinary reducing substances

The detection of reducing substances in the urine, using simple but non-specific tablets, has historically been a mainstay of first-line testing for IMD. The withdrawal from the market of Clinistest® (Bayer) in 2011 has prompted a review of this practice and a streamlining of investigations of disorders of monosaccharide metabolism. Thin layer chromatography (TLC) may be useful to identify sugars that are present, but may give a negative result in children with IMD in whom the abnormal pathway is not stressed, for example if an infant with classic galactosaemia has been placed on a lactose-free milk formula. There are also analytical concerns with using

Key investigations: confirm hyperammonaemia with free-flowing sample (arterial if necessary)
 venous blood gases
 amino acids (plasma)
 organic acids (urine)
 acylcarnitines
 liver function tests including clotting (to exclude liver failure)

sugar TLC, most notably a lack of a robust external quality assurance scheme and the reproducibility of results being highly operator dependent.

In the investigation of classic galactosaemia, where jaundice and liver dysfunction can rapidly deteriorate to hepatic failure, whole blood should be sent for urgent analysis of galactose 1-phosphate uridyl transferase activity. In older infants, with progressive liver dysfunction and hepatomegaly presenting after weaning, the diagnosis of hereditary fructose intolerance should be considered. Liver biopsy for aldolase activity and mutation analysis will be required for diagnosis.

Second-line investigations

Plasma and urinary amino acids

Amino acids are important intermediates in a number of metabolic pathways and are a significant source of energy, particularly during fasting. Their metabolism may involve potentially toxic intermediates that are normally further metabolized, but may accumulate in metabolic diseases involving amino acid metabolism and thus lead to organ damage. Amino acid analysis is therefore a key second-line investigation when an inherited metabolic disease is suspected (Box 24.4), and is frequently requested as part of a metabolic screen.

Individually, amino acid disorders are rare, with the most common (PKU) having an incidence of 1 in 10 000. However, the combined incidence of all disorders that can be diagnosed using amino acid analysis is in the order of 1 in 6000. As a group, they are heterogeneous, both in terms of clinical symptoms and age of presentation. The onset of symptoms may occur anywhere from the neonatal period to adulthood, but is classically associated with periods of protein catabolism, such as delayed feeding in a neonate, or intercurrent infections in an infant. Acute symptoms are associated with the accumulation of large amounts of amino acids that overwhelm a defective pathway, resulting in the production of toxic metabolites. There are certain presenting features in neonates, e.g. acute encephalopathy and ketosis, which should prompt consideration of amino acid analysis. However, the clinical presentation of many of these disorders is disease specific, e.g. gyrate atrophy in ornithine aminotransferase deficiency, and may warrant specific investigation. An understanding of the nuances of presentation in amino acid disorders is the key to making a diagnosis.

Amino acid disorders can be simply categorized as primary or renal disorders (Table 24.2). In primary disorders, there is a defective metabolic pathway with accumulation of specific amino acids or metabolites as a result of an enzyme deficiency. A classic example is maple syrup urine disease, caused by a deficiency in the enzyme branched chain oxoacid dehydrogenase, which leads to the accumulation of valine, leucine and isoleucine and the presence of the abnormal metabolite allo-isoleucine. In primary amino acid disorders, the most informative sample is plasma, giving a snap shot of the metabolic pathway. Urine is less useful in this group since the excretion of amino acids is much more variable

BOX 24.4 Indications for plasma or urine amino acid analysis

- Neonatal lethargy, coma, seizures or vomiting
- Hyperammonaemia
- Hypoglycaemia
- Ketosis
- Metabolic acidosis or lactic acidemia
- Metabolic decompensation or encephalopathy
- Unexplained liver disease
- Unexplained developmental delay
- Renal disorders, e.g. calculi, tubulopathy

TABLE 24.2 Renal amino acid disorders

Disorder	Urinary amino acid pattern
Cystinuria	Cystine, ornithine, arginine, lysine
Hartnup disease	Neutral amino aciduria
Lysinuric protein intolerance	Lysine, ornithine, arginine
Iminoglycinuria	Proline, hydroxyproline, glycine

(especially in prematurity) and is significantly prone to interference from medication. Urine is, however, essential for the diagnosis of renal amino acid disorders such as cystinuria. In this group, amino acid metabolism is intact, but renal tubular reabsorption of specific amino acids is defective. The abnormal pattern is therefore only observed in urine.

It is important to be aware of the type of investigation undertaken when amino acid analysis is requested. Simple urine 'spot tests', such as the cyanide-nitroprusside test for cystine and homocystine, are often employed by local hospitals as a preliminary to referral to a specialist centre. These simple assays are becoming increasingly obsolete and are limited by a lack of sensitivity and specificity and should not be used in isolation. Other screening techniques may be employed, such as thin layer chromatography, but again are limited in the detection of anything but gross abnormalities: some disorders, particularly those with mild biochemical changes, may be missed by these methods. If these qualitative techniques are employed, their limitations must be understood, and conveyed to the requesting clinician, so that diagnoses are not missed.

Amino acids are best analysed using quantitative techniques such as ion exchange chromatography. These methods are sufficiently sensitive to detect the newly recognized amino acid disorders characterized by low concentrations of amino acids, such as 3-phosphoglycerate dehydrogenase deficiency, a disorder of serine synthesis.

Ion exchange chromatography is most suited to 'routine' analysis, but is limited by the long analysis time in the acute situation. To complement the approach, rapid tandem mass spectrometry (TMS), with analysis of a targeted list of amino acids and other metabolites (see section on acylcarnitines below), allows a diagnosis to be made swiftly and treatment to be instituted in an acutely sick child. Combining rapid targeted TMS testing in the acute situation, with a routine approach that clearly states which disorders are excluded, may provide a balanced solution to the provision of amino acid analysis.

Urinary organic acids

Urine organic acid profiling is an important second-line investigation in which up to 150 different IMDs can be identified from a single analysis. Organic acid analysis can identify intermediary metabolites from most amino acid, carbohydrate, purine and pyrimidine, neurotransmitter, cholesterol and fatty acid pathways,

making it a powerful investigative tool. Using organic acid analysis, metabolic disorders can be identified by the presence of pathological concentrations of normal metabolites, for example fumaric acid in fumarase deficiency, or the presence of pathological (and in some cases pathognomic) metabolites such as succinylacetone in tyrosinaemia type I. Most laboratories use gas chromatography-mass spectrometry (GCMS) to undertake organic acid analysis, providing a qualitative interpretation of the profile. However, the use of quantitative analysis by stable isotope dilution should be considered when small concentrations of critical metabolites may lead to a diagnosis.

Many disorders can be detected by organic acid analysis regardless of whether the sample is collected when the child is acutely ill or not. However, some IMDs are clearly identifiable only during episodes of acute decompensation. Medium chain acyl-CoA dehydrogenase deficiency is one such disorder where the classic pattern of a medium chain dicarboxylic aciduria (adipic, suberic and sebacic acids), with an inappropriately low excretion of ketones in the presence of the pathognomic metabolite hexanoylglycine, may only be apparent when the child is acutely unwell. Samples collected during episodes of acute decompensation are therefore vital for investigation of IMDs. The indications for urinary organic acid analysis are summarized in [Box 24.5](#).

Urinary orotic acid

Increased urinary excretion of orotic acid is a feature of four IMDs involving the urea cycle (ornithine transcarbamoylase deficiency, citrullinaemia, argininosuccinic aciduria and argininaemia) (see [Fig. 24.1](#)) and is helpful in their diagnosis. There are a number of analytical techniques that can be used for identification of this key metabolite, for example GCMS or TMS, and it is often required as part of the rapid investigation of a sick infant.

Blood acylcarnitines

With the advent of TMS technology, acylcarnitine profiling has become a crucial investigation in the field of IMDs. The use of TMS for acylcarnitine profiling, combined with simultaneous analysis of other intermediary metabolites, enables the diagnosis of many of the treatable amino acid, organic acid, fatty acid oxidation

and urea cycle disorders. In a clinical emergency, if one of these disorders is considered, then discussion with a specialist metabolic service to arrange urgent analysis should be a priority.

Acylcarnitine profiling allows the quantitation of saturated and unsaturated acylcarnitine species required for the diagnosis of a number of IMDs. In addition, the determination of both free and total carnitine (i.e. overall carnitine status) is required for the investigation of suspected carnitine transporter defects. Typically, acylcarnitine analysis is undertaken on plasma or blood spot samples, with only a small sample usually being necessary. Bile samples, collected post-mortem, on to newborn screening cards, can be used if the suspicion of IMD is raised at autopsy.

It should be noted that some conditions can only be diagnosed confidently with the use of acylcarnitine profiling: an example is VLCADD. Acylcarnitine analysis should therefore be undertaken if a fatty acid oxidation defect is suspected; these disorders typically present with hypoketotic hypoglycaemia, but may be associated with cardiomyopathy, rhabdomyolysis or hepatomegaly. In a pregnant woman with AFLP or HELLP syndrome, the possibility of LCHADD in her infant should be considered. Rapid acylcarnitine profiling is required for the newborn infant of a mother with a history of either condition.

Blood lactate and pyruvate

Lactate and pyruvate are important intermediaries in a number of metabolic pathways, particularly in the production of ATP under anaerobic conditions. It is therefore not surprising that assessment of these pathways, by analysis of blood lactate, is an essential measurement in the investigation of a suspected IMD. In the absence of tissue hypoxia, and assuming the sample was collected properly, using an appropriate antiglycolytic agent, a blood lactate of >3 mmol/L should be considered abnormal and further investigations for an IMD initiated.

Lactic acidemia is found in many groups of IMDs (see [Box 24.1](#)) and may lead to a metabolic acidosis when the lactate concentration exceeds 5 mmol/L. It is a frequent finding in organic acidemias, urea cycle disorders and fatty acid oxidation disorders, as a result of secondary interference with the metabolism of coenzyme A, and is often accompanied by ketosis. These groups of IMDs can be rapidly distinguished with follow-up investigations such as organic acid, amino acid and acylcarnitine analysis.

The primary lactic acidemias, for example defects in pyruvate metabolism or respiratory chain function, often present with severe metabolic acidosis in the neonatal period. A distinguishing feature of this group, as opposed to the secondary IMD groups noted above, is that the clinical picture is unrelated to intake of protein. In the primary lactic acidemias, analysis of both blood lactate and pyruvate, calculation of the lactate:pyruvate (L:P) ratio and measurement of cerebrospinal fluid (CSF) lactate are of assistance in directing further investigations. It must be noted that pyruvate is

BOX 24.5 Indications for urinary organic acid analysis

- Unexplained metabolic acidosis
- Hypoglycaemia
- Ketonuria (urgent in newborn)
- Lactic acidosis
- Hyperammonaemia
- Encephalopathy
- Unexplained neurological disorder
- Multisystem failure
- Hepatic dysfunction

an extremely unstable analyte and needs careful sample handling with immediate precipitation of whole blood. However, if accurate measurement of lactate and pyruvate is undertaken, the L:P ratio can give valuable insight into the cytoplasmic redox status. An elevated L:P ratio (>25) is suggestive of a respiratory chain defect or pyruvate carboxylase deficiency, with a normal ratio (<25) suggesting a disorder of gluconeogenesis or pyruvate dehydrogenase deficiency.

Further information can be gained from assessing plasma lactate concentrations in relation to the fed and fasted states. This is of particular use in the investigation of glycogen storage disorders (GSDs). Lactic acidemia in the fasted state is a key finding in GSD type I (glucose 6-phosphatase deficiency), in contrast to GSD type III (amylo-1,6-glucosidase deficiency), in which the increase in lactate is most noticeable after feeding. In investigating these conditions, it is important that samples are collected both pre- and postprandially so that lactic acidemia is not missed. It is for this reason that lactate is a key measurement in many diagnostic fasts and 24h metabolite profiles (see below).

Urinary glycosaminoglycans

The mucopolysaccharidoses are a group of lysosomal storage disorders characterized biochemically by the accumulation of glycosaminoglycans (GAGs) in the urine. Clinically, they present with coarsening of the facies, in conjunction with features including skeletal abnormalities, hepatosplenomegaly and hearing loss. The majority of these features are not present at birth but develop progressively with age. If this group of disorders is suspected, a random urine sample should be collected for analysis of GAGs. In the first instance, quantitative analysis is usually undertaken with interpretation against age-related reference ranges. This is then followed-up by electrophoresis to identify the individual GAGs from the typical patterns characteristic of each disorder (see Table 24.3). Definitive diagnosis is by enzyme analysis.

Plasma very long chain fatty acids

Very long chain fatty acids, with carbon chain length ≥ 22 , are exclusively metabolized by β -oxidation in peroxisomes. The analysis of plasma VLCFAs is therefore an

important second-line investigation in suspected peroxisomal disorders. These are a genetically heterogeneous group but, in disorders both of peroxisomal biogenesis (such as Zellweger syndrome), and single peroxisomal protein defects (the most common of which is X-linked ALD), β -oxidation is impaired, leading to the accumulation of saturated VLCFAs. The finding of an elevated ratio of C26:C22 fatty acids is a clear indication of peroxisomal dysfunction. However, it should be noted that although analysis of VLCFAs identifies the presence of a peroxisomal disorder, results should be viewed in conjunction with the clinical findings, imaging and further laboratory analysis, such as erythrocyte plasmalogen, bile acid intermediates and pristanic acid to enable a precise diagnosis.

Functional and loading tests

The aim of functional or loading tests is to unmask IMDs that may be difficult to diagnose by conventional techniques. They are most often used in situations where metabolic findings are not clearly abnormal and the diagnosis is uncertain, for example many of the fatty acid oxidation disorders, where biochemical findings may be subtle, or absent, when the patient is well. If the window of opportunity to collect samples when the patient is hypoglycaemic or acutely unwell is missed, then a controlled diagnostic fast may be carried out to aid the diagnosis.

Diagnostic fast

During a diagnostic fast, blood samples are collected hourly. Investigations should include markers of intermediary metabolism (non-esterified fatty acids, hydroxybutyrate and lactate), acylcarnitines and counter-regulatory hormones (insulin, growth hormone and cortisol). Urine organic acids and blood acylcarnitine should be measured at the beginning and end of the fast. The blood glucose concentration is monitored using a point-of-care testing device appropriate for the detection of hypoglycaemia; such results must be confirmed in the laboratory. Given the risks associated with this procedure, diagnostic fasts must be performed under medical supervision in a specialist unit. In addition to providing valuable diagnostic information, a fast allows the determination of the

TABLE 24.3 Mucopolysaccharidoses

Type	Disorder	Urinary glycosaminoglycan	Enzyme deficiency
I	Hurler	Dermatan sulphate, heparan sulphate	α -Iduronidase
II	Hunter	Dermatan sulphate, heparan sulphate	Iduronate sulphatase
IIIA	Sanfilippo A	Heparan sulphate	Heparin sulphamidase
IIIB	Sanfilippo B	Heparan sulphate	N-acetyl- α -glucosaminidase
IIIC	Sanfilippo C	Heparan sulphate	N-acetyltransferase
IIID	Sanfilippo D	Heparan sulphate	N-acetylglucosamine sulphatase
IVA	Morquio A	Keratan sulphate	N-acetylgalactosamine 6-sulphatase
IVB	Morquio B	Keratan sulphate	β -Galactosidase
VI	Maroteaux-Lamy	Dermatan sulphate	N-acetylgalactosamine 4-sulphatase
VII	Sly	Dermatan sulphate, heparan sulphate, chondroitin sulphate	β -Glucuronidase

maximum safe fasting period before the onset of hypoglycaemia, and is often undertaken on a yearly basis in patients with glycogen storage disease.

Allopurinol loading test

Loading tests can be used to expose an enzyme defect, where there is residual activity. The allopurinol test can be used in this way to confirm heterozygote status in female carriers of OTC deficiency. Urine is collected for measurement of orotidine and orotic acid, before and after administration of a dose of allopurinol. Although this is a safe and noninvasive approach, not all at-risk females will be detected. This strategy, although still in use, is now being superseded by the use of mutation analysis.

Confirmatory investigations

Enzyme analysis: general principles

Final confirmation of the diagnosis of a suspected IMD often requires enzyme analysis. In some cases, confirmatory testing is not undertaken, because the diagnosis can be inferred from a typical clinical history and a characteristic pattern of abnormal metabolites. In conditions such as PKU, the use of an invasive procedure, such as liver biopsy, to obtain tissue for enzyme analysis would not contribute further to the management of the patient. However, the majority of patients with a suspected IMD will have enzyme analysis to confirm the diagnosis.

Enzyme analysis can be undertaken in various tissue types, ranging from blood cells to liver and muscle samples, obtained by biopsy. It is of particular importance that for IMDs that are tissue specific, an appropriate specimen is used, e.g. liver biopsy samples in the urea cycle disorders and muscle or liver in the glycogen storage disorders that are either muscle or liver specific. If a patient with a suspected IMD is not expected to survive, plasma, urine, skin and, if possible, muscle and liver biopsies should be collected. Skin biopsies are of particular use since fibroblast cultures can be established and DNA harvested if required.

Red cell galactose 1-phosphate uridylyltransferase. Classic galactosaemia, due to a deficiency in the enzyme galactose 1-phosphate uridylyltransferase (Gal-1-PUT or GALT), leads to the accumulation of galactose and other toxic metabolites on introduction of lactose into the diet. In the past, testing for urine reducing substances provided an easily available screening test for galactosaemia. Now, clinical suspicion should be urgently followed-up with confirmatory testing of red cell GALT activity. The requesting clinician must state clearly the transfusion status of the child, since previous blood transfusion will invalidate the result. If a child has been transfused, it may be possible to infer the diagnosis by analysing parental blood and demonstrating that they are heterozygotes.

Lysosomal enzyme screening. The lysosomal storage disorders are a group of approximately 40 different

BOX 24.6 Clinical and laboratory features suggestive of a possible lysosomal storage disorder

- Neonatal ascites

IMDs characterized by the accumulation of macromolecules in lysosomes, as a result of specific enzyme or protein transporter defects. The accumulated material results in an increase in the size and number of these organelles, leading to cellular dysfunction and subsequent pathological features. The lysosomal storage disorders are generally classified on the basis of the accumulated material, for example sphingolipidoses, mucopolysaccharidoses and mucopolysaccharidoses. These conditions typically present in a chronic and progressive manner, in many cases with neurological degeneration. The principal clinical features are summarized in [Box 24.6](#).

Diagnosis of this group of disorders is often difficult, as there is an overlap in the clinical presentation of each disease. A 'screening' approach is, therefore, adopted by specialist laboratories: this ensures the maximum possibility of making a diagnosis. Groups of lysosomal enzymes in plasma and leukocytes are analysed depending on the clinical features, for example whether the patient has neurodegeneration or the presence or absence of hepatosplenomegaly. The choice of enzymes is tailored to exclude the majority of lysosomal storage disorders. This approach requires good communication between the local hospital and specialist enzyme laboratory so that a systematic approach to the investigation is undertaken.

Complementation studies

Although in the vast majority of IMDs the enzyme deficiency is well characterized, there are still a number of disorders in which the protein or gene defect has not been identified. In these conditions, such as those that lead to decreased synthesis of adenosylcobalamin and the clinical features of cobalamin-responsive methylmalonic aciduria (classified as Cbl_a and Cbl_b), a different approach to confirm the diagnosis may be taken. To distinguish these different groups, complementation studies can be undertaken in cultured fibroblasts. The principle of the investigation is to compare the incorporation of a marker substance, in this case propionate, in parallel fused and unfused cell cultures. The classification of the patient in this way is of use in assessing the possible prognosis and excluding disease in other family members. However, it is likely that this approach will be superseded once the enzyme or gene locus is identified.

Genetic mutation analysis

Mutation analysis is playing an increasingly important role in the diagnosis of IMDs. The use of next generation sequencing has enabled a rapid and more cost-effective approach and is becoming a mainstay of diagnostic pathways.

Mutation analysis has many benefits in the diagnosis of IMDs. It is of particular use in prenatal diagnosis, where mutation analysis in chorionic villus samples (CVS) can be performed much earlier than enzyme diagnosis in cultured amniocytes. Once the mutation has been defined in the proband, testing of family members may overcome the need for invasive sampling, such as liver biopsies or functional tests that may give ambiguous results.

Where mutations are classified and the genotype/phenotype correlation is well recognized, this may provide useful information regarding prognosis and possible treatment options. In some disorders, such as MCADD, a common disease-causing mutation (A985G) is present in many cases, allowing the use of mutation analysis to secure the diagnosis. The approach of combining metabolite assays with mutation analysis confirms the diagnosis rapidly and may obviate the need for fibroblast culture. Problems may arise, however, when compound heterozygotes are identified: in these instances it might not be clear what the clinical outcome of a combination of potentially less severe mutations would be.

PRENATAL DIAGNOSIS

The availability of prenatal diagnosis gives a number of options to a family in whom a serious genetic disorder is suspected. In the field of IMDs, prenatal diagnosis is often requested if a previously affected child has a poor prognosis, particularly where the options for treatment are limited. Inherited metabolic diseases are generally diagnosed prenatally using either enzyme analysis in cultured amniocytes or mutation analysis in CVS.

Amniocentesis, undertaken in either the first or second trimester, provides fetal amniocytes for culture. Enzyme analysis can be undertaken in these cultures and the activity compared with appropriate reference ranges

to confirm the diagnosis. The limitation of this approach is the time scale: amniocyte culture typically takes 4–6 weeks to establish, leading to additional anxiety for the family and limited time for decision-making. Since only a small number of analyses are undertaken each year, prenatal diagnosis of IMDs using these techniques is undertaken at only a few specialized centres.

Chorionic villus sampling is generally undertaken at 9–12 weeks of gestation, providing the opportunity for earlier diagnosis and giving additional time for counselling and safer termination, if this option is chosen. In this technique, fetal villus cells obtained by amnioscopy are dissected from the maternal decidual tissue, and DNA extracted and used for mutation analysis. Adherence to strict techniques is paramount, to avoid maternal cell contamination that may result in diagnostic ambiguity.

MANAGEMENT

Many treatment modalities are adopted to manage IMDs, dependent on whether pathology results from deficiency of the product, the build up of a toxic metabolite or a combination of the two. At present, most treatments remain symptomatic rather than curative.

Strategies to replace a missing product

Supply of precursor

Enzymes catalyse reactions that would proceed at a much reduced rate in their absence. Provision of large doses of precursor can shift the reaction in the direction of making the product by a mass action effect: in some cases this is sufficient to ameliorate symptoms.

Hydroxycobalamin is converted in the body via a number of intracellular conversions from its dietary hydroxycobalamin form to its two active forms, adenosylcobalamin and methylcobalamin. In the cobalamin disorders, blocks in these conversions lead to accumulation of homocysteine, methylmalonate or both, dependent on the position of the block (Fig. 24.6). Cobalamin C disorder is the commonest of these rare IMDs. Patients present in the neonatal period and first year with neurological deterioration, poor feeding and hypotonia, and often develop

FIGURE 24.6 ■ Cobalamin metabolism.

seizures. Anaemia is common, as is multiorgan involvement including the kidneys, liver and heart. The diagnosis is suggested by elevated plasma homocysteine and urinary methylmalonate concentrations, in the absence of hydroxycobalamin deficiency. Diagnosis is confirmed by fibroblast incorporation studies and decreased synthesis of adenosyl- and methylcobalamin. Treatment with regular intramuscular hydroxycobalamin leads to a marked reduction in homocysteine and methylmalonate, but not complete biochemical normalization. Clinical improvement is limited even in prospectively treated affected siblings.

Replacement of product

Replacement of the deficient product of a blocked pathway is another solution to the treatment of some IMDs: it effectively bypasses the block. Its efficacy depends on the product being available and its potential to be given in a form that can be taken by the patient and then reach its site of action in a usable form.

Such an approach is used in the congenital disorder of glycosylation (CDG) Ib (phosphomannose isomerase deficiency). Glycosylation is an essential process in the body, as almost all proteins that are secreted or membrane bound are dependent on their glycans (carbohydrate side chains) for normal activity. The production of glycoproteins begins with the manufacture of the oligosaccharide precursor and its transfer to the nascent polypeptide chain in the endoplasmic reticulum, with subsequent modification within the Golgi apparatus to produce the desired glycan. Defects of the pathway were first established when examining transferrin, which has two glycans with four sialic acid residues. Defective glycosylation results in variation in the number of sialic acid residues, which affects the charge on the protein. This can be detected using isoelectric focusing, which shows additional bands. Children with CDG Ib present with recurrent vomiting and diarrhoea, coagulopathy, protein-losing enteropathy, hypoalbuminaemia, delayed growth and hyperinsulinaemic hypoglycaemia. Liver fibrosis has also been noted. Treatment with oral mannose effectively bypasses the block by replacing the missing product (Fig. 24.7). Clinically, there is a reduction in diarrhoea and vomiting with improved growth. Biochemically, the isoelectric focusing pattern normalizes

FIGURE 24.7 ■ Mannose therapy for CDG Ib (phosphomannose isomerase deficiency). Mannose is phosphorylated by hexokinase to mannose 6-phosphate, thereby bypassing the block. GDP, guanosine 5'-diphosphate; P, phosphate.

as glycan production beyond the block is normal. Plasma concentrations of antithrombin III, the cause of the coagulopathy, also return to normal.

In dihydropteridine reductase deficiency, there is decreased recycling of biopterin, the essential cofactor for phenylalanine hydroxylase, the enzyme responsible for the conversion of phenylalanine into tyrosine, with resultant phenylketonuria. In addition, biopterin is the essential cofactor for two other hydroxylases in the body, namely tyrosine and tryptophan hydroxylases, required for the production of L-DOPA and 5-hydroxytryptophan (5-HT), respectively. These are, in turn, converted to dopamine and serotonin, which are two of the major neurotransmitters in the brain. Dihydropteridine reductase deficiency was originally termed malignant PKU, as following the introduction of the PKU screening in the 1970s it became apparent that there were very rare patients who still went on to have marked developmental delay and characteristic axial hypotonia and limb dystonia, in spite of excellent phenylalanine control by diet. Now, all neonates with hyperphenylalaninaemia detected on newborn screening are screened for biopterin defects, usually performed on dried blood spots by measuring total biopterins. Dihydropteridine reductase deficiency is managed with a phenylalanine restricted diet and supplementation with 5-HT and L-DOPA. The latter is given in combination with carbidopa in the ratio 4:1. Carbidopa is a peripheral decarboxylase inhibitor, which reduces peripheral conversion of L-DOPA to dopamine, thereby increasing the amount of L-DOPA reaching the brain and reducing side-effects, which include nausea, vomiting, postural hypertension, dystonic reactions and psychological disturbance. Dose increments should be small, as initially patients are very sensitive to the effect of the treatment owing to upregulation of receptors. Dosage requirements are monitored clinically and by measuring the breakdown products of dopamine and serotonin, namely homovanillic acid (HVA) and 5-hydroxyindoleacetic acid (5-HIAA), in the CSF. A slightly greater dose of L-DOPA is given compared with 5-HT, to mimic the naturally slightly higher amounts within the brain. In addition, folinic acid is required to combat the associated central folate deficiency seen in this condition.

Replacement of the missing product is also used in pyridoxal phosphate-dependent seizures in pyridoxamine 5-phosphate oxidase deficiency. Pyridoxal phosphate is the active form of pyridoxine, required for a number of essential reactions in the body and particularly in the brain. Pyridoxamine 5-phosphate oxidase deficiency presents with devastating neonatal seizures, which can be effectively treated by giving pyridoxal phosphate orally. The cessation of seizures is immediate and dramatic but associated with transient hypotonia and apnoea. Treatment should therefore be initiated with full resuscitation facilities available.

Replacement of the missing product in utero has been successful in 3-phosphoglycerate dehydrogenase deficiency, a serine biosynthesis disorder, characterized by congenital microcephaly, severe psychomotor retardation and intractable seizures. The treatment of affected children with oral L-serine has proved effective in preventing the seizures: however, development is not normalized and

the congenital microcephaly suggests impaired fetal brain growth in utero. It has now been shown that giving L-serine to the mother during pregnancy can reverse the decrease in fetal head growth in utero with resultant normal neurological development. The key diagnostic investigation for this condition is analysis of serine concentration in CSF.

Synthetic analogues

It may not be possible to replace the product directly, owing to difficulties with absorption and denaturation when exposed to the acidity of the stomach and digestive enzymes. Synthetic analogues of the missing product are, however, used in some circumstances. N-acetylglutamate synthetase (NAGS) deficiency is a rare urea cycle defect that may present with devastating hyperammonaemic crises. N-acetylglutamate is an essential activator for carbamoylphosphate synthetase, the second enzyme in the urea cycle pathway (see Fig. 24.1). Carbamylglutamate, a synthetic analogue of N-acetylglutamate, is an effective treatment for NAGS deficiency. It allows activation of carbamoylphosphate synthetase, in the absence of a working NAGS enzyme, reducing the risk of hyperammonaemia and improving neurological outcome. In organic acidaemias, hyperammonaemia can occur as a result of secondary inhibition of NAGS; carbamylglutamate is used in their management.

Receptor agonists can be used where the site of action of a deficient product is a receptor. Aromatic amino acid decarboxylase (AADC) converts 5-HT into serotonin and L-DOPA into dopamine. Clinical features of AADC deficiency include intermittent oculogyric crises, limb dystonia, generalized hypotonia, developmental delay and autonomic dysfunction. The diagnosis is indicated by low concentrations of the neurotransmitter breakdown products, HVA and 5-HIAA, in CSF. Dopamine receptor agonists, such as pramipexole and rotigotine, are being used to reduce the frequency of crises, and also improve voluntary movements, but the benefits have so far been variable.

Alternate product

A further strategy employed in the treatment of IMDs is to use an alternate product to bypass the block. The classic example is the use of a ketogenic diet in deficiency of glucose transporter type 1 (GLUT1), a membrane transporter that transports glucose across the blood–brain barrier: a defective protein results in hypoglycaemia in the brain, with a normal plasma glucose concentration. Presentation is in infancy with epilepsy, global developmental delay and complex movement disorders. Diagnosis requires the simultaneous measurement of glucose in the plasma and CSF which reveals a decreased CSF:plasma glucose ratio. Although glucose is the preferred fuel for the brain, ketones may be used for energy and gain entry to the brain via the monocarboxylate cotransporter (MCT1) transporter, thus avoiding the block (Fig. 24.8). The ketogenic diet promotes ketogenesis by restricting carbohydrate (typically a 4:1 ratio of fat to combined protein and carbohydrate), with clinical improvement in seizure control, development and movements. The condition tends to stabilize after puberty, but the degree of residual impairment is highly variable.

FIGURE 24.8 ■ Providing alternate fuel utilizing ketones in the management of GLUT1 deficiency and pyruvate dehydrogenase deficiency. PDH, pyruvate dehydrogenase; GLUT1, glucose transporter protein 1; MCT1, monocarboxylate transporter 1; TCA cycle, transcarboxylic acid cycle.

Ketogenic diets are similarly used in pyruvate dehydrogenase deficiency, bypassing glycolysis.

Inhibition of product breakdown

Enzyme blocks in IMDs are not usually complete, and usually some product is made. Preventing or delaying breakdown of the product can have useful therapeutic effects. In AADC deficiency described above, a combination of a dopamine agonist and a monoamine oxidase inhibitor, such as tranlycypromine, can be used in combination. The latter prevents the natural breakdown of dopamine and serotonin and therefore boosts their concentrations. This has the positive effect of reducing the frequency of oculogyric crises and improving muscular tone.

Enzyme replacement therapy

Replacement of the missing enzyme is an obvious potential solution to the management of IMDs, but many obstacles have to be overcome, including production, purification and targeting of the enzyme. Access to the CNS across the blood–brain barrier remains a technical challenge. Nearly 40 years ago, it was noted that coculture of fibroblasts from Hurler and Hunter syndrome patients mutually corrected the defects in vitro, suggesting the existence of a diffusible substance that could correct the block. Twenty years later, the first enzyme replacement therapy (ERT) became commercially available. Gaucher disease (glucocerebrosidase deficiency) has been the forerunner of the ever expanding number of conditions considered for ERT. Storage of glucocerebrosidase occurs in liver, spleen and bone, and, in two out of the three forms, brain. Type 1 is the most common, presenting with hepatosplenomegaly, anaemia, lung infiltration and bony changes: the brain is not involved. Type 1 is prevalent in the Ashkenazi Jewish population. Type 2 is rapidly progressive with severe neurological involvement and hepatosplenomegaly. Type 3 has brain involvement, but a much milder course. Inheritance of all three forms is autosomal recessive. The diagnosis is made by measuring the glucocerebrosidase activity in leukocytes.

The absence of brain involvement in type 1 made it an obvious target for ERT as the enzyme does not cross the blood–brain barrier. The enzyme used is a recombinant modified human placental glucocerebrosidase, with an exposed mannose terminus to enhance lysosomal targeting, following uptake by macrophages. Uptake of glycoproteins is mediated via carbohydrate-specific receptors, which are present on macrophages. Enzyme replacement therapy has revolutionized the management of type 1 Gaucher disease, with improvement in haematological parameters, regression of organomegaly and reduction in bone pain. The enzyme is given fortnightly as an intravenous infusion, initially in hospital, but later at home, utilizing a home-care nursing team. Some individuals produce antibodies to the enzyme protein, but therapy can usually continue.

Fabry disease (α -galactosidase deficiency) is another condition for which ERT has been developed. Previously, treatment was supportive, including dialysis and the use of analgesics. Enzyme replacement therapy is effective in reducing plasma glycosphingolipid concentrations, preserving renal function, improving cardiac conduction and reducing pain.

Replacement enzymes have been developed for other lysosomal storage disorders, including: Hurler syndrome (α -iduronidase deficiency); Hunter syndrome (iduronate-2-sulphatase deficiency); Morquio syndrome Type A (N-acetylgalactosamine-6-sulfatase deficiency); Maroteaux Lamy syndrome (N-acetylgalactosamine-4-sulfatase deficiency); Pompe disease (acid maltase deficiency), and Wolman disease (lysosomal acid lipase deficiency). At present, relatively small numbers of patients have been treated, for relatively short time periods. It is hoped that early treatment will prevent storage occurring and therefore give optimal outcomes, but, for those conditions with neurological involvement, the lack of brain penetrance remains a concern.

Cofactor supplementation

Many enzymes have vitamin cofactors that are essential for normal function. Cofactor supplementation may increase residual enzyme activity in deficient patients. Although the absolute response may be quite small, because clinical features often only develop at extremely low levels of enzyme activity (<5%), even a small increase (e.g. by 1% of normal activity) may prove to be clinically significant.

Patients may have sensitive deficiencies that are totally correctable by giving the enzyme cofactor. Some conditions can be characterized by their response to cofactor supplementation. An example is homocystinuria (cystathionine β -synthase deficiency), which is classified as being either pyridoxine responsive or pyridoxine unresponsive. In patients who respond to pyridoxine, there is a reduction in fasting plasma homocysteine concentration and characteristic hypermethioninaemia, on pyridoxine supplementation. A pyridoxine challenge should therefore be undertaken in all new patients, with measurements of plasma homocysteine and methionine concentrations before, during and after supplementation. Some patients have a partial response to pyridoxine.

Once a diagnosis has been established, cofactors are routinely given in a number of IMDs, to assess whether any clinical benefit can be gained by supplementation (Table 24.4).

TABLE 24.4 Vitamin cofactors, supplementation of which may be beneficial in inherited metabolic disorders

Cofactor	Disorder
Ascorbic acid	Tyrosinaemia type III Transient tyrosinaemia of the newborn Glutathione synthase deficiency Congenital lactic acidosis
Biotin	Biotinidase deficiency Multiple carboxylase deficiency Propionic acidaemia Pyruvate carboxylase deficiency
Biopterin	Phenylalanine hydroxylase deficiency
Cobalamin	Methylmalonic aciduria
Folate (given as folic acid)	Dihydropteridine reductase deficiency Uridine monophosphate synthase deficiency Methylene tetrahydrofolate reductase deficiency Methionine synthase deficiency Primary hyperoxaluria type 1
Pyridoxine	Homocystinuria (cystathionine β -synthase deficiency) Ornithine aminotransferase deficiency Pyridoxine-responsive seizures
Pyridoxal phosphate	Pyridox(am)ine 5'-phosphate oxidase deficiency
Riboflavin	Glutaric aciduria type I Multiple acyl-CoA dehydrogenase deficiency
Thiamin	Congenital lactic acidosis Congenital lactic acidosis Maple syrup urine disease Pyruvate dehydrogenase deficiency
Tocopherol	Glutathione synthetase deficiency
Ubiquinone	Mitochondrial disorders

Organ transplantation

Purified enzymes for replacement therapy are available for only a very small number of IMDs. A more crude form of enzyme replacement is whole organ transplantation. This most frequently involves the liver, as this is the principal site of many metabolic pathways, for example the urea cycle. It is important to examine whether there are significant extrahepatic manifestations of the disorder for which transplantation is being considered. If there is significant enzyme expression in other tissues, then it may be that liver transplantation, although improving hepatic enzyme function, will not counteract these other harmful effects. This importance of extrahepatic morbidity is demonstrated by methylmalonic acidaemia, where liver transplantation fails to protect the patient from further neurological decompensation. In contrast, the risk of metabolic stroke post liver transplantation in propionic acidaemia appears much lower, even though the enzyme deficiencies affect the same catabolic pathway (see Fig. 24.9). Correcting the defect in the liver abolishes metabolic decompensation, thereby permitting a free diet. Cerebrospinal fluid propionate concentrations do not completely normalize and therefore it has been suggested that relaxing the diet post transplant, but continuing modest protein restriction, may abolish the risk of further neurological sequelae.

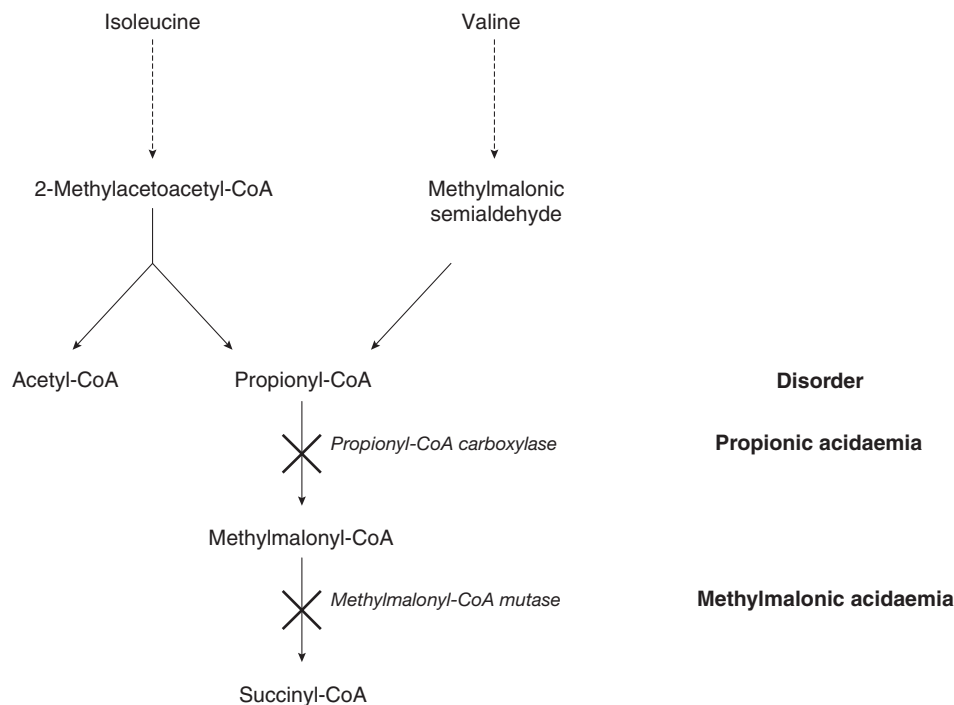

FIGURE 24.9 ■ Isoleucine and valine metabolism, showing the position of enzyme blocks in propionic acidaemia and methylmalonic acidaemia.

Liver transplantation can also be used in urea cycle defects, but the decision as to whether to transplant depends on the severity of the defect, the extent of pre-existing damage from previous hyperammonaemic crises and the future risk of longer term complications of the disease. The survival rate for liver transplantation has improved dramatically and, in children, is quoted as being >95% at five years. However, after transplantation, patients will require lifelong immunosuppressant therapy to prevent organ rejection, which increases the chance of significant sepsis and the development of lymphoproliferative disease. The use of partial liver transplantation, that is, transplanting a donor lobe without removing the native liver, has the added advantage of correcting the metabolic defect (100% liver activity is not required for normal function), while leaving the native liver (which is otherwise healthy) in situ. A partial liver transplant also has the potential, if gene therapy becomes standard practice, to allow the anti-rejection drugs to be stopped and the transplanted lobe to be rejected.

An alternative to transplantation of a whole liver, or a lobe of a liver, is hepatocyte transplantation. Neonates who present with OTC deficiency have a very poor prognosis. Mortality is extremely high and, even in prospectively treated patients (including those receiving a liver transplant in the first six months of life), neurological damage remains common. Hepatocyte transplantation has been used as a bridge to organ transplantation. Donor hepatocytes are infused into the hepatic circulation to seed in the native liver. Some of these cells engraft and replicate, thus increasing enzyme activity within the liver. This technique has been used to stabilize babies, and to avoid hyperammonaemic crises, before liver transplantation, which is usually carried out at about six months of age. Neurological outcome has been good. It is hoped that further refinement

of this technique may allow longer lasting effects that would obviate the requirement for later surgical transplantation. Conditions in which there is liver destruction are likely to benefit the most, as this provides a stimulus for hepatic regeneration to which the transfused hepatocytes respond. Hepatocyte transplantation would be appropriate for several inherited disorders including Crigler–Najjar syndrome, glycogen storage disease type Ia and infantile Refsum disease. Immunosuppression is still required, but, as with auxiliary liver transplantation, there is the potential for withdrawing immunosuppressants when gene therapy becomes feasible, as the native liver remains in situ. A further advantage of hepatocyte transplantation is that livers that might otherwise be considered unsuitable for liver transplantation can be used as a source of healthy hepatocytes, as can redundant liver lobes following the transplant of livers from adults into children.

Bone marrow transplantation has been used in a number of lysosomal disorders, fundamentally changing the natural history of these conditions. Bone marrow transplantation has an advantage over ERT, in that a small number of stem cells do pass beyond the blood–brain barrier and therefore have the ability to improve neurological outcome. Bone marrow transplantation has been attempted in nearly all lysosomal disorders, but has proven ineffective in some, particularly those in which there is severe rapid neurodegeneration, such as San Filippo syndrome (MPS III). Bone marrow transplantation has proven successful in MPS type I, which is the model lysosomal condition for bone marrow transplantation, but it needs to be performed early, ideally within the first 12–18 months of life. However, bone marrow transplantation does not ameliorate all the problems of this condition, including articular disease and spinal problems.

Gene therapy

Correction of single gene disorders by gene therapy (see also Chapter 43), replacing the faulty copy of the gene with a fully working copy, remains the ultimate goal for the treatment of IMDs. The technical challenges have proven considerable; for example the cystic fibrosis gene was first cloned at the end of the 1980s, and nearly 20 years later gene therapy remains in development.

The first condition for which gene therapy was used clinically was adenosine deaminase (ADA) deficiency, one of the causes of severe combined immunodeficiency disease (SCID). This is a combined profound impairment of both humoral and cellular immunity, presenting with multiple life-threatening recurrent infections. Bone marrow transplantation gives a good chance of complete cure; however, if no histocompatible donor is identified, ERT with polyethylene glycol-modified ADA (PEG-ADA) is given every one to two weeks, by intramuscular injection. Gene therapy trials started in the early 1990s, and involved the culture and collection of peripheral blood T cells of patients, insertion of a fully functional ADA gene, by means of a retroviral vector, and reinfusion into the patient. This improved patients' immune function, but required repeated treatments as lymphocytes have a finite life span of a few months. The technique was further developed using gene transfer into stem cells, which have an unlimited life span. However, the retroviral vector randomly inserted the gene into the cells' DNA. A total of four children subsequently developed leukaemia owing to the gene being inserted into an oncogene and therefore altering the control of this gene. Subsequent development and refinement of gene transfer technologies have allowed safer and more effective gene transfer and expression with 70% having sufficient improvement in immune function to remain off PEG-ADA. No serious adverse events have been reported with the refined vectors. Gene therapy trials are now under way for a number of IMDs.

Other molecular therapies

Nonsense mutations create a premature stop codon thus producing a truncated, usually non-functioning, protein. It is estimated that nonsense mutations account for 5–15% of disease-causing mutations. It was recognized that amino-glycosides could influence the ability to read through the premature stop codon and so produce a normal length functioning protein. Importantly, this affects only premature, and not normal, stop codons. Subsequent development of small read-through molecules has shown that boosting the affected enzyme by small amounts can significantly reduce disease severity. Clinical trials in cystic fibrosis have been promising and potential trials for patients with IMDs secondary to nonsense mutations are currently being planned.

Exon skipping is another technique to boost functioning protein production, by masking the faulty exon harboring a frameshift mutation, using small pieces of DNA (antisense oligonucleotides). Bypassing the frameshift mutation facilitates reading of the remaining exons. Animal work confirmed the principal in mouse models and now clinical trials have started in Duchenne muscular dystrophy and Huntington disease.

Strategies to reduce the formation of toxic metabolites

Reduction of metabolic load

For IMDs in which the pathological consequences are related to the accumulation of toxic substances, one of the simplest and most broadly used therapeutic strategies is to reduce the load on the block in the pathway, by reducing the amount of substrate to be processed by that enzyme. Phenylketonuria is the classic example: blood phenylalanine concentrations are reduced by limiting phenylalanine, by strict restriction of normal dietary protein intake. Phenylalanine is an essential amino acid and must not be removed from the diet completely so a small amount of natural protein is eaten to supply phenylalanine requirements. Measurement of blood phenylalanine concentrations is performed to monitor dietary control, usually by taking fingerprick samples onto Guthrie cards, which are sent to the laboratory by the family. Phenylalanine free amino acid supplements are prescribed to prevent dietary deficiency from the severe protein restriction. The availability of artificial low-phenylalanine foods on prescription has greatly improved the tolerability of the diet, owing to their variety and greater acceptability to the patient.

Reduction in metabolic load is also used acutely in a number of conditions that present with decompensations. In urea cycle defects, protein intake is stopped during the initial presentation, while other treatment strategies that help reduce the hyperammonaemia take effect. A similar approach is used in organic acidaemias, to reduce organic acid production. Once recovery is apparent, protein is re-introduced and intake is gradually increased. Removal of protein for longer than 72 h risks exacerbating catabolism, including that of muscle protein, with further production of organic acids (or of ammonia in urea cycle defects). It is therefore usual practice to introduce some protein after 48–72 h to promote anabolism. Patients with the severest blocks will still be able to tolerate 0.5 g/kg/24 h of protein for synthetic requirements and repair, without precipitating further decompensation.

Blockage of formation of toxic metabolites

In tyrosinaemia type I, the deficiency of fumarylacetoacetase results in the accumulation of fumarylacetoacetate, which causes hepatorenal toxicity. Nitisinone (NTBC) is a drug used to prevent the production of these toxic metabolites, by blocking the catabolic pathway of tyrosine at an earlier stage (4-hydroxyphenylpyruvate dioxygenase) (Fig. 24.10). This means that the patient has, in effect, been converted from having the severe, tyrosinaemia type I, phenotype to the milder, tyrosinaemia type III, phenotype. Clinically, tyrosinaemia type I presents with acute metabolic decompensation, associated with severe liver compromise and renal impairment and, in the longer term, the development of hepatocellular carcinoma. The clinical picture in type III is much milder, with some neurological involvement reported in some patients: liver and renal disease are not features. In view of the continued block in tyrosine catabolism, albeit at an earlier stage, a low tyrosine diet is still required, but the need for liver

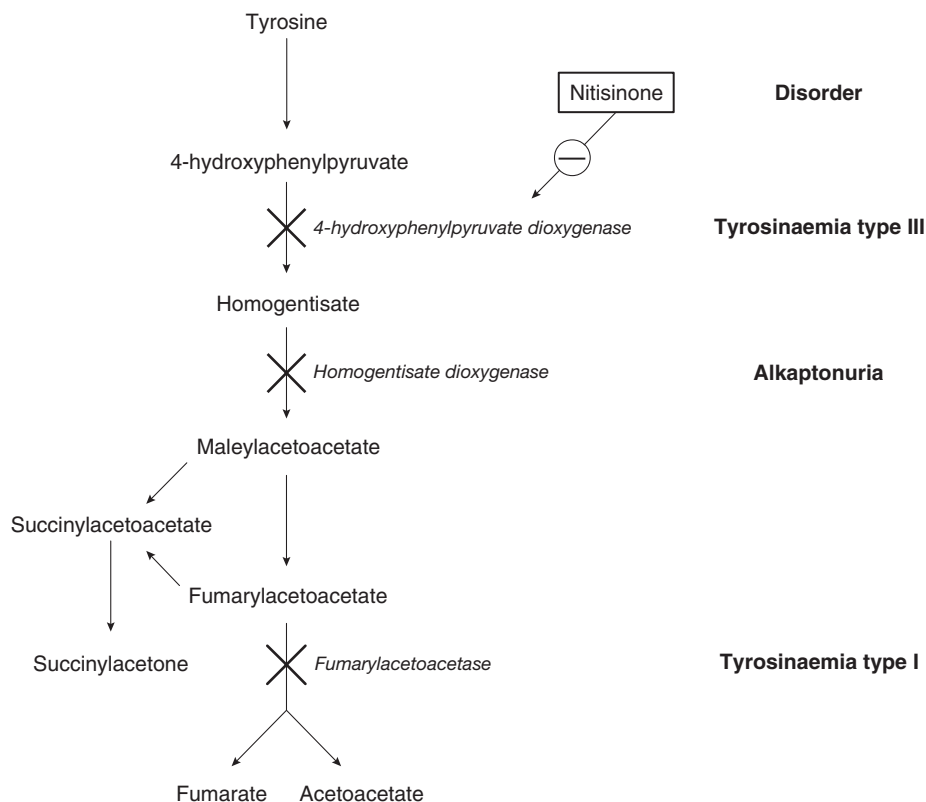

FIGURE 24.10 ■ Blocking the production of toxic metabolites: nitisinone blocks tyrosine catabolism at the level of 4-hydroxyphenylpyruvate dioxygenase, thus preventing the production of the toxic metabolites maleylacetoacetate and fumarylacetoacetate; this modifies the clinical phenotype to that of the milder tyrosinaemia type III from the more severe type I.

transplantation for hepatocellular carcinoma is dramatically reduced. Paradoxically, patients with milder tyrosinaemia type I that presents later, now do less well than those that present as neonates, as more hepatic fibrosis occurs before presentation and the introduction of NTBC.

Similarly, tyrosinaemia type III has a milder phenotype than alkaptonuria, caused by deficiency of homogentisate dioxygenase, the third enzyme in the pathway (see Fig. 24.10). This recessive condition, one of the conditions on which Garrod based his inherited metabolic traits theory, is manifest clinically by darkening of the urine on standing (usually presenting as staining of nappies). In the longer term, darkening of the sclerae and ear cartilage is observed, with subsequent darkening of the skin, especially over the nose, cheeks and axillae. In alkaptonuria, the joint involvement leads to arthritis, which can be severely debilitating. Low dose NTBC is now being evaluated in the management of this disorder.

Blockage of site of action of toxic metabolites

The effects of toxic metabolites can be limited by blocking their site of action. An example of this strategy is the use of dextromethorphan in the management of non-ketotic hyperglycinaemia, a glycine cleavage defect which results in high plasma concentrations of glycine. Glycine is a neurotransmitter with a central excitatory effect and inhibitory peripheral effect. Excessive concentrations, therefore, result in seizures with hypotonia. Infants

classically present with increased fetal movements (seizures in utero), hiccups and progressive apnoeas in the first days after birth, before developing encephalopathy and profound global developmental delay in the longer term. Sodium benzoate is used to reduce glycine levels, but this has little effect on long-term outcome. The use of partial antagonists of the N-methyl-D-aspartate (NMDA) receptor, the site of glycine binding, e.g. dextromethorphan and ketamine, improve seizure control, but do little to improve developmental outcomes.

Strategies to remove toxic substances

It may not be possible to reduce toxin production, and in acute decompensation, rapid clearance of toxic metabolites is required. This can be achieved either with the use of drugs that permit alternate pathways of excretion, or with dialysis or haemofiltration.

Drugs

Carnitine therapy is widely used in the management of IMDs for conjugating toxic metabolites and facilitating their urinary clearance as carnitine conjugates. This therapeutic approach is particularly used in organic acidaemias, e.g. propionic acidaemia and glutaric aciduria type I. Glycine is used in a similar way in isovaleric acidaemia. In urea cycle defects, sodium benzoate and sodium phenylbutyrate are used to conjugate with glycine and glutamine, respectively, which can then be excreted

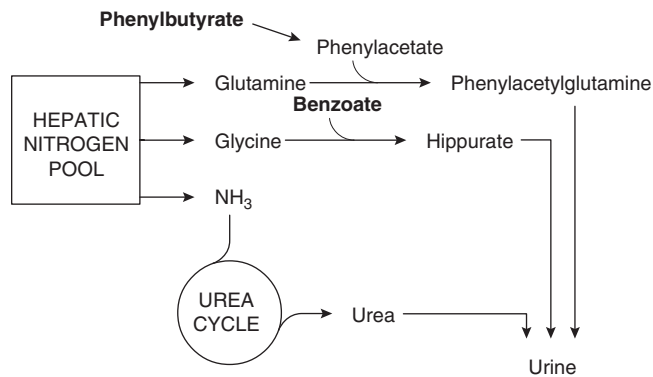

FIGURE 24.11 ■ Alternate pathway therapy in urea cycle defects; phenylbutyrate is metabolized to phenylacetate, which can combine with glutamine, allowing the latter to be excreted as phenylacetylglutamine; benzoate can combine with glycine to form hippurate, which can be excreted in the urine.

in the urine, bypassing the urea cycle and reducing its metabolic load (Fig. 24.11). However, as conjugation may be immature in neonates, these drugs may prove less effective in the newborn period. In organic acidemias, this treatment strategy is used to help control hyperammonaemia, which may cause sufficient vomiting to perpetuate the catabolic state driving metabolic decompensation.

Dialysis and haemofiltration

These techniques can be used effectively in acute settings, to clear toxic metabolites from the bloodstream. Originally, exchange transfusion was used for this purpose, but this procedure is inefficient and not without complications. Continuous venovenous haemofiltration, although not as efficient as haemodialysis at clearing toxic metabolites, has less impact on haemodynamic status. It is very effective at clearing lactate, ammonia, leucine and organic acids. Peritoneal dialysis is used in infants <2.5 kg, owing to the technical difficulties of performing haemodialysis on small babies.

Additional treatments

Appropriate nutritional support is essential to promote anabolism and prevent the catabolic drive to decompensation. To ensure that adequate calories are provided, when patients with IMDs require intravenous infusions, they are given fluids containing higher concentrations of glucose than are used in intravenous fluids administered to most other patients. A minimum of 10% dextrose (with appropriate electrolyte additives) is used in all age groups. Patients with congenital lactic acidosis are an exception as, in this group, the use of high concentrations of dextrose may exacerbate hyperlactataemia; in these patients, 5% dextrose-based solutions are used. Fat emulsions are used to provide additional calories, provided that a fat oxidation defect has been excluded. Patients known to have IMDs, are instructed to use an emergency regimen to help to reduce catabolism, during episodes of intercurrent

infection. This comprises a glucose polymer drink that has the advantage of easy absorption without a great osmotic load, thus reducing the risk of diarrhoea. These drinks can be administered at home during intercurrent illnesses, but if they are not tolerated, owing to vomiting or diarrhoea, admission to hospital is required, for intravenous dextrose therapy.

Substrate depletion

Different strategies are needed to manage storage disorders. Cystinosis is an autosomal recessive disorder presenting with a severe renal Fanconi syndrome and growth failure. The biochemical basis is a defective lysosomal membrane cystine transporter, leading to intracellular cystine accumulation. Cysteamine has been used successfully to reduce the progression of renal glomerular damage and improve growth. Cysteamine can combine with cystine to produce cysteine and a mixed disulphide cysteine-cysteamine, which can be exported by the cysteine and the lysine transporters, respectively.

Substrate deprivation

Substrate deprivation therapy is used in the management of lysosomal storage disorders. The principle is to reduce the amount of substrate synthesized so that it matches the impaired rate of catabolism. In this way, substrate does not accumulate. Miglustat is an inhibitor of glucosylceramide synthase, an essential enzyme in glycosphingolipid synthesis. It is used in the management of Gaucher disease type I and Niemann Pick C and is being investigated for the management of late onset Tay–Sachs disease.

CONCLUSION

Although the IMDs are individually rare, collectively they are an important cause of morbidity and mortality, particularly in the newborn, but in some cases in later life. Although the presentation of some IMDs is characteristic, for many it is non-specific, for example with growth failure, acidosis or hypoglycaemia. Nevertheless, the systematic use of investigations, starting with the simple and proceeding to more complex, will usually allow a diagnosis to be established and, when available, treatment to be commenced. Treatment is usually directed at overcoming the effect of the defective enzyme, but strategies for enzyme replacement are being developed and gene therapy may become more widely available in the future.

INTRODUCTION

National statistics for the UK record approximately 700 000 live births per year. In England and Wales in 2010, the infant mortality rate was 4.3 deaths per 1000 live births, the lowest ever recorded, which compares with an infant mortality rate of 12 deaths per 1000 live births in 1980. This considerable decrease in infant mortality can be partly explained by improvements in health care and more specifically, in midwifery and neonatal intensive care. The neonatal period, defined as the first four weeks of life, is associated with the highest mortality rate in childhood, with infants of very low (<1500 g) and low (<2000 g) birth weight accounting for a significant proportion of deaths. The mortality rate reflects the consequences of congenital malformation and disease and the difficulties of transition from intra- to extrauterine life, particularly in premature infants; such a high rate is not seen again until the seventh decade of life. For these reasons, the majority of this chapter is devoted to neonatal clinical biochemistry. Disorders of older children are only included where there are particular problems with interpretation of clinical biochemistry data.

The most common cause of admission to a neonatal intensive or special care unit is prematurity. 'Pre-term' in the practical sense rarely includes neonates of more than 32 weeks of gestation at birth. The problems of prematurity can be related to immaturity of vital systems, for example the lungs, kidneys and central nervous system, or inadequacy of energy stores or of nutrients such as

calcium and iron that are accreted during the third trimester of pregnancy. Another high-risk group is those neonates with a birth weight inappropriate for their gestational age. In most cases, these babies are small for gestational age (SGA), defined as birth weight below the 10th centile for newborns of the same gestational age in the same population. However, neonates born to mothers with diabetes may be overweight as a result of hyperglycaemia in utero.

POSTNATAL INVESTIGATION OF THE SMALL FOR GESTATIONAL AGE NEWBORN

Inappropriate birth weight is often readily explicable from the clinical history. Common causes of growth retardation are multiparity, pre-eclampsia, infection and drug addiction. An uncommon example would be a first-born SGA infant with microcephaly, the mother of whom should be investigated for possible hyperphenylalaninaemia by analysis of maternal plasma amino acids.

Intrauterine infections

Antenatal infections can affect the developing fetus, leading to congenital malformations and/or low birth weight. Many viruses have teratogenic effects on the fetus, so maternal infection in the first trimester, when organogenesis is occurring, tends to cause the greatest effect. In the UK, universal

TABLE 25.1 Reference ranges (5–95th centile) for serum immunoglobulins (g/L) in UK Caucasians

Age	IgG	IgA	IgM
Term cord blood	5.2–18.0	<0.02	0.02–0.20
0–2 weeks	5.0–17.0	0.01–0.08	0.05–0.20
2–6 weeks	3.9–13.0	0.02–0.15	0.08–0.40
6–12 weeks	2.1–7.7	0.05–0.40	0.15–0.70

screening for syphilis, hepatitis B, HIV and susceptibility to rubella infection is offered to all mothers in the early stages of pregnancy, with follow-up diagnosis and treatment available for both mother and infant as appropriate.

Intrauterine infection is indicated by an increase in the infant's serum IgM concentration (Table 25.1) and is often associated with prolonged unconjugated hyperbilirubinaemia and abnormal liver function tests. Measurement of the serum IgM concentration is only useful as an indicator of intrauterine infection before six weeks of age. After this time, the normal rise in serum IgM concentration may mask any early increase, and investigation requires specific serological testing.

Maternal drug abuse

Two percent of women in urban areas of the UK have been reported to have had a positive screening test for at least one prohibited substance at the time they first attended for antenatal care. These positive tests included amphetamines, barbiturates, cannabinoids, cocaine metabolites, methadone and opiates.

The consequence of maternal drug abuse is dependent upon the intensity of use. Infants may be born prematurely and/or SGA, and a proportion exhibit withdrawal symptoms during the neonatal period. The appearance of these symptoms depends upon the rates of clearance of the drugs and their active metabolites. For example, the irritability, tremors and convulsions of heroin withdrawal appear during the first 24h of life, whereas the same symptoms do not generally appear until after 24–48h when methadone is the substance involved.

A urine drug screen of a symptomatic neonate is often negative. Poor drug penetration across the placenta means that there are higher concentrations in maternal tissues and, consequently, it is more rewarding to screen maternal urine. The likelihood of detecting maternal drug abuse by investigating the urine of the neonate follows a decreasing order of cocaine > methadone > heroin > benzodiazepines.

RESPIRATORY DISORDERS

Respiratory distress

Up to 55% of the fetal cardiac output goes to the placenta. At birth there is an increase in peripheral resistance and a reduction in pulmonary vascular resistance, both of which

ensure the closure of the foramen ovale and constriction of the ductus arteriosus. Blood is then diverted through the pulmonary vessels and the adult type of circulation is established. In newborn infants, haemoglobin F (HbF) is the predominant haemoglobin, accounting for about 75% of the total. Haemoglobin F has a greater affinity for oxygen than haemoglobin A (HbA) and its oxygen dissociation curve is shifted to the left, ensuring adequate oxygen exchange at a significantly lower partial pressure of oxygen (PO_2). As the partial pressure of arterial oxygen (PaO_2) in blood rises with postnatal age, blood HbF concentrations fall, and by six months of age HbF accounts for only about 5% of the total haemoglobin.

Respiratory distress syndrome (RDS) may be caused by a variety of conditions (see Box 25.1). The most common cause in pre-term infants is hyaline membrane disease, primarily attributable to immature surfactant synthesis. Surfactant ensures patency of the alveoli by reducing the surface tension of the alveolar wall, and is made up of phosphatidylcholine (lecithin), phosphatidylglycerol and phosphatidylinositol. Surfactant synthesis begins by the 20th week of gestation. It increases slowly until the 34th week and then more rapidly as the type II alveolar cells mature. The rate of synthesis is sensitive to cold, hypoxia and acidemia and may be halved by postnatal exposure to temperatures <35°C or an arterial $[H^+] > 56$ nmol/L (pH <7.25). High intrauterine glucose concentrations, resulting from poorly controlled maternal diabetes mellitus, can also delay maturation of fetal surfactant synthesis. Fetal type II alveolar cell maturation may be enhanced by maternal steroid therapy. Corticosteroids are often given to women who are at risk of premature delivery at 24–34 weeks of gestation.

The incidence of hyaline membrane disease is inversely related to postconceptional age. The signs of the disease, which occur within four hours of birth, include sternal retraction, intercostal and subcostal recession, expiratory grunt and tachypnoea with a respiratory rate >60 per min. A characteristic 'ground glass' appearance is present on radiological examination of the chest. The appearance

BOX 25.1 Some causes of neonatal respiratory distress

Pulmonary

- Hyaline membrane disease
- Pneumonia
- Meconium aspiration
- Transient tachypnoea of the newborn
- Pneumothorax
- Pulmonary haemorrhage

Non-pulmonary

- Patent ductus arteriosus
- Acute blood loss
- Congenital heart disease
- Hypo/hyperthermia
- Metabolic acidosis
- Polycythaemia
- Intracranial birth trauma

of these reticulogranular opacities allows diagnosis of hyaline membrane disease with 90% confidence. Other entities that may produce similar opacities include immature lung, wet lung disease, neonatal pneumonia, idiopathic hypoglycaemia, congestive heart disease, maternal diabetes and early pulmonary haemorrhage.

Group B streptococcal pneumonia may present as early as four hours after infection, during birth, from this common vaginal organism. It occurs more often in the pre-term than the full-term infant. Measurement of serum C-reactive protein and microbiological investigations can be used to distinguish bacterial pneumonia from hyaline membrane disease.

Meconium aspiration and transient tachypnoea of the newborn (TTN) occur most often in full- or post-term infants. The passage of meconium (the contents of the fetal bowel) in utero is associated with fetal hypoxia. In some cases, the contaminated liquor is aspirated. Clinical symptoms usually appear 12–24 h after birth. Transient tachypnoea of the newborn occurs in term neonates, usually those born by caesarean section, and appears to be due to incomplete stimulation of adrenergic mechanisms for lung clearance during birth. Pneumothorax may occur as a complication of either of these conditions or as a result of mechanical ventilation of pre-term infants.

In RDS, the neonate develops hypoxia and a respiratory acidosis, both of which cause an increase in pulmonary vascular resistance and thus pulmonary hypertension with a left-to-right shunt. Hypoxia enhances anaerobic glycolysis and may result in lactic acidosis. Additional complications include brain damage and oedema, and hypotension that may lead to renal failure, paralytic ileus and/or necrotizing enterocolitis (NEC).

Non-pulmonary causes of respiratory distress are usually self-evident and normally improve with treatment of the underlying conditions (see Box 25.1). Up to 20% of infants weighing <1750 g at birth have a patent ductus arteriosus (PDA). Medical management of PDA includes fluid restriction and stimulation of diuresis. Pharmacological closure may be achieved using indometacin, an inhibitor of prostaglandin synthetase. Contraindications to this treatment include renal insufficiency (plasma creatinine concentration >160 µmol/L) with or without oliguria, bleeding disorders and NEC.

Management of respiratory distress

This may involve assisted ventilation with oxygen, aiming to maintain the P_{aO_2} in the range 6–12 kPa, P_{aCO_2} 5.5–8.0 kPa and arterial O_2 saturation (SaO_2) 88–95%. Although careful monitoring of blood gases is required, repeated blood sampling may cause anaemia. Anaemia may necessitate transfusion, usually with adult haemoglobin. Increased HbA may compromise oxygen uptake in the lungs in the presence of low alveolar P_{O_2} , thereby further aggravating tissue hypoxia. Correction of the metabolic acidosis with sodium bicarbonate can cause oedema and precipitate heart failure, owing to sodium and water overload. Too much oxygen may result in retrolental fibroplasia with retinal detachment and blindness.

Long-term ventilation is associated with bronchopulmonary dysplasia, hyperinflated emphysematous lungs with extensive alveolar destruction and widespread fibrosis. The proposed role of free oxygen radicals in the development of these complications has led many paediatricians to administer vitamin E routinely to all infants on ventilators.

Transcutaneous PO_2 (TcO_2) polarographic electrodes can be used to monitor oxygen treatment in infants who have good skin perfusion; the results correlate well with arterial PO_2 measurements. Transcutaneous PO_2 is measured at a skin temperature of 44 °C so the electrodes require frequent re-siting with recalibration in order to prevent skin burns. These problems do not occur with pulse oximetry, which measures SaO_2 of oxyhaemoglobin and reduced haemoglobin during an arterial pulse, by differential light absorption at 660 and 940 nm. The results correlate well with arterial PaO_2 measurements at SaO_2 values >65%, but are falsely low in the presence of methaemoglobin because its molar extinction characteristics imitate reduced haemoglobin.

Surfactant administered through an endotracheal tube significantly reduces the incidence and complications of respiratory distress in newborns at risk of developing hyaline membrane disease.

Apnoea of prematurity

Apnoea of prematurity, defined as a cessation of breathing for >20 s, with or without bradycardia and cyanosis, occurs in up to 85% of infants weighing <1000 g at birth. The major cause of apnoea is immaturity of the central respiratory drive, with poor sensitivity to changes in $PaCO_2$. This is compounded by the suppressed respiratory response to hypoxia, which serves to reduce oxygen requirements in utero and which persists in the pre-term infant. Poor coordination of the major respiratory muscles of the chest wall and the upper airways can lead to obstruction, usually at the level of the pharynx. Respiratory effort against a closed airway distorts the chest wall and activates the intercostal phrenic inhibitory reflex. Apnoea is worsened by infection, thermal instability and hypoglycaemia.

Apnoea of prematurity is treated with methylxanthines, which augment central respiratory drive and increase the sensitivity of chemoreceptors to changes in $PaCO_2$.

RENAL FUNCTION

The investigation of renal disorders and the monitoring of fluid and electrolyte replacement in pre-term infants are complicated by immaturity of organ function, and by the difficulty in collecting accurately timed urine samples.

Nephrons develop from about the sixth week of gestation and start producing urine from about the tenth week. The full complement of nephrons is present by the 36th week of gestation. Glomerular function develops more rapidly than tubular function. At term, the tubules are relatively short and underdeveloped. They increase in length and develop increasing absorptive and secretory

TABLE 25.2 Daily fluid and electrolyte requirements in infants and children compared with adults

	Water (mL/kg)	Sodium (mmol/kg)	Potassium (mmol/kg)
<1 month	150	2–6 (mean 4)	2–6 (mean 4)
<1 year	100		
1–3 year	90		
3–6 year	80		
6–9 year	70		
9–12 year	60		
Adult	30–40	1.5	1

function during the neonatal period. Functional immaturity is characterized by an inappropriately high urinary sodium excretion for the glomerular filtration rate (GFR) and an impaired response to a sodium load. This is pertinent to the management of pre-term infants, in whom the sodium requirement per kg body weight may be higher than that for term or older infants, with more mature tubular function (Table 25.2). The loops of Henle are principally juxtamedullary in position: they, too, are relatively short compared with those in older infants and adults and do not penetrate deeply into the renal medulla, thereby limiting renal concentrating ability.

In low birth weight infants, glomerular function is adequate for growth but may be inadequate to cope with the increased nitrogenous load during periods of catabolism, starvation, hypoxia, infection and infusion of nitrogen-containing solutions. Tubular function is adequate for the filtered load associated with a reduced GFR and can normally maintain an appropriate excretory function and systemic acid–base status during the anabolic growth phase.

The GFR increases with postconceptional age as renal blood flow increases and renal vascular resistance decreases; full functional maturity is not reached until about the second year of life.

Total body water constitutes about 85% of the body weight of pre-term infants weighing <1.0 kg at birth, compared with about 75% in term infants and 60% in adults (Fig. 25.1). Relatively more water is in the extracellular compartment than in the intracellular compartment. Total body sodium is about 45 mmol and potassium 75 mmol, and blood volume about 70 mL. During the first few weeks of life, there is a contraction of the extracellular space associated with an increase in urinary sodium loss. This results in an initial 10–15% reduction in body weight. The onset of natriuresis coincides with improvement of lung function and is probably related to a reduction in pulmonary vascular resistance and the release of natriuretic peptides. This contributes to the contraction of the extracellular fluid space. Excess fluid and sodium administration, before the onset of the natriuretic phase, may worsen respiratory distress, delay the closure of the ductus arteriosus and precipitate oedema with hyponatraemia. It is not appropriate to rely on spot urinary sodium concentrations to monitor water and sodium requirements during the first few weeks of life in a premature infant.

FIGURE 25.1 ■ Changes in body water as a function of age for pre-term and term infants. The timescale indicates expected date of birth and postnatal age.

Antidiuretic hormone (ADH) secretion, in response to volume reduction and hyperosmolality, occurs from about the 25th week of gestation. The interstitial osmolality of the renal medulla, which is the main determinant of the urine concentrating ability in the presence of ADH, is dependent on the countercurrent multiplication mechanism in the loops of Henle and on the interstitial concentrations of sodium, chloride and urea. The reduced GFR and urea clearance decrease the tubular reabsorption of urea and the interstitial urea concentration; consequently, the concentrating ability is impaired, despite appropriate ADH output. Even full-term infants have a limited capacity to conserve water, and urine osmolality rarely rises >700 mmol/kg. Approximate fluid requirements are shown in Table 25.2.

Hyponatraemia

In neonates, hyponatraemia may be caused by maternal fluid retention or overload during labour, or excess neonatal hypotonic fluid administration during the postnatal period. In addition, inappropriate antidiuresis may develop as a consequence of respiratory disease or intraventricular haemorrhage. In older infants, a dilutional hyponatraemia may be seen, caused by a combination of water retention and sodium depletion in response to increased intestinal or renal fluid losses. Signs of hyponatraemia are related to the rate of fall of plasma sodium concentration rather than to its actual value, and may include hypotension, drowsiness and convulsions. Congenital adrenal hyperplasia (CAH) must always be considered as a possible cause of hyponatraemia (see Chapter 21).

Hypernatraemia

As in adult patients, hypernatraemia may be caused either by water depletion or by excess sodium administration or

retention. Insensible water loss is significantly greater in pre-term infants compared with children and adults. The reasons include:

- greater surface area to body volume ratio
- increased skin blood flow
- increased metabolic and respiratory rates
- lack of subcutaneous fat
- greater transepidermal fluid loss.

The epidermis of the skin matures by about the 28th week of gestation with keratinization of the stratum corneum. Consequently, infants born before 28 weeks are at greater risk of excess fluid loss and may lose up to 60 mL/kg/24h of water through the skin, compared with about 10 mL/kg/24h in term infants. Additional environmental factors, such as temperature and humidity, also affect transepidermal fluid loss.

Impaired response to changes in blood volume and plasma osmolality make infants particularly vulnerable to developing hypernatraemia. Increased urinary free water loss may be caused by glycosuria secondary to either hyperglycaemia or to the low renal threshold for glucose. In pre-term infants, glycosuria may be present when the plasma glucose concentration is as low as 5.6 mmol/L. Diabetes insipidus, caused, for example, by intracranial injury at birth, may also result in an increase in free water clearance.

Although the major cause of sodium and water imbalance in premature infants is related to the functional immaturity of organs, it is important to be aware that some drugs may exacerbate the situation, e.g. sodium bicarbonate, indometacin and methylxanthine derivatives such as caffeine.

Morbidity and mortality from hypernatraemia are caused by the increased extracellular osmolality and its effects on fluid distribution between fluid compartments. Infants with hypernatraemia may present clinically with irritability and lethargy, convulsions and coma; lesions within the CNS include intracerebral and intraventricular haemorrhages, as well as sinus and small vessel thromboses. The majority of infants who survive suffer no long-term sequelae, although a minority develop persistent neurological abnormalities.

Hydrogen ions

Under normal circumstances, the kidneys can excrete the hydrogen ion load and generate sufficient buffering capacity to maintain normal systemic acid–base status, despite apparent immaturity of renal tubular function. However, if hydrogen ion production is increased, premature infants are prone to develop a metabolic acidosis in addition to the respiratory acidosis of respiratory distress. The proximal tubular threshold for bicarbonate reclamation is reduced, as is the distal tubular response to an ammonium chloride load: thus the generation of buffering capacity is reduced. In addition, urinary phosphate excretion, which is dependent on GFR, phosphorus intake and plasma phosphate concentration, may be significantly reduced in infants with phosphate depletion.

Metabolic acidosis is frequently related to disorders of respiratory and cardiac function. Echocardiography is invaluable in the investigation of congenital abnormalities of the heart and of left ventricular function. Inherited metabolic diseases, such as mitochondrial dysfunction with lactic acidosis and organic acidaemias, should be excluded early by appropriate investigations (see Chapter 24).

Interpretation of renal function tests

Renal function tests must be interpreted with caution in pre-term infants. Despite the low glomerular filtration rate (GFR), plasma urea concentrations are low in neonates compared with adults, because of increased utilization of nitrogen. Plasma concentrations fluctuate markedly in response to changes in the catabolic rate, GFR and nitrogen intake. Plasma creatinine concentrations are high at birth, being determined principally by maternal concentration: they fall initially and then gradually increase with respect to postnatal age and muscle mass. Measurements may be subject to analytical variation owing to negative interference by bilirubin, and reference intervals may therefore be method dependent.

The interpretation of tubular function tests may be complicated in premature infants in whom the presence of a generalized aminoaciduria and glycosuria may be misinterpreted as a type 2 renal tubular acidosis (RTA). However, despite immature tubular function, maximum phosphate reabsorption occurs in premature infants when plasma phosphate concentrations fall below about 1.5 mmol/L. Impaired response to an ammonium chloride load in the presence of a systemic acidosis may be wrongly interpreted as a type 1 RTA, rather than as a result of immaturity of distal tubular function.

CARBOHYDRATE METABOLISM

The fetus receives a constant, transplacental supply of glucose and amino acids, maintained by maternal intermediary metabolism. Although free fatty acids are transported across the placenta, they are not used for oxidative metabolism but are stored in adipose tissue as triglycerides (triacylglycerols). At birth, the umbilical vein plasma glucose concentration is about 70% that of the maternal circulation. After birth, the plasma glucose concentration falls, resulting in an increase in the circulating concentrations of glucagon, catecholamines and growth hormone (GH), which, together with a fall in plasma insulin concentration, stimulate the release of glucose from hepatic glycogen and activate lipolysis and gluconeogenesis (Fig. 25.2). Increased hepatic cAMP synthesis is associated with glycogenolysis and, through induction of synthesis of phosphoenolpyruvate carboxykinase, gluconeogenesis. Substrates such as pyruvate, lactate and alanine, which are diverted to gluconeogenesis, are no longer available to form malonyl-CoA and hence fatty acids. As the cytosolic concentration of malonyl-CoA falls, its inhibitory effect on carnitine palmitoyltransferase I activity is

FIGURE 25.2 ■ Changes in energy metabolism at birth. Plasma glucagon rises and insulin falls after birth, in response to falling plasma glucose concentrations. Hepatic glycogenolysis is stimulated. Increased synthesis of phosphoenolpyruvate carboxykinase (PEPCK) stimulates gluconeogenesis. The -ve sign indicates that pyruvate is no longer used to form malonyl-CoA. Malonyl-CoA-dependent inhibition of carnitine palmitoyltransferase (CPT) is reduced and free fatty acids (FFA) can be transferred into the mitochondria where they are subject to β -oxidation. Activation of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) synthase permits hepatic ketone synthesis. The dotted lines indicate transfer (active or passive) across membranes.

reduced. Carnitine palmitoyltransferase I plays a role in transferring long chain free fatty acids, released from triglycerides through the action of hormone-sensitive lipase, into the mitochondria where they undergo β -oxidation. Activation of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) synthase enhances the hepatic formation of ketones from acetyl-CoA.

Although glucose is the major source of energy for the brain, fetal and neonatal brains have an enhanced capacity to utilize ketones, lactate and amino acids as alternative fuels. Circulating free fatty acids and glycerol appear within 3 h after birth in the fasting full-term infant, but plasma concentrations of ketones begin to rise only after 12–48 h of fasting. This relative resistance to ketonaemia is caused by the high turnover of ketones in the neonate, for example ketones can be metabolized at a rate of 13–22 pmol/kg/min, after only 8 h of fasting and may account for up to 25% of the infant's basal energy requirements. Such a high ketone turnover is observed only after several days of fasting in adults.

The maintenance of normal plasma glucose concentrations during the immediate postpartum period

depends upon regulated insulin and glucagon secretion, adequate reserves of both glycogen and triglycerides and the possession of operational intermediary metabolism. When all these factors are present and functioning appropriately, glucose production can reach 5–8 mg/kg/min in full-term infants, compared with about 2 mg/kg/min in adults. This requirement for a high rate of glucose production is related to the higher brain to body mass ratio of infants.

Neonatal hypoglycaemia

Hypoglycaemia of the newborn is defined as a blood glucose concentration of <2.5 mmol/L. It occurs in up to 0.4% of all newborns, but is much more common in infants of diabetic mothers (previously diagnosed as having diabetes or with gestational diabetes) and in low birth weight and premature infants. Signs of hypoglycaemia include:

- jitteriness
- feeding problems
- abnormal cry
- floppiness
- pallor
- apnoea
- cyanosis
- convulsions.

The severity of symptoms will, in part, depend on the rate of fall of the plasma glucose concentration and on the infant's ability to adapt to alternative sources of energy. In all cases, early diagnosis and the prompt restoration of normoglycaemia are critical in order to minimize damage to the developing CNS.

Infants at risk of developing hypoglycaemia should be monitored regularly. Hypoglycaemia detected by point-of-care testing should be confirmed by laboratory testing, as falsely low results may be obtained in the presence of a high packed cell volume and poor peripheral perfusion of the site of testing.

The aetiology of neonatal hypoglycaemia must be identified so that causes of persistent hypoglycaemia associated with rare disorders and inherited diseases of intermediary metabolism can be excluded (see below). Some causes of hypoglycaemia that may occur during the neonatal period or later in infancy are shown in [Box 25.2](#).

The major cause of hypoglycaemia in pre-term infants is inadequacy of energy stores that would normally have accumulated during the last trimester of pregnancy. The glycogen content of fetal liver increases by 300%, from 0.9 to >3.9 g/100 g, between 31 and 40 weeks of gestation. Small for gestational age infants also have reduced energy stores and they, too, are at risk of hypoglycaemia. Infants in shock, for example following perinatal asphyxia or because of neonatal sepsis, may develop hypoglycaemia owing to underperfusion of the liver.

Hyperinsulinism is the most common cause of severe and persistent hypoglycaemia in term infants. Hyperinsulinaemic infants are particularly prone to complications of hypoglycaemia, as the high insulin

BOX 25.2 Some causes of neonatal hypoglycaemia

- Inadequate energy stores
 - Prematurity
 - Small for gestational age
- Impaired hepatic glucose production
 - Perinatal asphyxia
 - Neonatal sepsis
 - Hormone deficiency (hypopituitarism, adrenal insufficiency)
- Transient hyperinsulinism
 - Infants of diabetic mothers
 - Erythroblastosis fetalis
 - Idiopathic transient hyperinsulinism
- Persistent hypoglycaemia
 - Persistent hyperinsulinaemic hyperglycaemia of infancy due to adenomatous or diffuse hyperplasia of the islets of Langerhans
 - Inherited metabolic diseases

concentrations inhibit lipolysis and the generation of alternative energy sources, such as ketones.

Hyperinsulinism in infants born to diabetic mothers is due to in utero hyperglycaemia-induced hyperplasia of the islets of Langerhans. Idiopathic transient hyperinsulinism may occur in interuterine growth-retarded infants and those suffering from perinatal asphyxia.

Persistent hyperinsulinaemic hypoglycaemia of infancy (PHHI), previously called familial hyperinsulinism, pancreatic nesidioblastosis or hyperinsulinaemic hypoglycaemia, causes recurrent severe hypoglycaemia that may present in term newborn infants or during the first few weeks of life. It can be subdivided into two types: focal adenomatous hyperplasia of the islets of Langerhans and diffuse (but discrete) hyperplasia. Mutations in several different genes that code for proteins involved with insulin release have been identified as being responsible. These include mutations associated with the two subunits of the β cell ATP-sensitive potassium channel – the sulphonylurea receptor proteins (SUR1) and the inward rectifier potassium channel proteins (Kir 6.2). Activating mutations in the glucokinase (GK) and glutamate dehydrogenase (GDH) genes have also been identified in this disorder. Glutamate dehydrogenase is a regulator of insulin secretion in pancreatic β cells and of ureagenesis in the liver, and defects in enzyme activity are characterized by hyperinsulinism with mild, asymptomatic hyperammonaemia. In many patients, the only therapeutic option is partial pancreatectomy, which carries the long-term risk of diabetes mellitus as apoptosis depletes the β -Cell mass. Those forms of PHHI resulting from mutations in GK and GDH are more amenable to pharmacological intervention, for example with diazoxide.

If the amount of glucose required to prevent recurrence of hypoglycaemia exceeds about 10 mg/kg/min, then hyperinsulinaemia is likely. If there is no known history of maternal diabetes mellitus or any of the other classic features (e.g. cherubic appearance and polycythaemia), blood samples taken during the hypoglycaemic episode should be assayed for insulin and 3-hydroxybutyrate.

In hyperinsulinaemic hypoglycaemia, the plasma insulin concentration is inappropriately high for the low plasma glucose concentration; plasma C-peptide concentrations are not a reliable reflection of pancreatic β -Cell function in neonates because of renal immaturity and reduced GFR. A plasma 3-hydroxybutyrate concentration <1.1 mmol/L during hypoglycaemia suggests that fatty acid oxidation and ketone synthesis are impaired. This can be due to hyperinsulinaemia, inadequate adipose stores or to a defect in β -oxidation of fatty acids.

The symptomatic treatment of hypoglycaemia is not without its complications, which include hyperglycaemia associated with hyperosmolality and cerebral hemorrhage, glycosuric osmotic diuresis and water overload.

CALCIUM AND PHOSPHORUS METABOLISM

Disorders of calcium and phosphorus metabolism are relatively common in pre-term infants. Calcium and phosphorus are actively transported across the placenta with fetal plasma concentrations higher than those in the maternal circulation. The transplacental transport is probably enhanced by locally synthesized 1,25-dihydroxy vitamin D ($1,25(\text{OH})_2\text{D}$) and by parathyroid hormone-related peptide (PTHrP), for which receptors have been identified in the placenta. The high plasma calcium concentration suppresses fetal parathyroid gland activity and probably inhibits fetal $1,25(\text{OH})_2\text{D}$ synthesis. During the last trimester of pregnancy, there is a three-fold increase in fetal calcium and phosphorus uptake (Table 25.3): the changes in fetal hormone concentrations facilitate bone mineralization and growth. Consequently, infants born prematurely during the last trimester of pregnancy are significantly disadvantaged and are prone to develop complications of calcium and phosphorus metabolism.

Disorders of calcium and phosphorus metabolism

Hypercalcaemia

Hypercalcaemia is relatively uncommon during the neonatal period. The condition may occur in phosphorus-depleted premature infants receiving unsupplemented breast milk or parenteral nutrition: it is invariably associated with hypophosphataemia. Treatment with phosphorus supplementation alone may precipitate acute hypocalcaemia. Idiopathic hypercalcaemia, with a normal or high

TABLE 25.3 Fetal calcium and phosphorus accumulation

Postconceptional age (weeks)	Body weight (kg)	Accretion rate (mmol/kg/day)	
		Calcium	Phosphorus
28	1.0	3.0	2.0
40 (term)	3.0	3.4	3.0

normal plasma phosphate concentration, is more common in mature infants but may occur in premature infants receiving high-dose vitamin D prophylaxis. It may also be associated with subcutaneous fat necrosis of infants. This disorder usually affects healthy full-term infants who have suffered perinatal asphyxia. These infants usually develop subcutaneous plaques over the buttocks and back. The condition is caused by excess production of $1,25(\text{OH})_2\text{D}$ by the granulomatous cells, similar to that observed in sarcoidosis in adults. Although very rare, it is the most common cause of hypercalcaemia in full-term neonates.

Hypercalcaemia during infancy and childhood is also rare but may be caused by immobilization, primary hyperparathyroidism, familial hypocalciuric hypercalcaemia or infantile hypercalcaemia (Williams syndrome). Familial hypocalciuric hypercalcaemia is a rare, autosomal dominant condition caused by mutations in the calcium sensing receptor (CASR). It is characterized by mild hypercalcaemia and a low urine calcium excretion and does not usually require treatment. Infants with mutations of the *CASR* gene may occasionally present in the neonatal period with severe hypercalcaemia (neonatal severe primary hyperparathyroidism). Features of Williams syndrome include failure to thrive, hypercalcaemia, elfin-like facial features, supravalvular aortic stenosis and learning disabilities. Microdeletion of the 7q11.23 region on chromosome 7, which contains the elastin gene, can be demonstrated by fluorescence in-situ hybridization (FISH).

Hypocalcaemia

Some causes of neonatal hypocalcaemia are shown in Box 25.3. After parturition, plasma total and ionized calcium concentrations fall, reaching a nadir between the 24th and 48th hour of life, then rising, such that the ionized calcium concentration is 1.10–1.40 mmol/L by

BOX 25.3 Some causes of neonatal hypocalcaemia

Early

- Prematurity (inversely related to postconceptional age)
- Infants with perinatal asphyxia
- Infants of diabetic mothers

Late

- Mineral depletion
 - Unsupplemented breast milk
 - Inadequate parenteral nutrition
 - Maternal vitamin D deficiency
- Exchange transfusion
- Iatrogenic
 - Diuretic therapy
 - High phosphorus intake
- Organ disease
 - Liver disease
 - Renal disease
- Endocrine disorders
 - Transient hypoparathyroidism
 - Hypoparathyroidism
 - DiGeorge syndrome

about the fifth day of life. Plasma ionized calcium concentrations as low as 0.70 mmol/L have been observed in pre-term infants without apparent clinical abnormalities. The degree of fall is inversely related to gestational age and is more marked in infants born to diabetic mothers and those with perinatal asphyxia. These changes, which are usually self-limiting, are probably caused by transient suppression of fetal parathyroid gland activity.

Permanent causes of hypocalcaemia include hypoparathyroidism, either X-linked or autosomal recessively inherited, or as part of the DiGeorge syndrome and pseudohypoparathyroidism. DiGeorge syndrome is associated with hypoplasia or aplasia of the parathyroid glands and congenital heart anomalies with partial or complete absence of the thymus. Many infants have a partial deletion of chromosome 22q11.

Pseudohypoparathyroidism is characterized by hypocalcaemia and hyperphosphataemia with appropriately increased secretion of parathyroid hormone (PTH) but end-organ resistance to its effect: in the common form of the condition this is caused by mutations in the *GNAS* gene. Clinically, infants with this disorder present with a constellation of features known as Albright hereditary osteodystrophy. Signs include short stature, dysmorphism, obesity and shortening of the fourth and fifth metacarpals. There may be associated hypothyroidism; subcutaneous calcification may also occur.

Osteopenia of prematurity

Significant failure of bone mineralization, or osteopenia, occurs in >50% of premature infants weighing <1000 g at birth. Osteopenia has a reported incidence of up to 13% in infants weighing <1500 g at birth.

Osteopenia of prematurity is caused by impaired mineralization of normal osteoid of the epiphyseal growth plate with proliferation of unmineralized osteoid. The clinical condition usually presents between the 6th and 12th postnatal weeks, associated with a fall-off of longitudinal growth, with continued growth in head circumference and frontal bossing. Swelling of the costochondral junctions of the ribs may result in the classic 'rachitic rosary'. Softening of the rib cage with impaired chest wall compliance and patchy lung atelectasis impairs ventilation and may cause late onset respiratory distress, so that ventilatory support may be required. Multiple non-traumatic fractures may also be present.

The aetiology of osteopenia of prematurity is multifactorial but the condition is primarily caused by deficient mineral substrate intake, particularly of phosphorus. Human breast milk is capable of providing up to 1.4 mmol/kg/24h of calcium and 0.9 mmol/kg/24h of phosphorus. Although these calcium and phosphorus intakes are adequate to enable normal bone mineralization and skeletal development in term infants, they fall far short of the mineral accretion that should have taken place during the last trimester of pregnancy and are not sufficient for a rapidly growing pre-term infant. Infants born as early as 26 weeks are able to hydroxylate vitamin D in the 25 position, but there may be maturational delay of the renal 1α -hydroxylase enzyme, and, consequently,

concentrations of $1,25(\text{OH})_2\text{D}$ may be inappropriately low until about the third week of extrauterine life. This, coupled with the limited absorptive capacity of the pre-term intestinal tract, contributes to the mineral substrate deficiency.

The biochemical changes in plasma that may identify those infants at risk of developing clinically significant osteopenia of prematurity are shown in Table 25.4. Plasma alkaline phosphatase activity fluctuates considerably during the neonatal period, but rises rapidly to values above six times the upper adult reference limit in the majority of infants at risk. High plasma enzyme activities are inversely related to growth velocity, a fall in which is an early clinical manifestation of the disorder. Plasma phosphate concentrations are invariably low-normal or low and urinary phosphate excretion is significantly reduced. Plasma calcium concentrations are a poor indicator of impending rickets and may be low, normal or even raised, depending upon the aetiology and stage of the disorder. Urinary calcium excretion is variable and related to the plasma phosphate concentration: the lower the plasma phosphate, the greater the urinary calcium excretion.

The treatment for this common form of osteopenia of prematurity is to increase calcium and phosphorus intake in order to maintain a normal plasma calcium concentration, but, more importantly, to keep the plasma phosphate close to about 1.50 mmol/L. Vitamin D supplementation, in an active form such as 1- α -calcitriol, is often administered. Following successful treatment, plasma alkaline phosphatase activity may continue to rise for about two weeks before falling to expected pre-term values.

Rickets during childhood

Rickets occurs in growing children as a result of defective mineralization of growth plates: it is similar to osteomalacia in adults. The major cause of rickets during childhood is nutritional vitamin D deficiency. Other causes include malabsorption and anticonvulsant therapy. Hypocalcaemia with secondary hyperparathyroidism is invariably present and children may present with tetany and convulsions. Older infants may present with a characteristic waddling gait.

Inherited forms of rickets must be considered in the differential diagnosis. They can be divided into two main groups: those associated with hypophosphataemia, caused by an isolated or generalized renal tubular defect, and those in which the main defect is in vitamin D metabolism (Box 25.4). X-linked dominant hypophosphataemic rickets is the most common form and occurs in about one in 20 000 live births. Hypophosphataemia, with isolated

BOX 25.4

Classification of inherited causes of osteopenia/rickets

Isolated renal tubular defect

- X-linked hypophosphataemic rickets
- Autosomal dominant/recessive hypophosphataemic rickets

Generalized renal tubular defect

- Renal tubular acidosis type 2
 - Cystinosis
 - Classic galactosaemia
 - Hereditary fructose intolerance
 - Tyrosinaemia type I
 - Wilson disease
- Renal tubular acidosis type 1

Defective vitamin D metabolism

- 1α -Hydroxylase deficiency
- End-organ resistance

hyperphosphaturia, usually presents during the first year of life and is associated with growth retardation. Remission may occur when the epiphyseal plates fuse and growth ceases, but the condition can relapse in later life. Female patients are less severely affected than males, the difference being caused by the random inactivation of one of the paired X chromosomes (lyonization). In females, presentation may be as osteomalacia in adulthood. A low-normal or low plasma concentration of $1,25(\text{OH})_2\text{D}$ in the presence of hypophosphataemia is suggestive of an altered feedback control on 1α -hydroxylase and impaired vitamin D metabolism.

Although rare, cystinosis is the most common cause of rickets in infants with type 2 RTA or Fanconi syndrome. Rickets develops by the second year of life and is probably caused by a combination of hypophosphataemia, systemic acidosis and impaired renal hydroxylation of vitamin D. In contrast, infants with type 1 RTA develop hypercalcaemia and nephrocalcinosis and may present clinically with polyuria and polydipsia, renal stones or rickets, usually before the fifth year of life. The diagnosis of cystinosis is confirmed by the finding an increased concentration of white cell cystine.

Plasma alkaline phosphatase activity in infancy

Plasma alkaline phosphatase (ALP) fluctuates considerably in the pre-term infant, and activities up to six times the adult reference limit are considered appropriate for age.

TABLE 25.4 Biochemical changes in osteopenia of prematurity and reference intervals compared with adults

Analyte (in plasma)	Units	Reference interval (Adults)	Reference interval (Pre-term infants, 3–10 weeks)	Change in osteopenia of prematurity
Alkaline phosphatase	U/L	30–130	<600	Raised
Phosphate	mmol/L	0.80–1.50	1.50–2.55	Low-normal or low
Calcium	mmol/L	2.20–2.60	2.15–2.65	Low, normal or high
Albumin	g/L	35–50	25–40	Variable

FIGURE 25.3 ■ Age- and sex-related changes in plasma alkaline phosphatase activity during childhood and adolescence.

Plasma ALP consists primarily of the bone isoform in infants, although fetal intestinal ALP, the gene for which is normally suppressed after the 30th week of gestation, may be present in the plasma of pre-term neonates receiving an oral fat intake. The hepatic isoform of ALP is rarely detected before one year of age, even in the presence of hepatic disease. Placental ALP is not present in the plasma of the newborn. Age and sex variation in plasma ALP during childhood and adolescence is shown in [Figure 25.3](#).

Transient hyperphosphatasaemia of infancy is a rare disorder of unknown aetiology that occurs in infants and children up to the age of about five years, although it may occasionally present in older children and adults. It is characterized by a rapid rise in plasma ALP activity to values >20 times the upper adult reference limit and a subsequent return to normal, usually within three months. There is no associated bone or liver disease and the disorder has no proven long-term sequelae. Its early recognition is important as it prevents unnecessary investigations (see Chapter 13).

DISORDERS OF LIVER FUNCTION

Bilirubin metabolism

Bilirubin is formed in the reticuloendothelial system of the liver, spleen and bone marrow from the breakdown of haemoglobin. Unconjugated bilirubin is transported in plasma bound to albumin, which has two bilirubin binding sites, one high and one low affinity, with a maximum binding capacity of about 20 μmol bilirubin/g albumin.

Bilirubin crosses the sinusoidal membranes of hepatocytes by non-energy-dependent passive diffusion. It becomes bound to Y protein (ligandin) and is transported to the smooth endoplasmic reticulum where it is conjugated, by the enzyme uridine diphosphate (UDP)-glucuronosyl transferase, to form a water-soluble mono- and then diglucuronide. The monoglucuronide is the predominant conjugate of bilirubin in the newborn, but only accounts for about 15% of total bilirubin conjugates in adults. The ability of the neonatal liver to conjugate bilirubin is limited (see below), but by two years of age, the conjugating capacity greatly exceeds the rate of delivery of bilirubin to the liver and only 1% of the enzyme activity is required to clear bilirubin at the normal rate of production.

Bilirubin conjugates are secreted across the canalicular membrane into the bile by a multispecific anion transporter. The rate of secretion of bilirubin into the biliary canaliculi is dependent on the active secretion of bile salts and the rate of bile flow. Up to 25% of the conjugated bilirubin may be hydrolysed within the intestinal lumen, either non-enzymatically, under alkaline conditions, or by the mucosal enzyme β -glucuronidase, to unconjugated bilirubin, which is reabsorbed and returned to the liver via the enterohepatic circulation. Conjugated bilirubin is converted to bile pigments (urobilinoids), primarily by intestinal bacteria in the distal ileum and colon.

Unconjugated hyperbilirubinaemia: physiological jaundice

Bilirubin bound to albumin in the blood may be displaced by drugs, such as antibiotics, and by hormones and free fatty acids. Free bilirubin is lipid soluble and can cross the blood–brain barrier, where its toxic effects result in irreversible brain damage (kernicterus). This is thought to be caused by uncoupling of oxidative phosphorylation. Significant free bilirubin occurs when the plasma total bilirubin concentrations exceed 340 $\mu\text{mol/L}$ in term infants, with a conjugated bilirubin <25 $\mu\text{mol/L}$. The absence of a clear relationship between circulating bilirubin concentrations and the development of kernicterus in pre-term infants has led to the ‘action level’ for total bilirubin being reduced to as low as 170 $\mu\text{mol/L}$. Putative additional risk factors for the development of kernicterus include acidosis, sepsis and hypothermia. National guidelines have been adopted for the detection and management of neonatal hyperbilirubinaemia to prevent the potential devastating effects. However, given that the cause may be a sudden and unpredictable haemolytic crisis, kernicterus has yet to be completely eliminated.

Hyperbilirubinaemia is usually treated with phototherapy, which converts the bilirubin to water soluble isomers but, if severe, may require treatment by exchange transfusion. This latter procedure may be complicated by a fall in plasma ionized calcium concentration and there is an associated risk of cardiac arrest.

Transient unconjugated hyperbilirubinaemia, presenting with jaundice on the second or third day of extra-uterine life and persisting for about two weeks, is known as ‘physiological jaundice of the newborn’. In premature infants, such jaundice may last for up to four weeks. During the first week of life, plasma bilirubin concentrations rise to >220 $\mu\text{mol/L}$ in 6% of healthy full-term neonates and a greater proportion of pre-term neonates. The cause is controversial and almost every phase of bilirubin metabolism and transport has been implicated. Bilirubin synthesis is increased during the first three weeks of life, particularly in premature infants, because of the reduced erythrocyte half-life. The high bilirubin production (100–140 $\mu\text{mol/kg}$ body weight/24h), almost three times the normal adult production, exceeds the capacity of the neonatal liver to clear unconjugated bilirubin from the plasma, owing to reduced membrane uptake and ligandin production, the low activity of UDP-glucuronosyl transferase and inefficient bile acid metabolism and transport.

After the third week of life, the increased bilirubin load is derived principally from the enhanced reabsorption of unconjugated bilirubin from the gut. The reduced uptake and conjugation of the increased load by the liver of the premature infant contributes to the prolonged 'physiological' jaundice in this age group. It has been suggested that bilirubin, through its oxidation to biliverdin, provides a scavenging mechanism for free radicals produced during disease and that physiological jaundice may have a beneficial role in the neonate.

Unconjugated hyperbilirubinaemia: pathological causes

Unconjugated hyperbilirubinaemia that occurs within 24h of birth, which rises rapidly ($>85 \mu\text{mol/L}/24\text{h}$) or which is persistent, should prompt investigation for the secondary conditions shown in **Box 25.5**. Haemolytic disease of the newborn is now uncommon following the widespread use of prophylactic rhesus immune globulin: when it occurs, jaundice develops within the first six hours of life. Congenital spherocytosis and ABO haemolytic disease are usually associated with less severe jaundice. The latter condition resolves as the circulating erythrocytes coated with anti-A and anti-B antibodies are broken down.

Erythrocyte glucose 6-phosphate dehydrogenase deficiency is a common inherited cause of haemolytic disease and should be ruled out in neonates with persistent hyperbilirubinaemia. Haemolysis in this condition may be precipitated by exposure to chemicals, drugs and infection and may be more severe in the Mediterranean and Oriental type than in that seen in African-Americans.

Congenital infections such as syphilis, rubella and toxoplasmosis may cause increased erythrocyte turnover and haemolysis, which can contribute to unconjugated hyperbilirubinaemia.

Inherited disorders of bilirubin metabolism presenting in childhood

Inherited glucuronosyl transferase deficiency (Crigler-Najjar syndrome) is a rare disorder of impaired bilirubin conjugation that presents with progressive unconjugated hyperbilirubinaemia from birth. In type I, there is complete absence of hepatic glucuronosyl transferase activity. The disorder is inherited as an autosomal recessive trait. With modern management of phototherapy (10–12 h/day) and exchange transfusions, kernicterus is now less common, but affected individuals still go on to develop

BOX 25.5 Pathological causes of unconjugated hyperbilirubinaemia in the neonate

- Rhesus haemolytic disease of the newborn
- ABO haemolytic disease
- Congenital spherocytosis
- Glucose 6-phosphate dehydrogenase deficiency
- Prenatal infection
- Hypothyroidism
- Inherited disorders of bilirubin metabolism

severe neurological complications during adolescence. Many individuals are treated by liver transplantation by the age of five years. Heterozygotes have normal plasma bilirubin concentrations but hepatic enzyme activity is reduced by about 50%. Some heterozygotes may present in the neonatal period with unconjugated hyperbilirubinaemia.

In type II, glucuronosyl transferase activity is detectable but markedly reduced. Unconjugated hyperbilirubinaemia presents at birth and persists into adult life. Milder forms of the disorder are indistinguishable from Gilbert syndrome, a benign autosomal dominant disorder characterized by mild fluctuating unconjugated hyperbilirubinaemia. Type II glucuronosyltransferase deficiency is inherited as an autosomal dominant trait with variable penetrance. As hepatic enzyme activity normally exceeds the rate of bilirubin delivery, small changes in enzyme activity can significantly alter the expression of the disorder. Treatment with phenobarbital, which induces enzyme activity, results in a rapid decline in plasma bilirubin concentration, maximal by the sixth day, in infants with the type II disorder but not with type I.

Conjugated hyperbilirubinaemia and hepatocellular disease

Conjugated hyperbilirubinaemia, defined in infants as a conjugated plasma bilirubin concentration of $>25 \mu\text{mol/L}$, is always pathological. As in adults, the cause may be extra- or intrahepatic cholestasis or hepatocellular necrosis (**Box 25.6**). Routine liver function tests are often poor discriminators of the aetiology during the neonatal period, but the presence of pale stools is suggestive of cholestasis.

The biliary atresias comprise a group of disorders in which all grades of bile duct obstruction may be present, from a marked reduction in bile duct numbers to complete absence. Conjugated hyperbilirubinaemia develops during the first week of life and continues to increase, causing a fluctuating jaundice and failure

BOX 25.6 Some causes of neonatal/childhood liver disease

Neonatal

- Cholestasis
 - Biliary atresia
 - Choledochal cyst
 - α_1 -Antitrypsin deficiency
 - Defects of bile acid synthesis
 - Parenteral nutrition
- Hepatocellular disease
 - Infection
 - Neonatal haemochromatosis
 - Inherited metabolic diseases (Zellweger syndrome, tyrosinaemia type I, classic galactosaemia, fructose intolerance, Niemann–Pick type C)

Childhood

- Viral hepatitis
- α_1 -Antitrypsin deficiency
- Wilson disease
- Cystic fibrosis

to thrive. Early diagnosis, by abdominal ultrasound and isotope studies, is important, as extrahepatic atresia can be successfully treated surgically with the Kasai procedure (hepatic portoenterostomy). Liver transplantation is undertaken in some cases.

α_1 -Antitrypsin deficiency is probably the most common inherited metabolic disorder to cause neonatal conjugated hyperbilirubinaemia sufficient to mimic severe biliary atresia. Liver disease occurs in those patients with the PiZZ phenotype, of whom 10–20% present with neonatal cholestasis. The diagnosis must be confirmed by determining the phenotype/genotype.

Defects in the synthesis of bile acids (cholic acid and chenodeoxycholic acid) from cholesterol are rare inherited causes of cholestatic jaundice. The jaundice is usually associated with steatorrhoea and malabsorption of the fat-soluble vitamins. Defining defects of bile acid synthesis depends upon the identification of unusual profiles of bile acids or alcohols in urine.

Prolonged parenteral nutrition may cause cholestatic liver disease with a progressive rise in plasma alkaline phosphatase activity and a later rise in the plasma aminotransferases. The aetiology is unclear but it may be caused by an ascending cholangitis, secondary to intestinal stasis. The condition usually resolves when parenteral feeding is stopped and enteral feeding is started or resumed but, in some children, the abnormalities persist and chronic liver disease may supervene. Some children have been successfully treated with combined liver and small bowel transplantation.

Hepatocellular disease in neonates is associated with raised plasma aminotransferase activities, reduced plasma albumin and prolonged prothrombin time. Clinically, there may be oedema and ascites. When liver damage has occurred in utero, for instance in congenital infections and some inherited metabolic diseases, infants may present soon after birth with the neurological effects of intracranial bleeding before liver disease becomes apparent clinically.

Postnatally acquired infection may be superimposed on an inherited metabolic disease, such as tyrosinaemia type I or classic galactosaemia.

Neonatal haemochromatosis is a rare inherited disorder characterized by jaundice, hepatic failure and hypoglycaemia in the newborn period. Although the distribution of iron overload in the liver and in extrahepatic tissues, such as the heart and pancreas, is similar to that of hereditary haemochromatosis, the two conditions are distinct. The aetiology of neonatal haemochromatosis is unclear; it is probably inherited as an autosomal recessive trait. The transferrin saturation (80–90%) and serum ferritin concentration are both markedly raised.

In many infants, it is impossible to differentiate cholestasis and hepatocellular disease. Several inherited metabolic diseases are associated with neonatal hepatocellular disease. Sometimes there are clinical pointers to a diagnosis, such as the craniofacial dysmorphism of the peroxisomal disorder Zellweger syndrome (p. 462). In the absence of any specific clinical signs, the following investigations should be performed:

- blood: gases, $[H^+]/pH$
- plasma: lactate, glucose, ammonia, amino acids, α_1 -antitrypsin, prothrombin time (international normalized ratio).

Given that the liver has significant metabolic turnover, it is not surprising that inherited metabolic diseases, such as fatty acid oxidation defects, glycogen storage disease type I and urea cycle disorders, are associated with early liver disease. Affected infants are acutely ill and the diagnosis may be indicated by hypoglycaemia or hyperammonaemia, in addition to deranged liver function tests.

Disorders in which the major initial biochemical findings relate to the liver include the acute form of tyrosinaemia type I (fumarylacetoacetate hydrolase deficiency). Signs and symptoms of the acute neonatal onset form include acute liver failure with hepatomegaly, a tubulopathy, hypoglycaemia, failure to thrive, vomiting, diarrhoea and a cabbage-like odour; some infants may present with a neurological crisis. Plasma tyrosine and methionine concentrations are markedly raised. Urine organic acid analysis shows raised concentrations of the tyrosine metabolites, 4-hydroxyphenyllactic and 4-hydroxyphenylpyruvic acids, and succinylacetone. Of these biochemical findings, only the latter, succinylacetone, is specific to the defect, and allows differentiation from transient tyrosinaemia of infancy. Tyrosinaemia type I can now be successfully treated using 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC), which inhibits the enzyme 4-hydroxyphenylpyruvate dioxygenase and thus the formation of fumarylacetoacetate and succinylacetone. Succinylacetone inhibits the enzyme porphobilinogen synthase; consequently, older individuals with tyrosinaemia type I may present with features resembling those of acute intermittent porphyria. Hepatocellular carcinoma is a significant complication, and patients should be monitored regularly by measuring plasma α -fetoprotein.

There are three separate inherited disorders of galactose metabolism. The most common and severe of these (classic galactosaemia) is galactose 1-phosphate uridylyltransferase (GALT) deficiency. The acute clinical presentation of galactosaemia includes vomiting and diarrhoea, hepatic dysfunction, with a pronounced coagulopathy, an *Escherichia coli* septicaemia due to impaired leukocyte bactericidal activity, and cataracts. Galactose 1-phosphate uridylyltransferase activity should be measured in red blood cells.

Dietary galactose restriction can reverse these acute problems, but the development of long-term complications, such as developmental delay, speech abnormalities and premature ovarian failure, may not be affected by the early institution of therapy. The poor treatment outcome in classic galactosaemia is due either to endogenous production of galactose 1-phosphate through the action of epimerase or to the low intracellular availability of UDP-galactose, a necessary component of some glycolipids and glycoproteins.

Liver disease in older children

The most common causes of liver disease in childhood are viral, autoimmune and drug-induced hepatitis. However, some metabolic diseases, such as α_1 -antitrypsin deficiency, tyrosinaemia, Wilson disease or cystic fibrosis should be excluded. A Fanconi-like picture with osteopenia and rickets may indicate the presence of renal tubular damage secondary to tyrosinaemia type I, Wilson disease

or hereditary fructose intolerance. Tyrosinaemia type I may also present with hypertension and a porphyria-like crisis, owing to succinylacetone-induced inhibition of 5-aminolaevulinic acid dehydratase (ALAD), the rate-limiting enzyme in the porphyrin metabolic pathway.

Wilson disease

This recessively inherited disorder is caused by the impaired hepatic incorporation of copper into caeruloplasmin and by reduced biliary excretion of copper. Copper accumulates in the liver and later in the brain and kidneys. The disorder may present with acute liver failure, cirrhosis or chronic hepatitis after four years of age but asymptomatic hepatocellular damage has been found earlier in life. A more detailed account of Wilson disease is given in Chapter 14.

Reye syndrome or Reye-like illness

Hepatitis associated with acute encephalopathy and fatty infiltration of tissues is known as Reye syndrome. The onset of the disorder may be precipitated by a variety of conditions, including viral illness, especially varicella or influenza A or B, drugs, such as salicylates or sodium valproate, and toxins, including insecticides and aflatoxins.

The condition usually presents in children aged 3–12 years. Following a viral-like illness, the child develops persistent vomiting and a progressive encephalopathy, with irritability, confusion and, in its most severe form, coma. Jaundice is rarely present. Biochemical features include hypoglycaemia, raised plasma ammonia concentration and aminotransferase activity and a prolonged prothrombin time.

Several inherited metabolic disorders present clinically and biochemically in a manner similar to Reye syndrome. These include disorders of medium and long chain fatty acid oxidation and some organic acidaemias. Reye syndrome should not be diagnosed in a child <3 years of age until a genetic defect has been excluded. Given the possible link between Reye syndrome and salicylates it is recommended that they are not given to children under

16 years. This has led to a significant drop in the number of cases recorded.

CONCLUSION 514

INTRODUCTION

Haematology is the study of blood, its formation, composition, functions and diseases. Blood cell formation (haemopoiesis) is described in Chapter 27. Haematology laboratories perform a wide range of tests of the composition and function of the blood that assist the clinician in the diagnosis and management of disease. They are typically divided into three principal sections: general haematology, haemostasis and blood transfusion. This chapter provides an overview of the different diagnostic techniques offered in each.

GENERAL HAEMATOLOGY

The general haematology laboratory performs numerical, morphological and biochemical analysis of blood samples (now often as part of a combined blood sciences laboratory). Blood samples must be anticoagulated, for example with ethylenediamine tetra-acetic acid (EDTA) for determination of full blood count and reticulocyte count, blood film examination and plasma viscosity and

tri-sodium citrate for coagulation tests and measurement of erythrocyte sedimentation rate.

Analysis of the full blood count

The full blood count (FBC) is the most requested test profile in haematology. It comprises:

- haemoglobin (Hb) concentration
- red blood cell (RBC) count
- red cell indices (volume and haemoglobin content)
- white blood cell (WBC) count
- white blood cell differential count (neutrophils, lymphocytes, monocytes, eosinophils and basophils)
- platelet count.

The FBC is a valuable first-line screening test from which further investigations may be generated (see [Table 26.1](#)). The clinician uses information from the FBC in conjunction with the clinical history, physical examination and other investigations to help formulate and distinguish between differential diagnoses.

Full blood counts are usually performed on fully automated analysers, which provide accurate quantitation of cell parameters and can generate alerts, commonly

TABLE 26.1 Haematology adult typical reference ranges (based on those used in the authors' laboratory)

Parameter	Units	Range (females)	Range (males)
Hb	g/L	115–165	130–180
RBC	10 ¹² /L	3.80–5.80	4.50–6.50
HCT	L/L	0.37–0.47	0.40–0.54
MCV	fL	80.0–100.0	80.0–100.0
MCH	pg	27.0–32.0	27.0–32.0
MCHC	g/L	285–330	285–330
WBC	10 ⁹ /L	3.6–11.0	3.6–11.0
PLT	10 ⁹ /L	140–400	140–400
Neutrophils	10 ⁹ /L	1.8–7.5	1.8–7.5
Lymphocytes	10 ⁹ /L	1.0–4.0	1.0–4.0
Monocytes	10 ⁹ /L	0.2–0.8	0.2–0.8
Eosinophils	10 ⁹ /L	0.1–0.4	0.1–0.4
Basophils	10 ⁹ /L	0.01–0.1	0.01–0.1
ESR (age <50)	mm/h	3–9	1–7
ESR (age ≥50)	mm/h	5–15	2–10
Plasma viscosity	mPa/s	1.50–1.72	1.50–1.72
Reticulocytes	10 ⁹ /L	76–130	76–130
Serum B ₁₂	ng/L	180–1000	180–1000
Serum folate	µg/L	>4.0	>4.0
Serum ferritin	µg/L	10–300	25–350

All values are for whole blood unless stated. Hb, haemoglobin; RBC, red blood cells; HCT, haematocrit; MCV, mean cell volume; MCH, mean cell haemoglobin; MCHC, mean cell haemoglobin concentration; WBC, white blood cells; PLT, platelets; ESR, erythrocyte sedimentation rate.

known as 'flags', to the presence of unusual characteristics that may warrant review of a blood film.

Haemoglobin

The main function of haemoglobin, which is present solely within the red cells, is to transport oxygen from the lungs to the tissues (see Chapter 5). Haemoglobin is measured by spectrometry. Diluted whole blood is mixed with a reagent (e.g. Stromatolyser™) that results in cell lysis and conjugates the haemoglobin with a compound such as potassium cyanide or sodium lauryl sulphate prior to measurement of its absorbance. The presence of high concentrations of substances that increase absorbance, e.g. triglyceride-rich lipoproteins, may cause a falsely raised haemoglobin result with some methods.

Cell counting

Blood cells are counted and sized either by electrical impedance or laser light scattering methods. The impedance method utilizes the fact that blood cells are very poor conductors of electricity. When a cell passes through a small aperture across which an electric current is applied, there is a measurable rise in the electrical impedance, with the pulse height being proportional to the volume of the cell. Each cell generates a separate impulse. Light scatter utilizes the fact that cells scatter light when passed through a laser beam: the number of cells can be counted and information about the cells can be obtained according to the pattern of scatter. White cell counting is performed after lysis of the red cells.

Clumping of cells results in underestimation of cell numbers. This may occur, for example, as a result of autoagglutination of red cells in cold agglutinin disease or in vitro clumping of platelets because of inadequate mixing with EDTA anticoagulant.

Red cell indices

The red cell indices are a combination of measured and derived red cell parameters. The red cell indices usually reported are:

- mean cell volume (MCV)
- haematocrit (HCT) or packed cell volume (PCV), the percentage volume of red cells in the blood
- mean cell haemoglobin (MCH), the average mass of haemoglobin per red cell
- mean cell haemoglobin concentration (MCHC), the average concentration of haemoglobin per red cell.

Some analysers measure the MCV and calculate the HCT or PCV; others measure the HCT and calculate the MCV.

Mean cell volume is useful when assessing anaemia. For example, it is reduced in iron deficiency anaemia and increased in megaloblastic anaemia.

Mean cell haemoglobin is reduced in iron deficiency anaemia and thalassaemias; further tests such as ferritin and HbA₂ measurement may be performed to differentiate between these two conditions.

Mean cell haemoglobin concentration is reduced in iron deficiency but is probably a more useful tool within the laboratory than clinically. It is very stable in health, so it can be used as an internal quality control; a significant change in the daily mean MCHC indicates a drift in analyser calibration or a fault in its function. The MCHC is also useful for detecting anomalous results: a falsely raised Hb concentration, for example as a consequence of lipaemia, or a falsely reduced RBC count, for example owing to red cell autoagglutination, will result in a falsely raised MCHC.

The formulae for the derived parameters are as follows:

$$\text{MCV (fL)} = \frac{\text{HCT (L/L)} \times 1000}{\text{RBC (10}^{12}\text{/L)}}$$

$$\text{MCH (pg)} = \frac{\text{Hb (g/L)}}{\text{RBC (10}^{12}\text{/L)}}$$

$$\text{MCHC (g/L)} = \frac{\text{Hb (g/L)}}{\text{HCT (L/L)}}$$

White cell differential

The white blood cells are involved in the cellular immunological response to infection and other causes of inflammation. The five types of white blood cell differ in volume, conductivity, light scattering properties, uptake of fluorescent dyes and cytochemical stains, and resistance to lytic agents. These properties, used in various

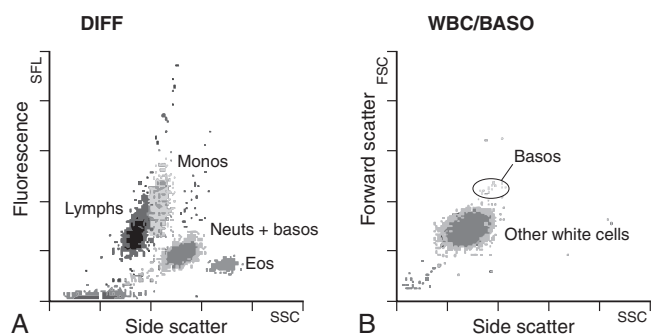

FIGURE 26.1 ■ Five-part WBC differential from Sysmex XE2100™ analyser. Note that neutrophils and basophils cannot be separated in the side fluorescence (SFL) vs side scatter (SSC) population scattergram (A). The basophil count is obtained by treating the white cells with an acidic reagent that shrinks all white cells, leaving bare nuclei, except for basophils, which remain intact (B). The neutrophil count is then derived by subtracting the basophil count from the combined neutrophil and basophil count. Lymphs, lymphocytes; monos, monocytes; neuts, neutrophils; eos, eosinophils; basos, basophils.

combinations, enable their identification. **Figure 26.1** shows typical white cell scattergrams for a normal blood sample.

Platelet count

The main function of platelets is to form a plug at sites of damage to vascular endothelium. A low platelet count (thrombocytopenia) may result from decreased production, increased consumption or abnormal pooling in the spleen. Decreased production is a consequence of either general marrow failure or selective depression, for example by viral infection, drugs and chemicals. Platelet consumption is a feature of certain types of autoimmune diseases and occurs in disseminated intravascular coagulation (which is often a result of septicaemia) and thrombotic thrombocytopenic purpura. A high platelet count (thrombocytosis) may be seen as part of a reactive process such as infection or in myeloproliferative neoplasms. Automated haematology analysers routinely measure the platelet count by impedance or laser light scattering; the reference method uses flow cytometry after labelling the platelets with CD41 or CD61 antibodies.

Reticulocyte count

Reticulocytes are immature red cells, which are released from the bone marrow into the circulation one to two days before maturation. An increase in the reticulocyte count is indicative of an increase in red cell production (erythropoiesis) to meet physiological demand, for example in haemolytic anaemia.

Reticulocytes contain ribosomal RNA, which can be detected by two main methods. When unfixed red cells are incubated with dyes such as new methylene blue, the ribosomal RNA precipitates out and appears as a blue reticular network within the cells, which can be visualised using a light microscope, allowing the reticulocytes to be counted. Most automated FBC analysers now perform reticulocyte counts by flow cytometry, using a fluorescent dye that binds to the ribosomal RNA; the number of

reticulocytes can be expressed as a percentage of total red cells and as an absolute count.

Erythrocyte sedimentation rate and plasma viscosity

Erythrocyte sedimentation rate (ESR) expressed in mm/h, is a measure of the rate at which red blood cells settle when an anticoagulated blood sample is left to stand in a column.

Plasma viscosity is usually measured by an automated viscometer. The plasma is drawn through a capillary tube under constant pressure and temperature; the rate of flow is measured and expressed as viscosity of plasma relative to distilled water.

Measurement of ESR or plasma viscosity may be useful when assessing the acute phase response. Both are affected by the presence of large proteins such as fibrinogen, α_2 -macroglobulin and immunoglobulins, and are therefore usually raised during an acute phase response. They are non-specific screening tools for inflammation, and are useful in monitoring of diseases such as rheumatoid arthritis and response to treatment for example with non-steroidal anti-inflammatory drugs and anti-tumour necrosis factor.

Plasma viscosity has several advantages over ESR. For example, it is not affected by physiological and environmental factors. Measurement is rapid, reproducible and lends itself better to quality assurance procedures than measurement of ESR. Conversely, ESR is a cheap test, but is influenced by factors such as anaemia, sex, age and (in females) stage of the menstrual cycle and must be carried out within about six hours of venepuncture.

Flow cytometry

White cells express characteristic nuclear, cytoplasmic and surface antigens; this is referred to as the immunophenotype of the cell. Immunophenotyping has been made possible by the availability of a large number of antibodies, which target specific cellular antigens. For example, antibodies that are directed against the CD19 antigen will bind to B lymphocytes.

Immunofluorescence forms the basis of flow cytometric investigations. It uses antibodies conjugated to fluorescent dyes (fluorochromes) such as fluorescein isothiocyanate (FITC), phycoerythrin (PE) and phycoerythrin cyanin (PC). Whole blood or bone marrow is incubated with one or more antibodies, each conjugated to a different fluorochrome. The cells are then injected in single file into the path of a laser beam. As the cell passes through, the light is scattered in all directions. Forward scatter (FSC) is influenced by cell size whereas side scatter (SSC) is influenced by the cellular structure and contents. The different cell populations can be visualized by plotting SSC against FSC. As the cell-antibody complex passes through the laser beam it fluoresces. The different wavelengths of light emitted are filtered, enabling specific cell populations to be selected (gated) and the data can be displayed as dot plots or histograms. The dot plots show the intensity of fluorescence as well as the number of cells

that are positive for the particular antigen; the intensity of fluorescence is proportional to the strength of antigen expression. In the example shown in [Figure 26.2](#), whole blood was incubated with three antibody-dye conjugates, CD8-FITC, CD4-PE and CD3-PC5.

Flow cytometry allows rapid immunophenotyping of cells. This is essential in the diagnosis and classification of leukaemias and lymphomas, but is also a useful tool in the assessment of non-malignant conditions and for monitoring the CD4+ lymphocyte count during the treatment of human immunodeficiency virus (HIV) infection. Flow cytometry can also be used to confirm feto-maternal haemorrhage (see [p. 512](#)), by the detection of Rh D positive fetal cells and measurement of haemoglobin F in the fetal cells.

Haematinic studies

These comprise direct measurement of the concentration of ferritin (a measure of iron status), vitamin B₁₂ and folate. They are discussed further in [Chapter 27](#).

Haemoglobinopathy screening

The haemoglobinopathies and the techniques used for their diagnosis are discussed in [Chapter 29](#).

Tests for infectious mononucleosis

Infectious mononucleosis (IM), also known as glandular fever, is caused by the Epstein-Barr virus (EBV), which infects B lymphocytes. It is associated with a high titre of a heterophile antibody, so-called because it also reacts with red cells of other species, for example sheep, ox and horse. This antibody has been termed the Paul-Bunnell antibody, named after John Paul and Walls Bunnell who discovered them.

The Paul-Bunnell antibody is not adsorbed by guinea pig kidney, in contrast to other heterophile antibodies (Forssman antibodies). Differential adsorption tests utilize this principle; the patient's serum is incubated with ox red cells and separately with guinea pig kidney antigen, after which horse red cells (reagent) are added to the mixtures. Red cell agglutination only in the latter mixture indicates the presence of the Paul-Bunnell antibody.

An alternative test is the latex agglutination test. A reagent containing latex microspheres coated with purified Paul-Bunnell antigen is mixed with the patient's serum; agglutination indicates presence of the Paul-Bunnell antibody.

Definitive confirmation of EBV infection requires serological detection of a rise in the titre of specific

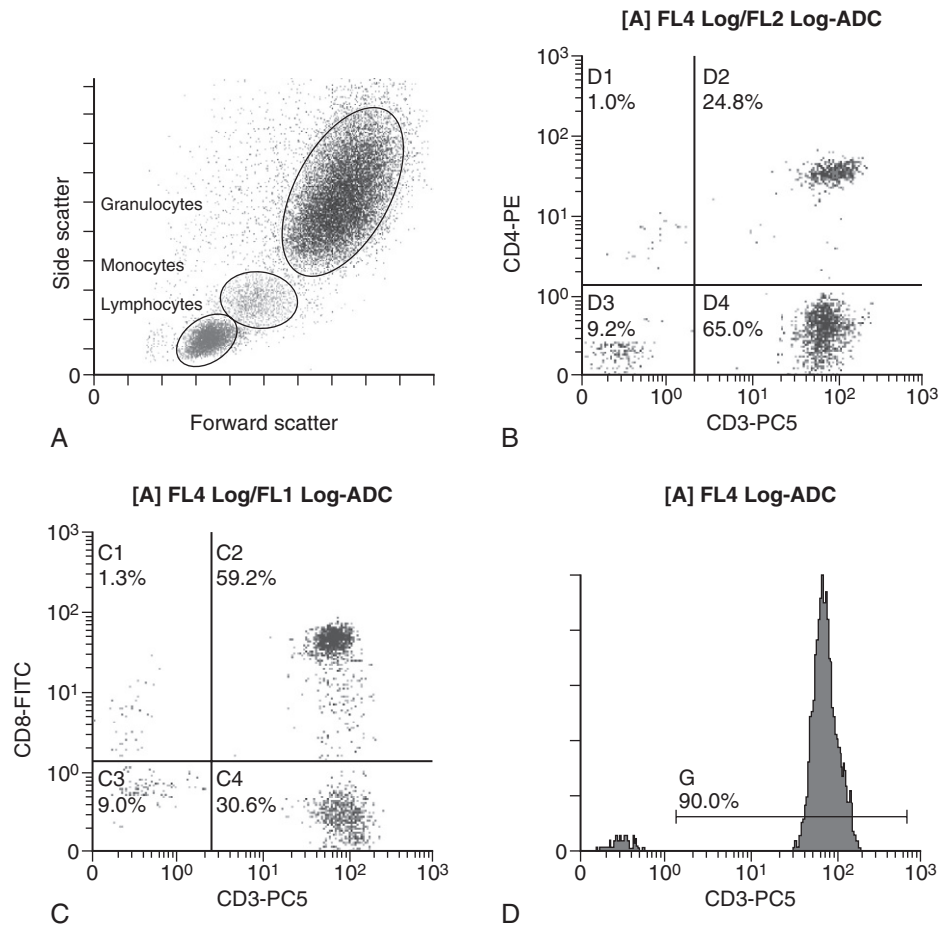

FIGURE 26.2 ■ Scatter plots, dot plots and histogram printouts from Beckman Coulter FC500 flow cytometer. (A) Side scatter vs forward scatter, showing white cell populations. Note: Granulocytes is the collective name for neutrophils, eosinophils and basophils.

anti-EBV capsid antigen IgM, which occurs in the first few weeks following infection.

MORPHOLOGY

Blood film examination

Microscopic examination of a well stained blood film is an essential part of many haematological investigations. The film may be made either manually or by an automated slide maker. After being air dried, it is stained with Romanowsky dyes such as May–Grünwald Giemsa or modified Wright stain, which contain azure B and eosin. This enables the assessment of the size, shape, maturity and contents of blood cells by light microscopy. Blood film examination is useful in the investigation of the causes of anaemia and to diagnose white cell disorders such as leukaemia and parasitic infections such as malaria. Less commonly, a blood film may be requested for specific reasons such as to look for acanthocytes (red cells with irregular spicules), which are associated with abetalipoproteinaemia, liver disease and several rare degenerative neurological diseases.

Normal red cell morphology

In health, there is little variation in the shape and size of red blood cells. On a well spread and stained blood film, red cells appear circular in outline, with a well stained outer rim and a paler central area that occupies approximately a third of the cell (see Fig. 26.3). The normal red cell appears slightly smaller than the nucleus of a small lymphocyte. It is referred to as normocytic (normal size) and normochromic (normal staining characteristics).

Valuable information can be obtained from the shape of a red cell, as shown in Figure 26.4. In many haematological conditions there may be an increase in the proportion of non-specifically abnormal red cells, termed poikilocytosis. It is also good practice to check the patient's biochemistry results, to corroborate the morphological

FIGURE 26.3 ■ Normal red cells. Shows area of central pallor (arrow) occupying one-third the size of the cell.

features; for example, if acanthocytes are present, the liver function tests should be checked, as acanthocytes are commonly present in liver disease.

Morphology of the anaemias

Anaemia is a condition in which the number of red blood cells, or their oxygen-carrying capacity, is insufficient to meet physiological needs. This is conventionally defined as a reduction in haemoglobin concentration below the reference range, i.e. <130 g/L in adult males and <115 g/L in adult females. The causes and assessment of anaemia are discussed in Chapter 27.

Iron deficiency anaemia

In iron deficiency anaemia, the red cells are smaller than normal (microcytosis). This is because the maturing red cells undergo an extra cellular division before the critical haemoglobin concentration required to arrest mitosis is achieved. The cells are also hypochromic, with a larger area of central pallor (see Fig. 26.5). Polychromatic cells (immature red cells that have a bluish hue on routine staining because of retained ribosomal ribonucleic acid) may be present, indicating increased erythropoiesis.

Megaloblastic anaemia

Megaloblastic anaemia is commonly caused by deficiency of vitamin B₁₂ or folate, both of which are essential for DNA synthesis, or the administration of drugs that interfere with DNA synthesis (e.g. methotrexate). Defective DNA synthesis results in the nucleus maturing at a slower rate than the cytoplasm, thereby producing a red cell that is larger than normal (macrocyte). Teardrop cells and red cell fragments may also be seen, as a consequence of ineffective erythropoiesis (see Fig. 26.6). A common finding is the presence of hypersegmented neutrophils (defined as presence of a nucleus with more than five lobes).

Autoimmune haemolytic anaemia

Haemolytic anaemia is a term used to describe anaemia caused by a shortened red cell lifespan. In autoimmune haemolytic anaemia, the red cells are coated with antibody (usually IgG) that is directed against the patient's own cells. When these cells circulate through the reticuloendothelial system, the surface of the red cells is eroded, leading to a change in their shape from a biconcave disc to a sphere (see Fig. 26.7).

Microangiopathic haemolytic anaemia

Microangiopathic haemolytic anaemia is a term that is used to describe the anaemia that results from physical damage to the red cells following the occlusion of arterioles and capillaries as a result of fibrin deposition or platelet aggregation. There are numerous causes, including infections (resulting, for example in disseminated intravascular coagulation (Fig. 26.8) or haemolytic uraemic syndrome), physical trauma (e.g. from mechanical heart valves) and autoimmune (e.g. thrombotic thrombocytopenic

Red cell abnormality	Possible causes	Red cell abnormality	Possible causes
 Target cell	Iron deficiency, liver disease, post-splenectomy, haemoglobinopathies, e.g. thalassaemia	 Elliptocyte	Hereditary elliptocytosis, some haemoglobinopathies, iron deficiency, myelofibrosis, megaloblastic anaemia
 Stomatocyte	Liver disease, alcoholism	 Ovalocyte	S.E. Asian ovalocytosis, macro ovalocytes – impaired DNA synthesis, e.g. B12 and folate deficiency
 Sickle cell	Diseases associated with the presence of haemoglobin S, e.g. sickle cell disease, haemoglobin SC disease	 Keratocyte (horned cell)	Microangiopathic haemolytic anaemia, e.g. disseminated intravascular coagulation, thrombotic thrombocytopenic purpura
 Tear drop cell	Myelofibrosis, metastatic marrow infiltration, megaloblastic anaemia	 Schistocyte (red cell fragment)	Microangiopathic and mechanical haemolytic anaemia
 Spherocyte; no area of central pallor	Immune haemolytic anaemia, post-splenectomy, hereditary spherocytosis, severe burns	 Echinocyte (crenated red cell); short, regular spicules	Multi-organ failure including hepatic and renal failure. Most commonly an artefact when a blood film is made from an old sample
 Irregularly contracted red cell; similar to spherocyte but not round	Haemoglobinopathies, oxidant damage especially in G6PD deficiency	 Acanthocyte; irregular spicules	Liver disease, abetalipoproteinaemia, inherited acanthocytosis

FIGURE 26.4 ■ Red blood cells. Commonly observed morphological changes in red cells and the disorders in which they arise.

FIGURE 26.5 ■ Iron deficiency anaemia (IDA). Hb 58g/L, MCV 52.1 fL, MCH 12.7pg, PLT $608 \times 10^9/L$, ferritin $<5 \mu\text{g/L}$. Blood film shows microcytic hypochromic red cells, polychromatic red cells and pencil cells. The film also shows two neutrophils, a lymphocyte and an increase in platelet numbers.

FIGURE 26.6 ■ Megaloblastic anaemia Hb 86g/L, MCV 121.9fL, MCH 43.9pg, PLT $110 \times 10^9/L$, Vit B₁₂ 62ng/L. Blood film shows macrocytic red cells, including oval macrocytes. The film also shows teardrop cells, a hypersegmented neutrophil and reduced platelet numbers.

FIGURE 26.7 ■ Warm autoimmune haemolytic anaemia. Hb 104 g/L, reticulocytes $604 \times 10^9/L$, haptoglobin <0.2 g/L (reference range 0.7–3.2), direct antiglobulin test positive. Blood film shows numerous spherocytes, polychromatic cells and a red cell containing a Howell–Jolly body. Howell–Jolly bodies are typically found in patients who have undergone splenectomy. The film also shows two neutrophils, a monocyte and a lymphocyte.

FIGURE 26.9 ■ Haemolytic uraemic syndrome. Hb 84 g/L, WBC $24.3 \times 10^9/L$, PLT $23 \times 10^9/L$. Blood film shows numerous red cell fragments, some with the characteristic horn shape (keratocyte) and reduced platelet numbers. The WCC is increased because of neutrophilia as a result of bacterial infection with *E. coli*.

FIGURE 26.8 ■ Disseminated intravascular coagulation (DIC). Hb 89 g/L, WBC $3.0 \times 10^9/L$, PLT $77 \times 10^9/L$. Blood film shows numerous schistocytes and reduced platelet numbers.

FIGURE 26.10 ■ *Plasmodium falciparum* malaria. Hb 149 g/L, WBC $6.1 \times 10^9/L$, PLT $111 \times 10^9/L$. Blood film stained by the dilute Giemsa method, showing *Plasmodium falciparum* trophozoites (ring forms) in three red cells (arrows).

purpura). The blood film contains numerous fragmented cells (called schistocytes), and immature red cells (which have variable blue–grey colouration (polychromasia) owing to the presence of ribosomal material) released by the marrow in an attempt to compensate for the shortened red cell survival (see Fig. 26.9).

Malaria

Malaria is caused by infection with parasites of the *Plasmodium* species. It causes anaemia through marrow suppression, splenic pooling and sequestration of red cells. There is also haemolysis because of removal and destruction of parasitized red cells, and intravascular haemolysis when the sporozoites are released from the infected red cells. There are four *Plasmodium* species, each having distinct morphological features that can be recognized by microscopic examination of a stained thick blood film in the majority of infected patients (see Fig. 26.10).

Normal white cell morphology

In health, five types of WBCs (also called leukocytes) are found in the peripheral blood (see Fig. 26.11). Their function is to protect the body against infection and other foreign invasion. This is facilitated by phagocytosis (neutrophils, eosinophils, basophils and monocytes) and humoral and cell mediated immunological activity (lymphocytes).

The most common cause of a raised WBC count (leukocytosis) is a neutrophil leukocytosis (neutrophilia), which may occur after severe exercise or tissue damage, and in bacterial infections, metabolic disorders and neoplasms of both haematological and non-haematological aetiology. The monocyte count may be raised in chronic bacterial infections and malignancies (again of both solid and haematological origin). A raised lymphocyte count (lymphocytosis) may be found in viral infections such as infectious mononucleosis and mumps, in chronic lymphocytic leukaemia and non-Hodgkin

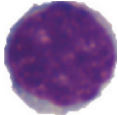

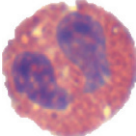

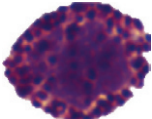

Cell type	Morphological features
	Neutrophil Deep purple staining nucleus with some chromatin clumping. Nucleus has 2–5 lobes separated by fine filaments of chromatin. Pale blue cytoplasm with an irregular outline. Numerous fine azurophilic or grey–blue granules.
	Lymphocyte Round or irregular cells with clear, pale blue cytoplasm. Nuclear chromatin varies from dense to more finely stained with occasional nucleoli present. Can be subdivided into three groups based on size and granularity: small lymphocyte large lymphocyte large granular lymphocyte.
	Monocyte Irregularly shaped cell with a large amount of cytoplasm. Cytoplasm is grey–blue and often described as having a ‘ground glass’ appearance. The cytoplasm may contain vacuoles and/or fine azurophilic granules. The nucleus makes up 70–80% of the cell and is often oval or kidney shaped.
	Eosinophil Usually has a bilobed nucleus. Pale blue cytoplasm packed with eosinophilic (red–orange) granules.
	Basophil The nucleus often has two lobes but is difficult to see as it is obscured by the large basophilic (purple) granules within the cytoplasm. The cytoplasm stains pale blue.

FIGURE 26.11 ■ White blood cells. Normal morphological features of the myeloid and lymphoid white blood cells, shown in order of prevalence in the peripheral blood.

lymphoma. Allergic disorders, parasitic infections and Hodgkin lymphoma are associated with a raised eosinophil count.

A low WBC count (leukopenia) is usually a reflection of a reduction in the concentration of neutrophils (neutropenia) or of all blood cells (pancytopenia). Causes of neutropenia include therapeutic drugs, autoimmune diseases and viral infections, whereas pancytopenia is generally caused by marrow failure.

Abnormal white cell morphology

Morphological abnormalities may be divided into those resulting from benign and malignant disorders. Benign disorders include:

- toxic changes in neutrophils in bacterial infection; neutrophils often exhibit coarser granules in the cytoplasm, cytoplasmic vacuolation and Döhle bodies (Fig. 26.12)
- neutrophil hypersegmentation in megaloblastic anaemia (Fig. 26.6)
- atypical lymphocytes in viral infection (Fig. 26.13)
- inherited disorders, for example Pelger–Huët anomaly and May–Hegglin anomaly.

Haematological malignancies

The haematological malignancies are clonal diseases originating from a single cell in the bone marrow or lymphoid tissue that has become genetically altered. They represent approximately 7% of all malignant diseases. They include acute leukaemias, chronic leukaemias, myeloproliferative neoplasms, myelodysplasia, non-Hodgkin lymphoma and multiple myeloma and its related disorders. The World Health Organization (WHO) classification of tumours of haematopoietic and lymphoid tissues is widely used to classify these malignancies. This system is based on morphologic, immunophenotypic, cytogenetic, molecular genetic and clinical features.

Acute leukaemia

Acute leukaemias have a rapid onset and progression and are invariably fatal if left untreated. They are characterized by an accumulation of early haematopoietic cells, known as blast cells (see Fig. 26.14), in the bone marrow. Morphologically, acute leukaemia is defined as the presence of >20% blast cells in the bone marrow or

FIGURE 26.12 ■ Bacterial infection. Hb 101 g/L, WBC $4.9 \times 10^9/L$, PLT $218 \times 10^9/L$. Blood film shows toxic changes in a neutrophil: coarse granulation of the nucleus, cytoplasmic vacuolation and Döhle bodies (arrows) on the edge of the cytoplasm. Döhle bodies may also be found in myelodysplastic syndromes and acute myeloid leukaemia.

FIGURE 26.13 ■ Infectious mononucleosis. Hb 165 g/L, WBC $23.9 \times 10^9/L$, lymphocytes $13.9 \times 10^9/L$, PLT $195 \times 10^9/L$. Blood film shows two atypical lymphocytes with basophilic cytoplasm. These are T lymphocytes that react against B lymphocytes infected with EBV. The film shows a typical appearance of red cells 'wrapped' around the lymphocytes.

A

B

FIGURE 26.14 ■ Two cases of acute myeloid leukaemia (AML). (A) Hb 111 g/L, WBC $1.0 \times 10^9/L$ (3.6–11.0), blast cells $0.69 \times 10^9/L$, PLT $16 \times 10^9/L$. Blood film shows three myeloblasts containing two or more nucleoli. The film also shows a neutrophil and a lymphocyte. (B) Hb 127 g/L, WBC $30.3 \times 10^9/L$, blast cells $13.3 \times 10^9/L$, PLT $31 \times 10^9/L$. Blood film shows a myeloblast containing two Auer rods in the cytoplasm and reduced platelet numbers.

peripheral blood. The acute leukaemias are a heterogeneous group of conditions; the role of morphology in classifying them into subtypes of myeloid and lymphoid leukaemias has been superseded by the use of molecular genetics, cytogenetics and immunophenotyping. This allows classification of these complex disorders into prognostically relevant categories, and aids decision-making over the role of chemotherapy or the requirement for bone marrow transplantation after disease remission has been induced. The use of molecular genetics is becoming increasingly important in monitoring both the response of the disease to treatment and detecting patients at risk of relapse.

Chronic leukaemia

Chronic leukaemias are characterized by their slower disease progression and can broadly be divided into myeloid and lymphoid types.

Chronic myeloid leukaemia is a clonal disorder of pluripotent stem cells, as shown by the presence of the Philadelphia (Ph) chromosome, an abnormal chromosome 22, which results from translocation $t(9:22)(q34;q11)$ between chromosome 9 and 22. The fusion gene *BCR-ABL1* is also created as a result of the translocation. The white cell count is usually $>50 \times 10^9/L$ and the blood film shows all the stages of the myeloid series, from myeloblasts through to neutrophils, and an increase in basophils (see Fig. 26.15).

Chronic lymphoid leukaemias are characterized by an accumulation of mature B or T lymphocytes. Included in this group are chronic lymphocytic leukaemia, prolymphocytic leukaemia, hairy cell leukaemia and plasma cell leukaemia. Chronic lymphocytic leukaemia is the most common of the chronic lymphoid leukaemias and occurs in older subjects, typically between 60 and 80 years of age. Immunophenotyping shows the cells to be of B-lineage.

FIGURE 26.15 ■ Chronic myeloid leukaemia. Hb 101 g/L, WBC $125.6 \times 10^9/L$, PLT $338 \times 10^9/L$. (A) and (B) are photographs of the same blood film showing all stages of differentiation of the myeloid lineage. Usually this is only seen in the bone marrow.

FIGURE 26.16 ■ Chronic lymphocytic leukaemia. Hb 73 g/L, WBC $950 \times 10^9/L$ (no neutrophils), PLT $85 \times 10^9/L$. Blood film shows numerous small lymphocytes and some smear cells (fragile lymphocytes damaged during spreading of blood film).

FIGURE 26.17 ■ Myelofibrosis. Hb 86 g/L, WBC $4.3 \times 10^9/L$, PLT $56 \times 10^9/L$. Blood film shows numerous teardrop cells, some polychromatic cells, one neutrophil and few platelets.

The lymphocyte count is usually $>5 \times 10^9/L$ and the blood film shows presence of predominantly small lymphocytes and smear (smudge) cells (see Fig. 26.16).

Myeloproliferative neoplasms

These are clonal disorders of haemopoietic stem cells, characterized by increased marrow proliferation of one or more myeloid cell lineages: granulocytic, erythroid, megakaryocytic and mast cells. The major myeloproliferative disorders are polycythaemia vera, essential thrombocythaemia and primary myelofibrosis (see Fig. 26.17). A single acquired mutation of the cytoplasmic kinase Janus-associated kinase 2 (JAK-2) is found in 90% of patients with polycythaemia vera and in 50% of those with essential thrombocythaemia and primary myelofibrosis.

Myelodysplasia

Myelodysplastic syndrome is a term used to describe a heterogeneous group of clonal disorders of haemopoietic stem cells. The bone marrow shows increased

proliferation but, owing to ineffective haemopoiesis, there is a reduction in all myeloid cell lineages (pancytopenia) in the peripheral blood. There is dysplasia in at least one of the cell lineages. The blood film often shows hypogranular neutrophils, pseudo-Pelger neutrophils, large hypogranular platelets and a dimorphic red cell population (see Fig. 26.18). Myelodysplastic syndrome occurs in older subjects, with a median age of 69 years. The risk of developing acute leukaemia depends upon numerous prognostic factors, including the number of blasts present in the marrow, the number of blood cell types affected and cytogenetic changes.

Non-Hodgkin lymphoma

Non-Hodgkin lymphoma refers to a heterogeneous group of clonal lymphoid tumours. The term lymphoma is generally used to describe tumours arising in lymph nodes, the spleen and other solid organs, in contrast to leukaemias, in which the bone marrow is predominantly involved, but in some cases there is

FIGURE 26.18 ■ Myelodysplasia (MDS). Hb 110 g/L, WBC $33.6 \times 10^9/L$, PLT $209 \times 10^9/L$. Blood film shows two dysplastic neutrophils with few or no cytoplasmic granules. One of the neutrophils is a pseudo-Pelger cell (bi-lobed). Both neutrophils contain Döhle bodies.

FIGURE 26.19 ■ Follicular lymphoma Hb 101 g/L, WBC $38.5 \times 10^9/L$, lymphocytes $37.7 \times 10^9/L$, PLT $85 \times 10^9/L$. Blood film shows abnormal lymphocytes, two of which have deep nuclear clefts.

no clear distinction between the two. Characteristic lymphoma cells may be seen in the blood film, for example lymphocytes with a cleaved nucleus in follicular lymphoma (see Fig. 26.19).

Multiple myeloma and related disorders are clonal malignancies of B lymphocytes. They are discussed in Chapter 30.

HAEMOSTASIS

Introduction

Haemostasis plays an essential role in preventing excess blood loss following injury. It is a complex process involving interactions between blood vessel walls, platelets and coagulation factors to form a haemostatic plug with the consequent activation of fibrinolysis, whereby the clot is gradually dissolved. Excessive activation of procoagulant mechanisms can lead to thrombosis and vascular

occlusion; therefore a delicate balance is maintained via negative and positive feedback pathways.

Following blood vessel injury, the vessel constricts to reduce blood flow, and subendothelial collagen and tissue factor is exposed. Platelets adhere to the collagen and are activated, releasing procoagulant particles and undergoing a change in membrane configuration to expose negatively charged phospholipids and coagulation factor receptors. The initial platelet plug formed is unstable but is rapidly stabilized by activation of the coagulation cascade, resulting in the formation of fibrin.

The coagulation cascade

Historically, the coagulation process was divided into separate *intrinsic* and *extrinsic* pathways, terminating in the final *common* pathway with the formation of a stable fibrin clot. It is now established that the coagulation cascade is a single series of more complex interactions.

In vivo, blood coagulation is initiated by the exposure of tissue factor (TF) following endothelial cell damage. The TF binds to factor VII, and functions as a cofactor in the activation of factor VII, with the resulting TF:FVII_a complex activating factor X and factor IX, enabling the conversion of prothrombin to thrombin. The TF:FVII_a complex is quickly inhibited by tissue factor pathway inhibitor but the thrombin already generated enables the coagulation process to continue as it feeds back to activate coagulation factors V, VIII and XI, resulting in amplification of the brief initiator process. The ultimate goal of the coagulation process is the generation of thrombin, which converts fibrinogen to fibrin. Fibrin monomers spontaneously join together via hydrogen bonds, forming insoluble fibrin polymers; these are then cross linked by factor XIII_a, changing the relatively unstable primary platelet plug into a stable clot. In vitro, however, consideration of coagulation screen results in terms of the traditional pathways allows for the simpler interpretation of the common laboratory tests (see Fig. 26.20).

Once a stable clot has been produced and bleeding has ceased, the clot is reorganized and resorbed by a process called fibrinolysis. The main enzyme responsible is plasmin, which is formed from plasminogen.

In order to restrict coagulation factor activation to the site of injury, naturally occurring inhibitors including anti-thrombin, protein C and protein S are produced.

Laboratory tests of coagulation

Laboratory tests of coagulation attempt to mimic in vitro the complex in vivo coagulation processes, but cannot do so completely. The generation of an abnormal result does not therefore necessarily mean that the patient has a bleeding diathesis, and a normal result does not completely exclude a bleeding diathesis. It is important that the test results are interpreted in the clinical context; the indiscriminate use of coagulation screens is best avoided.

The standard tests for coagulation include prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen concentration, D-dimer concentration and

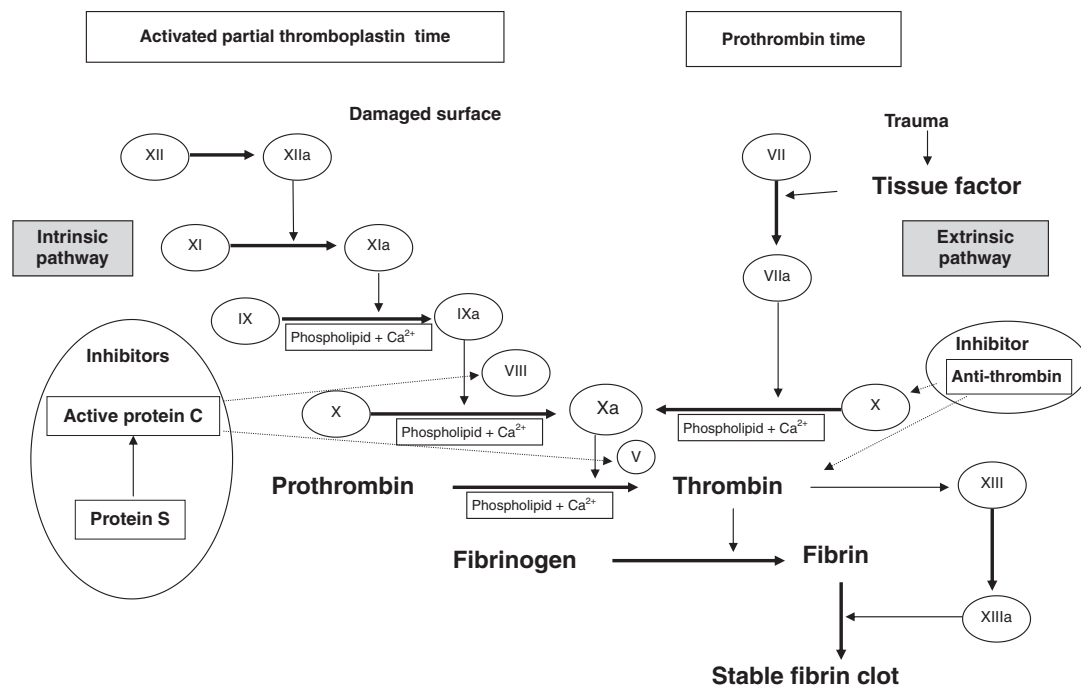

FIGURE 26.20 ■ Coagulation cascade to illustrate use of laboratory tests and the function of naturally occurring inhibitors.

thrombin time (TT). The PT measures the coagulation factors involved in the classic extrinsic and common pathways and the APTT is used to test the coagulation factors involved in the classic intrinsic and common pathways.

Prothrombin time and APTT are measured by techniques that ultimately detect the formation of fibrin clot by either mechanical or optical methods.

Prothrombin time

Plasma is mixed with thromboplastin, which contains TF, phospholipids and calcium ions, all of which are required for the activation of the extrinsic pathway. This causes a fibrin clot to form via the extrinsic and common pathways. Different thromboplastin reagents result in differing prothrombin times but internationally standardized results can be generated by correlating the thromboplastin used with the WHO reference standard. This converts the PT result to an International Normalized Ratio (INR), which is used for monitoring patients on warfarin.

Activated partial thromboplastin time

Measurement of the APTT involves induction of the formation of a fibrin clot via the intrinsic and common pathways. Plasma is first incubated with partial thromboplastin, which contains a contact activator, e.g. micronized silica or kaolin, which activates factor XII and phospholipids, triggering the intrinsic pathway. The factor XII_a in turn activates factor XI; this reaction is not significant *in vivo* but is used *in vitro* to produce factor XI_a independently of the extrinsic pathway. A second reagent containing calcium ions is then added, to enable the process to proceed to the formation of a fibrin clot.

Fibrinogen and thrombin time

Fibrinogen concentration can be estimated from the optical density changes observed when PT is measured using the optical method. A more accurate measurement can be performed using the thrombin clotting time. In this investigation, a thrombin-containing reagent is added to a dilution of the patient's plasma: the resultant clotting time is proportional to fibrinogen concentration.

D-dimer concentration

D-dimers are cross-linked D fragments: they are only produced as a result of the breakdown of cross-linked fibrin and not from the degradation of fibrinogen and soluble fibrin. Around 2–3% of plasma fibrinogen is physiologically converted to cross-linked fibrin and then degraded. Thus a small quantity of D-dimer is present in the plasma of healthy individuals. Increased amounts of cross-linked fibrin degradation products are found in states of coagulation activation and increased plasma D-dimer concentration may indicate an increased rate of fibrinolysis; this may be a consequence of the presence of a deep venous thrombosis (DVT) or pulmonary embolus (PE), or a result of disseminated intravascular coagulation (DIC). It should be noted that the main diagnostic value of D-dimer measurement lies in its negative predictive value; raised concentrations are commonly found post surgery, in pregnancy, in malignancy and in other situations associated with activation of the fibrinolytic system, resulting in many false positives.

Plasma D-dimer concentration is usually measured by latex particle enhanced immunoassay. There are also many assays that measure fibrin degradation products (FDPs) often using latex agglutination techniques.

The diagnostic value of FDPs is reduced by the fact that they may be generated from the breakdown of both fibrin and fibrinogen and thus their presence is not necessarily associated with clot formation.

Specific factor assays

Deficiency of individual clotting factors is detected by adding the patient's plasma to artificially produced plasma that is deficient in one specific factor. Measurement of PT or APTT on this mixture enables calculation of factor concentration. Results are expressed as a percentage of normal activity. An abnormal result may reflect the presence of an inhibitor antibody as well as factor deficiency. This can be identified by performing a correction study where plasma from healthy subjects is added to the test plasma, in a 50:50 ratio. If correction is less than expected, the presence of an inhibitor of coagulation should be suspected.

Interpretation of coagulation tests

If a patient presents with a history of excessive bleeding or easy bruising, the use of the simple laboratory screening tests will guide the clinician to the likely underlying cause and what further investigations are appropriate. A guide to the interpretation of the results is given in [Table 26.2](#).

Haemophilia

The most common clotting factor deficiency associated with bleeding is factor VIII deficiency, also known as haemophilia A, followed by factor IX deficiency

(haemophilia B). Inheritance of both conditions is sex-linked and can be caused by a number of different mutations. The severity of the bleeding disorder depends on the amount of active clotting factor: individuals with <1% are classified as having severe haemophilia, those with 1–5% have moderate haemophilia and those with mild haemophilia have 5–40% of normal concentrations of active clotting factor. Patients with severe haemophilia suffer from recurrent severe and spontaneous bleeds. Bleeding may occur anywhere in the body but those that are associated with the most serious complications are joints, muscles, gastrointestinal tract and the brain. Most patients with severe haemophilia require regular prophylactic supplementation with recombinant factor concentrate and additional supplementation following episodes of bleeding or to cover surgery (see [p. 513](#)). Patients may develop antibodies (or inhibitors) to the factor infused, rendering it ineffective. In these situations, recombinant activated factor VII and activated prothrombin complex concentrates (factor VIII inhibitor bypassing activity, FEIBA) can be useful in the treatment of bleeding. Patients with mild haemophilia tend to bleed only after surgery or serious trauma and can often be managed successfully with desmopressin, which releases stored factor VIII from blood vessel walls.

Disseminated intravascular coagulation

Disseminated intravascular coagulation can become catastrophic if not treated rapidly. It may be triggered by numerous disorders, such as sepsis, disseminated malignancy and amniotic fluid embolism. These lead to the formation of small blood clots in blood vessels throughout the body,

TABLE 26.2 Screening tests used in the diagnosis of coagulation disorders

Screening tests	Coagulation disorders indicated by abnormal result	Most common cause of coagulation disorder
Prothrombin time (PT)	Deficiency or inhibition of one or more of the following coagulation factors: VII, X, V, II or fibrinogen	Warfarin therapy Prematurity Disseminated intravascular coagulation (DIC)
Activated partial thromboplastin time (APTT)	Deficiency or inhibition of one or more of the following coagulation factors: XII, XI, IX VIII, X, V, II or fibrinogen	Haemophilia (factor VIII) Christmas disease (factor IX) Heparin therapy Liver disease DIC
Fibrinogen	Inflammatory or neoplastic conditions	Low concentrations: DIC Liver disease Fibrinolytic therapy High concentrations: Inflammation Neoplastic conditions
D-Dimer	Fibrin clot lysis	Pulmonary embolus Deep vein thrombosis DIC Postoperative Infection Cancer Pregnancy (raised in normal pregnancy)
Thrombin time	Deficiency or abnormality of fibrinogen or inhibition of thrombin by heparin or fibrinogen degradation products (FDPs)	Heparin therapy DIC Other thrombin inhibitors Hypofibrinogenaemia Dysfibrinogenaemia

consuming coagulation factors and platelets and resulting in abnormal bleeding, e.g. from venesection sites, gastrointestinal tract and surgical wounds. Coagulation screen results will show prolonged PT and APTT, and low fibrinogen and high D-dimer concentrations. In these circumstances, the underlying cause should be corrected as soon as possible and platelets, fresh frozen plasma (FFP) and cryoprecipitate infused if bleeding is severe (see p. 513).

BLOOD TRANSFUSION

Introduction

In the UK, blood donation is entirely voluntary and open to healthy individuals aged 17–65 years at the time of first donation. Donors undergo rigorous health assessments; individuals with lifestyle risks or a recent history of infection are excluded from donating. Each donation is of 450 mL of whole blood and is tested for human immunodeficiency virus (HIV), hepatitis B and C, and syphilis, along with determination of the Rh and ABO blood group, before it is released to be transfused into a recipient.

Hospital blood transfusion laboratories perform a range of tests required for supply of patient-compatible blood and blood products and in the investigation of haemolysis resulting from blood incompatibility (including haemolytic disease of the newborn).

Blood group antigens

The red cell membrane carries a range of surface antigens. Those that differ between individuals of the same species as a result of genetic polymorphisms (alloantigens), and can therefore elicit an immune response between donor and recipient blood, are termed the blood group antigens. There are around 30 recognized blood group systems.

ABO blood group

This blood group system is considered the most important, because of the high risk of a severe haemolytic transfusion reaction if ABO incompatible blood is transfused.

There are three antigens in the ABO blood group system, A, B and H. The *ABO* gene is located on chromosome 9 and has three alleles, *A*, *B* and *O*. The *A* allele encodes a glycosyltransferase that adds N-acetylgalactosamine to the glycoprotein H antigen that is expressed on all normal red cells. The *B* allele encodes a different glycosyltransferase that adds D-galactose. The *O* allele is a deletion that results in loss of enzyme translation and

therefore presence of unmodified H antigen. *A* and *B* are co-dominant alleles; AB individuals express both antigens.

Individuals produce antibodies to the antigen that they lack on their red cells. Landsteiner's law states that, for whichever ABO antigen is not present on the red cells, the corresponding antibody is found in the plasma (see Table 26.3). Antibodies to A and B antigen develop in the first few months of life, without exposure to the red cell antigen, as a result of environmental exposure to bacteria. They are referred to as 'naturally occurring' antibodies. ABO antibodies are usually IgM but may be IgG.

It is essential that the ABO group of transfused red cells is compatible with the ABO blood group of the patient. Transfusion of even a few millilitres of red cells into patients who have the corresponding antibody results in a severe immune reaction, which may be fatal. Cells of blood group O are compatible with patients of all ABO blood groups so individuals of group O can be referred to as *universal donors*. Conversely, individuals of blood group AB can receive blood from any of the other groups and are referred to as *universal recipients* (see Table 26.3).

Rh blood group

The Rh (formerly rhesus) blood group consists of over 45 antigens, of which D, C, E, c and e antigen are usually typed in donor blood. All patient samples for blood grouping are routinely typed for their RhD status because the D antigen is clinically the most important after the ABO antigens. About 85% of the population express the D antigen and are called RhD positive; the remainder are termed RhD negative. The D antigen is highly immunogenic so individuals who are RhD negative but receive RhD positive blood are likely to produce anti-D antibodies. Anti-D has the potential to cause a severe haemolytic transfusion reaction and cause haemolytic disease of the newborn (HDN) (see below).

Expression of the D antigen is variable. Some patients express only small amounts of the D antigen; their RhD status is termed weak D. Other patients express only part of the D antigen; their RhD status is described as partial D. Partial RhD individuals can produce antibody to the part of the D antigen, which they lack, so they should receive RhD negative red cells if they require transfusion.

Other important blood groups and antibodies

Kell, Kidd, Duffy and MNS blood groups are clinically important because antibodies to antigens of these blood groups can cause either transfusion reactions or HDN or both. They are included routinely in antibody identification panels.

TABLE 26.3 ABO antigen, antibodies, genotype and compatibility

ABO group	Antigen on red cell	Antibody in plasma	Genotype	Compatible ABO group
A	A	Anti-B	AA or AO	A, O
B	B	Anti-A	BB or BO	B, O
O	None	Anti-A,B	OO	O
AB	A and B	None	AB	AB, A, B, O

The Kell antibody (Anti-K) is the most commonly found antibody after those to the ABO and Rh blood group antigens. A third of all non-ABO, non-Rh allo-antibodies are anti-K. It is good practice to give Kell-negative blood to patients who already have antibodies to other blood group antigens. Women of child-bearing age who require blood transfusion should also be transfused with Kell negative blood of the appropriate ABO and Rh grouping.

The Kidd antibodies (Anti-Jk(a) and Anti-Jk(b)) form another important antibody system that can cause severe acute and delayed transfusion reactions. Anti-Jk(a) is the most commonly implicated antibody in delayed transfusion reactions. Anti-Jk(a) may fall to low or undetectable concentrations in the patient's plasma over time so can be difficult to detect.

Laboratory transfusion tests

Blood grouping and antibody screen

Commonly referred to as 'group and save', this is the most requested test and comprises two parts: ABO and RhD grouping, and an antibody screen.

ABO and D grouping Antisera are mixed with the patient's red cells; this is known as the forward group. In ABO grouping, the patient's plasma is also mixed with known A and B cells: the reverse group. The positive and negative patterns of agglutination determine the patient's ABO and RhD group (see Table 26.4). This can be performed manually or by automated methods but the principles remain the same.

Antibody screening This procedure is designed to detect clinically significant alloantibodies to blood group systems other than ABO. There are two stages to an antibody screen: sensitization and haemagglutination.

The patient's plasma is incubated at 37°C with two or three red cell samples of known blood group phenotype. These samples are always group O to avoid reactions that would result from ABO incompatibility. The antibody-antigen complex formation that occurs is termed sensitization. In the second stage, anti-human globulin (AHG) reagent is added, to encourage cross linking between sensitized red cells, as most antibodies are of the IgG class so cannot directly form cross links. If agglutination occurs, further tests are required to identify the antibody or antibodies present. This procedure is known as the indirect antiglobulin test (IAT).

The patient's sample is retained and stored in accordance with national guidelines. It can subsequently be used in order to crossmatch blood for that patient, as described later. It is essential that, if a patient has recently been transfused, they are re-tested prior to any further transfusion in order to detect any new antibodies they may have developed in response to the previous transfusion.

Antibody identification panels

Antibodies that need to be identified are those that can cause transfusion reactions or HDN. Following a positive antibody screen, further tests are done to identify the antibody using the same theory as for antibody screening. The antibody panel usually contains at least ten different red cell reagents of known phenotype. There are usually two sets of red cell reagents in one panel set, one of which has been treated with an enzyme that cleaves off part of the red cell membrane, as a result of which some antigens are lost from the red cell membrane (MNS and Duffy systems) and others are exposed in order to produce stronger antibody binding (the Rh system). The use of both sets of cells is important as the differences in reaction for different blood group systems can help determine antibody identity, particularly when multiple antibodies are present.

Crossmatching (compatibility testing)

Crossmatching is designed to ensure compatibility of donor units with the recipient. The procedure can be either non-serological or serological. There are three main types of crossmatch:

- electronic crossmatch or blood issue (non-serological)
- immediate spin crossmatch (serological)
- full crossmatch (serological).

Electronic crossmatch is the quickest to perform, enabling issue of blood within five minutes. A prerequisite is that a group and antibody screen has already been performed for that patient. In this non-serological process, the laboratory computer system checks for ABO and RhD compatibility. For a sample to be suitable for electronic crossmatching, a number of requirements must be met. There are some minor differences between guidelines issued by the British Committee for Standards in Haematology (BCSH) and the American Association of Blood Banks (AABB), but the following elements are generally considered essential in the UK:

TABLE 26.4 A selection of ABO and D grouping results

Known reagent	Anti-A	Anti-B	Anti-A,B	Anti-D	Anti-D	A cells	B cells	
Patients cells/plasma	Cells	Cells	Cells	Cells	Cells	Plasma	Plasma	
	-	-	-	+	+	+	+	O Pos
	+	-	+	+	+	-	+	A Pos
	-	+	+	-	-	+	-	B Neg
	+	+	+	-	-	-	-	AB Neg
	Forward group				Reverse group			

- the ABO and RhD grouping procedure must have been performed on a fully automated grouping machine
- results must have been transferred to the laboratory computer system electronically, with no manual editing of results
- there must be two concordant ABO and RhD records on file for that patient
- no clinically significant antibodies have been detected presently or historically.

Transfusion laboratories may also adhere to additional locally determined rules, for example only donor units that have been electronically entered onto the computer system (via barcode scanning) being considered suitable for electronic issue. Not all laboratories perform electronic crossmatch, as some may not be equipped with automated analysers or do not have a laboratory computer system that is capable of processing the required algorithm.

Immediate spin crossmatch is designed principally to detect ABO incompatibility. It may be used in an emergency when there is insufficient time to perform a full antibody screen. It may also be performed when the criteria for electronic issue are not fully met, for example if a sample has been run on an automated analyser that has not been able to interpret the group correctly. This could be caused by weak expression of anti-A, anti-B or RhD. It is also important that there is no record of the patient having clinically significant antibodies presently or historically. This is a manual technique performed in tubes: the patient's plasma and donor red cells are incubated and then centrifuged to check for haemagglutination or haemolysis that would indicate ABO compatibility. Using this technique, it takes 10–15 min for blood to be issued from the laboratory.

Full crossmatch is performed if time or equipment availability do not permit a sample to be processed on a blood grouping analyser, or following automatic processing if the patient is known to have clinically significant antibodies presently or historically. Some laboratories may not have adopted the immediate spin or the electronic crossmatch and therefore continue to use the full crossmatch routinely. In this procedure, the patient's plasma is incubated with donor units and checked for compatibility using the IAT technique described in the previous section. Using this technique, it takes 45 min for blood to be issued from the laboratory.

Investigation of suspected transfusion reaction

Serious or life-threatening acute reactions are very rare. Acute haemolytic transfusion reactions are most commonly a consequence of errors in taking or labelling the sample, collecting wrong blood from the blood bank, inadequate checking of the product at the bedside or laboratory errors. Symptoms, such as the patient having a feeling of impending doom, agitation, flushing or pain at the venepuncture site or in the abdomen, flank or chest can occur after transfusion of only a few drops of blood.

Clinical signs include fever and hypotension; generalized oozing from wounds or puncture sites can occur and there may be haemoglobinaemia or haemoglobinuria. Life-threatening transfusion reactions can also occur with platelet and FFP transfusions, for example owing to bacterial contamination or transfusion-related acute lung injury.

Following a suspected transfusion reaction, urgent blood tests (full blood count, assessment of kidney and liver function), along with assessment of the urine for haemoglobinuria, should be undertaken. The donor units and giving set should be returned to the laboratory, along with a fresh blood sample. The blood sample and donor units along with the original 'group and save' sample are then tested retrospectively for compatibility. At this point, it is also important to confirm the blood group of any units transfused and send the giving set and donor packs for culturing. Blood cultures should be taken if the patient has a persistent fever, and a coagulation screen performed to exclude developing DIC if the reaction is severe.

Haemolytic disease of the newborn

Haemolytic disease of the newborn (HDN) is a condition in which the neonatal red cells have a shortened lifespan because antibodies of maternal origin have crossed the placenta and coated them. These cells are then removed by the immune system. The mother will have produced the antibodies following fetal–maternal haemorrhage. It is not uncommon in pregnancy for small 'silent' bleeds to occur that are too small for detection. Antibodies that cause HDN are of the IgG class. The most common cause of HDN is ABO incompatibility, in which cases the haemolysis is usually mild. More severe cases of HDN can be caused by anti-D, anti-c and anti-K. Anti-K suppresses neonatal red cell production as the K antigen is one of the first antigens to be expressed on the red cells during red cell production.

Standard UK antenatal practice is that samples are taken for blood group and antibody screening when the patient is booked for antenatal care (8–12 weeks of gestation) and again at 28 weeks. If the mother is RhD negative, samples are also sent at delivery. Expectant mothers who have produced antibodies during pregnancy require close monitoring. Depending on when the antibody is first detected, BCSH guidelines state that grouping and antibody screening should be performed and antibody titre determined every four weeks up to the 28th week of pregnancy and then every two weeks thereafter. The antibody titre can be used as a guide to the potential severity of HDN, with the exception of anti-K for which there is no quantitative test and little correlation between concentration and the severity of HDN.

In the UK, the incidence of HDN caused by anti-D has been reduced following the implementation of national anti-D prophylaxis programmes for antenatal women. Pregnant women who are RhD-negative are given prophylactic anti-D sufficient to deal with any silent bleeds. Routine prophylaxis can either be given as two doses of 500 IU anti-D administered at 28 weeks and then 34 weeks of gestation or a single dose of

1500 IU administered at 28 weeks. At delivery, an RhD negative mother is given more anti-D if the baby is RhD positive. The amount they receive depends upon the results of a Kleihauer test, which is a slide test for the number of fetal cells in the maternal circulation (see Fig. 26.21). If any sensitizing events occur during the pregnancy, it will be necessary to administer a top-up dose of anti-D.

Blood products

Red cells

Red cells are the most common blood product issued by a transfusion laboratory. Indications for red cell transfusion include active bleeding, acute anaemia caused by trauma or surgery, and chronic anaemia secondary to malignancy. For surgery in which blood loss is expected, red cells are cross-matched in advance in accordance with a maximum surgical blood ordering schedule (a schedule of the number of red cell units routinely crossmatched for each type of elective surgical procedure). Red cell concentrates have a maximum shelf-life of 35 days and must be stored at $4 \pm 2^\circ\text{C}$.

Transfusion of emergency group O RhD negative blood is an important option in life-threatening situations when there is insufficient time to provide crossmatched blood. These units must be easily available especially to the emergency department and theatres. The criteria for the selection of donor units should be determined locally, for example negative for the C and E Rh antigens and the Kell antigen, low titre of ABO antibodies and cytomegalovirus negative.

Platelets

Platelet transfusions are indicated for the prevention and treatment of haemorrhage in patients with thrombocytopenia or defective platelet function. They are, however, contraindicated in post transfusion purpura, thrombotic thrombocytopenia purpura and heparin induced thrombocytopenia as they would increase the risk of thrombosis.

FIGURE 26.21 ■ Kleihauer film. There is a good distinction between the three cell types: maternal cells (A), fetal cells (B) and white cells (C). The presence of RhD positive fetal cells is confirmed by flow cytometry.

Platelet concentrates can be produced by pooling together platelets from whole blood donations or by obtaining platelets by apheresis. Platelets must be stored at $22 \pm 2^\circ\text{C}$ and have a shelf-life of up to seven days with continuous gentle agitation.

Fresh frozen plasma

Fresh frozen plasma (FFP) contains all clotting factors found in plasma. Indications for its use are limited but it is most often used in patients with massive bleeding where clotting factors are being consumed or are diluted owing to the administration of large volumes of red cells or crystalloids. It must be stored at $< -25^\circ\text{C}$ and for a maximum of 24 months. It is most effective if used within four hours of thawing but can be stored at 4°C post thawing for up to 24h.

Cryoprecipitate

Cryoprecipitate is a plasma fraction rich in fibronectin, fibrinogen, factor VIII and von Willebrand factor. It is used particularly in patients who have low plasma fibrinogen concentrations such as during massive transfusions and in DIC. Like FFP, it must be stored at $< -25^\circ\text{C}$ and for a maximum of 24 months.

Factor concentrates

Factor concentrates can be either fractionated or recombinant. Fractionated products are produced by pooling multiple donations, which increases the risk of viral transmission to the recipient, making recombinant products the preferred option. Recombinant factor concentrates are used in patients with inherited deficiencies of clotting factors, either prophylactically or during bleeding episodes (see p. 509). Prothrombin complex concentrate, rich in factors II, VII, IX and X, is used for the emergency correction of warfarin-induced bleeding. Factor VII concentrate, although only licensed for use in inherited or acquired haemophilia with significant inhibitors or Glanzmann thrombasthenia (a platelet function disorder), is being increasingly used if life-threatening bleeding persists despite optimization of laboratory measured clotting and platelet parameters.

Risks of transfusion

The incidence of adverse events caused by blood transfusion is low, although the consequences are potentially severe. The main adverse risk is that of receiving the incorrect blood component. Strict procedures are in place to ensure vein to vein traceability of all blood products and to reduce the risks of misidentification of either the patient or donor. The very rare but fatal complication of transfusion-associated graft versus host disease, whereby immunocompetent donor lymphocytes are infused into an immunocompromised patient (from bone marrow transplantation or other defects in T cell immunity), is prevented by the irradiation of blood products to inactivate any residual white cells. The risk of transmitting infections is very small provided that appropriate screening and selection of donors is in place.

Regulations

In the UK, blood transfusion laboratories have to comply with a range of specific regulations and standards of practice, which are monitored by the Medicines and Healthcare Regulatory Authority (MHRA). The key standards are incorporated into UK law, making infringement a criminal offence. Adverse incidents associated with blood transfusion must be reported to the MHRA.

CONCLUSION

- The full blood count is the most requested test profile in haematology and is a valuable first line screening test from which further investigations can be generated.
- Blood film examination is an essential part of a haematological investigation, as valuable information can be obtained from cell morphology.
- Prothrombin time, activated partial thromboplastin time, thrombin time, D-dimer and fibrinogen measurements are useful screening tests for coagulation disorders but should be interpreted within the clinical context.
- The blood transfusion laboratory performs a vital role in the provision of safe and effective blood product support.
- Antibody identification is an essential procedure in the prevention of transfusion reactions and haemolytic disease of the newborn.

ACKNOWLEDGEMENTS

We would like to thank our colleagues Rebecca Pleasance, Gemma Greenall and Colin Greig, who critically reviewed the material in this chapter and made many helpful suggestions. Rebecca Pleasance also provided the photographs and some of the text used in Figures 26.4 and 26.11.

CONCLUSION 532

INTRODUCTION

Blood is often considered a liquid organ that acts as the transport system of the body. It is composed of a liquid (plasma) in which cells are suspended. There are three types of cells. Red cells are the most numerous; they play a vital role in the provision of oxygen to the organs and peripheral tissues. The white cells comprise the phagocytes, granulocytes and monocytes, which are mobilized in the blood to sites of infection and inflammation where they pass into the tissues to engulf and destroy bacteria and other objects deemed foreign by the body, and the lymphocytes which, via the secretion of antibodies and cytokines, coordinate defence against acute infection and maintain long term immune surveillance. Finally, the platelets, in conjunction with coagulation proteins in the plasma, allow prompt and effective haemostasis in the event of injury.

This chapter will focus on the structure and function of the red cells, or erythrocytes, and the pathophysiological mechanisms underlying the disorders of red cells that result in anaemia.

THE FORMATION, STRUCTURE AND FUNCTION OF THE NORMAL RED CELL

Formation

The first primitive blood cells develop in the embryo during the third week after conception and are seen in

the yolk sac. These cells migrate to the liver and spleen, which become the major sites of blood formation (erythropoiesis) until after birth. From approximately five months' gestation, erythropoiesis begins to occur in bone marrow. This is called medullary erythropoiesis (as opposed to extramedullary erythropoiesis, when cells are produced in other sites such as the liver and spleen). By birth, medullary erythropoiesis is occurring in the marrow cavity of nearly every bone in the body. With maturity, many of the marrow cavities become replaced with fat and, by adulthood, erythropoiesis is limited to the axial skeleton (sternum, vertebrae and pelvis only). The other sites retain the ability to produce blood cells if marrow function is compromised by various pathological processes.

Red cells survive for approximately 120 days and therefore the bone marrow needs to generate new haemopoietic cells continuously. It is estimated that the average adult requires synthesis of 10^{11} red cells per day. Red cells originate from pluripotent uncommitted stem cells that are capable of producing any type of blood cell. The earliest recognizable committed progenitor for erythroid cells is the colony forming unit – granulocyte, erythroid, megakaryocyte, macrophage (CFU-GEMM). This has a limited self-renewal capacity and may mature into the various haemopoietic lineages depending on various stimuli within the bone marrow microenvironment. The first unique erythroid progenitor is the burst

forming unit – erythroid (BFU-E), from which further progeny develop into recognizable erythroid cells (see Fig. 27.1). Maturation of the erythroid cells involves primarily haemoglobin synthesis, which is vital for the subsequent function of the cell, and also condensation and eventual extrusion of the nucleus, removing the ability of the cell to proliferate. This process takes approximately seven days and results in the release of a reticulocyte, an immature red cell slightly larger than the mature red cell with a blue tinged cytoplasm owing to residual nuclear material. The reticulocyte then travels from the marrow to the spleen where the residual nuclear remnants are removed, producing the mature red cell.

Thus, effective erythropoiesis requires a delicate balance between maintaining a pluripotent stem cell pool and allowing the development and terminal differentiation of the progeny to mature erythroid cells. The exact process by which this is achieved has not been elucidated but involves many transcription factors such as runt-related transcription factor 1 (RUNX1), acute myeloid leukaemia 1 (AML-1) protein, TEL oncogene (ETV6) and mixed lineage leukaemia (MLL) protein orchestrating, either alone or in conjunction with others, the intricate signalling processes required to produce mature erythroid cells. The dysregulation of these transcription factors, often via genetic mutations, results in a range of haematological malignancies that afford scientists a means of studying the role of these

factors in normal erythropoiesis. GATA-1, with its co-factor FOG-1 (friend of GATA-1), is one of the most important transcription factors involved in the terminal differentiation of the erythroid cell. Its name is derived from its ability to bind to DNA sites with the consensus sequence (AT)GATA(AG) within the promoter regions of many of the genes encoding red cell membrane proteins and enzymes.

Erythropoiesis is the production of mature, haemoglobin-rich, red cells that carry oxygen to the tissues of the body. It is therefore not surprising that hypoxia is a major driver of erythropoiesis via the induction of hypoxia inducible factor (HIF), a transcription factor pivotal to coordinating the body's response to hypoxia. This binds to hypoxia response elements (HREs), resulting in the activation of genes for proteins that play a vital role in oxygen delivery, such as vascular endothelial growth factor (leading to new blood vessel formation) and erythropoietin (a hormone which stimulates erythropoiesis).

Structure of the red cell

Red cells have a biconcave disc shape and a membrane structure that gives them particular strength and deformability to allow their passage through capillary networks, allowing the effective oxygenation of the tissues. The membrane consists of a phospholipid bilayer, with charged hydrophilic phosphatidyl groups forming the outer and inner surfaces, and a hydrophobic interior.

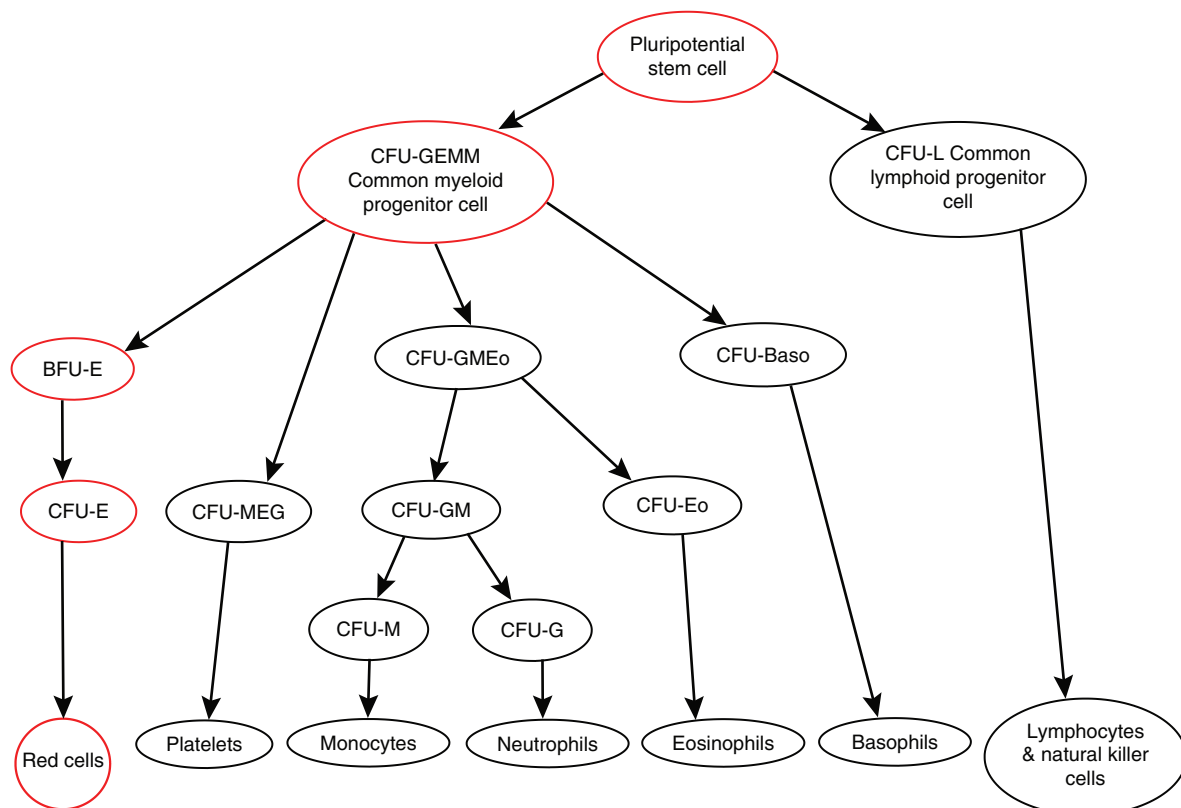

FIGURE 27.1 ■ Schematic representation of haemopoiesis. BFU, burst forming unit; CFU, colony forming unit; E, erythroid; Eo, eosinophil; GEMM, granulocyte, erythroid, monocyte, megakaryocyte; GM, granulocyte, monocyte; L, lymphocyte; M, monocyte; MEG, megakaryocyte.

It is stabilized by integral membrane proteins that span the lipid bilayer, providing numerous functions, including the transmembrane passage of ions and interaction with the proteins of the cytoskeleton below. The cytoskeletal protein spectrin forms tetramers that aggregate into a hexameric scaffolding that lies on the cytoplasmic surface of the cell membrane to preserve its shape and structure. The ankyrins anchor membrane proteins to spectrin and maintains correct orientation of membrane ion channels. Abnormalities in any of these proteins result in an alteration of shape and flexibility of the red cell with a consequent reduction in survival. This is the pathological basis of the inherited haemolytic anaemias, of which the commonest is hereditary spherocytosis.

Function of the red cell

The most important function of the red cells is to transport oxygen from the lungs to the tissues and to return the carbon dioxide they produce to the lungs. Normal adult haemoglobin consists of two α globin chains and two β globin chains; a haem prosthetic group is bound to each chain. Haem comprises a tetrapyrrole IX α ring bound to a single Fe^{2+} ion. The binding of a single molecule of oxygen to a haem group results in a change in conformation of the haemoglobin molecule that promotes further oxygen binding to the other subunits. These allosteric interactions allow for the efficient uptake and release of oxygen. In order to achieve this, the red cell requires a source of both ATP and reducing power. ATP generation is vital to maintain the deformability of the membrane and to regulate water and ion exchange. The reducing power of the red cell is required both to protect against the oxidation of the lipid bilayer and to reduce the methaemoglobin that is formed when ferrous iron (Fe^{2+}) is oxidized to its ferric form (Fe^{3+}) back to functional deoxyhaemoglobin. Anaerobic glycolysis is the main pathway responsible for supplying the cell with both ATP and nicotinamide adenine dinucleotide (reduced) (NADH), a cofactor for methaemoglobin reductase, the enzyme that catalyses the reduction of methaemoglobin to functional haemoglobin (see Fig. 27.2).

The pentose phosphate pathway produces nicotinamide adenine dinucleotide phosphate (reduced) (NADPH) and pentose sugars. The latter are returned to the mainstream of glycolysis if necessary. Reduced nicotinamide adenine dinucleotide phosphate is essential for keeping glutathione in the reduced state, thus enabling it to perform its antioxidant functions. These consist mainly of eliminating hydrogen peroxide and free radicals and thus preventing oxidation of the red cell membrane or haemoglobin. The Rapoport–Luebering shunt is responsible for producing 2,3-diphosphoglycerate (2,3-DPG) from the 1,3-diphosphoglycerate that is produced in anaerobic glycolysis. 2,3-Diphosphoglycerate modulates the oxygen affinity of haemoglobin (see Chapter 5).

Various non-glycolytic enzymes contribute to red cell metabolism in a complementary fashion. Some of these are involved in glutathione metabolism as shown in Figure 27.2. Others catalyse nucleotide metabolism

and participate in adenylate salvage pathways. During maturation of the reticulocyte, the ribosomal DNA is catabolized to its constituent nucleotides by the enzyme ribonuclease. The resulting nucleotides of adenine are useful to the cell and are processed through appropriate salvage pathways. Nucleotides of pyrimidine, however, can be harmful and must be eliminated. This is achieved through their dephosphorylation by a specific enzyme, pyrimidine 5'-nucleotidase, following which the resultant nucleosides leave the cell by passive diffusion.

As the red cell matures, it extrudes its nucleus and mitochondria, and becomes incapable of protein synthesis. Thus, none of the enzymes contained within the red cell can be replaced and the decline in metabolic activity results in a more rigid and fragile cell membrane. This becomes damaged during its passage through the capillaries and the red cell is eventually removed by cells of the reticuloendothelial system, particularly the macrophages of the spleen.

ANAEMIA

Anaemia is defined as a blood haemoglobin concentration below that which would be expected for a healthy individual of that age or sex. Regardless of its cause, the symptoms of anaemia are similar, reflecting the effects of poor oxygen delivery to tissues. These symptoms may often be vague and include tiredness, headaches and breathlessness.

Anaemia may be classified on the basis of the size of the red cells (microcytic, normocytic and macrocytic). This chapter, however, will discuss anaemias using a classification based on kinetic aspects of red cell production as follows:

- reduction in red cell production
 - nutritional deficiencies
 - inherited causes
 - acquired causes
- increased red cell loss
 - bleeding
 - haemolysis (inherited or acquired).

ANAEMIAS ASSOCIATED WITH A REDUCTION IN RED CELL PRODUCTION

Iron deficiency anaemia

Iron deficiency anaemia is one of the commonest causes of anaemia worldwide and has significant socioeconomic consequences. Other haematinics essential for adequate erythropoiesis are vitamin B_{12} and folate.

Iron physiology

Iron plays a vital role in many metabolic processes. It is an essential component of both haemoglobin and myoglobin and also plays an important part in electron transfer and the generation of energy (e.g. in cytochrome *c* oxidase and catalase). Non-haem iron is also important in DNA synthesis as it is essential for

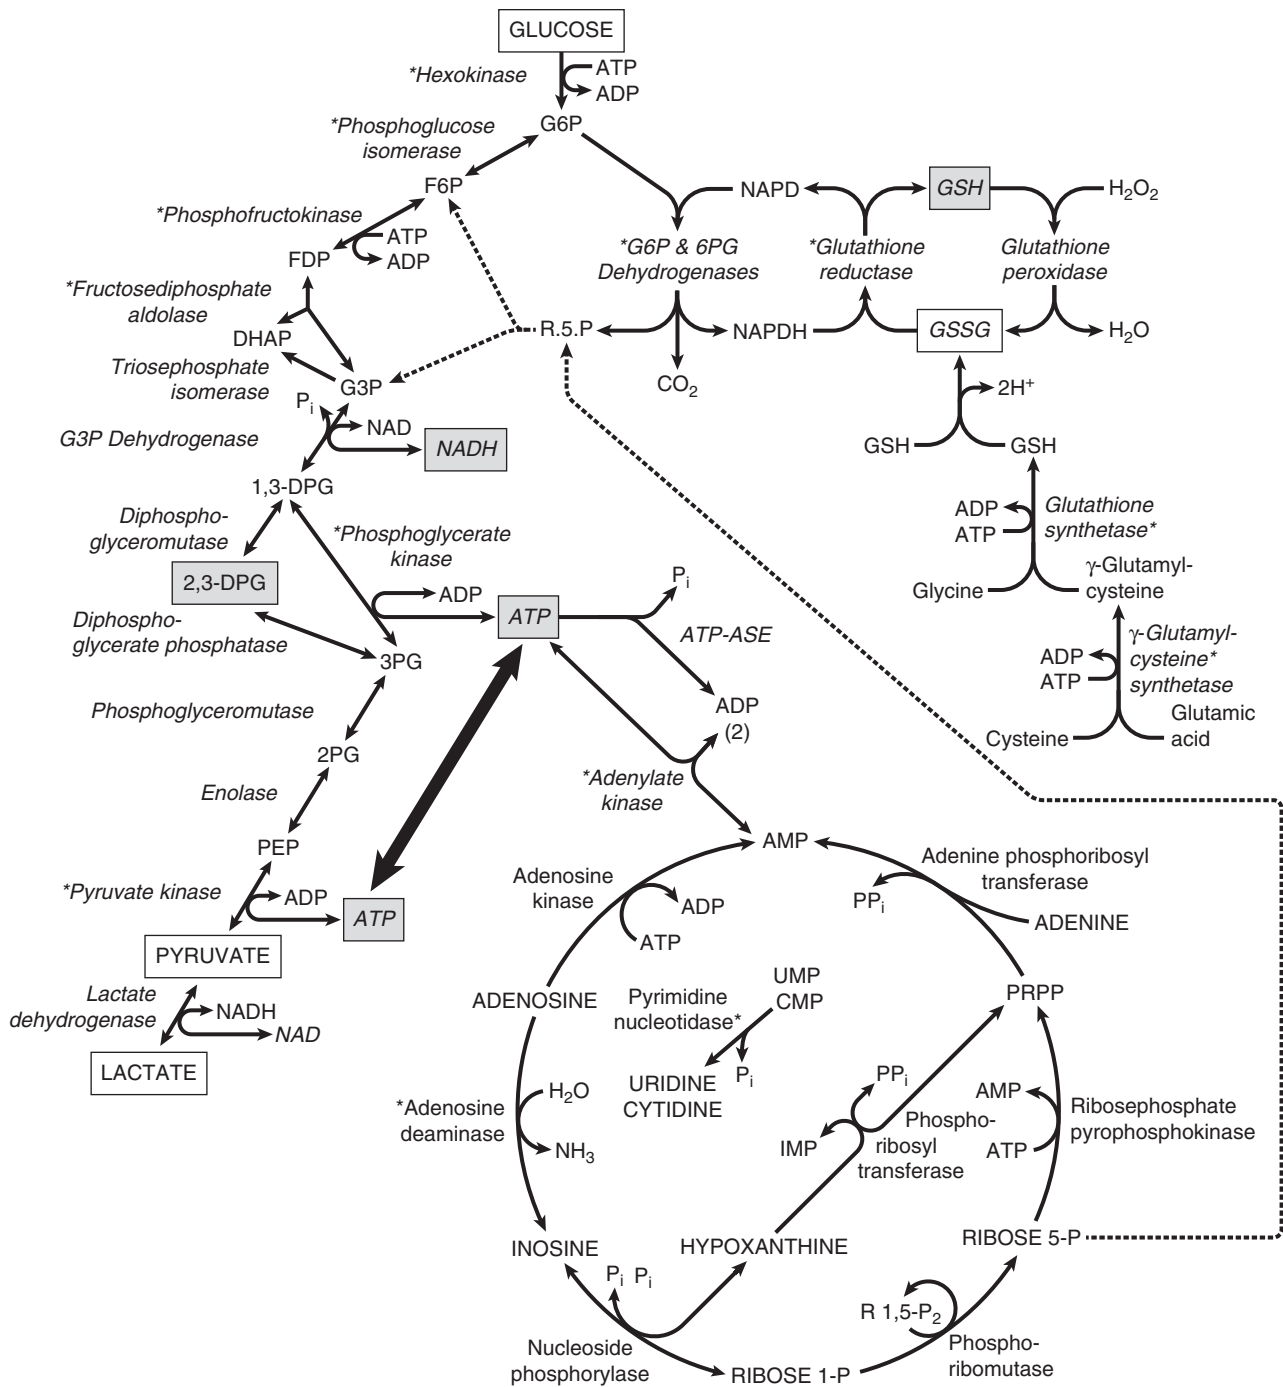

FIGURE 27.2 ■ Pathways of energy metabolism in human erythrocytes. Glucose 6-phosphate (G6P) may be degraded anaerobically to two molecules of lactate via the Embden–Meyerhof (glycolytic) pathway (on the left) or oxidatively via the dehydrogenases of the pentose phosphate pathway. Ribose 5-phosphate (R5P) can re-enter anaerobic glycolysis after conversion to fructose 6-phosphate (F6P) and glyceraldehyde 3-phosphate by enzymes of the terminal pentose phosphate pathway and is also a product of adenosine or inosine degradation. 2,3-Diphosphoglycerate (2,3-DPG) may be generated instead of ATP by diversion of triose through the Rapoport–Luebering shunt. Glutathione may be directly synthesized from constituent amino acids, and its cycling from oxidized (GSSG) to reduced form (GSH) is dependent on generation of reduced pyridine cofactor (NADPH). Asterisks (*) indicate those enzymes found to be defective in association with hereditary haemolytic anaemia. Abbreviations: ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; ATPase, adenosine triphosphatase; CMP, cytidine monophosphate; DHAP, dihydroxyacetone phosphate; 1,3-DPG, 1,3-diphosphoglycerate; 2,3-DPG, 2,3-diphosphoglycerate; FDP, fructose 6-phosphate; G3P, glyceraldehyde 3-phosphate; G6P, glucose 6-phosphate; GSH, reduced glutathione; GSSG, oxidized glutathione; IMP, inosine monophosphate; NAD, nicotinamide adenine dinucleotide (oxidized); NADH, nicotinamide adenine dinucleotide (reduced); NADP, nicotinamide adenine dinucleotide phosphate (oxidized); NADPH, nicotinamide adenine dinucleotide phosphate (reduced); PEP, phosphoenolpyruvate; 2PG, 2-phosphoglycerate; 3PG, 3-phosphoglycerate; P_i, inorganic phosphate; PP_i, inorganic pyrophosphate; PRPP, phosphoribosyl pyrophosphate; R1P, ribose 1-phosphate; R1,5-P₂, ribose 1,5-diphosphate; R5P, ribose 5-phosphate; UMP, uridine monophosphate.

TABLE 27.1 The normal requirements and body stores of the vitamins and minerals essential for erythropoiesis

Vitamin	Dietary sources	Site of absorption	Body stores	Adult daily requirement
Iron	Red meats, fish, poultry, fortified cereals, beans, spinach	Duodenum and proximal jejunum	3–4 g	Male 1 mg Female 1.6 mg
Folate	Dark green leafy vegetables, liver, dried beans and peas, fortified flours and cereals	Duodenum and upper jejunum	10 mg	100 µg
B ₁₂	Liver, kidney, shellfish, and other foodstuffs of animal origin	Distal ileum	2–3 mg	1 µg

the function of ribonucleotide reductase. Many of these roles are aided by the fact that iron may exist in two stable oxidized states, as soluble ferrous (Fe^{2+}) iron and as insoluble ferric (Fe^{3+}) iron.

Iron requirements. The total body content of iron in normal adults is 3–4 g (see Table 27.1). Approximately two-thirds is contained in haemoglobin and the remainder in myoglobin, iron containing enzymes and the reticuloendothelial cells. Approximately 30 mg of iron is required per 24 h for haemoglobin in new red cells and the majority of this is supplied from the reticuloendothelial macrophages that recycle the iron from senescent red cells. However, approximately 1 mg of iron is lost from the body every 24 h and needs to be replaced from dietary sources. Women of childbearing age have additional blood loss from menses or pregnancy, resulting in a further 0.5 mg average loss of iron per 24 h. Infants and adolescents require additional iron during periods of rapid growth. A normal diet provides approximately 15 mg of iron but most is in the form of insoluble iron complexes and only 5–10% is absorbed.

Iron absorption. Absorption of iron occurs in the proximal duodenum. It is aided by the low pH of the hydrochloric acid secreted into the gastric lumen and the presence of reducing agents such as ascorbic acid, which help maintain the iron in the more soluble ferrous form. In contrast, other agents such as tannins, phytates and phosphates bind the iron within the intestinal lumen, inhibiting its absorption.

Although iron has an essential metabolic function, excess is toxic and therefore it is not surprising that iron metabolism is tightly regulated.

Hepcidin plays a critical role in iron metabolism. This 25 amino acid peptide is produced predominantly in the liver, from an 84 amino acid precursor. Its synthesis is stimulated by iron and inflammation (driven by IL-6) and inhibited by iron deficiency, hypoxia (via HIF) and conditions such as ineffective erythropoiesis where the concentration of growth differentiating factor 15 (GDF-15) in the developing erythroblasts is increased. Hepcidin negatively regulates iron homeostasis by binding to ferroportin: the resultant hepcidin-ferroportin complex is phosphorylated, internalized by the cell, ubiquitinated and subsequently degraded in the lysosomes. Ferroportin is a transmembrane protein that functions as a basolateral exporter of iron, playing an essential role in the release of iron from macrophages,

intestinal enterocytes and placental syncytiotrophoblasts, allowing the uptake and transfer of iron by transferrin to sites of need. Thus the stimulation of hepcidin production results in reduced iron absorption and mobilization (see Fig. 27.3). Genetic haemochromatosis (see Chapter 14), where there is significant iron accumulation and deposition in various body tissues resulting in cirrhosis, cardiac failure and diabetes, is a consequence of a defect in the hepcidin pathway.

Iron transport and storage. Transferrin, a single chain polypeptide produced in the liver, acts as the plasma transporter of iron, binding two molecules of ferric iron per molecule. The transferrin-iron complex binds to transferrin receptors, cell surface glycoproteins consisting of two identical 95 kDa subunits linked by a disulphide bridge, localized on cells dependent on iron for function, e.g. for the production of haemoglobin, myoglobin or iron dependent enzymes. After binding, the complex is internalized and degraded, releasing the iron. Ferritin is the primary iron storage protein, found in all tissues but especially the reticuloendothelial system, with small amounts in the plasma. Each molecule of ferritin can store up to 4000 atoms of iron and consists of 24 subunits of two different types, H and L. Variation in the proportion of H and L subunits results in molecular heterogeneity, for example heart and red cell ferritin contains more H subunits than ferritin from liver and spleen, which are rich in L subunits.

The synthesis of all the proteins involved in iron metabolism is finely controlled at the molecular level by having iron response elements (IREs) within their mRNA. In iron replete situations, iron response proteins (IRPs), present in the cytoplasm of many cells, are non-functional by virtue of the binding of an iron-sulphur complex. However, when the cell is iron deplete, the IRPs bind to IREs to stimulate the gene transcription of proteins that enhance iron absorptive capacity.

Causes of iron deficiency anaemia

Iron deficiency is most commonly secondary to blood loss, usually from gastrointestinal or menstrual sources. In the developing world, hookworm infestation resulting in gastrointestinal blood loss is the commonest cause of iron deficiency anaemia; the resultant reduced working capacity has significant socioeconomic impact. Coeliac disease, which is associated with flattening of the duodenal mucosal villi with subsequent malabsorption, accounts for 5% of cases of iron deficiency. Other causes

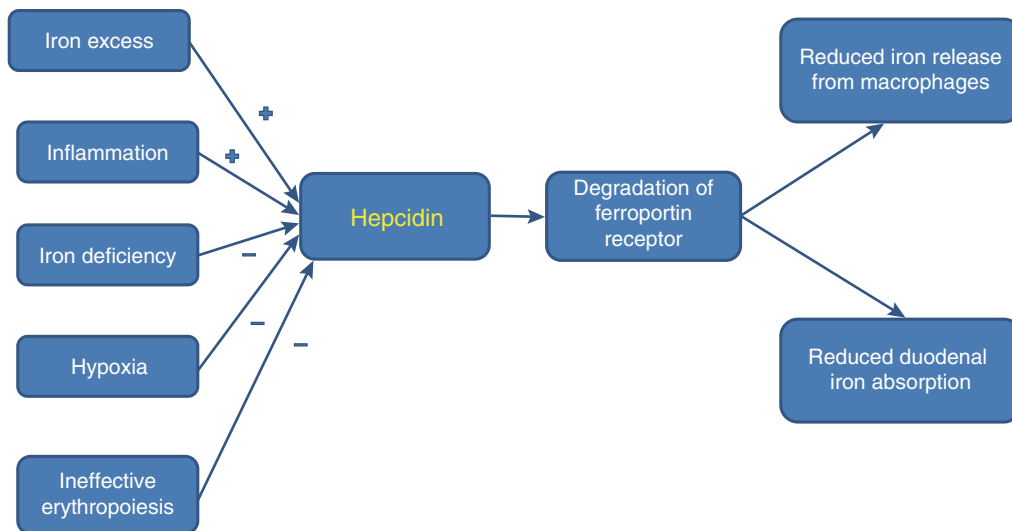

FIGURE 27.3 ■ Factors affecting hepcidin production by the liver and consequent iron absorption and utilization. When hepcidin production is stimulated by conditions such as iron excess or inflammation, it binds to and results in the degradation of ferroportin in enterocytes and macrophages, preventing the absorption and utilization of iron. Conditions associated with iron deficiency or ineffective haemopoiesis inhibit hepcidin production, thereby resulting in iron accumulation.

include inadequate dietary iron during periods of rapid growth such as puberty.

Clinical consequences of iron deficiency

Iron deficiency causes a hypochromic microcytic anaemia (see Chapter 26) with additional clinical features such as koilonychia (a spoon-shaped malformation of the nails), angular stomatitis, glossitis, alopecia and pica. There are concerns that significant iron deficiency in infants results in impaired mental development.

Laboratory determination of iron status

Red cell parameters. Iron deficiency is associated with a reduction in the red cell mean corpuscular volume (MCV) and mean cell haemoglobin concentration (MCHC).

Hypochromic red cells. Some automated analysers allow the determination of numbers of hypochromic red cells. Counts of >6% are suggestive of iron deficiency.

Serum iron. Measurement of serum iron concentration alone provides little useful information of iron status as values show considerable variation within normal individuals. Low concentrations are seen in iron deficiency but are also seen in the anaemia of chronic disease and after surgery.

Serum ferritin. This parameter provides an accurate reflection of iron stores in healthy individuals with normal concentrations ranging from 15 µg/L to 300 µg/L. However, it is an acute phase reactant and its concentration may therefore be falsely normal in iron deficiency with coexistent inflammation.

Serum iron binding capacity, transferrin and transferrin saturation. In the plasma, each molecule of transferrin binds up to two iron ions. Thus, the total iron binding

capacity (TIBC) of plasma reflects serum transferrin concentration. It is raised in iron deficiency and pregnancy. Transferrin saturation is a ratio of serum iron concentration to TIBC expressed as a percentage. A value of <16% is suggestive of iron deficiency whereas elevated fasting transferrin saturations of >55% in males and >50% in females are suggestive of iron overload. In the anaemia of chronic disease, both serum iron and TIBC are reduced, thus the transferrin saturation is usually normal.

Serum transferrin receptor. As erythroblasts mature, cleavage releases the extracellular portion of the transferrin receptor into the plasma. The concentration of the transferrin receptor rises in iron deficiency but not in the anaemia of chronic disease. Transferrin receptor concentration can be measured by enzyme immunoassay, although the assay is only available in a few specialist centres.

Hepcidin. Assays for this protein are under development but as yet are poorly standardized. Controversy exists as to whether urinary or serum hepcidin measurements are superior.

Bone marrow aspiration. At present, staining bone marrow aspirates for iron is the 'gold standard' for assessing iron deficiency.

The megaloblastic anaemias resulting from vitamin B₁₂ and folate deficiency

The megaloblastic anaemias give rise to characteristic morphological appearances: the red cells are macrocytic and hypersegmented neutrophils are present (see Chapter 26). Ineffective erythropoiesis is apparent, manifest in the serum by raised unconjugated bilirubin and reduced haptoglobin concentrations and markedly raised lactate dehydrogenase (LDH) activity. Megaloblastosis arises when either drugs or deficiencies of cobalamin or folate interfere with DNA synthesis.

Folate metabolism

Folates are a group of compounds derived from pteroylglutamic acid (see Fig. 27.4). Excellent dietary sources of folates include green leafy vegetables, liver, yeast and nuts (see Table 27.1).

Folate requirements. A normal diet in the developed world contains about 250 µg of folates per day but <1% of this is in the form of folic acid. The principal naturally occurring folates are tetrahydrofolate (THF), 5-methyl tetrahydrofolate (5-methyl THF) and 10-formyl tetrahydrofolate (10-formyl THF), which are polyglutamated. Total body folate in the adult is 10 mg, providing sufficient stores for four months given a daily metabolic requirement of 100 µg (see Table 27.1).

Absorption of folate. The majority of folate is absorbed in the upper small intestine, where pteroylpolymethylglutamate hydrolase on the mucosal brush border hydrolyses folate polymethylglutamates to the monomethylglutamate form. They are then converted to 5-methyl THF and transported by an active carrier mediated mechanism across the enterocytes and into the portal blood.

Within the plasma, one third of 5-methyl THF is loosely bound to albumin whilst the remainder is unbound. It is taken up by active transport into replicating cells. Here the folates play a vital role by acting as coenzymes in the transfer of single carbon groups in pathways involved in the synthesis of purines, pyrimidines (for DNA and RNA synthesis) and methionine (for methyl donor reactions) (see Table 27.2).

Causes of folate deficiency

- Nutritional.
- Malabsorption: diseases of the small intestine, coeliac disease, tropical sprue.
- Excessive utilization or loss: pregnancy, prematurity, haemolytic anaemias, skin conditions, inflammatory conditions, haemodialysis.
- Antifolate drugs: anticonvulsants, trimethoprim, methotrexate.

Features of folate deficiency

Folate deficiency is thought to cause megaloblastic anaemia by inhibiting thymidylate synthesis, which is required for DNA production. It causes a macrocytic anaemia with hypersegmented neutrophils and a megaloblastic bone marrow. It may be associated with a pancytopenia. For further details on morphology, see Chapter 26.

Laboratory determination of folate status

Both serum and red cell folate concentrations can be measured by immunoassay. Serum folate concentration is affected by recent dietary intake and may be low after only a short period of inadequate diet. Conversely, serum folate concentration may rise in vitamin B₁₂ deficiency owing to a blockage in the conversion of 5-methyl THF, the major circulating form, to THF.

Red cell folate may be a more accurate test of body folate status as its concentration is not affected by recent diet. However, red cell folate concentration is also reduced in vitamin B₁₂ deficiency.

Vitamin B₁₂ metabolism

Structure of vitamin B₁₂. The vitamin B₁₂ (cobalamin) molecule is centred on an atom of cobalt; this is the only known function of cobalt in humans. The surrounding corrin ring is made up of four pyrrole units in a similar manner to porphyrins (see Fig. 27.5), with variations in two substitutions above and below the ring giving rise to the various forms of the vitamin. Vitamin B₁₂ is mainly contained within the mitochondria in the 5'-deoxyadenosyl form, where it plays a role in the conversion of L-methylmalonyl-CoA to succinyl-CoA. The other main form, methylcobalamin, is found within the cytoplasm and plasma where it is a cofactor for the conversion of homocysteine to methionine, a vital part of the pathway that creates a universal methyl donor (see Fig. 27.6).

Source of vitamin B₁₂. Vitamin B₁₂ is synthesized only by microorganisms and the only source for humans is food of animal origin. Liver is the richest source of vitamin B₁₂, but it is present in almost all animal products, including milk. No vegetable food source contains significant amounts of vitamin B₁₂ unless contaminated by bacteria (see Table 27.1).

Vitamin B₁₂ requirements. An adult human requires only 1 µg of vitamin B₁₂ per 24 h and has stores of 2–3 mg. Thus, it can take 3–4 years for vitamin B₁₂ deficiency to develop (see Table 27.1).

Absorption of vitamin B₁₂. Dietary vitamin B₁₂ is bound to food proteins and must be freed by gastric acid. The parietal cells of the stomach secrete the glycoprotein intrinsic factor (IF), which combines with vitamin B₁₂ to form a complex, which resists proteolytic digestion. The vitamin B₁₂-IF complex passes through the small intestine until it binds to cubilin, a surface receptor on the enterocytes of the terminal ileum, where it is internalized. The enterocytes of the ileum have a limited capacity to absorb vitamin B₁₂ because of a limited number of receptor sites; about half of a dose of 1 µg of vitamin B₁₂ will be absorbed, the proportion falling markedly with higher doses. The enterocytes have a refractory period of about 6 h before they can absorb any more vitamin B₁₂.

Within the enterocyte, the vitamin B₁₂ is liberated and, after binding to the β-globulin carrier transcobalamin II (TCII), is released into the blood. The TCII-vitamin B₁₂ complex is termed 'holotranscobalamin'. Transcobalamin II readily releases the vitamin B₁₂ to the bone marrow and other tissues, and, for this reason, holotranscobalamin is also described as 'active B₁₂'. Other transcobalamins also exist; transcobalamin I and III derive mainly from specific granules found in neutrophils and bind vitamin B₁₂ tightly, in contrast to TCII, and do not release it into the tissues. Congenital TCII deficiency can occur, the affected infant presenting with megaloblastic anaemia a few weeks after birth.

Dihydropteroyl glutamic acid (Dihydrofolate)

Tetrahydropteroyl glutamic acid (Tetrahydrofolate)

5-methyl tetrahydrofolate

10-formyl tetrahydrofolate

FIGURE 27.4 ■ Pteroylglutamic acid and derivatives. The nitrogen atoms in the 5 and 10 positions are the sites involved in single carbon transfer reactions. Tetrahydrofolate and its 5-methyl and 10-formyl derivatives are shown as polyglutamates.

TABLE 27.2 Reactions in which pteroylglutamate acid derivatives are involved

Folate derivative involved as:	Reaction
Single carbon donor	
10-formyl tetrahydrofolate (THF)	Purine synthesis
5,10-methylene THF	Thymine synthesis
5,10-methylene THF	Synthesis of glycine from CO ₂ and NH ₄ ⁺
5-methyl THF	Homocysteine → methionine
Single carbon acceptor	
THF (forms 5,10-methylene THF)	Serine → glycine
THF (forms 5-formimino THF)	Breakdown of histidine

FIGURE 27.5 ■ The corrin ring surrounding an atom of cobalt that forms the core of cobalamin. The other two ligands to cobalt (above and below the plane of the corrin ring), and substituents on the pyrrole units, are not shown.

Causes of vitamin B₁₂ deficiency

- Nutritional: this is rare and is only seen in very strict vegans.
- Malabsorption: the commonest cause of vitamin B₁₂ malabsorption is the autoimmune condition, pernicious anaemia, where gastric atrophy develops secondary to an inflammatory infiltrate. Autoantibodies to gastric parietal cells are seen in 90% of individuals with the condition and 50% develop IF autoantibodies, which either prevent vitamin B₁₂-IF complex formation (binding antibodies) or the subsequent attachment of the vitamin B₁₂ to the enterocyte mucosa (blocking antibodies).
- Gastric causes: such as total or partial gastrectomy.
- Intestinal causes: ileal resection and diseases of the terminal ileum such as Crohn disease or tropical sprue prevent vitamin B₁₂ absorption. Deficiency is also associated with intestinal blind loop syndrome (because of metabolism of the vitamin B₁₂ by the overgrowth of intestinal bacteria) and fish tapeworm (*Diphyllobothrium latum*), which binds cobalamin, preventing its absorption.

FIGURE 27.6 ■ The link between folate and vitamin B₁₂ deficiency in megaloblastic anaemia. 5,10-Methylene tetrahydrofolate polyglutamate is required for a rate-limiting step in DNA synthesis, the conversion of deoxyuridine monophosphate to deoxythymine monophosphate. Vitamin B₁₂ is required in one of the reactions converting the main circulating form of folate, 5-methyl THF, to 5,10-methylene THF.

- Acquired: prolonged nitrous oxide exposure oxidizes methylcobalamin to an inactive state and results in functional vitamin B₁₂ deficiency. This has been seen in dentists and anaesthetists. Metformin may be associated with low serum vitamin B₁₂ concentrations. The exact mechanism for this is unknown but it has been postulated to be caused by metformin interfering with the calcium dependent channels responsible for the ileal absorption of the vitamin.

Features of vitamin B₁₂ deficiency

Vitamin B₁₂ is a coenzyme in the interconversion of the different forms of folate (see Fig. 27.6), so its deficiency results in a megaloblastic anaemia identical to that seen in folate deficiency. Deficiency may also result in neurological symptoms (e.g. peripheral neuropathy, dysfunction of the posterior columns of the spinal cord and sometimes psychotic illnesses and dementia). The precise mechanism for this has not been elucidated but may be linked with impaired conversion of homocysteine to methionine, resulting in either reduced availability of S-adenosylmethionine impairing sphingomyelin synthesis or in the toxic accumulation of the homocysteine metabolite S-adenosylhomocysteine.

Laboratory determination of vitamin B₁₂ status

Serum vitamin B₁₂. This is usually measured by automated immunoassay. Normal concentrations are 160–1000 ng/L. A low concentration is not specific for vitamin B₁₂ deficiency and may be found in one-third of patients with folate deficiency and in normal pregnancy.

Measurement holotranscobalamin (TCII - bound vitamin B₁₂, or 'active B₁₂') may be a more sensitive and specific indicator of physiologically relevant vitamin B₁₂ deficiency.

Serum methylmalonate and homocysteine. Vitamin B₁₂ deficiency results in the elevation of methylmalonate and homocysteine concentrations (see Fig. 27.6). However, concentrations of both compounds fluctuate and may be raised in renal impairment, smoking and (on single occasions) in up to 30% of normal volunteers, making definition of a specific cut-off level difficult.

Deoxyuridine suppression test. The conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP) during DNA synthesis is by methyl group transfer, facilitated by both vitamin B₁₂ and folate. The other source of dTMP is via phosphorylation of deoxythymidine, catalysed by thymidine kinase, which is subject to feedback inhibition by its product, dTMP. Normal marrow, pre-incubated with dUMP, successfully converts this to dTMP, and incorporates less subsequently added tritiated thymidine into DNA. If the marrow is deficient in either vitamin B₁₂ or folate, methyl group transfer is reduced, so the cells have greater capacity to incorporate tritiated thymidine into DNA following pre-incubation with dUMP.

Antibody tests. Tests for the presence of antibodies to gastric parietal cells are positive in 90% of patients with pernicious anaemia; however, this test is not specific as it is also positive in around 15% of healthy elderly people. The presence of IF antibodies is more specific but is found in only 50% of patients with pernicious anaemia.

Schilling test. This test, which measured the 24-h urinary recovery of vitamin B₁₂ following an oral radiolabelled dose of the vitamin, is now obsolete.

Anaemias due to reduction in red cell production: inherited causes

Inherited disorders of haemoglobin synthesis, such as sickle cell anaemia, result in ineffective erythropoiesis and a microcytic anaemia. These disorders are covered in Chapter 29.

Other inherited disorders of red cell production are rare and usually present in infancy. Fanconi anaemia is an autosomal recessively inherited disorder of a group of DNA repair proteins. Patients have various somatic deformities, a pancytopenia and markedly increased risk of both solid and haematological malignancies. Diamond-Blackfan syndrome is associated with an anaemia secondary to a reticulocytopenia and carries an increased risk of acute myeloid leukaemia.

Anaemias associated with reduction in red cell production: acquired causes

Anaemia of chronic disease

Chronic diseases are often associated with an elevation of proinflammatory cytokines such as TNF- α and IL-6. These

cytokines are potent inducers of hepcidin, which acts to inhibit intestinal iron absorption and the release of iron from macrophages. Thus iron studies in chronic diseases reveal a low serum iron and iron binding capacity with a raised ferritin. The anaemia of chronic disease is usually normocytic, but in approximately 20% of cases, is microcytic.

Aplastic anaemia

Stem cell failure can be caused by toxins affecting cell production. This may be predictable dose dependent toxicity, such as following exposure to high dose irradiation, cytotoxic drugs and benzene. Rarely, the aplasia occurs as an idiosyncratic reaction to drugs such as non-steroidal anti-inflammatories and chloramphenicol, or as a reaction to viruses such as hepatitis, which is probably immune mediated. It is sometimes associated with an acquired defect in the glycosylphosphatidylinositol (GPI) anchor, which plays an important role in the attachment of a number of cell surface antigens, protecting the cells from complement mediated premature destruction. This rare disorder is called paroxysmal nocturnal haemoglobinuria (PNH) (see p. 529).

Myelodysplasia

The myelodysplastic syndromes are a heterogeneous group of disorders where there is ineffective haemopoiesis, resulting in progressive multilineage cytopenia and an increased propensity to transform to an acute leukaemia. The incidence of these conditions rises with age, with median onset in the seventh decade.

Malignant infiltration of the bone marrow

Infiltration of the marrow causes loss of normal haemopoietic tissue. This gives rise to a characteristic leukoerythroblastic appearance on a blood film. Immature white cells, nucleated red cells and red cells with a teardrop shape appear and the platelet count falls. Leukoerythroblastic anaemia is a characteristic finding when a malignancy has metastasized to the marrow. It also occurs in myelofibrosis, where there is an increase in reticulin fibres in the bone marrow and splenomegaly.

ANAEMIAS ASSOCIATED WITH INCREASED RED CELL LOSS

Bleeding

Acute bleeding, from any source, results in a reticulocytosis and thus, the anaemia may be normocytic or even macrocytic if the reticulocyte count is high, as these cells are larger than mature red cells. With time, iron stores become diminished and a microcytic anaemia develops.

Haemolysis

Haemolysis may be defined as the premature destruction of red cells, that is, the shortening of their normal life span of approximately 120 days. The destruction of the

red cells may be effected by the macrophages in the reticuloendothelial system, for example in the spleen, liver or bone marrow; such destruction is said to be *extravascular*. Alternatively, destruction of red cells may take place within the circulation, i.e. *intravascular* haemolysis. Often there is a combination of both mechanisms. Normally, the bone marrow responds to the anaemia by increasing red cell production, and where this balances the loss of red cells, there is said to be a compensated haemolytic state. If the rate of the destruction exceeds the capacity of the marrow's compensatory increase in erythropoiesis, a haemolytic anaemia ensues.

Thus, haemolytic anaemias are usually characterized by a triad of pathological features:

- increased red cell destruction resulting in *anaemia*
- increased red cell production resulting in *reticulocytosis*
- increased haemoglobin catabolism resulting in *jaundice*.

Laboratory features of haemolysis

In extravascular haemolysis, the haem moiety released from haemoglobin as a consequence of increased red cell destruction is broken down to protoporphyrin, with the liberation of the iron, which enters the plasma pool and is bound to transferrin, increasing its saturation. Protoporphyrin is metabolized to carbon monoxide and biliverdin, which is subsequently further reduced to bilirubin. An increased plasma unconjugated bilirubin concentration to $> \sim 50 \mu\text{mol/L}$ results in jaundice. As unconjugated bilirubin is bound to albumin, it is not excreted in the urine, but there is increased urinary excretion of its metabolic end-product, urobilinogen (see Chapter 13).

In contrast, in intravascular haemolysis, there is release of haemoglobin into the plasma (haemoglobinaemia) and, when the renal threshold for haemoglobin is exceeded, haemoglobin is excreted in the urine (haemoglobinuria). Some of the haemoglobin in the glomerular filtrate is reabsorbed and degraded by the proximal tubular cells, with the iron released being deposited as haemosiderin. As the tubular cells desquamate, the presence of the intracellular haemosiderin iron can be detected in the urinary sediment by Perls reaction, which is positive for up to six weeks after the episode of intravascular haemolysis. The loss of iron may be sufficiently great to result in overt iron deficiency anaemia, in contrast to the iron accumulation seen in extravascular haemolysis.

Free haemoglobin in the plasma readily dissociates from its tetrameric structure to dimeric units consisting of α - and β -subunits. The haemoglobin α chain binds readily to the β chains of haptoglobin, a glycoprotein produced by the liver. The haemoglobin-haptoglobin complex is rapidly cleared by the reticuloendothelial system. In chronic haemolytic states, there is an increased removal of haptoglobin at a rate that exceeds the synthetic capacity of the liver, resulting in low or undetectable plasma haptoglobin concentrations. The return to a normal concentration takes approximately one week following cessation of the haemolytic process.

Any free plasma haem resulting from haemolysis forms complexes with either haemopexin or albumin.

The haem-haemopexin complex is taken up and metabolized by the liver, resulting in a decrease in plasma haemopexin concentration. The haem-albumin complex may be oxidized to methaemalbumin, which has a characteristic absorption spectrum and gives a brownish colour to the patient's plasma. Acute kidney injury is often seen in intravascular haemolysis. Studies have revealed that haem is directly toxic to renal tubular cells and may form intratubular casts with Tamm-Horsfall protein. The mitochondria of renal cells appear particularly susceptible to haem-mediated damage, with resultant impaired mitochondrial oxygen consumption and autophagocytosis. The kidney protects itself during intravascular haemolysis by inducing haemoxygenase-1 and ferritin production, which act to degrade the haem and bind any resultant free iron, respectively (see Fig. 27.7).

Causes of haemolytic anaemias

The disorders that cause haemolysis form a diverse group. Some of them are very common, for example sickle cell anaemia and thalassaemia, which affect millions worldwide, while some are very rare, for example aldolase deficiency, with only a few families reported in the world literature. The clinical features are equally diverse, varying from little or no clinically evident haemolysis as, for example, with hereditary elliptocytosis, to life-threatening acute intravascular haemolysis associated with *Plasmodium falciparum* malaria (blackwater fever). Clinical manifestations other than haemolysis may complicate the situation further; for example, sickle cell anaemia is associated with vaso-occlusive episodes that may result in life-threatening problems such as pulmonary crises, while some of the inherited deficiencies of enzymes such as triose phosphate isomerase and phosphoglycerate kinase are associated with severe neurological disease.

A classification of haemolytic disorders based on the site of haemolysis would identify very few disorders causing only intravascular haemolysis, as the vast majority are associated with predominantly extravascular haemolysis. Therefore, the best classification of haemolytic disorders is based on whether the haemolysis is inherited or acquired, as summarized in Box 27.1.

Inherited haemolytic anaemia

It is convenient to consider inherited red cell defects under three headings: membrane defects, enzymes defects and haemoglobinopathies. The haemoglobinopathies are considered further in Chapter 29.

Membrane defects

The commonest haemolytic anaemia caused by a membrane defect is hereditary spherocytosis. It is usually inherited in an autosomal dominant manner, resulting in haemolysis of varying severity; the majority of patients have a mild anaemia, although severe haemolysis resulting in neonatal kernicterus has been reported. It is characterized by spherocytic, osmotically fragile cells and in most cases is caused by a defect

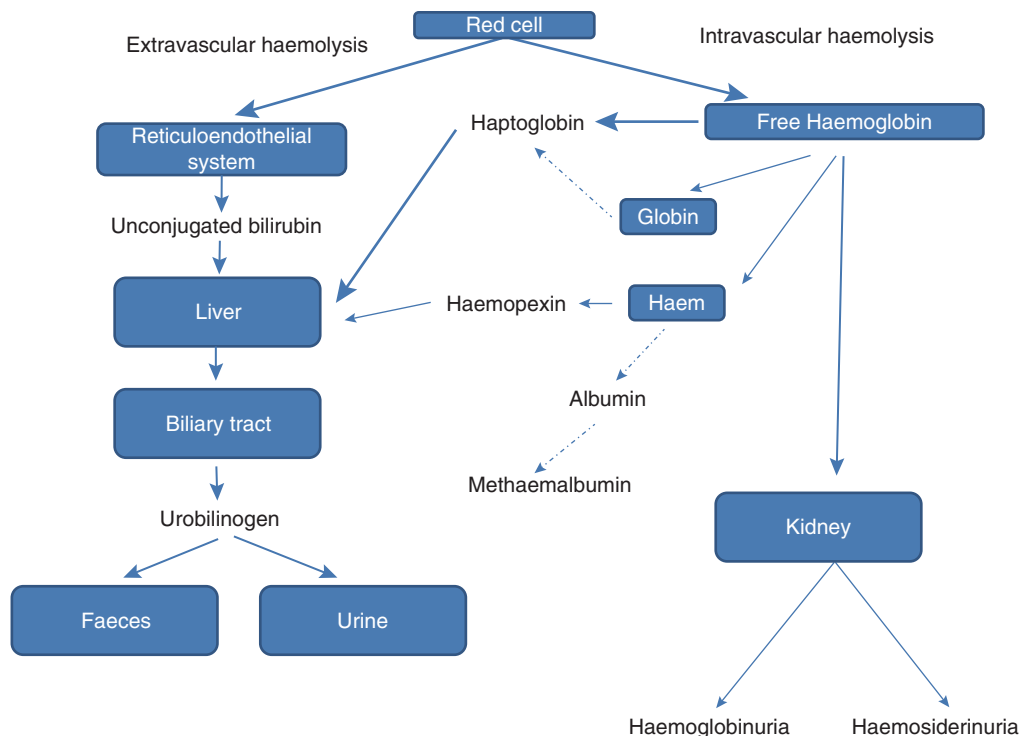

FIGURE 27.7 ■ The pathway of haemoglobin metabolism in haemolytic anaemias. Haemoglobin is liberated from the breakdown of the red cells and becomes bound to haptoglobin. Any free haem binds to haemopexin. Both scavenger proteins are taken up by macrophages within the reticuloendothelial system. When these plasma proteins are consumed, the haem may be either free in the plasma or bound to albumin.

in the ankyrin–spectrin complex, although defects in other membrane proteins can also cause the condition. Extravascular haemolysis occurs predominantly in the spleen because of the poor deformability of the cells. Splenectomy is sometimes considered in patients, as prolongation of the red cell life span results in amelioration of the clinical features.

Hereditary elliptocytosis is a more heterogeneous disorder characterized by large numbers of elliptically shaped red cells in the peripheral blood. It is caused by defects in the spectrin tetramers (see p. 517). There is an increased incidence in West Africa, possibly because of protection from infection by *Plasmodium falciparum*; in vitro studies have demonstrated reduced ability of this organism to parasitize red cells with the defects seen in hereditary elliptocytosis.

Hereditary stomatocytosis (HS) is rare and is associated with the appearance of ‘mouth like’ red cells on blood film. These cells are leaky to cations: hence the condition is associated with pseudohyperkalaemia. Splenectomy should be avoided, owing to the risk of thrombosis in these individuals. The variant termed dehydrated HS, or hereditary xerocytosis, may be associated with perinatal ascites, which resolves spontaneously within the first year of life.

Enzyme defects

These may be grouped under three headings:

- disorders of the pentose phosphate pathway and related enzymes of glutathione metabolism

- disorders of anaerobic glycolysis
- disorders of nucleotide metabolism.

Disorders of the pentose phosphate pathway and related enzymes of glutathione metabolism. The pentose phosphate shunt provides the reducing power of the red cell in the form of NADPH, which maintains glutathione in the reduced form (GSH) via the closely linked glutathione pathway. The GSH protects the red cells from oxidative damage; inadequate supplies result in peroxidation of the red cell membrane, denaturation of haemoglobin and its precipitation as Heinz bodies, resulting in reduced cell deformability and intravascular haemolysis.

The commonest disorder of the pentose phosphate pathway is a defect of the enzyme glucose 6-phosphate dehydrogenase (G6PD), affecting 400 million people worldwide. The gene for the enzyme is located on the X chromosome. The wild type is *G6PD(B)*. More than 300 variants have been described with differences in maximum enzyme activity and/or gene expression. The best known of these affects people of African origin, *G6PD(A-)*, or from Mediterranean countries, *G6PD(Med)*. Most individuals with G6PD deficiency are asymptomatic but liable to have acute haemolytic crises under oxidative stress from certain drugs (see Table 27.3), ingestion of fava beans or acute infection. Favism has been described in Mediterranean countries since classical times.

The cause of the haemolysis is a failure to produce enough GSH to protect the red cell membrane from

BOX 27.1 Classification of haemolytic disorders**Congenital****Red cell membrane defects**

- Hereditary spherocytosis
- Hereditary elliptocytosis
- Acanthocytosis in abetalipoproteinaemia
- Hereditary stomatocytosis
- Rh_{null} disease

Red cell enzyme defects

- Disorders of pentose phosphate pathway and related enzymes of glutathione metabolism
 - Glucose 6-phosphate dehydrogenase
 - Glutamylcysteine synthetase
 - Glutathione synthetase
 - Glutathione reductase
- Disorders of anaerobic glycolysis
 - Pyruvate kinase
 - Hexokinase
 - Phosphoglucose isomerase
 - Phosphofructokinase
 - Triose phosphate isomerase
 - Phosphoglycerate kinase
- Disorders of nucleotide metabolism
 - Pyrimidine 5'-nucleotidase deficiency
 - Adenosine deaminase hyperactivity
 - Adenosine triphosphatase deficiency
 - Adenylate kinase deficiency

Haemoglobinopathies

- Globin chain synthesis, i.e. thalassaemias
- Globin chain structure

Acquired**Immune haemolytic anaemias**

- Incompatible blood transfusion
- Haemolytic disease of the newborn

- Autoimmune (warm reacting antibody)
 - Idiopathic
 - Infection, e.g. *Mycoplasma pneumoniae*
 - Lymphoproliferative disorders
 - Other malignant disorders
 - Immunodeficiency states
 - Systemic lupus erythematosus (SLE) and other autoimmune disorders
 - Drugs
- Autoimmune (cold reacting antibody)
 - Cold haemagglutinin disease (idiopathic or secondary)
 - Paroxysmal cold haemoglobinuria

Non-immune haemolytic anaemia

- Infections
 - Protozoal, e.g. malaria, toxoplasmosis, leishmaniasis
 - Bacterial, e.g. clostridial infection, bartonellosis
- Traumatic and microangiopathic disorders
 - Prosthetic cardiac valves
 - Haemolytic uraemic syndrome
 - Thrombotic thrombocytopenic purpura
 - Disseminated intravascular coagulation
 - Hypertension, including pregnancy-associated hypertension
 - March haemoglobinuria
 - Thermal injury
- Chemical agents
 - Oxidant drugs (see Table 27.3)
 - Non-oxidant agents, e.g. water, copper
 - Venoms
- Disorders of the red cell membrane
 - Vitamin E deficiency in neonates
 - Spur cell anaemia in chronic liver disease
 - Paroxysmal nocturnal haemoglobinuria

TABLE 27.3 Drugs and chemicals associated with significant haemolysis in subjects with G6PD-deficiency

Drugs	Definite association	Possible association	Doubtful association
Antimalarials	Primaquine Pamaquine Pentaquine	Chloroquine	Quinacrine Quinine
Sulfonamides	Sulfanilamide Sulfacetamide Sulfapyridine Sulfamethoxazole	Sulfamethoxypyridazine Sulfadimidine	Sulfoxone Sulfadiazine Sulfamerazine Sulfisoxazole
Sulfones	Thiazolesulfone Diaminodiaphenylsulfone (dapson)		
Nitrofurans	Nitrofurantoin		
Antipyretic analgesics	Acetanilid		Aminopyrine Paracetamol (acetaminophen) Phenacetin Aspirin
Others	Nalidixic acid Naphthalene Niridazole Phenylhydrazine Toluidine blue Trinitrotoluene (TNT) Methylthioninium chloride Phenazopyridine	Chloramphenicol Vitamin K analogues	4-aminosalicylic acid (PAS) L-DOPA Vitamin C Dimercaprol Doxorubicin Probenecid

oxidative stress. Glucose 6-phosphate dehydrogenase is the first and most important enzyme in the pentose phosphate pathway that generates the NADPH that is required for glutathione reduction. Normal *in vivo* flux uses only a small percentage of the maximum enzyme capacity. This explains why G6PD variants with low residual activities are compatible with almost normal function of the red cell. Only under oxidative stress is the protective capacity overwhelmed, leading to predominantly extravascular haemolysis.

In a relatively small number of sporadic cases, the G6PD variant is functionally so abnormal that there is chronic extravascular haemolysis even without any additional oxidative stress.

Disorders of anaerobic glycolysis. Deficiencies of the glycolytic enzymes hexokinase (HK), phosphoglucose isomerase (PGI), phosphofructokinase (PFK), aldolase (ALD), triose phosphate isomerase, phosphoglycerate kinase (PGK), enolase and pyruvate kinase (PK) have all been reported in association with chronic haemolytic anaemia. Almost all cases reported are inherited in an autosomal recessive mode except for PGK deficiency, which is X-linked. All are relatively rare; the commonest in this group is PK deficiency, which has a prevalence of ~1:20000.

Because the glycolytic pathway is mainly concerned with the generation of ATP, it has been proposed that the primary pathogenic defect is low red cell ATP concentration causing rigidity of the red cells. However, the expected reduction in ATP concentration is not a constant finding. This may be partly explained by the presence of increased numbers of reticulocytes, which have higher concentrations of ATP, and/or the preferential destruction of the most metabolically affected red cells, giving a distorted picture of the concentration of the ATP at the time of investigation. It is likely, however, that a number of different factors contribute to the haemolytic process depending on the various metabolic abnormalities resulting from the enzyme deficiency.

Disorders of nucleotide metabolism. The most important abnormalities of nucleotide metabolism that are clearly associated with chronic haemolytic anaemia are deficiency of pyrimidine 5'-nucleotidase (P5N) and hyperactivity of adenosine deaminase (ADA).

The mechanisms of haemolysis in these conditions have not been established, although some interesting hypotheses have been proposed as logical explanations of the biochemical findings. In patients who are homozygous for P5N deficiency, there is an accumulation of pyrimidine nucleotides in the red cells. This could affect the metabolism of the cells by competing with adenine nucleotides, which are the normal cofactors of a number of important enzyme reactions, and by interfering with the function of the pentose phosphate pathway.

In some cases of ADA hyperactivity, there is a low red cell concentration of ATP. It has been hypothesized that this leads to depletion of adenosine through irreversible deamination, so that insufficient adenosine is available for the salvage pathway via adenosine kinase to replenish normal losses from the adenine nucleotide pool.

Acquired haemolytic anaemias

The acquired haemolytic anaemias can be divided into two main groups:

- immune haemolytic anaemias, where the production of antibodies mediates red cell destruction
- non-immune haemolytic anaemias, which are of numerous diverse causes.

Immune haemolytic anaemias

These may be caused by autoantibodies produced against epitopes on the surface of the patient's own normal red cells or by the development of alloantibodies, antibodies produced by the patient against foreign antigens introduced through blood transfusions or neoantigens that develop on red cells during drug induced haemolysis.

The autoimmune haemolytic anaemias are characterized by a positive Coombs test, which detects antibodies, with or without complement, bound to the surface of the red cell. These antibodies are often directed against the rhesus antigen system; they may be of any immunoglobulin subclass and display different thermal activities, hence the term 'warm' and 'cold' acting antibodies. The resulting haemolysis is usually extravascular in nature because of the ability of the autoantibody to fix complement, allowing opsonization and subsequent uptake by the macrophages of the spleen and liver. However, some autoantibodies produced are able to activate the complement pathway through to cell lysis, resulting in a more severe intravascular haemolysis.

Autoimmune haemolytic anaemias may occur without an obvious underlying cause (primary autoimmune haemolytic anaemia) or may be secondary to other conditions such as lymphoma, chronic lymphocytic leukaemia and autoimmune diseases including systemic lupus erythematosus and rheumatoid arthritis.

Non-immune haemolytic anaemias

The main causes of non-immune haemolysis are infections, traumatic and microangiopathic disorders, chemical and physical agents and acquired disorders of the red cell membrane.

Infections. The most important infection associated with haemolytic anaemia is *Plasmodium falciparum*, in which both extravascular haemolysis, from destruction of parasitized erythrocytes in the reticuloendothelial system, and intravascular haemolysis, when the parasites break out of cells, are seen. Rarely, the latter may be extreme enough to produce the dramatic picture known as blackwater fever, with severe intravascular haemolysis associated with a high percentage of parasitized erythrocytes, haemoglobinuria and acute kidney injury.

Other protozoal and bacterial infections that can be associated with haemolysis are listed in [Box 27.1](#).

Traumatic and microangiopathic disorders. The common mechanism in these conditions is contact between red cells and an abnormal surface in the circulation. Cardiac prosthetic valves and intracardiac patch repairs

have been associated with haemolytic anaemia, which is intravascular, though usually mild.

Microangiopathic haemolytic anaemia is a term used to describe a variety of conditions in which there is increased fibrin deposition in the microcirculation. This results in increased red cell fragmentation either directly by damage to red cells by fibrin strands or indirectly by the stress imposed by other cells flowing past cells trapped on fibrin strands. The end-result is intravascular haemolysis. Such conditions include haemolytic uraemic syndrome, which is seen mainly in childhood and in which renal failure is a prominent feature, and thrombotic thrombocytopenic purpura (TTP), which is associated with the diagnostic pentad of various neurological signs, red cell fragmentation, thrombocytopenia, purpura and renal failure. In haemolytic anaemia associated with hypertension (including pregnancy-associated hypertension), there is little fibrin deposition and it is postulated that there is increased fragmentation of red cells trapped at the endothelial surface as a result of the shearing stress of the flow of arterial blood. March haemoglobinuria is a rare and benign condition in which there is red cell destruction in the feet caused by mechanical trauma from walking or running over long distances.

Acquired disorders of the red cell membrane.

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired disorder of the red cell membrane. It is associated with an acquired somatic mutation in the *PIGA* gene on the X chromosome. This encodes the enzyme complex phosphatidylinositol N-acetyl-aminyl-transferase subunit A (PIGA), which plays a pivotal role in the biosynthesis of glycosylphosphatidylinositol (GPI) anchors. These are responsible for the attachment of a large number of surface antigens to the cell membrane, including proteins that protect the cell membrane from complement-mediated attack. Thus GPI anchor deficiency renders the red cells susceptible to complement mediated cell lysis and intravascular haemolysis ensues. The condition is associated with the clinical triad of intravascular haemolysis, bone marrow failure and thrombosis.

Zieve syndrome is an uncommon disorder seen in alcoholics, in which intravascular haemolysis is possibly a consequence of changes in the lipid composition of the cell membrane. Vitamin E deficiency in neonates results in the loss of the protective antioxidant effect of this vitamin and an oxidative haemolysis ensues.

DIAGNOSIS OF HAEMOLYSIS

The search for evidence supporting the presence and cause of haemolysis can be considered in terms of clinical evidence and the results of laboratory investigations.

Clinical evidence

The clinical history should pay particular attention to the onset of jaundice and to any precipitating factors. The colour of the urine may suggest the presence of haemoglobinuria, suggesting intravascular haemolysis. Anaemia

is often asymptomatic, either because of its mild degree or because of its chronicity. However, severe symptomatic anaemia is likely to be of recent onset and suggests an acquired aetiology. The general medical history, including previous surgery, is important but particular attention should be paid to travel, drug history and exposure to chemicals at work or recreation.

A family history may help to establish an inheritance pattern. The majority of families with congenital non-spherocytic haemolytic anaemias caused by enzymopathies show an autosomal recessive transmission, while most non-spherocytic anaemias with unstable haemoglobin or red cell membrane defects show an autosomal dominant pattern. The most important exceptions are the X-linked deficiencies of G6PD and PGK. In these, the affected individuals are hemizygous males or, very infrequently, homozygous females. The vast majority of heterozygous females are clinically unaffected and difficult to detect.

General physical examination provides additional information. In thalassaemia major, frontal bossing and prominence of the maxillae produce a characteristic facial appearance (see p. 553). Splenomegaly is often a prominent finding, particularly in the congenital haemolytic anaemias.

Laboratory investigations

These should be directed to answering two basic questions: is there any haemolysis and if so, what is the mechanism and cause?

Laboratory investigations for the presence of haemolysis

Red cell morphology. In haemolytic anaemias, there is a varying degree of anaemia accompanied by a reticulocytosis. The underlying cause of haemolysis may be suggested by the presence of specific morphological abnormalities (see Chapter 26), for example, spherocytes in both hereditary spherocytosis and autoimmune haemolytic anaemia, and red cell fragmentation in microangiopathic haemolytic anaemia. Heinz bodies, which are composed of denatured haemoglobin, are seen in G6PD deficiency, and some unstable haemoglobins, formed after exposure to oxidant drugs and chemicals, are revealed using the supravital stain crystal violet. Haemoglobin H inclusions (seen in α thalassaemia) can be demonstrated using brilliant cresyl blue. Excessive basophilic stippling, indicating the presence of undegraded RNA, suggests a block in the catabolism of RNA during reticulocyte maturation and is a constant finding in pyrimidine 5'-nucleotidase deficiency.

Total and unconjugated bilirubin. Haem breakdown results in the release of hydrophobic unconjugated bilirubin that is transported, bound to albumin, to the liver where it is conjugated. Therefore, haemolysis results in an increase in plasma unconjugated bilirubin concentration.

Haptoglobin. Any free haemoglobin released from red cell breakdown complexes with haptoglobin and is then cleared by the reticuloendothelial system. A decrease in

the plasma haptoglobin concentration occurs when the daily haemoglobin turnover is doubled, irrespective of whether the haemolysis is extravascular or intravascular. Haptoglobin is more rapidly depleted in intravascular haemolysis. However, congenital ahaptoglobinaemia is seen in 2% of the Caucasian population and concentrations may also be lowered in megaloblastic anaemia (because of ineffective erythropoiesis) and in liver disease. Haptoglobin is an acute phase protein, its concentration rising in many inflammatory conditions, in pregnancy and during use of oral contraceptives and corticosteroids. Under these circumstances, a normal haptoglobin concentration does not exclude haemolysis.

Haemopexin. Haemopexin binds free haem in plasma and in severe intravascular haemolysis, when haptoglobin is depleted, plasma haemopexin falls to very low concentrations or becomes undetectable. However, in mild haemolysis, plasma haptoglobin concentration may be reduced or undetectable but plasma haemopexin concentration normal or only slightly reduced. Low concentrations of haemopexin may be found in renal or liver disease without any evidence of haemolysis and high concentrations are seen in diabetes mellitus, infection or carcinoma. This assay is only available at a few specialized centres.

Methaemalbumin. This is found in plasma when haptoglobin is depleted in the more severe intravascular haemolytic anaemias. It may be detected by the Schumm test: methaemalbumin reduced by the addition of ammonium sulfide shows an intense absorption band in the green spectrum.

Free haemoglobin. Free haemoglobin does not appear in the plasma until all available haptoglobin has been depleted, so it may be undetectable in mild degrees of haemolysis. Therefore, an increased plasma free haemoglobin concentration indicates a significant degree of intravascular haemolysis, provided that the possibility of *in vitro* lysis of red cells during red cell sampling or processing has been excluded. Free haemoglobin in the urine (haemoglobinuria) is also a good indicator of intravascular haemolysis. False positives may occur owing to haematuria (intact red cells in urine) or myoglobinuria, which must be excluded.

Haemosiderinuria. After glomerular filtration, some free haemoglobin is absorbed by renal tubular cells and then broken down. The released iron is deposited as insoluble haemosiderin and is ultimately excreted in the urine when desquamation of the tubular cell occurs. Haemosiderin can be demonstrated within these cells by staining a cytospin preparation of the urine by the Perls technique. Haemosiderinuria can be detected for several weeks after a haemolytic episode, even when there has not been overt haemoglobinuria. Thus, the demonstration of intracellular haemosiderin in the urine is a good sign of mild intravascular haemolysis.

Red cell survival. This can be measured using radiolabelled (usually with ^{51}Cr) autologous red cells. Daily measurements can allow for the calculation of red cell

survival, usually combined with surface counting over the liver and spleen to estimate the relative contribution of each reticuloendothelial organ to the red cell destruction. If uptake of radiolabelled red cells is seen predominantly in the spleen, removal of this organ should ameliorate the haemolysis. This test is performed only in specialist centres.

Laboratory investigations for the cause of haemolysis

After the diagnosis of haemolysis has been made, further investigations are required to establish the precise cause of the reduced red cell survival. These should be directed along a logical pathway to avoid requests for inappropriate tests.

Coombs test (direct antiglobulin test). This is used to detect the presence of red cells coated with immunoglobulin or complement, which is the hallmark of immune haemolysis. The test can be modified to allow the detection of specific immunoglobulin subclasses or complement fractions by the use of specific antisera.

Tests for abnormal haemoglobin. The screening tests for haemoglobinopathy may be described under three main headings, indicating the main haemoglobin property being investigated:

- structural abnormalities, e.g. electrophoresis, isoelectric focusing, high performance liquid chromatography
- functional abnormalities, e.g. sickling test, demonstration of Heinz bodies
- unbalanced haemoglobin synthesis, e.g. quantitation of haemoglobin A₂ and haemoglobin F.

The detailed investigation of haemoglobinopathies is discussed in Chapter 29.

Osmotic fragility tests. These tests are no longer recommended in the routine assessment of haemolytic anaemias, having been replaced by flow cytometry techniques (see below). They are based on spectrophotometric assessment of the lysis of red cells after incubation in water or hypotonic saline for variable periods of time. Normal red cells, as a consequence of their biconcave shape, have an ability to take up more water before they lyse. Spherocytes, because of their high volume to surface area, have a very limited ability to take in water and thus lyse more readily. Conversely, cells with a reduced volume to surface area ratio, such as the cells in thalassaemia or iron deficiency, and reticulocytes, are relatively resistant to lysis. The tests are usually normal in enzyme defects apart from a tail of reduced fragility from the reticulocytes. A normal osmotic fragility does not exclude a diagnosis of hereditary spherocytosis as it may be normal in 10–20% of cases.

The autohaemolysis test. This measures the spontaneous haemolysis of blood incubated at 37 °C for 24 h. It is a useful screening test in cases of suspected haemolytic anaemia if the blood film is not morphologically suggestive of hereditary spherocytosis. If the test

is entirely normal, then an intrinsic red cell defect is unlikely. Correction of the autohaemolysis by the addition of glucose (as an energy source) suggests a membrane defect, as these are associated with increased glucose consumption because of the increased cation leak through the membrane. In enzyme defects, the addition of glucose has no effect as the cells cannot use this energy source.

Flow cytometry. The use of the eosin 5-maleimide (EMA) binding test is now the recommended first-line investigation for the diagnosis of hereditary spherocytosis, where there is no family history or the blood film appearances are atypical. Eosin 5-maleimide binds to band 3 protein (so named on the basis of its electrophoretic mobility). This protein interacts with both ankyrin and protein 4.2 and, in turn, with the spectrin cytoskeleton, which is disrupted in hereditary spherocytosis, resulting in a decreased flow cytometric fluorescence signal. The test has a high level of specificity (99.1%) and sensitivity (92.7%) and can be performed rapidly.

Flow cytometry has also become the gold standard for the diagnosis of PNH, replacing the acid haemolysis (Ham) test. It uses fluorescent-labelled monoclonal antibodies to detect various GPI-anchored surface antigens, principally CD55 (decay accelerating factor) and CD59 (membrane inhibitor of reactive lysis), whose absence on the surface of red cells is compatible with a diagnosis of PNH.

Tests for enzyme deficiencies

It is useful for laboratories to be able to screen for the common red cell enzyme deficiencies, such as G6PD and PK, and to indicate where the defect lies in the less common disorders, but further detailed investigations are best performed in specialist laboratories. It is important that leukocytes and platelets are removed from the samples as they generally have higher enzyme concentrations than the red cells. Also, it should be remembered that reticulocytes have increased concentrations of many 'age-dependent' enzymes, particularly HK, PK, ALD and pyrimidine 5'-nucleotidase. Therefore, if possible all samples should be tested either alongside a control sample with a similar reticulocyte count or the activity of the enzyme under investigation compared with that of a second 'age-dependent' enzyme.

Glucose 6-phosphate dehydrogenase. Screening tests for this enzyme deficiency depend on the inability of the cells to convert an oxidized substrate, such as NADP, to a reduced form that fluoresces under long wavelength UV light. Red cells with <20% of normal G6PD activity do not fluoresce. Problems in interpreting this test are common, particularly in heterozygous women and affected males with G6PD(A-) deficiency and reticulocytosis. In the latter situation, the presence of increased numbers of reticulocytes, which contain increased amounts of G6PD(A-), may give false negative results. Thus negative results do not always exclude enzyme deficiency, while positive results should be confirmed by quantitative assay.

Pyrimidine 5'-nucleotidase. Screening for this deficiency is based on the different spectrophotometric properties of cytidine nucleotides (pyrimidine nucleotides), which absorb maximally in acidic solutions at 280 nm, whilst adenine and guanine (purine nucleotides) and uridine absorb at 260 nm. Normally, >96% of nucleotides in red cells are purine analogues, but this falls to <50% in cases of pyrimidine 5'-nucleotidase deficiency, where the pyrimidine nucleotides accumulate, causing the absorbance ratio to fall.

Red cell metabolites. 2,3-Diphosphoglycerate (2,3-DPG), ATP and GSH are present in red cells in sufficiently high concentrations (millimolar) to be readily measurable by spectrophotometric techniques in most laboratories, providing valuable information on red cell enzymopathies. An increase in 2,3-DPG occurs in most anaemias. Furthermore, hypoxaemia, alkalosis and hyperphosphataemia all lead to increases in 2,3-DPG, irrespective of anaemia. A low concentration of 2,3-DPG is a useful indicator of an enzymopathy early in the glycolytic pathway. Hexokinase, PFK and PGI deficiencies have been frequently, but not invariably, associated with low concentrations of this metabolite. Extremely low 2,3-DPG concentrations have also been reported in a case of complete diphosphoglyceromutase deficiency, in which there is a high haemoglobin concentration because of an increased oxygen affinity in the absence of haemolysis.

A moderate reduction in GSH concentration has been reported in several patients with congenital nonspherocytic haemolytic anaemia including G6PD deficiency. However, very low concentrations of GSH could also be an indication of deficiency in either of the two enzymes of GSH biosynthesis: glutathione synthetase and γ -glutamylcysteine synthetase. In both enzymopathies, some patients have neurological disease in addition to the haemolytic anaemia, which is exacerbated by oxidative stress. For unknown reasons, high concentrations of GSH are present as an epiphenomenon in pyrimidine 5'-nucleotidase deficiency and several syndromes of dyserythropoietic anaemia and ineffective erythropoiesis. Neonates have higher red cell GSH concentrations than adults.

Glycolytic intermediates. The *in vivo* concentrations of glycolytic intermediates are probably the best available measure of the functional status of the glycolytic enzymes. Theoretically, when a given enzyme is functionally defective, it should cause a metabolic block leading to an accumulation of its precursor metabolites and a relative reduction in the concentration of those after it. However, this is not always seen for various reasons, including the increased activity of the enzymes in reticulocytes, but measurement of the glycolytic metabolites may still provide a useful screening test for a metabolic block in some circumstances. For example, PK deficiency may be suspected because of relatively high concentrations of metabolites preceding the PK step, i.e. phosphoenolpyruvate, 2-phosphoglycerate, 3-phosphoglycerate and 2,3-DPG.

CONCLUSION

In the accurate assessment of a patient presenting with anaemia, the clinical history plays a vital role in distinguishing between congenital and acquired causes. This is further supplemented by utilizing the following investigations:

- examination of blood film morphology
- serum ferritin, vitamin B₁₂ and folate concentrations
- coombs test and reticulocyte count
- haemoglobin electrophoresis.

This strategy should result in a specific diagnosis for the majority of individuals, with only a minority (<5% in the UK) requiring more specialized investigations.

CONCLUSION 548

INTRODUCTION AND OVERVIEW

The porphyrias are a group of eight metabolic disorders that result from inherited or acquired functional abnormalities of enzymes of the haem biosynthetic pathway (Table 28.1 and see Fig. 28.1, below). No disease has yet been associated with defects in the 5-aminolaevulinic acid (ALA) synthase-1 (*ALAS1*) gene that encodes the ubiquitous isoform of ALAS, the first enzyme of the pathway. However, gain of function mutations in the erythroid-specific ALAS (*ALAS2*) gene cause X-linked dominant protoporphyria (XLDPP), whereas loss of function causes X-linked sideroblastic anaemia.

The principal clinical features of the porphyrias are neurovisceral or cutaneous, or both. This chapter approaches the subject from a practical perspective, describing how and why patients present, how they are diagnosed and how patients and their families should be managed. A list of frequently used abbreviations is provided in Box 28.1.

Biochemistry of haem synthesis

Haem is essential for life and is synthesized in all cells, although the major sources are bone marrow (80%) and liver (15%). Haemoproteins include haemoglobin and myoglobin, which are the most abundant; the mitochondrial respiratory cytochromes; enzymes such as catalase and tryptophan pyrrolase, and the cytochrome P450 enzymes that are components of many essential metabolic processes, including the metabolism of xenobiotics.

The haem synthetic pathway comprises eight steps, each catalysed by a specific enzyme, of which the first and last three are mitochondrial and the remainder cytosolic (Fig. 28.1). The first enzyme, ALAS,

catalyses the condensation of succinyl-CoA and glycine into 5-aminolaevulinic acid and is the rate-controlling step in all cells. Regulation of ALAS1 in the liver and other non-erythroid tissues is via inhibition by haem, the end product of the pathway, a characteristic that underlies both the pathogenesis and treatment of acute attacks of porphyria. In erythroid cells, regulation of haem synthesis is iron dependent. The second step is the synthesis of porphobilinogen (PBG), a watersoluble, colourless monopyrrole, catalysed by ALA dehydratase. The third step is the polymerization of four molecules of PBG to form the colourless linear tetrapyrrole, 1-hydroxymethylbilane (HMB), by the enzyme hydroxymethylbilane synthase (HMBS, also known as PBG deaminase). This linear molecule is cyclized into the tetrapyrrole ring structure, uroporphyrinogen III, by the enzyme uroporphyrinogen III synthase.

The porphyrinogens are colourless, non-fluorescent, unstable compounds, which rapidly oxidize to their red-purple porphyrin equivalents. Porphyrins absorb light, are fluorescent and therefore photosensitizing. These properties also make them relatively straightforward to measure in the clinical biochemistry laboratory. Uroporphyrinogen III, which is hydrophilic by virtue of its eight carboxy groups, is converted to coporphyrinogen III by uroporphyrinogen decarboxylase, which catalyses the sequential removal of four carboxyl residues. Two further carboxyl groups are removed in an oxygen-dependent dehydrogenation-decarboxylation reaction catalysed by the enzyme coproporphyrinogen oxidase (CPOX) to form protoporphyrinogen, which is then oxidized to protoporphyrin IX by protoporphyrinogen oxidase (PPOX). Progressive decarboxylation makes these precursors and the corresponding porphyrins increasingly hydrophobic, which determines their

TABLE 28.1 Overview of the porphyrias indicating inheritance, prevalence and main clinical presentation

Disorder	Enzyme	Inheritance	Prevalence (overt disease)	Clinical presentation
Acute porphyrias				
ALA dehydratase deficiency porphyria (ADP)	ALA dehydratase (ALAD)	AR	Unknown	Acute neurovisceral attacks
Acute intermittent porphyria (AIP)	Hydroxymethyl-bilane synthase (HMBS) ^{a,b}	AD	1–2:100 000	Acute neurovisceral attacks
Hereditary coproporphyrria (HCP)	Coproporphyrinogen oxidase (CPOX) ^b	AD	<1:250 000	Bullous photosensitivity/acute neurovisceral attacks
Variagate porphyria (VP)	Protoporphyrinogen oxidase (PPOX) ^b	AD	1:250 000	Bullous photosensitivity/acute neurovisceral attacks
Non-acute porphyrias				
Congenital erythropoietic porphyria (CEP)	Uroporphyrinogen synthase (UROS)	AR	<1:10 ⁶	Bullous photosensitivity
Porphyria cutanea tarda (PCT)	Uroporphyrinogen decarboxylase (UROD)	AD ^c	1:25 000 (20% familial)	Bullous photosensitivity
Erythropoietic protoporphyria (EPP)	Ferrochelatase (FECH)	AR	1:100 000	Acute photosensitivity
X-linked dominant protoporphyria (XLDPP)	ALA synthase-2	X linked	Unknown	Acute photosensitivity

AR, autosomal recessive; AD, autosomal dominant.

^aAlso known as PBG deaminase.

^bEnzyme activities are half normal.

^cIn about 20% of patients.

routes of excretion (see Fig. 28.2). The final step in the pathway is insertion of ferrous iron (Fe^{2+}) into protoporphyrin to form haem, catalysed by ferrochelatase (FECH). In the absence of iron, other divalent cations, such as zinc, may be inserted. Although only the III isomer can progress through the pathway to form protoporphyrin IX and haem, HMB may spontaneously cyclize into the uroporphyrinogen I isomer. This forms a substrate for uroporphyrinogen decarboxylase (UROD) and may be converted to coproporphyrinogen I, but is not metabolized further. Adult reference ranges for porphyrins and their precursors are shown in Table 28.2.

Overview of the porphyrias

Clinically manifest porphyria is always associated with detectable overproduction of haem precursors. Each enzyme deficiency, and the increase in activity in XLDPP, gives rise to a specific pattern of overproduction, which defines the corresponding disease (Table 28.3). Three clinical manifestations may occur: acute neurovisceral attacks, skin lesions or both. Acute attacks of porphyria are always accompanied by overproduction of ALA and, in all but ALA dehydratase deficiency porphyria (ADP), of PBG. Porphyrias causing skin lesions are characterized by overproduction of porphyrins. Four of the eight porphyrias can present with acute neurovisceral attacks: the very rare autosomal recessive ADP and the three autosomal dominant acute porphyrias, acute intermittent porphyria (AIP), hereditary coproporphyrria (HCP) and variagate porphyria (VP). Hereditary coproporphyrria and VP can present with skin photosensitivity or acute attacks, or

both. In the other four porphyrias, two types of photosensitization may occur: accumulation of hydrophobic free protoporphyrin in erythropoietic protoporphyria (EPP) and XLDPP is associated with acute photosensitivity, while accumulation of the more water-soluble porphyrins in porphyria cutanea tarda (PCT) and congenital erythropoietic porphyria (CEP) leads to fragile skin and bullae.

Molecular genetics of the porphyrias

All the porphyrias, apart from the sporadic form of PCT, are single gene disorders that are inherited in autosomal dominant, recessive or X-linked patterns (see Table 28.1). Characteristics and chromosomal locations of individual genes are shown in Table 28.4. The *HMBS* and *UROS* genes are alternatively spliced to produce erythroid and ubiquitous isoforms. Disease-specific mutations that abolish or markedly decrease enzyme activity have now been identified in the genes for all the autosomal dominant porphyrias (Human Gene Mutation Database: www.hgmd.org). In most countries, mutational analysis has revealed extensive allelic heterogeneity, with large numbers of mutations identified in each gene, most of which are present in only one or a few families. The main exceptions are the W198X *HMBS* mutation in Sweden and the R59W *PPOX* mutation in South Africa. In both countries, these mutations have been multiplied by founder effects and account for the high prevalence of AIP in Sweden and of VP among individuals of Afrikaans ancestry in South Africa. The proportion of different types of mutation varies little between the diseases, with missense, nonsense, splice site and frameshift mutations contributing to the overall heterogeneity. Large deletions appear

FIGURE 28.1 ■ The haem biosynthetic pathway. The side chains are denoted by: A, acetic acid; M, methyl; P, propionic acid; V, vinyl. For other abbreviations, see [Box 28.1](#).

BOX 28.1 Abbreviations used for porphyrias, and metabolites and enzymes of the haem pathway

ADP	ALA dehydratase deficiency porphyria	HEP	Hepatoerythropoietic porphyria
AIP	Acute intermittent porphyria	HMB	Hydroxymethylbilane
ALA	5-Aminolaevulinic acid	HMBS	Hydroxymethylbilane synthase
ALAD	ALA dehydratase	PBG	Porphobilinogen
ALAS	ALA synthase	PBG-D	Porphobilinogen deaminase
CEP	Congenital erythropoietic porphyria	PCT	Porphyria cutanea tarda
CPOX	Coproporphyrinogen oxidase	PPOX	Protoporphyrinogen oxidase
EPP	Erythropoietic protoporphyria	UROD	Uroporphyrinogen decarboxylase
FECH	Ferrochelatase	UROS	Uroporphyrinogen synthase
HCP	Hereditary coproporphyria	VP	Variegate porphyria
		XLDPP	X-linked dominant protoporphyria

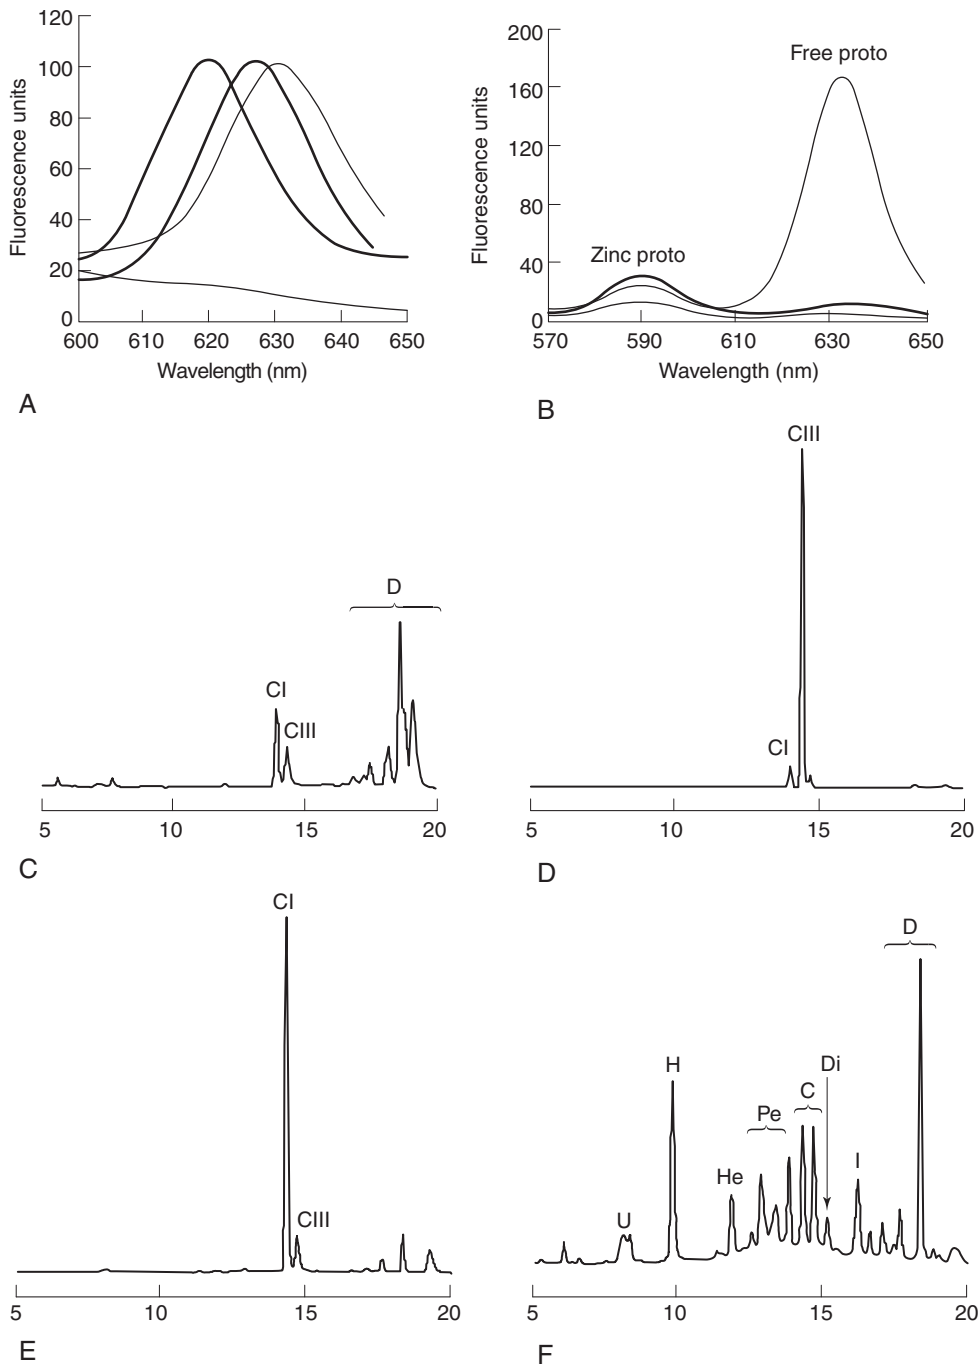

FIGURE 28.2 ■ Examples of key laboratory findings that allow the porphyrias to be distinguished biochemically. (A) Plasma porphyrin fluorescence scans showing the three distinct emission peaks at 620 nm (AIP, CEP, PCT, HCP), 626 nm (VP) and 631 nm (EPP). A negative plasma scan (lower line) is also shown. (B) Fluorescence emission scan of whole blood allows zinc chelated protoporphyrin (proto) (increased in anaemia and lead poisoning) to be distinguished from free protoporphyrin, which is increased in EPP. Markedly increased zinc chelated and free protoporphyrins are characteristic for XLDPP. The lower line indicates a normal scan. High performance liquid chromatography (HPLC) analysis of faecal porphyrins allows three porphyrias with a plasma fluorescence emission peak at 620 nm to be distinguished (faecal porphyrin excretion is normal in AIP). (C) Normal faecal porphyrin HPLC trace indicating predominantly coproporphyrin (C) isomer and dicarboxylic (D) porphyrins (protoporphyrin, pemptoporphyrin, deuteroporphyrin). (D) Faecal porphyrin pattern found in HCP indicating increased coproporphyrin, which is almost entirely the III isomer. (E) Faecal porphyrin trace seen in CEP indicating increased coproporphyrin isomer I. (F) Faecal porphyrin pattern seen in PCT patients indicating the increased excretion of partially decarboxylated intermediates; heptacarboxylic (H), hexacarboxylic (He) and pentacarboxylic (Pe) porphyrins as well as isocoproprophyrin (I) and dehydroisocoproprophyrin (Di), which are pathognomonic for PCT. U, uroporphyrin.

TABLE 28.2 Adult reference ranges for porphyrins and their precursors

Specimen	Metabolite	Reference range
Urine	5-Aminolaevulinic acid	<3.8 µmol/mmol creatinine
	Porphobilinogen	<1.5 µmol/mmol creatinine
	Total porphyrin	<40 nmol/mmol creatinine
	Uroporphyrin	<40%
	Coproporphyrin I	5–40%
Faeces	Coproporphyrin III	40–80%
	Total porphyrin	10–200 nmol/g dry weight
	Coproporphyrin I	5–43%
	Coproporphyrin III	5–37%
	Copro I/III ratio	0.3–1.4
Erythrocytes	Dicarboxylic porphyrin ^a	10–85%
	Total porphyrin	0.4–1.7 µmol/L erythrocytes

^aMainly protoporphyrin but includes pempto-, deuterio- and mesoporphyrins, which are the products of bacterial action on protoporphyrin.

to be uncommon. Perhaps not surprisingly in view of the large number of different mutations, no clinically useful genotype–phenotype correlation has yet been identified in any autosomal dominant porphyria. With current methods of analysis, the sensitivity of mutation identification is over 95% in AIP and VP.

Incomplete penetrance is an important feature of all the autosomal dominant porphyrias; only a proportion of those who inherit a disease-specific mutation develop the disease. In this chapter, the terms latent or presymptomatic will be used to describe individuals who have inherited a porphyria gene but at the time of investigation have not had symptoms. Estimates of penetrance for the autosomal dominant acute porphyrias derived from family studies range from 10% to 40% and are influenced by age and rigour of phenotype definition. In the UK, about 80% of adults identified by family studies as carrying a gene for an acute porphyria never have an acute attack severe enough to require hospitalization. This figure is consistent with the observation that about 30% of patients with AIP present without a family history of the disease, yet family studies almost always reveal

TABLE 28.3 The main biochemical findings in symptomatic porphyria

Porphyria	Urine	Faecal porphyrins	Plasma porphyrins ^a	Erythrocyte porphyrins
Acute porphyrias				
ADP	ALA, coproporphyrin	Normal	Normal	Protoporphyrin (zinc)
AIP	ALA, PBG, uroporphyrin	Normal or slight increase in normal porphyrin pattern	615–620 nm	Normal
HCP	ALA, PBG, coproporphyrin III	Coproporphyrin III (isomer III:I ratio >1.4)	615–620 nm	Normal
VP	ALA, PBG, coproporphyrin III	Protoporphyrin > coproporphyrin III	624–627 nm	Normal
Non-acute porphyrias				
CEP	Uroporphyrin I, coproporphyrin I	Coproporphyrin I	615–620 nm	Protoporphyrin (zinc and free), uroporphyrin I
PCT	Uroporphyrin (I and III), heptacarboxylic porphyrin	Isocoproporphyrin, heptacarboxylic	615–620 nm	Normal
EPP	Normal	Increased protoporphyrin in 40%	626–634 nm	Protoporphyrin (free)
XLDPP	Normal	Protoporphyrin may be increased	626–634 nm	Protoporphyrin (zinc and free)

Porphyria analyses on random urine, faeces and EDTA-preserved blood allow the individual porphyrias to be distinguished. Individual urine and faecal porphyrins are separated and measured by high-performance liquid chromatography with fluorescence detection. Note that EPP cannot be diagnosed by urine porphyrin analysis alone.

^aEmission maximum of plasma fluorescence peak (for examples, see Fig. 28.2).

TABLE 28.4 The molecular genetics of the porphyrias

Disorder	Gene	Chromosome	Gene size (kb)	Exons	cDNA (codons)
ADP	<i>ALAD</i>	9q34	13	13	330

U, ubiquitous; E, erythroid.

latent porphyria in their families, de novo mutation being uncommon. Studies of blood donors suggest that the gene for AIP may be present in about 0.06% of the general population. The low clinical penetrance of the acute porphyrias probably reflects a combination of environmental (see below) and genetic influences. The latter have not been identified but are likely to be at loci distant from the disease gene. Factors that determine clinical penetrance in familial PCT are described on page 544.

Clinical penetrance of the autosomal recessive porphyrias, ADP, CEP and EPP is close to 100%, although age at first presentation may be variable. They also show extensive allelic heterogeneity, with most patients whose parents are not consanguineous being compound heterozygotes. Other features of their genetics, and those of XLDPP, are discussed later in this chapter.

PORPHYRIAS PRESENTING WITH ACUTE ATTACKS

The autosomal dominant acute porphyrias

AIP, HCP and VP are autosomal dominant conditions that put the patient at risk of acute neurovisceral attacks, which may be life-threatening. In VP and HCP, skin lesions, indistinguishable from those of PCT, may occur either independently or in combination with acute attacks. In the UK, acute attacks of porphyria are estimated to affect about nine per million of the population, most of whom have AIP. Symptomatic VP is approximately half as common as AIP. HCP is the rarest of these acute porphyrias.

Pathophysiology of acute attacks

Acute neurovisceral attacks occur when hepatic haem synthesis is induced in the presence of deficient HMBS activity, resulting in an accumulation of the haem precursors ALA and PBG. In AIP, this is a primary deficiency, but in VP and HCP, it has been proposed that the deficiency is secondary to inhibition of HMBS by other metabolites in the haem pathway. The exact cause of neuronal damage has not been fully established, but current evidence from liver transplantation suggests that it is due to a hepatic neurotoxin, probably ALA. The neurological lesions comprise axonal degeneration and patchy demyelination of peripheral neurons with chromatolysis of anterior horn cells, brain stem nuclei and ganglia of the autonomic nervous system. There may also be diffuse neuronal loss and gliosis of the CNS. The result is damage to autonomic, motor and CNS neurons, giving rise to the characteristic clinical presentation, described below.

Clinical presentation of acute attacks

Acute attacks of porphyria are extremely rare before puberty and unusual after the menopause, having a peak occurrence in the third and fourth decades. Women are more frequently affected than men. In most patients, an

attack will cease once the diagnosis has been made, appropriate treatment given and likely precipitants removed. However, particularly when there is delay in establishing the diagnosis, prolonged and very severe, life-threatening and sometimes fatal acute attacks may occur. Commonly ascribed precipitants include prescribed and illicit drugs, alcohol (particularly binge drinking), systemic infection and dieting either alone or in combination. In women, attacks may be related to the menstrual cycle, usually the luteal phase. However, in some cases no obvious aetiology is found.

An acute attack of porphyria normally starts with continuous abdominal pain, which becomes progressively more severe and is associated with nausea, vomiting and constipation. The patient may also complain of pain in the lower back, buttocks and inner thighs. The abdominal pain is typically diffuse, with no localizing signs or evidence of an acute abdomen on examination. The severity of pain appears out of keeping with the physical signs and often requires the administration of large parenteral doses of opiates. In the absence of an obvious cause, this may trigger concerns about opiate dependence among clinical staff who have no previous experience of the condition. Diminishing pain, particularly where no treatment has been given, does not always herald the end of an acute attack, and patients should be carefully monitored for the development of neuropathy. The autonomic neuropathy that results in the gastrointestinal symptoms also gives rise to tachycardia and hypertension in approximately two-thirds of patients. Patients frequently become dehydrated during an acute attack and may also develop hyponatraemia, which may worsen if inappropriate volumes of hypotonic intravenous fluid are infused. Plasma sodium concentration can fall quickly to extremely low values, precipitating convulsions, which occur in about 5% of patients. Seizures may also occur as a neurological manifestation of the acute attack, and present a particularly difficult management problem as many antiepileptic drugs are implicated as a cause of acute attacks. Rhabdomyolysis, which may lead to renal failure, is a recognized but rare complication of an acute attack.

Severe and untreated attacks can result in a predominantly motor peripheral neuropathy. In most cases, this is a symmetrical distal neuropathy resulting in wrist and foot drop, but occasionally there is progression to a flaccid paresis resembling Guillain-Barré syndrome and requiring prolonged ventilatory support. Prognosis for full recovery is excellent when attacks can be treated and halted. However, patients who require ventilatory support frequently experience a difficult recovery period, characterized by recurrent relapses triggered by the requirement for multiple prescribed drugs and complications such as infection. A small number of patients experience sensory changes such as dysaesthesia or hypoaesthesia in a similar distribution to the motor neuropathy. Other neurological signs reported include cranial nerve involvement including the optic nerve, which can lead to blindness.

The CNS is frequently involved. Acute mental changes are common and include anxiety, insomnia, confusion,

hallucinations and paranoia, which resolve completely following the acute attack. There is no evidence that any form of chronic psychiatric illness is associated with any of the acute porphyrias. Less common CNS features are cerebellar syndrome, pyramidal signs, transient cortical blindness and altered consciousness.

Most patients have only one or a few attacks, with a major attack often being followed by two or three minor ones before full remission. However, about 5% of AIP patients suffer from frequent acute attacks, which in women may be premenstrual, and which may continue for several years (see p. 541). Obvious triggers are usually not found and the repeated admissions to hospital can severely affect the quality of life, particularly if patients have young families. Repeated admissions and high opiate requirement may also lead medical staff who are unfamiliar with the condition to question the diagnosis and the patient's motives.

Chronic complications

Some patients develop a chronic pain syndrome. Pain is usually in the peripheries, often constant and may be triggered by minor stimuli. The cause of this is unknown; management is particularly difficult since it is important to avoid addictive analgesics. Treatment with haem arginate (see p. 540) is usually of no benefit.

Studies from several countries have demonstrated an increased risk of hepatocellular carcinoma (HCC) in the absence of chronic liver disease in patients with an acute hepatic porphyria even when this is clinically latent. The risk is particularly high in Sweden, where a recent study found a standardized increased risk ratio of 64 for AIP gene carriers aged over 54 years and recommended that AIP patients over the age of 50 years should be screened annually for HCC by ultrasound examination. The benefit from screening in other countries has yet to be assessed. It has also been suggested that all HCC patients in whom no obvious cause is found should be screened for acute porphyria.

Renal impairment has been described as a complication of AIP, affecting particularly those patients who have previously suffered acute attacks. Hypertension is also common in these patients, but in many, the decline in renal function precedes the onset of hypertension, which may also be a consequence of the porphyria. Renal biopsies have shown glomerular sclerosis and interstitial fibrosis, but no evidence of inflammation or immunodeposits. A proportion of patients may progress to end-stage renal failure, requiring dialysis and/or renal transplantation. Patients who have had active disease should therefore have their renal function and blood pressure monitored regularly, and antihypertensive therapy should be instituted in an attempt to limit progression of renal impairment.

Diagnosis of acute porphyria

Diagnosis of an acute attack in a newly presenting patient requires the demonstration of increased excretion of urinary PBG in a fresh, random sample of urine that has been protected from light. An assay capable of

quantitative or semiquantitative measurement of PBG should ideally be available in all acute hospitals. In practice, many non-specialist units use rapid qualitative screening tests, particularly out of hours, which have low sensitivity and poor specificity. All positive screening tests should be confirmed by a specific quantitative method with expression of results in relation to creatinine to correct for urine concentration. *If urine PBG and ALA concentrations are normal during the early phase of an acute illness, all acute porphyrias, including ADP, are excluded as a cause of that illness.* However, both PBG and ALA may return to within normal limits within a few days after the onset of symptoms in VP and HCP, and negative findings should be interpreted with caution when there has been a delay in collecting samples. However, in both these disorders, urinary and faecal porphyrins remain elevated for a prolonged period. Conversely, urinary PBG excretion usually remains elevated for many months or even years after an acute attack in AIP, and an increased PBG does not necessarily indicate an acute attack unless a marked increase from baseline can be shown to coincide with symptoms. Management of a clinically diagnosed acute attack should be started immediately, without waiting for confirmation of a positive screening test or determination of the type of acute porphyria.

Establishment of the type of acute porphyria requires analysis of plasma and faecal porphyrins (see Table 28.3; Fig. 28.2). Faecal porphyrin analysis is essential to distinguish HCP, in which coproporphyrin III accounts for most of the increased faecal porphyrin excretion, from AIP, in which faecal porphyrin excretion is normal or only slightly increased without any change in the coproporphyrin isomer ratio. Variegate porphyria can easily be identified by demonstrating a characteristic plasma porphyrin fluorescence emission peak at 625–628 nm. Enzyme analyses and genetic studies are not required for the diagnosis of new cases of clinically overt porphyria. Their use in family studies is detailed later in the chapter.

Laboratory monitoring of patients during and after acute attacks by regular measurement of porphyrin precursors is rarely indicated; treatment should be guided by clinical assessment. The one exception is where a severe attack has progressed to flaccid paresis and clinical assessment is difficult. In these circumstances, weekly monitoring may provide useful information on whether the condition is stable or deteriorating.

Management of an acute attack

Supportive treatment. As soon as the acute attack is confirmed, drugs or other recognized precipitants should be withdrawn. Safe and effective management of symptoms and complications, with support from an expert centre, is essential to minimize the stress; effective pain relief is a major component. This invariably requires opiates, and support from a specialist pain team can be very helpful as very high doses may be required. A phenothiazine may be used for anxiety and restlessness, and to decrease the opiate requirements. Antiemetics should be prescribed for nausea and vomiting. Adequate fluid and energy intake should be ensured, if necessary by intravenous

infusions of 0.9% sodium chloride containing a minimum of 5% dextrose, with regular monitoring of electrolyte status in view of the risk of hyponatraemia. Where drug treatment of precipitants such as infection, coexisting conditions or other features of an acute attack, such as hypertension, tachycardia or convulsions, are required, care should be taken to select medications that are considered safe. Information on drug safety is continually under review and safe drug lists are likely to change regularly (see Welsh Medicines Information Centre: www.wmic.wales.nhs.uk). Where no safe alternative is on the list, an expert centre should be consulted for further advice on patient management. Information about specialist centres offering support in Europe is available from the European Porphyria Network (EPNET): www.porphyrria-europe.org.

Specific treatment. Specific treatment is aimed at suppressing hepatic haem precursor production by administering intravenous haem, which binds to albumin and is transported to the liver, where it downregulates ALAS activity. Treatment is effective if given early, preferably within the first 24–48 h. It will not reverse established neuropathy due to axonal degeneration. Within Europe, haem is available as haem arginate (Normosang® Orphan Europe) and is provided as a concentrated stock solution (25 mg/mL), which should be diluted immediately before use in 100 mL 0.9% saline and administered at a dose of 3 mg/kg body weight in a single intravenous infusion over at least 30 min on each of four consecutive days. As there is no evidence for toxicity, it is practical in most adults to infuse the entire contents of the vial for each dose. However, in smaller patients it may be possible to obtain two doses from each vial, limiting the overall cost of treatment. The main side-effect of therapy is thrombophlebitis at the site of infusion. This can be minimized by careful flushing of the infusion site with normal saline, and re-siting the i.v. cannula after each infusion. Alternatively, the haem can be diluted in 20% human serum albumin, which has proved to be effective in preventing thrombophlebitis, particularly in patients who require regular haem arginate infusions. Lyophilized haem (Panhematin®, Abbott) for intravenous infusion is available in the USA, but is less stable than haem arginate, and has more potential side-effects, including thrombocytopenia and coagulopathy.

With the advent of intravenous haem therapy, carbohydrate loading, which also decreases hepatic ALAS1 activity, is no longer indicated as a specific treatment unless haem is unavailable or there is a delay in obtaining it. High-dose carbohydrate (300–500 g glucose/24 h) should be given intravenously via a central venous catheter.

Preventing acute attacks

All patients should be advised about avoiding factors that increase the risk of an acute attack. These include drugs, alcohol and fasting or dieting, particularly diets in which carbohydrate is avoided completely. Weight reducing diets should be undertaken under the supervision of a dietitian. Patients should also be encouraged to register with an organization such as the MedicAlert Foundation,

which provides jewellery inscribed with appropriate information in case of emergencies. It is helpful to provide patients with written information explaining the disorder and, where applicable, they should be provided with details of existing patient support groups (e.g. the British Porphyria Association: www.porphyrria.org.uk). They should also be offered the opportunity to see a clinician with a special interest in porphyria on at least one occasion. Patients in remission (i.e. those who have had an acute attack) should be followed-up annually, preferably at a specialist centre or in conjunction with one. Local follow-up is also important in order to ensure contact with clinical services should admission be required. Through such shared care arrangements, most intervening problems can be managed successfully through correspondence or over the telephone.

Severely affected patients

A minority of patients with acute porphyria suffer from repeated acute attacks, occasionally as often as every 3–4 weeks. The majority are women with AIP in their 20s and 30s and their management can present a major challenge to clinicians and the acute medical services. A careful history should be taken to ascertain any obvious provoking factor, such as smoking, alcohol, drugs or stage of the menstrual cycle. An individualized management protocol should be drawn up by the local physician with help from a recognized national porphyria service; these operate in many European countries, including the UK, where the National Acute Porphyria Service (NAPS) has been commissioned specifically to support the management of patients with active porphyria. The patient should be encouraged to seek early medical intervention as prompt treatment may abort an acute attack, limiting the length of inpatient stay. This is best achieved by rapid direct access to inpatient facilities and the support of a clinical team who knows the patient and is experienced in dealing with the treatment of acute attacks.

When attacks appear to be associated with the luteal phase of the menstrual cycle, they may be reduced in frequency and/or severity by suppression of ovulation using gonadotrophin releasing hormone agonists. If this succeeds and is to be continued for longer than six months, measures to prevent osteoporosis become essential. Oestrogen supplementation, preferably in the form of patches, is tolerated by some patients, and diminishes any menopausal symptoms, but carries a small risk of provoking further attacks. Progestogens should not be used and most women will therefore require regular endometrial monitoring under the supervision of a gynaecologist. Adequate vitamin D and calcium intake should be ensured, by supplementation if required. Bisphosphonates have also been used in this situation to reduce the risk of osteoporosis.

Regular infusion of haem arginate reduces the frequency and severity of acute attacks in many patients. The minimum effective dose frequency, varying between monthly and weekly single infusions, should be established for each individual patient. There is no typical regimen. Where this treatment is being considered, it is often helpful to contact an expert porphyria centre to discuss the individual details with a clinician with experience

of its use. An indwelling central venous line is invariably required, although the specific type of line used should be dictated by local expertise and patient choice. Dilution of haem arginate in albumin solutions may reduce the need to replace blocked venous catheters.

Where these measures fail to control the attacks with resulting repeated life-threatening crises, problems with central venous access arise, progressive renal dysfunction occurs or quality of life is assessed as very poor, patients should be considered for liver transplantation, which is curative. Careful counselling and assessment is required, preferably in centres with experience with orthotopic liver transplantation (OLT) for this indication. Referral should ideally be before any chronic damage becomes irreversible. Liver transplantation has also confirmed that overproduction of haem precursors by the liver is central to the pathogenesis of acute attacks. This evidence has supported a project to develop gene therapy using a recombinant viral vector targeting the liver as a treatment for AIP.

Recurrent acute abdominal pain should not automatically be ascribed to the porphyria, particularly if the patient reports that the pain is not the same as previously experienced. Other conditions should be considered, as failure to diagnose these can have serious, possibly fatal consequences. In this situation, measuring urine PBG and/or ALA may be helpful in patients with VP or HCP. In AIP patients, a baseline measurement is required to aid interpretation of later results.

Chronic pain, which may be neuropathic, is a common problem in patients who have suffered regular acute attacks. Pain may be in the abdomen, limbs or lower back and may, in some cases, be present almost continuously. Although there may be an initial response to haem arginate, suppression of ovulation or other methods used to manage recurrent acute attacks, this is rarely sustained. Opiates are not a long-term solution in view of the risk of dependence, and should not be prescribed between acute attacks. Analgesia with a non-steroidal anti-inflammatory drug can, in some cases, be successful, and some patients may benefit from medication used to treat neuropathic pain such as gabapentin or pregabalin. Detailed discussion with the patient to explain that these symptoms are not due to an acute attack can be reassuring.

Managing asymptomatic relatives of patients

Once the diagnosis of a specific type of acute porphyria has been established in a new patient, screening should be offered to family members, so that those found to be affected, most of whom will have latent porphyria, can be offered specific advice as to how to limit the risk of suffering an acute attack.

Family studies. Metabolite measurements are highly specific but are almost always normal before puberty and have low sensitivity in adults (Table 28.5). Enzyme measurements are more sensitive but their sensitivity and specificity are limited by the overlap between activities in disease and in normal subjects. They have now largely been replaced by mutation detection by DNA analysis, which is specific and 100% sensitive if the mutation that causes porphyria in the family under investigation is known. It is essential, therefore, that children, and those family members whose specific porphyrin biochemistry is normal, be offered gene testing. Enzyme measurements, for example erythrocyte HMBS assay for detection of latent AIP, and gene tracking using intragenic single nucleotide polymorphisms, may be useful in the few families in which a disease-specific mutation cannot be identified.

Safe prescribing

Prescription drugs are an established precipitant of acute attacks and, even in known porphyria patients, careless prescribing has induced acute attacks or made evolving ones worse. It is therefore essential to provide information concerning the safe use of prescription medication to both those affected and their clinicians. A recent initiative in Europe has resulted in a review of the available evidence on a significant proportion of the current pharmacopoeia and provided an overall assessment of safety for individual drugs (www.drugs-porphyrria.org).

Drugs can be classified into three broad groups, based on clinical experience, experimental evidence and an understanding of their metabolism and excretion. These are: *Not Porphyrinogenic* (safe); *Porphyrinogenic* (unsafe); and *Of Uncertain Safety* (i.e. should be used with caution), which the European system subclassifies into three groups: *Probably Not Porphyrinogenic*, *Possibly Porphyrinogenic* and *Probably Porphyrinogenic*. In the first instance, clinicians should be encouraged to prescribe from a list of drugs that are known to be safe and to avoid those that are definitely unsafe. However, no drug should be seen as completely unusable as there may be clinical situations where a safe alternative is either unsuitable or not available. In these circumstances, an assessment of benefit versus risk should be made, taking into account the severity of the medical condition and porphyria activity. Support from a national centre with expertise in managing porphyria, and access to the most up-to-date drugs information, should also be obtained. If an unsafe drug has to be prescribed, urine PBG should be measured before starting, and at regular intervals during treatment.

TABLE 28.5 Screening asymptomatic relatives for latent acute porphyria

Porphyria	Screening method	Age range (years)	Sensitivity (%)	Specificity (%)
AIP	Urinary PBG >1.5 µmol/mmol	Age ≥15	43	100
HCP	Faecal coproporphyrin III/I molar isomer ratio >1.4	Age ≥7	64	100
VP	Plasma porphyrin fluorescence peak at 624–626 nm	Age ≥15	62	100
AIP, HCP, VP	Detection of known mutation by DNA analysis	All ages	100	100

Specific situations

Pregnancy. Although acute attacks do occur during pregnancy, there does not appear to be a significantly increased risk and most patients tolerate pregnancy, delivery and the puerperium without any adverse consequence. However, it is usually recommended that pregnancy should be delayed until patients have been free of severe acute attacks for a year. Patients should not be allowed to experience prolonged periods of stress and fasting during labour. Effective pain relief, including spinal or epidural anaesthesia, should be administered and, where necessary, intravenous fluids containing glucose should be used to prevent the development of a catabolic state. Where an acute attack does occur during pregnancy, haem preparations have been used and there have been no reports of any adverse effects.

Anaesthesia. General anaesthesia can be safely undertaken in porphyria patients, provided care is taken to select drugs that are known to be safe. General measures to reduce stress and limit periods of fasting should also be instituted, and postoperative complications, such as infection treated aggressively with drugs chosen from the safe list. Regional and dental anaesthesia using local anaesthetics have been safely undertaken in many acute porphyria patients without problem.

Rare forms of acute porphyria

ALA dehydratase deficiency porphyria

5-Aminolaevulinic acid dehydratase deficiency porphyria (ADP) is an autosomal recessive acute porphyria, presenting with neurovisceral symptoms, that results from deficient ALAD activity; the biochemistry is characterized by marked increases in the plasma concentration and urinary excretion of ALA. The prevalence cannot be accurately assessed, but is extremely low with fewer than ten cases reported worldwide to date, and, as yet, none from the UK.

In addition to the very elevated plasma and urinary ALA, other biochemical features include a normal or slightly increased urine PBG, markedly elevated urine coproporphyrin excretion, normal faecal porphyrin and increased erythrocyte protoporphyrin. Confirmation of the diagnosis requires exclusion of lead poisoning, which gives rise to similar biochemical features, and demonstration of decreased ALAD activity in erythroid and non-erythroid cells that is not reversed by addition of excess zinc and a sulphhydryl group reducing agent. Mutational analysis may also be helpful in confirming the diagnosis, and may be required for genetic counselling.

Clinical presentation is variable with reported ages of presentation from birth through to 63 years. The predominant presentation is with acute attacks of abdominal pain and neuropathy that resemble those seen in the autosomal dominant acute porphyrias, and similarly may be triggered by factors such as prescribed drugs that induce ALAS activity. Heterozygote carriers are asymptomatic, but may be at increased risk from the effects of environmental toxins, such as lead, that inhibit ALAD activity. Treatment with hematin and glucose has not been

effective in all cases. Liver transplantation in a patient with ADP did not protect the patient from further acute attacks, nor correct the biochemical abnormalities. The marked enzyme deficiency in other tissues, particularly nervous tissue, probably contributes to the poor clinical outcome in this autosomal recessive condition.

Homozygous acute porphyrias

Homozygosity for null mutations of haem biosynthetic genes is lethal in early embryonic development. However, very rare so-called homozygous variants of all the autosomal dominant acute porphyrias have been reported, in which patients are homozygous or compound heterozygous for mutations that have some residual activity. All present in childhood and have other phenotypic differences from their (heterozygous) autosomal dominant counterparts.

Homozygous AIP is clinically the most severe of these variants and is usually associated with a progressive leukodystrophy. Both homozygous HCP and homozygous VP present with skin lesions in childhood with, in the latter, clinodactyly (curving of the little finger towards the ring finger) and sometimes other abnormalities, including short stature and neurological defects. Acute attacks have been reported in homozygous HCP but not homozygous VP. Missense mutations in exon 6 of the *CPOX* gene cause harderoporphyria, a relatively benign condition characterized by neonatal jaundice, persistent mild haemolytic anaemia, skin lesions and excretion of the tricarboxylic porphyrin, harderoporphyrin, in faeces. All these variants can be distinguished from their (heterozygous) autosomal dominant counterparts by demonstrating very low activity of the relevant enzyme and by mutational analysis. Erythrocyte protoporphyrin concentrations are also increased in all these conditions and this may serve as a useful initial diagnostic indicator. With the exception of harderoporphyria, porphyrin excretion patterns in the homozygous acute porphyrias are indistinguishable from those of the autosomal dominant forms.

THE CUTANEOUS PORPHYRIAS

Bullous porphyrias

The bullous porphyrias all give rise to identical skin lesions, and so cannot be distinguished with certainty on clinical grounds alone. Although patients with CEP or hepatoerythropoietic porphyria (HEP, see p. 545) tend to present in infancy or childhood, and those with PCT, VP or HCP in adulthood, exceptions do occur: occasionally PCT presents in early childhood, while the skin lesions of late onset CEP may first appear in adults and be mistaken for PCT. Biochemical investigation is essential for accurate diagnosis (see Table 28.3). It is important to distinguish between the disorders in view of the differences in prognosis, treatment and susceptibility to acute attacks. In addition, clinically identical skin lesions, termed pseudoporphyria, can occur in the absence of any disturbance of porphyrin metabolism as a consequence of

drug reactions, prolonged use of sun beds and in association with long-term haemodialysis.

Pathophysiology of skin lesions

Porphyrin-induced photosensitivity results from the absorption of visible light at the surface of the skin. Porphyrins enter the dermis from the plasma and interact with light of 400–410 nm wavelength, which is capable of penetrating to the level of the dermis and basement membrane. This photoactivation of the porphyrin ring gives rise to an unstable, excited-state molecule, which can release energy as light or react with oxygen by resonance energy transfer to form a singlet oxygen species or superoxide anion. These reactive oxygen species cause cellular damage via reactions with lipids, proteins and DNA, resulting in complement activation, degradation of mast cells and damage to the dermis and basement membrane. This process gives rise to the characteristic features evident on histopathology: perivascular accumulation of amorphous hyaline material involving the small vessels of the dermis. This PAS-positive material includes deposits of immunoglobulin and complement and appears to emanate from the walls and lumens of the blood vessels. Bullae occur where the epidermis splits from chronically damaged, thickened basement membrane and forms a roof for a pocket of clear fluid. The dermal papillae are distorted and flattened by the accumulated amorphous hyaline material and the floors of the bullae have a characteristic festooned appearance.

Skin symptoms and signs

The skin lesions may occur in any sun-exposed area, most frequently the backs of the hands, the forearms, the face and the feet, particularly when open sandals are worn. Fragile skin that tears following minor mechanical stress is the commonest feature. Injury can occur in response to everyday household activities, and patients frequently wear gloves to avoid damaging their skin. Vesicles and bullae filled with clear fluid are commonly present, as are small white spots or milia (Fig. 28.3). Haemorrhagic bullae are uncommon. Bullae rupture easily and form crusted lesions that heal slowly, resulting in chronic scarring of the skin and areas of depigmentation. Secondary infection of open lesions may occur, which worsens the scarring and in severe cases, may result in photomutilation and disfiguration. Other features include hypertrichosis, usually on the forehead and temples; this is particularly noticeable and troubling in women. Less common clinical features include hyper- or hypopigmentary changes, onycholysis, conjunctival damage and scarring alopecia. Because of the chronic nature of the conditions, the relationship to sunlight is not always recognized by the patient.

Biochemical features and diagnostic approach

Each of the bullous porphyrias has a characteristic pattern of porphyrin excretion during active disease that allows the conditions to be distinguished (see

A

B

FIGURE 28.3 ■ The skin lesions associated with bullous photosensitivity. (A) Chronic scarring due to skin fragility, partially healed erosions from ruptured bullae and milia on the back of the hand. (B) A typical clear fluid-filled blister on the sun-exposed back of the hand.

Table 28.3). Ideally, samples of urine, faeces and EDTA-anticoagulated blood should be sent for full porphyrin analysis on all patients. However, the single most useful analysis in patients with active skin lesions is a plasma porphyrin fluorescence emission scan, which, if normal, excludes active cutaneous porphyria (see Fig. 28.2). Many dermatologists now follow this approach and will send the other samples required for diagnosis only if the plasma porphyrin screen is abnormal. However, it is essential that the plasma scan be undertaken in a fluorometer that is sufficiently sensitive, which requires it to be fitted with a red-sensitive photomultiplier. An increased plasma porphyrin fluorescence emission peak with a maximum at 624–627 nm is diagnostic for VP. However, it does not necessarily indicate active porphyria, as positive plasma scans are found in approximately 60% of adults with latent VP and in most of those in remission. An emission maximum at 615–620 nm is consistent with skin lesions caused by porphyria but does not distinguish between PCT, CEP or HCP. However, these conditions can be unequivocally differentiated by urinary and faecal porphyrin analyses.

Individual disorders

Porphyria cutanea tarda. Porphyria cutanea tarda (PCT) is the commonest of the porphyrias, with a prevalence of approximately 1:25 000. It results from partial deficiency of the enzyme uroporphyrinogen decarboxylase (UROD) in the liver and is characterized biochemically by overproduction of uroporphyrin, 7-, 6- and 5-carboxyl porphyrins and isocoporphyrin. In many patients, there is evidence for underlying liver cell damage, and biochemical tests of liver function are often abnormal. Histopathological examination usually reveals only minor abnormalities: mild fatty infiltration with some hepatocyte necrosis and periportal inflammation. Cirrhosis is present in fewer than 20% of patients, but when it does occur, it carries a much greater risk of hepatocellular carcinoma than does comparable cirrhosis without PCT.

The majority of patients in the UK (80%) have sporadic or type I PCT, in which UROD deficiency is restricted to the liver. Most of the remaining 20% have familial or type II PCT, in which UROD deficiency is present in all tissues and is inherited in an autosomal dominant pattern. As with other autosomal dominant porphyrias, the clinical penetrance of familial PCT is low, with symptoms in fewer than 10% of those who inherit the condition. Porphyria cutanea tarda may also be caused by exposure to various halogenated aromatic hydrocarbons as in the outbreak of hexachlorobenzene poisoning in south-eastern Turkey in the late 1950s.

Whether the patient has familial or sporadic PCT, overproduction of sufficient porphyrin to produce symptoms appears to require a decrease in hepatic UROD activity to well below 50% of normal. This is brought about through the reversible inactivation of UROD by a porphomethene inhibitor formed from uroporphyrinogen by an iron-dependent oxidative mechanism, probably catalysed by hepatic cytochrome P450s. Less inactivation of UROD is required for symptoms to occur in familial PCT, where prior enzyme activity is half-normal and, although there is a wide overlap, patients tend to present at a younger age than those with sporadic PCT. Other risk factors for both types of PCT include alcohol misuse, conditions that increase hepatic iron content such as hereditary haemochromatosis, hepatotropic viruses (particularly hepatitis C virus, HCV) and HIV, and prescribed oestrogens: two or more risk factors are often present. Most patients have some hepatic iron overload but amounts are usually below those in overt haemochromatosis. Among patients of northern European descent, about 20% are homozygous for the haemochromatosis (*HFE*) gene C282Y mutation, irrespective of the type of PCT, but heterozygosity for this mutation is a less important risk factor. Prevalences for antibodies to HCV range from 8% to 79%, being highest in southern Europe and the USA and lowest in northern Europe. When PCT develops in HCV, it is usually an early manifestation; in contrast, it occurs as a late complication of HIV infection. Conditions less frequently associated with PCT include chronic renal disease, diabetes mellitus, systemic lupus erythematosus and various haematological malignancies.

Clinical management of patients with PCT should start with the identification of any predisposing factors that can be withdrawn or treated. Newly diagnosed patients should be investigated for underlying liver disease, tested for iron overload by measuring transferrin saturation and *HFE* genotyping, and screened for hepatitis viruses and, if indicated, HIV infection. Where there is evidence of chronic liver disease, referral to a hepatologist is advisable. All patients should be given general advice about avoidance of sunlight, encouraged to protect their hands from trauma by wearing gloves and advised to seek early treatment of any infected lesions. In contrast to patients with acute porphyrias, patients with PCT need not avoid any drugs, apart from antimalarial doses of chloroquine and its derivatives.

Two effective treatments for PCT are available. Venesection of a unit of blood at one- or two-weekly intervals to deplete hepatic iron stores prevents inactivation of hepatic UROD and eventually restores enzyme activity to basal levels. Treatment should be continued until transferrin saturation falls to 16% or less or the patient becomes anaemic (haemoglobin less than 120 g/L). Serum ferritin concentration is less satisfactory for monitoring, as values may be affected by concomitant liver disease. If it is used, treatment should continue until the concentration is 25 µg/L or less. Although resolution of skin lesions occurs within 3–9 months, biochemical remission usually takes longer as large quantities of porphyrins stored in the liver are released and excreted in the urine. Other methods used to reduce iron stores include subcutaneous desferrioxamine and, in patients with renal failure, erythropoietin without iron supplementation. Treatment with low-dose chloroquine (125 mg twice weekly) or hydroxychloroquine (100 mg twice weekly), which complexes with uroporphyrin and mobilizes it for excretion from the liver, is also effective. Larger doses will provoke an acute hepatotoxic reaction with systemic symptoms and should be avoided. Clinical improvement usually becomes evident within 3–4 months and treatment should be continued until total urinary porphyrin excretion falls to normal. Chloroquine treatment may be combined with venesection if response to monotherapy is slow. Choice between these two treatments is often determined by local preference. There is little evidence that chloroquine worsens liver disease, but it is potentially hepatotoxic in PCT and should probably be avoided in patients with severe liver disease. Iron depletion should be used for all *HFE* C282Y homozygotes; it is the only effective method in renal failure and ensures compliance, but is more expensive. Both treatments produce prolonged remission and, particularly in sporadic PCT, may prevent relapse. Nevertheless, long-term management should take into account the possibility of relapse, and patients in remission may benefit from an annual review. Patients with significant liver disease, familial haemochromatosis or other associated conditions should be managed by an appropriate specialist.

Determination of the type of PCT is best carried out by mutational analysis of the *UROD* gene. However, it is not essential for clinical management. Treatment is the same for both types, while the low clinical penetrance, absence of potentially life-threatening symptoms and

availability of effective treatments means that mutational analysis for family studies is difficult to justify, except perhaps for those rare families in which more than one individual has overt PCT.

Hepatoerythropoietic porphyria. This is a rare variant of familial PCT in which patients are homo- or heteroallelic for *UROD* mutations. Uroporphyrinogen decarboxylase activity is markedly decreased in all tissues, although the liver appears to be the main source of excess porphyrins. Skin lesions usually appear in early childhood and are identical to those of PCT. They persist and may occasionally become as severe and disfiguring as in CEP. Other organs are rarely affected; although severe anaemia has been described in HEP, most patients have no significant haematological abnormalities. Differentiation from other early onset porphyrias requires analysis of urinary, faecal and erythrocyte porphyrins, with measurement of erythrocyte *UROD* activity and/or mutational analysis of the *UROD* gene. Photoprotection is the only effective treatment. There is no associated iron overload and patients do not respond to phlebotomy or chloroquine. For most patients, the disease does not appear to affect survival.

Congenital erythropoietic porphyria. Congenital erythropoietic porphyria (CEP), or Gunther disease, is a rare bullous porphyria, with a UK prevalence of 1 in 3 million. It is pan-ethnic, although like other autosomal recessive conditions prevalence is increased in communities where consanguinity is common. Marked deficiency of *UROS* results in the accumulation of large amounts of uroporphyrin I, formed by non-enzymatic cyclization of HMB, and, to a lesser extent, of coproporphyrin I. The main source of excess porphyrin production is the bone marrow, with less than 1% produced from other tissues. The severity of the condition varies from hydrops fetalis, resulting from in utero haemolytic anaemia, to the late onset forms in which the disease becomes manifest in late childhood and young adults. The severity appears to correlate with the level of residual enzyme activity, with the more marked deficiency resulting in very high plasma and red cell porphyrin concentrations, which result in two major pathophysiological consequences: marked skin photosensitivity and haemolytic anaemia with ineffective erythropoiesis and splenomegaly. Most porphyrin is released from cells destroyed in the bone marrow but some comes from red cells sequestered and destroyed by the spleen. The haemolytic anaemia associated with CEP, which may be caused by porphyrin-induced damage to erythroid cell membranes, further stimulates erythropoiesis, increasing porphyrin overproduction.

The majority of patients present soon after birth with skin blisters, occasionally in response to phototherapy treatment for neonatal hyperbilirubinaemia, and red-brown staining of their nappies. The skin lesions are more severe and extensive than in other bullous porphyrias, and progressive damage can lead to photomutilation affecting the ears, nose, eyelids and fingers. Porphyrins also accumulate in bone and teeth, causing discolouration, evident as erythrodontia – reddish-brown teeth that fluoresce red on UV illumination. Bone marrow hyperplasia may lead

to osteolytic lesions. Other skeletal abnormalities include decreased bone density, possibly resulting from low vitamin D due to strict avoidance of sunlight, leading to pathological fractures. The hands are frequently severely affected with contractures, atrophy and bone resorption of the terminal phalanges.

The variable phenotype dictates the treatment approach, and early on in the course of the disease, mutational analysis of the *UROS* gene can provide useful information as there is some correlation between genotype and phenotype. Homozygosity for a mutation present on about 30% of CEP alleles, C73R, carries a particularly poor prognosis. Depending on the combination of mutations, this information can be used to classify the likely clinical severity as mild, moderate or severe and predict likely treatment requirements. Mutational analysis may also be required for prenatal diagnosis.

As with other cutaneous porphyrias, the mainstay of treatment is avoidance of sunlight; special measures such as fitting filters to house and car windows may be required. Aggressive treatment of any infected skin lesions with antibiotics is essential. Regular blood transfusions aimed at maintaining the haematocrit above 33% suppresses erythropoiesis and can successfully decrease porphyrin production and improve photosensitivity. In patients with transfusion-dependent anaemia, it is essential to use desferrioxamine or other iron chelators to control iron accumulation, which has been an important cause of death in the past. If hypersplenism occurs, splenectomy may reduce haemolysis and transfusion requirements. Other treatment modalities reported on small numbers or individual patients, and shown to be of limited benefit, include β -carotene, oral activated charcoal, plasmatorbent therapy, hydroxyurea and haematin infusion. Bone disease can be managed with bisphosphonate therapy and vitamin D supplementation where deficiency is evident. Prophylactic vitamin D should also be considered.

Allogeneic bone marrow transplantation (BMT) has been undertaken successfully in more than ten patients with CEP, resulting in a marked decrease in porphyrin production and photosensitivity in all cases. The main limitation is the availability of suitable donors. Use of cells from a heterozygous donor does not appear to affect the outcome. The major risks are the morbidity and mortality associated with the procedure itself, and bone marrow transplantation should therefore be reserved for the most severely affected patients. Clinical care for patients with CEP should be provided by a multidisciplinary team, including a dermatologist, haematologist, ophthalmologist and a porphyria expert, in order to assist patients and their families make informed decisions about this form of treatment.

Gene therapy for the erythropoietic porphyrias, particularly CEP, is being actively pursued. The success of BMT indicates that introduction of active enzyme into a sufficient number of deficient cells by ex vivo transformation should be curative. Gene delivery methodology has been successfully developed for other bone marrow disorders, for example X-linked severe combined immunodeficiency.

Erythropoietic protoporphyria and X-linked dominant protoporphyria

Two clinically indistinguishable porphyrias present with acute photosensitivity without skin fragility. In both, the photosensitivity results from accumulation of protoporphyrin in the skin. The concentration of protoporphyrin is also increased in erythrocytes, plasma, liver and other tissues. Most patients with this presentation have erythropoietic protoporphyria (EPP) but about 5% have XLDPP.

The excess protoporphyrin is produced mainly or, in XLDPP, exclusively by erythroid cells in bone marrow. In EPP, protoporphyrin accumulation results from a decrease in ferrochelatase (FECH) activity to less than 35% of normal. Almost all patients are compound heterozygotes for one of a large number of *FECH* mutations that abolish or severely decrease FECH activity and a hypomorphic allele (*FECH* IVS3–48C) that has about three-quarters of the activity of the normal allele and is present in around 10% of white Europeans, 30–45% of Asians and <3% of Africans. About 3% of patients lack the hypomorphic allele but have *FECH* mutations on both alleles, at least one of which retains some FECH activity. Within families, EPP segregates as an autosomal recessive disorder that may show pseudo-dominant inheritance in populations where the frequency of the hypomorphic allele is high. A late onset form of EPP associated with myelodysplasia or myeloproliferative disease and caused by acquired somatic *FECH* mutation has also been described.

X-linked dominant protoporphyria is caused by mutations in *ALAS2* that disrupt the C-terminal region of erythroid *ALAS2*, thereby increasing its activity and leading to increased formation of protoporphyrin. Unlike in EPP, FECH activity is normal, which enables conversion of some of the protoporphyrin that accumulates to zinc-protoporphyrin. Families normally show inheritance through several generations. This pattern is unusual in EPP and is an important indicator of the possible presence of XLDPP. As might be expected for a gain in function mutation on an X chromosome, both sexes are similarly affected, though skewed inactivation of the mutant chromosome may lead to mild or no disease in a small number of women.

The diagnosis of both conditions can be established by demonstrating an increase in erythrocyte protoporphyrin using a method that distinguishes between free protoporphyrin and its zinc chelate, which is the predominant form in normal and iron-deficient erythrocytes. In EPP, almost all the protoporphyrin is in the free form; more than 15% of zinc-protoporphyrin in a patient with a markedly increased total protoporphyrin indicates possible XLDPP, in which zinc-protoporphyrin forms from 20% to 70% of the total (see Fig. 28.2). Mutational analysis of *ALAS2* is required to confirm a diagnosis of XLDPP. Protoporphyrin is increased in plasma in EPP and XLDPP and has a fluorescence emission peak at 626–635 nm. Faecal protoporphyrin excretion is increased in about 40% of EPP patients, and some of those with XLDPP, but is not specific for either condition and is of limited value diagnostically. Protoporphyrin is hydrophobic and is not excreted in urine, which therefore cannot be used to diagnose or exclude EPP or XLDPP.

Skin symptoms and signs

Both conditions are characterized by life-long acute photosensitivity with pain and swelling of sun-exposed skin, usually becoming evident within the first two years of life. Although symptoms typically appear in early childhood, diagnosis may be delayed for many years unless there is a family history. Patients give a characteristic history of burning pain within minutes of exposure to sunlight, which may only be relieved by cold water or wet towels. There may also be priming phenomena, whereby exposure to sunlight sensitizes the skin, lowering tolerance to sunlight on subsequent occasions. The oedema evident immediately after exposure has usually resolved by the time a doctor sees the child, hence the difficulty in diagnosis. With prolonged exposure, an erythematous reaction or even blistering can occur. Over time, patients develop chronic skin lesions with a waxy, thickened appearance. Chronic exposure of the face leads to linear scarring of the forehead and cheeks, with furrowing around the mouth (Fig. 28.4). Occasionally, marked thickening of the skin develops over the joints of the hands and fingers.

A

B

FIGURE 28.4 ■ The skin lesions associated with chronic sunlight exposure in erythropoietic protoporphyria. (A) Linear and pitted scarring of the forehead. (B) The back of the hands and fingers showing marked thickening of the skin with a waxy, lichenoid appearance.

Severe acute photosensitivity has a serious adverse effect on quality of life, sometimes worsened by delayed or incorrect diagnosis. Childhood can be a particularly difficult period and adult patients frequently state that they do not want to have children if they have to go through a similar experience.

Treatment

Avoidance of sunlight is the mainstay of management of acute protoporphyrin-induced photosensitivity. Outdoor clothing should include full-length garments to cover the arms and legs, a wide brimmed hat (or peaked hat with a cloth covering the neck), closed shoes and gloves if possible. Sunscreen creams must be formulated to block wavelengths around 400–420 nm. The most effective are those based on titanium dioxide, which acts as a reflectant, and a specially formulated product available in three tinted versions (coral, beige and coffee) is available in the UK (Tayside Pharmaceuticals, Ninewells, Dundee). Where prevention fails, cold compresses and application of local corticosteroid creams to the affected area can provide symptomatic relief. Antihistamines may also provide some relief by reducing the immediate release of histamine by mast cells.

Several specific treatments have been proposed, although none has proved to be completely reliable. The most promising is narrow-band UV therapy, which induces sunlight tolerance equivalent to a sun protection factor (SPF) of 8. Effective treatment is limited by availability of equipment and the requirement for regular therapy. More traditionally, patients should be offered a trial of β -carotene therapy, which is believed to work by quenching oxygen radicals and/or interfering with the absorbance of light by protoporphyrin. Efficacy is variable, with a significant proportion of patients reporting no benefit. However, it is important to ensure an adequate dose of between 100 and 300 mg/day, sufficient to achieve plasma concentrations of 11–15 $\mu\text{mol/L}$ (6–8 mg/L). Hormonal tanning agents based on α -melanocyte stimulating hormone (α -MSH) analogues are currently being investigated as a treatment and have shown promise in early trials.

Bone marrow transplantation (BMT) has also been used successfully in several EPP patients, either to treat a coexistent haematological malignancy or to protect a transplanted liver from recurrence of protoporphyrin hepatopathy (see below). Although in most EPP patients, the risk of BMT outweighs the benefits, if it becomes possible to identify patients with a high risk of protoporphyrin liver disease, BMT could be used to cure the condition and eliminate the need for liver transplantation.

Chronic complications and their management

Mild microcytic, normochromic anaemia, which is associated with reduced iron indices, is common in both conditions, affecting up to a third of EPP patients. Bone marrow studies show scattered sideroblasts and perimitochondrial iron accumulation, suggesting defective utilization of iron for haem synthesis. Iron therapy is, therefore, unlikely to resolve the anaemia and, in some cases, has been reported to worsen photosensitivity.

The most serious complication of EPP and XLDP is progressive protoporphyrin liver disease, which affects 1–2% of patients and may lead to severe acute liver failure. Excess protoporphyrin is excreted via the biliary tract and deposits of protoporphyrin are present in the hepatocytes of many patients. In a minority, this leads to liver damage that, although initially mild as indicated by small increases in plasma transaminase activities, will in some cases progress to cirrhosis. Further deterioration leads to cholestatic jaundice and abdominal pain that may be similar to the neurovisceral pain experienced in the acute porphyrias. Hypersplenism and the accompanying haemolysis stimulate erythropoiesis and, in combination with the decreased biliary protoporphyrin excretion, result in increased red blood cell protoporphyrin concentrations and worsening photosensitivity. This fulminant or decompensated liver failure is usually fatal unless the patient receives a liver transplant. Perioperative risks include severe phototoxic burns as a result of high levels of circulating protoporphyrin. This can be reduced by pre-operative treatments that reduce protoporphyrin concentrations; it is essential that the theatre lights be filtered. In addition, patients are at risk of neuronal damage leading to abdominal pain and profound motor neuropathy requiring ventilation. Finally, protoporphyrin liver disease can recur in the transplanted liver and, in these circumstances, bone marrow transplantation to correct the metabolic defect and prevent further hepatic damage is the only viable option.

There is no reliable way of predicting which patients are at risk of severe liver disease, although there appears to be an increased risk in patients with XLDP and those with true autosomal recessive EPP (mutations on both *FECH* alleles). All patients should therefore be seen regularly throughout their lives by a porphyria specialist to monitor both erythrocyte protoporphyrin concentrations and liver function. Patients in whom liver function is found to be abnormal, or whose protoporphyrin concentrations are markedly increased, should be referred to a hepatologist for full assessment and liver biopsy. At this stage, treatment to halt the progressive liver damage caused by the increasing protoporphyrin concentrations should be instituted. This should include avoiding alcohol, measures to enhance protoporphyrin excretion such as oral cholestyramine, activated charcoal or bile acids (ursodeoxycholic or chenodeoxycholic acid). In patients with incipient liver failure, particularly those awaiting liver transplantation, this should be combined with measures to reduce protoporphyrin production using hypertransfusion or haematin infusion to suppress erythropoiesis. Finally, exchange transfusion and plasmapheresis can be used to reduce circulating protoporphyrin concentrations immediately prior to transplantation.

SECONDARY DISORDERS OF PORPHYRIN METABOLISM

Abnormalities of porphyrin production and excretion may occur as a secondary manifestation of a large number of disorders other than the porphyrias (Table 28.6). These secondary disturbances of porphyrin metabolism

TABLE 28.6 Secondary disorders of porphyrin metabolism

Porphyrin abnormalities	Condition	Differentiation from porphyria
Increased coproporphyrin I and III in urine	Hepatobiliary dysfunction Chronic liver disease Alcohol, drugs Severe illness, infections	Normal urinary PBG/ALA Normal plasma porphyrin Normal faecal porphyrins
Increased dicarboxylic porphyrins in faeces	Increased haem in gut: diet or bleeding	Normal faecal coproporphyrin Normal plasma and erythrocyte porphyrin Normal urine porphyrins
Increased erythrocyte zinc protoporphyrin	Iron deficiency Haemolytic and other anaemias Lead poisoning	Normal or slightly increased erythrocyte free protoporphyrin Normal plasma porphyrin
Increased urinary ALA and coproporphyrin III	Lead poisoning	PBG normal or increased much less than ALA Increased blood lead
Increased plasma porphyrin	Chronic renal failure (particularly long-term haemodialysis) Cholestatic jaundice	Normal faecal porphyrins

are usually mild, but together are far more common than the inherited porphyrias and may cause clinical and diagnostic confusion unless recognized for what they are.

Urinary coproporphyrin excretion may be increased in any condition that impairs hepatobiliary excretion, by ingestion of alcohol and drugs that induce cytochrome P450 isoforms, in poisoning by lead, other heavy metals and halogenated hydrocarbons, and in many severe illnesses, including infections. In normal individuals, coproporphyrin I predominates in bile, while the III isomer is excreted mainly in urine. As biliary excretion declines, the proportion of coproporphyrin I increases in urine. In alcoholism uncomplicated by liver disease, and in lead poisoning, urinary excretion of coproporphyrin III is increased. In Dubin–Johnson syndrome, coproporphyrin I comprises 80% or more of the total urinary coproporphyrin excretion, which is usually normal or near normal: this pattern has been regarded as diagnostic and distinct from the patterns found in Rotor syndrome and primary biliary cholestasis, which resemble those of other hepatobiliary disorders.

When total urinary porphyrin alone is measured, secondary coproporphyrinuria may suggest the presence of a porphyria but can readily be distinguished by demonstrating normal urinary PBG and ALA and faecal porphyrin excretion, with measurement of blood lead if increased coproporphyrin III or ALA suggests lead poisoning.

Haem is metabolized by the gut flora to protoporphyrin and related dicarboxylic porphyrins. Thus, even small increases in the haem content of the gut, which may not be large enough or occur sufficiently distally in the gut to produce a positive test for occult blood, may increase the total porphyrin content of faeces. Fractionation by HPLC shows that the increase is caused entirely by dicarboxylic porphyrins. Provided a dietary source of extra haem can be excluded, this finding may indicate alimentary tract bleeding of pathological significance.

Erythrocyte porphyrin concentrations are increased in iron deficiency, some other anaemias and in lead poisoning. In these conditions, the erythrocyte porphyrin is almost entirely zinc protoporphyrin and plasma porphyrin

concentrations are normal. In some patients with iron deficiency, faecal porphyrin content may also be increased by gastrointestinal bleeding.

Plasma porphyrin concentrations are increased in cholestatic jaundice and in chronic kidney disease. Patients on long-term haemodialysis may develop a bullous dermatosis on sun-exposed skin that resembles PCT. Since PCT is also associated with end-stage kidney disease, and can be successfully treated by decreasing hepatic iron stores, it is important to distinguish between the two conditions. Plasma uroporphyrins and heptacarboxylic porphyrins are increased in both, though usually to a greater extent in PCT. Faecal isocoproporphyrin is increased only in PCT and its measurement is more reliable than plasma porphyrin analysis for identifying PCT in such patients.

CONCLUSION

The porphyrias are metabolic diseases characterized biochemically by the excessive production of porphyrins and their precursors as a result of defects in the enzymes leading to haem synthesis. Decreased haem synthesis leads to increased activity of the rate-limiting enzyme, 5-aminolaevulinic acid synthetase and accumulation of the substances involved in the pathway before the block. Porphyrias can be classified as acute (characterized by attacks of a predominantly neurovisceral nature) and chronic (characterized by photosensitivity). Some exhibit both characteristics. They can be distinguished by the pattern of porphyrin excretion, which is unique to each condition.

CONCLUSION 559

INTRODUCTION

Since the discovery of its central role in oxygen transport in the 19th century, haemoglobin has proved to be a source of fascination to scientists and physicians alike, and is arguably the most widely studied protein in man. Its principal disorders, the thalassaemias and sickle cell disease, quantitative and qualitative defects of synthesis, respectively, are among the most common serious inherited diseases in man and have been pivotal in efforts to understand the molecular basis of human diseases.

It is estimated that about 7% of the world's population carry the mutation for at least one type of haemoglobinopathy, and that 400 000 babies are born each year with a severe form. Approximately 230 000 babies are born each year with sickle cell disease in sub-Saharan Africa, and 120 000 are born with severe thalassaemia in southern and South-East Asia. There is good epidemiological and experimental evidence that the extraordinarily high frequency of haemoglobinopathies and their geographical distribution are due to the relative protection that they provide against malaria and its serious complications. This principally involves improved survival and reproductive success for heterozygotes compared with the normal population, which outweighs the reduced reproductive success of homozygotes. Thalassaemia reaches polymorphic frequencies (>1%) in nearly all populations, except those of northern Europe, northern Asia and the indigenous peoples of Australia, the Americas and the Arctic. The common abnormal haemoglobins have more limited distributions (Fig. 29.1).

Since there is considerable overlap in the world distribution of thalassaemias as well as the common structural haemoglobin variants, co-inheritance of more than one haemoglobin abnormality is common. This generates an extremely diverse range of clinical phenotypes.

The structure and function of haemoglobin

Haemoglobin is a tetramer comprising two α and two β globin chains ($\alpha_2\beta_2$). One molecule of haem, which contains iron and can bind to oxygen, is attached to each globin chain, lying in a hydrophobic cleft. The amino acid sequence of this haem pocket shows marked homology between different animal species, suggesting a specific and important function. Through its iron atom, each haem group is capable of binding one molecule of oxygen. The reversible binding of oxygen to haemoglobin is allosteric, giving rise to the characteristic shape of the oxygen dissociation curve (Fig. 29.2). On binding oxygen, conformational changes occur in both individual globin chains and the tetrameric structure of haemoglobin. The predominant change is closure of the gap between the two β -chains. The site at which this occurs is of critical functional importance. 2,3-Diphosphoglycerate (2,3-DPG), the principal regulator of oxygen affinity in red cells, binds to this part of the haemoglobin molecule. This serves to separate the two β -chains, favouring the deoxygenated conformation and thereby reducing the oxygen affinity of haemoglobin. The observation that oxygen affinity is often reduced in anaemic patients is explained by the adaptive increase in intracellular 2,3-DPG concentration. This enhances oxygen delivery to the tissues and is one of the important reasons why patients frequently tolerate chronic anaemia with very few symptoms. Conversely, the higher oxygen affinity of fetal blood necessary to maintain adequate maternal–fetal oxygen transport is, in large measure, due to the lower affinity of 2,3-DPG for fetal haemoglobin (HbF).

The other main physiological influence on haemoglobin oxygen affinity is the Bohr effect. First recognized at the turn of the century through the effect of carbon dioxide on lowering the oxygen affinity of whole blood, it is now known to reflect the sensitivity of oxygen binding by haemoglobin to changes in blood pH. An increase in

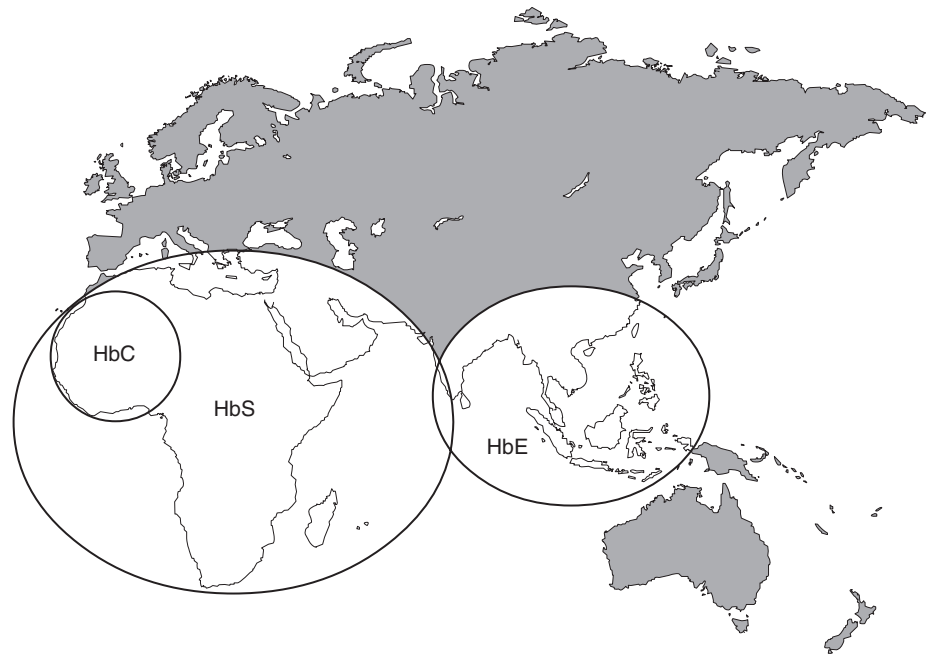

FIGURE 29.1 ■ Primary geographic distribution of haemoglobins (Hb) S, C and E.

FIGURE 29.2 ■ The oxygen dissociation curves of normal (AA) and sickle (SS) haemoglobin (Hb).

hydrogen ion concentration stabilizes the deoxygenated conformation of the haemoglobin molecule, and so physiological acidosis leads to a reduction in the oxygen affinity. If acidosis is sustained, this effect may be counterbalanced by the reduction in intracellular 2,3-DPG concentration due to modulation of red cell glycolysis. Several inherited variants of haemoglobin have been described that stabilize the molecule in either the oxy or deoxy conformation. In some cases, the interaction with 2,3-DPG or the Bohr effect is modified.

A further factor affecting haemoglobin function is temperature. An increase in temperature reduces oxygen affinity, whereas a fall increases it. As the human is normally isothermic, this is usually of little consequence in terms of physiological adaptation, though during exercise, when oxygen consumption is increased, a raised temperature in the muscles together with an increase in hydrogen ion concentration favours release of oxygen by

haemoglobin. Extreme hypothermia has many adverse consequences, including increased haemoglobin oxygen affinity causing reduced oxygen delivery to tissues.

The genetic control of haemoglobin synthesis

Human globins are encoded by the α and β gene clusters located on chromosomes 16 and 11, respectively (see Fig. 29.3). The α -like genes include an embryonic gene (ζ) and two adult genes (α_1 and α_2). The β -like genes comprise an embryonic gene (ϵ), duplicated fetal (γ) and adult (β and δ) genes. Expression of these genes is developmentally regulated during fetal life. The array of α - and β -like genes on their respective chromosomes reflects the order in which they are expressed. The control of the switch from embryonic, to fetal and then to adult globin synthesis, seems to be controlled by the interaction between several transcription factors, the locus control regions upstream of the gene cluster and the promoter regions of the individual genes.

Normally, the synthesis of α - and β -like chains is carefully balanced to avoid the accumulation of free globin chains, although it is not clear how this balance is maintained. In the thalassaemias, where this balance is severely disturbed, the excess of one type of globin chain is central to the pathophysiology.

The switch in globin synthesis during development has important implications for clinical expression of the haemoglobinopathies. Complete failure of α -chain synthesis, which, since the α genes are duplicated on each chromosome, occurs only when there is loss of function involving all four α genes, becomes evident early in fetal life. By contrast, even if there is little or no normal β -chain synthesis, the effects will not be manifest until the switch from fetal γ to adult β gene expression is completed after birth. This switch is gradual, and abnormalities of β globin synthesis rarely result in clinical problems

FIGURE 29.3 ■ Organization of the human globin gene cluster and developmental changes in haemoglobin.

before three months of age. Reversing this switch, and reactivating fetal haemoglobin is also potentially curative for diseases caused by mutations of the β globin genes.

THE THALASSAEMIAS

The thalassaemias are one of the commonest human autosomal recessive disorders, with approximately 120 000 severely affected individuals born annually worldwide. The most common and clinically significant forms are α and β thalassaemia and the β thalassaemia-like structural variant, haemoglobin E. These may be further subdivided according to whether there is no output of globin (α^0 or β^0 thalassaemia) or some preservation of globin chain synthesis (α^+ and β^+ thalassaemia). In the case of α thalassaemia, this is complicated further by the duplication of expressed α genes. α Thalassaemia is clinically significant only when three or four α globin genes are lost. The clinical consequences of thalassaemia in the homozygous (or compound heterozygous) state may be understood in terms of the imbalance in globin chain synthesis that results from absent or reduced synthesis of either α or β globin. Unpaired α or β globin chains are toxic, and damage the developing red cell, causing it to die whilst still in the marrow, which is characteristic of thalassaemia and called ineffective erythropoiesis. Heterozygotes are

unaffected clinically, and manifest the condition as slight anaemia with reduced red cell size and haemoglobin content. Increasing globin chain imbalance, as occurs in homozygous and compound heterozygous states, results in more marked anaemia and bone marrow expansion, with corresponding development of symptoms.

A characteristic of thalassaemia syndromes is their marked phenotypic heterogeneity. For over 20 years now, the molecular basis of thalassaemia has been studied and understood in great detail. The number of mutations identified as causing thalassaemia is large and continues to grow. However, in most populations, a small range of 5–10 different thalassaemia mutations accounts for about 90% of the mutant alleles found in that particular area.

α Thalassaemia

Though particularly common in South-East Asia, where carrier rates may reach 50%, α thalassaemia is widely distributed in all major populations apart from northern Europeans (see Fig. 29.1). The pathophysiological effects of α thalassaemia reflect the degree of impairment in α globin production (see Table 29.1). The majority of cases are due to deletions involving one or both α globin genes.

Haemoglobin Bart's hydrops fetalis is the most severe form of α thalassaemia, where all four α genes are affected, abolishing or severely diminished α chain synthesis.

TABLE 29.1 The α thalassaemia syndromes

Phenotype	Number of functional α genes	Genotype ^a	%Hb Bart's at birth	HbH inclusions
Normal	4	$\alpha\alpha/\alpha\alpha$	0	None
α Thalassaemia trait (minor)	3	$-\alpha/\alpha\alpha$	0–2	None
	2	$-\alpha/-\alpha$ or $---/\alpha\alpha$	2–8	Occasional
HbH disease	1	$---/-\alpha$	10–40	Numerous
Hb Bart's hydrops fetalis	0	$---/---$	80	Present in some cases

^a $-\alpha$, denotes loss of function of one α gene on a chromosome, i.e. α^+ thalassaemia.

$---$, denotes loss of function of both α genes on a chromosome, i.e. α^0 thalassaemia.

The disease becomes manifest in fetal life. With the failure of normal production of fetal haemoglobin ($\alpha_2\gamma_2$), surplus fetal γ -chains combine to form tetramers (γ_4) recognized electrophoretically as haemoglobin Bart's. The fetus is only able to survive at all in utero because of the presence of increased amounts of the embryonic haemoglobin Hb Portland ($\zeta_2\gamma_2$). Haemoglobin Bart's possesses markedly increased oxygen affinity and is ineffective as an oxygen transporter. In an attempt to compensate for impaired tissue oxygen delivery, there is erythroblastosis with extramedullary haemopoiesis, leading to hepatic and splenic enlargement. Severe functional anaemia leads to tissue hypoxia, increased capillary permeability, and cardiac failure, which lead ultimately to fetal hydrops and death in utero or stillbirth in late pregnancy.

Haemoglobin H disease occurs when there is loss of function of three out of four α genes. There is sufficient residual α -chain synthesis to allow production of some normal fetal and adult haemoglobin, and fetal development is generally normal. A variable amount (10–40%) of Hb Bart's is detectable at birth. After birth, the excess β -chains form tetramers detectable electrophoretically as the fast variant haemoglobin H (β_4). Haemoglobin H (HbH) precipitates within red cells with the formation of inclusion bodies leading to shortened red cell survival. Staining of these inclusions with the redox dye brilliant cresyl blue serves as a useful diagnostic test. The clinical effects of HbH disease vary considerably. Most patients have a mild to moderate haemolytic anaemia, which may be exacerbated during pregnancy or parvovirus B19 infection, accompanied by splenomegaly. Growth and development are usually normal. As in other congenital haemolytic anaemias, there is an increased tendency to form pigment gallstones.

It follows that Hb Bart's hydrops fetalis and HbH disease occur only when at least one parent carries the α^0 genotype ($-/\alpha^0$). This provides an explanation for the observation that these disorders occur primarily in southern China, South-East Asia and the eastern Mediterranean where α^0 thalassaemia is prevalent, and are not seen in other parts of the world, for example Africa and India, where α^0 thalassaemia is very rare.

Individuals in whom one or two α genes are dysfunctional are clinically unaffected, although they show thalassaemic red cell indices and traces of Hb Bart's at birth (see Table 29.1). This form of α thalassaemia trait is very common in most populations, with a 3.7 kb deletion accounting for most cases. Non-deletional forms of α thalassaemia are increasingly recognized as DNA analysis becomes more widespread and sophisticated.

β Thalassaemia

β Thalassaemia is prevalent throughout tropical and North Africa, the Mediterranean, Middle East and large parts of south and South-East Asia, including India (see Fig. 29.1). In some parts of the world, for example Cyprus, the heterozygote (carrier) frequency may reach 15%. Over 300 different mutations of the β globin gene or its promoter are known to cause β thalassaemia, the majority being single nucleotide substitutions (point mutations) or small deletions. Geographically, these

segregate non-randomly, so that four or five specific mutations account for the majority of β thalassaemia genes in individual ethnic or geographic groups. Each mutation typically occurs on a single β globin gene haplotype, suggesting that in most instances individual β thalassaemia mutations have arisen historically on a single occasion.

Though both α and β thalassaemia share reduced globin chain synthesis, the pathogenesis of anaemia in severe forms of these conditions is distinct. In severe forms of β thalassaemia (β thalassaemia major), there is severe impairment or absence of β -chain production. As a consequence, excess α -chains accumulate and precipitate in red cell precursors leading to their destruction within the bone marrow. There is also a degree of shortened red cell survival, although ineffective erythropoiesis predominates. Red cells containing fetal haemoglobin (HbF) survive preferentially since there is less globin chain imbalance. The anaemia produces tissue hypoxia, which stimulates erythropoietin production and massive expansion of erythropoiesis in the bone marrow and extramedullary sites.

If untreated, β thalassaemia major leads to severe anaemia, failure to thrive, impaired growth and bony distortion, with death in early childhood. As a result of the expansion in erythropoiesis, there are bone deformities and enlargement of the liver and spleen. Medullary expansion of the facial bones and skull gives rise to a characteristic 'thalassaemic' facies, splaying of the teeth and frontal bossing. With the advent of effective therapy, this picture is now seldom seen in the developed world. The treatment of β thalassaemia major comprises regular blood transfusion to maintain the haemoglobin above 95 g/L. At this level of haemoglobin, bony deformity and hypersplenism due to anaemia are minimized. Leukocyte-depleted blood should be used to prevent alloimmunization against white cell antigens. The blood should be matched for an extended range of blood groups, including ABO, Rh and Kell, to reduce the frequency of alloantibody formation.

An inevitable complication of multiple red cell transfusions is iron accumulation. If untreated, this leads to iron deposition throughout the body, which may cause endocrine dysfunction with diabetes, hypogonadotrophic hypogonadism and hypoparathyroidism, and, ultimately, death due to cardiac failure and liver damage. This may be prevented by the use of iron chelators. Desferrioxamine, which increases both urinary and faecal iron excretion, is administered parenterally, usually by continuous overnight subcutaneous infusion, since it is ineffective orally. Ascorbic acid may enhance urinary iron excretion when given with desferrioxamine. The clinical efficacy of desferrioxamine is limited by its subcutaneous route of administration, and two oral iron chelators are currently licensed for use. Deferiprone is probably less effective than desferrioxamine at removing hepatic iron, but may be particularly effective at removing cardiac iron, and can be used in combination with desferrioxamine. Side-effects include arthropathy and unpredictable neutropenia, and weekly full blood count monitoring is recommended for those taking it. Deferasirox is a newer oral chelator with similar efficacy to desferrioxamine and a good safety profile. The degree of iron overload and the efficacy of

chelation can be monitored by measuring serum ferritin concentration, liver biopsy to quantitate iron and non-invasive measurements using magnetic resonance imaging (MRI) and the superconducting quantum interference device (SQUID). Cardiac and hepatic MRI using T2* and R2 protocols are increasingly used. Accurate quantitation of the volume of transfused blood is also valuable in assessing the degree of iron overload.

With adequate transfusion and chelation therapy, most children with β thalassaemia major attain normal growth and sexual development and survive well into adult life. Allogeneic bone marrow transplantation from human leukocyte antigen (HLA)-matched siblings has been used with considerable success for treatment of β thalassaemia major. The best results, with disease-free survival rates of up to 95%, have been obtained in younger children with little or no evidence of end-organ damage due to iron overload. Trials of gene therapy are taking place in France and the USA, with one patient to date successfully rendered transfusion-independent, although with one cell clone predominating, owing to the inadvertent activation of a potential oncogene.

As in other thalassaemia syndromes, there is considerable heterogeneity in the clinical expression of β globin gene mutations. Much of this heterogeneity is unexplained, but two factors have been identified: first, the extent to which β globin production is impaired, which reflects the nature of the underlying gene mutation, and second, co-inheritance of other interacting genetic determinants that modify clinical severity. Mutations that severely disrupt or abolish β globin synthesis (β^0 thalassaemia) include those that prevent normal splicing of mRNA (splice junction or cryptic splice site mutations) or generate a non-functional mRNA by premature translation termination (nonsense mutations), and small nucleotide deletions or insertions that result in the normal triplet genetic code being read out of frame (frameshift mutations). Other mutations, for example those of the β globin chain promoter, which alter the level of gene expression (transcriptional mutations), usually result in reduced rather than absent β globin synthesis (β^+ or β^{++} thalassaemia). Among the independent genetic factors that ameliorate the clinical effects of β thalassaemia are co-inheritance of α thalassaemia, which partially redresses the imbalance in globin chain synthesis and therefore results in less ineffective erythropoiesis, and hereditary persistence of fetal haemoglobin (HPFH). HPFH can be directly linked to the β globin cluster, and its causes include large deletions and point mutations in the promoter regions of the γ globin genes. Three other major loci which control HbF concentrations have now been identified: the *Xmn1*

BOX 29.1 Causes of β thalassaemia intermedia

Homozygous β thalassaemia

- Homozygous β^{++} thalassaemia
- Compound heterozygote β^+/β^{++} thalassaemia
- Co-inheritance of α thalassaemia
- Co-inheritance of factors promoting increased HbF synthesis

Heterozygous β thalassaemia

- Co-inheritance of triplicated α globin genes ($\alpha\alpha\alpha/\alpha\alpha$ or $\alpha\alpha\alpha/\alpha\alpha\alpha$)
- Dominant β thalassaemia

$\delta\beta$ Thalassaemia

- Homozygous $\delta\beta$ thalassaemia
- Heterozygous $\delta\beta$ thalassaemia/ β thalassaemia

polymorphism in promoter region of the γ globin genes, the *HMP1* locus on chromosome 6q23.3 and *BCL11A* on chromosome 2. These factors account for some cases of the clinical syndrome thalassaemia intermedia, in which there is a variable degree of anaemia, without dependence on regular blood transfusions (Box 29.1).

The heterozygous (carrier) state for β thalassaemia (β thalassaemia trait) is usually harmless. Some of the phenotype characteristics of β thalassaemia heterozygotes are shown in Table 29.2. Most individuals have slightly reduced haemoglobin concentrations and an elevated red cell count. A raised HbA₂ ($\alpha_2\delta_2$) concentration is an important diagnostic marker and distinguishes β thalassaemia trait from α thalassaemia, in which the HbA₂ is normal or low. This presumably reflects a higher output from the δ globin gene, which normally plays a minor role in adult haemoglobin synthesis (normal HbA₂ <3.2%) in the face of reduced β globin production. Similarly, HbF concentrations are frequently slightly raised in β thalassaemia heterozygotes. Rarely, dominant β thalassaemia occurs.

STRUCTURAL HAEMOGLOBIN VARIANTS

Over 700 qualitative variants have been identified, in which the haemoglobin molecule is structurally, and in some cases functionally, altered. These arise from diverse molecular defects, most commonly single amino acid substitutions, but also insertion or deletion of amino acids and polypeptide fusion as a result of recombination between globin genes, for example haemoglobin Lepore. The most common structural variants are haemoglobins S, C, D^{Punjab} and E, which each affect many millions of people worldwide.

TABLE 29.2 The β thalassaemia syndromes

Genotype	Heterozygote			Homozygote		Clinical status
	MCH and MCV ^a	% HbA ₂	% HbF	% HbA	% HbF	
β^0	Reduced	Raised	<4	0	>94	Thalassaemia major
β^+	Reduced	Raised	<4	5–50	50–90	Thalassaemia major
β^{++}	Slightly reduced	Raised or borderline	<2	50–90	10–50	Thalassaemia intermedia

^aMCH, mean cell haemoglobin; MCV, mean cell volume.

Sickle cell anaemia

Sickle cell anaemia (HbSS), caused by homozygous inheritance of structurally abnormal haemoglobin, is one of the commonest genetic disorders with an estimated 60 million carriers worldwide and 230 000 affected infants born annually in Africa alone. The prototypic molecular disease, it was the first human disorder to be understood at a molecular level. The landmark discovery of sickle haemoglobin (HbS) more than half a century ago by Pauling and Itano, was succeeded by demonstration of the underlying single amino acid substitution and the gene mutation responsible. Sickle haemoglobin polymerizes on deoxygenation to produce long molecules that damage and distort the red cell, producing the classic sickle-shaped erythrocytes that give the disease its name. The resulting microvascular occlusion and shortened red cell survival combine to produce a clinical syndrome that comprises anaemia, vaso-occlusion, vasculopathy, haemolysis, inflammation, hypercoagulability, organ damage and susceptibility to infection due to hyposplenism.

A single base change (CAG→CTG) in the sixth codon of the β globin gene determines the substitution of valine for glutamic acid, which results in the structural variant sickle haemoglobin S. While the sickle mutation occurs predominantly in those of African origin, with smaller numbers affected in the countries of the Mediterranean littoral, Saudi Arabia and India, population migration has resulted in its spread globally. The allele frequency of β^s is thought to be high because of protection against the complications of severe malaria in the heterozygous state, as described earlier for thalassaemia mutations.

Although HbSS is the commonest cause of sickle cell disease, this condition occurs with other genotypes, in which there is co-inheritance of a different β globin mutation. The most important of these compound heterozygous states are: HbSC disease, HbS β^+ thalassaemia and HbS β^0 thalassaemia, although about 15 different genotypes have been identified as causing sickle cell disease. Among sickling disorders, HbSS and S β^0 thalassaemia are the more severe clinically, with a greater degree of anaemia (haemoglobin 60–80 g/L) and more severe organ damage. While HbSC and S β^+ thalassaemia are perceived as milder genotypes than HbSS, there is considerable overlap and some types of end-organ damage, particularly proliferative retinopathy, occur more frequently, particularly in HbSC disease. Other genetic factors that may influence disease expression include co-inheritance of α^+ thalassaemia and high fetal haemoglobin (HbF) levels, both of which may ameliorate the severity of sickle cell disease.

The primary pathophysiological event in sickling is intracellular polymerization of deoxy HbS. The $\beta 6$ valine substitution alters the surface charge of haemoglobin, resulting in interaction between haemoglobin tetramers and the formation of 14-stranded polymers. These are then ordered into parallel arrays of fibre bundles, which can be visualized by electron microscopy. The formation of polymer fibres (or gelation) is affected by four main variables: oxygen tension, HbS concentration, temperature and the presence of non-sickling haemoglobins. The mean corpuscular haemoglobin concentration (MCHC)

has a profound effect on the kinetics of sickling through its effect on the delay period between deoxygenation and polymerization. Small increases in haemoglobin concentration, as occur with cellular dehydration, may therefore act as a trigger for the sickling process.

Polymer formation is accompanied by several changes in the membrane of sickle erythrocytes, making them less deformable, increasingly fragile and leaky to cations. These changes are thought to result not only from interactions between sickle haemoglobin and the membrane but also from oxidative damage caused by free radicals, concentrations of which have been shown to be increased in these cells. These membrane changes are initially reversible but become increasingly pronounced as the cell undergoes repeated cycles of sickling and unsickling, culminating in an irreversibly sickled cell (ISC). The percentage of ISCs has been used as a marker for the sickling process but correlates poorly with the clinical condition of the patient. Red cell membrane phospholipids are abnormally distributed in these cells, with the normal inner leaflet amino-phospholipids being rearranged on the outer leaflet of the lipid bilayer. Cation homeostasis is also disordered, with potassium loss exceeding sodium gain, resulting in cellular dehydration and increased concentration of intracellular haemoglobin. This is accompanied by an up to four-fold increase in intracellular calcium. There is increased intravascular haemolysis, leading to a high plasma concentration of free haemoglobin, which binds nitric oxide avidly and results in a functional nitric oxide deficiency; this is implicated in the development of vasculopathy, which contributes to the complications of pulmonary hypertension, priapism and cerebrovascular disease. Other pathological processes include hypercoagulability, inflammation, oxidative stress and reperfusion injury, all of which contribute to the multisystem nature of the disease.

The polymerization of HbS and associated membrane changes cause a marked decrease in the ability of these cells to flow through the microvascular circulation, resulting in compromised oxygen delivery and setting up a vicious circle of worsening vaso-occlusion. There is also evidence of increased adherence of these red cells to vascular endothelium, which would increase deoxygenation and obstruct the flow of other red and white cells through the microvasculature.

The clinical manifestations of sickle cell disease are protean and include both acute and chronic complications. The majority of symptoms are attributable to the effects of vascular occlusion, since the anaemia is usually well tolerated. Sickle cell disease is a multisystem disease. Acute episodes or 'crises' can take several forms, including pain or severe anaemia; acute worsening of anaemia can be due to splenic or hepatic sequestration, or transient erythroid hypoplasia secondary to parvovirus B19 infection. The most common symptom is acute, severe pain, which may be preceded by infection, dehydration and cold exposure, though often no particular trigger is identified. Vaso-occlusion, which commonly involves the bones, results in avascular necrosis of the bone marrow with associated inflammation and increased intramedullary pressure. This results in painful swelling of the hands and feet (dactylitis) in early infancy. In older children and

adults, the juxta-articular areas of long bones, flat bones like the ribs and pelvis and the vertebral column are most commonly affected. The management of acute pain is supportive, ensuring adequate analgesia, hydration and oxygenation. Other acute complications include priapism, retinal artery occlusion and sudden death.

Sickle cell patients are at increased risk of bacterial infection due largely to loss of splenic function and, historically, overwhelming pneumococcal sepsis has been the major cause of early mortality. In developed countries, this risk has been significantly reduced by the introduction of pneumococcal prophylaxis in the form of pneumococcal vaccines and daily oral penicillin. The major cause of mortality after early childhood is the acute chest syndrome, which results from a combination of infection, infarction and fat embolism in the lungs, and is characterized by fever, severe chest pain, dyspnoea and pulmonary infiltrates. This complication needs prompt and vigorous management including oxygenation, hydration, intravenous antibiotics and blood transfusion. Increasing numbers of patients in developed countries are surviving to late middle and old age, and progressive multi-organ failure, particularly involving the kidneys, is an increasingly common form of death. From a very early age, most children with SCD display a number of renal abnormalities, including glomerular hyperfiltration and nephrogenic diabetes insipidus. Many go on to develop significant albuminuria in later childhood, with progressive renal failure contributing to death in about 30% of adults.

Stroke due to occlusion of the large cerebral vessels affects about 11% of patients by the age of 20, with the highest incidence between the ages of two and five years. Without treatment, there is a high rate of recurrence. Long-term transfusion significantly reduces the risk of a further stroke but carries with it the necessity for iron chelation to prevent siderosis. Transcranial Doppler scanning identifies children with early vasculopathy who are at high risk of stroke. Regular blood transfusion of children with such cerebral vasculopathy has been shown to be an effective form of primary stroke prevention, both in clinical trials and practice.

Pulmonary hypertension affects up to 5% of adults with sickle cell disease, and is thought to be associated with an increased risk of premature death. Increased rates of haemolysis have been linked to the pathology, and it may be part of a more general vasculopathy.

Chronic organ damage due to sickling may take several forms. Ischaemic damage to the bones and joints results in progressive destruction which, in the case of avascular necrosis of the hip, may lead to severe disability. Chronic restrictive lung disease may follow recurrent episodes of infection and infarction. As in other chronic haemolytic states, gallstones are common and found in nearly one-third of young adults with sickle cell disease. Proliferative retinopathy can result in bleeding, retinal detachment and blindness. Stasis and occlusion of the small vessels in the lower limbs may cause leg ulceration.

The prognosis for patients with sickle cell disease in developed countries has been transformed by early diagnosis, improved supportive care and, most importantly, prophylaxis against pneumococcal infection. At least 85% of HbSS patients and 95% of HbSC patients in the

USA now survive to 20 years and 50% of patients survive beyond the fifth decade. Relatively little is known about the natural history of the condition in African countries, but the majority of children with sickle cell disease are thought to die before the age of five years. This markedly higher mortality in Africa reflects the importance of environmental factors, and is probably mainly related to malaria, pneumococcal and other infections. Sickle cell disease remains a disease without a cure. Haematopoietic stem cell transplantation has been successfully performed in a few patients but carries a procedure-related risk with 5% mortality. In the absence of reliable predictors of clinical severity, which varies widely among affected patients, this is difficult to justify in most cases. The role of transplantation is likely to increase as the procedure becomes safer and able to draw from a wider range of donors. Human trials of gene therapy are currently planned, but as yet, no patients have been successfully treated.

The search for effective anti-sickling agents has targeted the essential steps in the pathophysiology of sickle cell disease: polymer formation, membrane changes and interactions with the microvasculature. The first approach, aimed at combating polymer formation, either by altering oxygen affinity or increasing HbF concentrations, seems most likely to be successful. Hydroxycarbamide (hydroxyurea), which increases HbF concentrations, has been shown to reduce the frequency of acute pain and acute chest syndrome in randomized controlled trials, and is now an important therapeutic option in adults and children suffering frequent episodes of pain or severe chest problems.

Other structural haemoglobin variants

There are several hundred less common structural haemoglobin variants, most of which are very rare and have no clinical or functional consequences. An exception is the β globin variant haemoglobin E (β^{26} Glu→Lys), which is probably the most prevalent haemoglobin variant, being carried by an estimated 84 million individuals worldwide, mainly in South-East Asia. Haemoglobin E has an electrophoretic mobility similar to that of HbC and HbA₂ at pH 8.9 but can be differentiated by citrate agar electrophoresis at acid pH. Unlike most other structural variants, inheritance of HbE is associated with a β thalassaemia phenotype with microcytosis and hypochromia. This is because the β^E mutation activates a cryptic splice site that inhibits the normal splicing mechanism. Haemoglobin E is also unstable, which may contribute to the unexpectedly severe phenotype that occurs when HbE is co-inherited with β thalassaemia mutations. This compound heterozygous state results in thalassaemia major in about half of cases.

The other common abnormal haemoglobins are C and D^{Punjab}, which affect millions, predominantly in West Africa and the Punjab region of India, respectively. In the homozygous state, there is mild haemolysis, with few if any symptoms. Co-inheritance of both of these variants with HbS results in sickle cell disease.

The unstable haemoglobin variants usually result from neutral substitutions affecting amino acid residues that contact the haem group and generally present as a

congenital Heinz body haemolytic anaemia, for example Hb Köln and Hb Bristol. Heinz bodies are inclusion bodies seen in some red cells consisting of degraded haemoglobin. The diagnosis is made by the heat denaturation or isopropanol precipitation tests and identification of the globin mutation by protein or DNA analysis. Owing partly to the instability of the variant haemoglobin, only half of these variants are detectable by electrophoresis.

Amino acid substitutions involving either α - or β -chains in the vicinity of the haem group can also result in altered oxygen affinity or a propensity to methaemoglobin formation. Haemoglobin variants in which oxygen affinity is significantly increased (e.g. Hb Chesapeake, Hb San Diego) are associated with erythrocytosis (polycythaemia). Low-affinity haemoglobins (e.g. Hb Kansas) and HbM variants (e.g. HbM Boston) cause cyanosis, usually with no associated signs or symptoms of disease. The possible consequences of abnormal haemoglobins are summarized in Table 29.3.

LABORATORY DIAGNOSIS OF HAEMOGLOBINOPATHIES

The primary investigation of a haemoglobinopathy should include a full blood count, peripheral blood film and haemoglobin electrophoresis (see Fig. 29.4). The full blood count allows assessment of haemoglobin formation, as judged by the red cell indices, the mean cell volume (MCV) and mean cell haemoglobin (MCH). Microcytosis (MCV <76 fL) and hypochromia (MCH <27 pg), in the face of a normal or raised red cell count ($>5.5 \times 10^{12}/L$) in an iron-replete patient, suggest a diagnosis of thalassaemia. In the case of β thalassaemia major or intermedia, this is associated with a significant degree of anaemia, whereas in thalassaemia trait the haemoglobin is usually normal or only marginally reduced. Examination of a blood film stained by a Giemsa method may be helpful in confirming the diagnosis. However, definitive diagnosis often rests on electrophoretic or chromatographic analysis of haemoglobin in red cell haemolysates. Cellulose acetate electrophoresis at alkaline pH (8.9–9.1) is the most widely used method, being simple, rapid, inexpensive and effective in separating the common haemoglobin variants. In homozygous sickle cell anaemia, HbS predominates. A variable amount of HbF is present, higher proportions

(>10%) generally being associated with a milder clinical course. Haemoglobin A₂ concentration is usually normal.

Solubility testing based on the reduced solubility of deoxy-HbS in the presence of reducing agents, for example sodium dithionite, has a limited role in the diagnosis of sickle cell disease since it does not differentiate the homozygous disease and carrier states. In an emergency situation, a positive solubility test taken in conjunction with a significantly reduced haemoglobin and typical red cell morphology points strongly towards a diagnosis of sickle cell disease. This should be confirmed by haemoglobin analysis at the earliest opportunity. Several other variants, including HbD, HbG and Hb Lepore, have an electrophoretic mobility identical to that of HbS on cellulose acetate but may be distinguished by the negative sickle solubility test and citrate agar gel electrophoresis at acid pH (6.0). Similarly, haemoglobins C, E and O, which co-migrate on cellulose acetate at alkaline pH, can be differentiated by citrate agar electrophoresis. Both HbE and Hb Lepore are associated with thalassaemic red cell indices, which further aids their distinction from electrophoretically similar variants. Isoelectric focusing improves the resolution of some structural variants and can also be used for neonatal screening of eluates from Guthrie (dried blood spot) cards, since it reduces interference from methaemoglobin present in such samples.

High performance liquid chromatography (HPLC) is a fast and sensitive method for separation and quantitation of haemoglobins that, in some cases, allows identification of variants not possible by other techniques. Since it is largely automated and requires minute quantities of sample, HPLC has become the method of choice for large-scale population testing such as neonatal screening programmes. Universal neonatal screening for sickle cell disease has been used in the USA and England for some time, and similar programmes are being introduced into other European, Middle Eastern and African countries, depending on the prevalence of the conditions and the resources available. Such programmes have resulted in significant benefits in terms of reduced mortality and morbidity due to improved care, early implementation of prophylaxis against pneumococcal infection and parental education. In β thalassaemia, the proportion of individual haemoglobins varies with the underlying genotype. Homozygous β^0 thalassaemia is associated with

TABLE 29.3 The functional and clinical consequences of abnormal haemoglobins

Functional abnormality	Clinically expressed ^a	Clinical disorder	Example	Molecular abnormality
None	No	None	HbG Philadelphia	$\alpha 68$ Asn→Lys

^aThe abnormality may be expressed in the homozygous (Hom), heterozygous (Het) or compound heterozygous (Co het) state.

^bThis chain terminator mutation results in an α globin chain with an additional 31 amino acids.

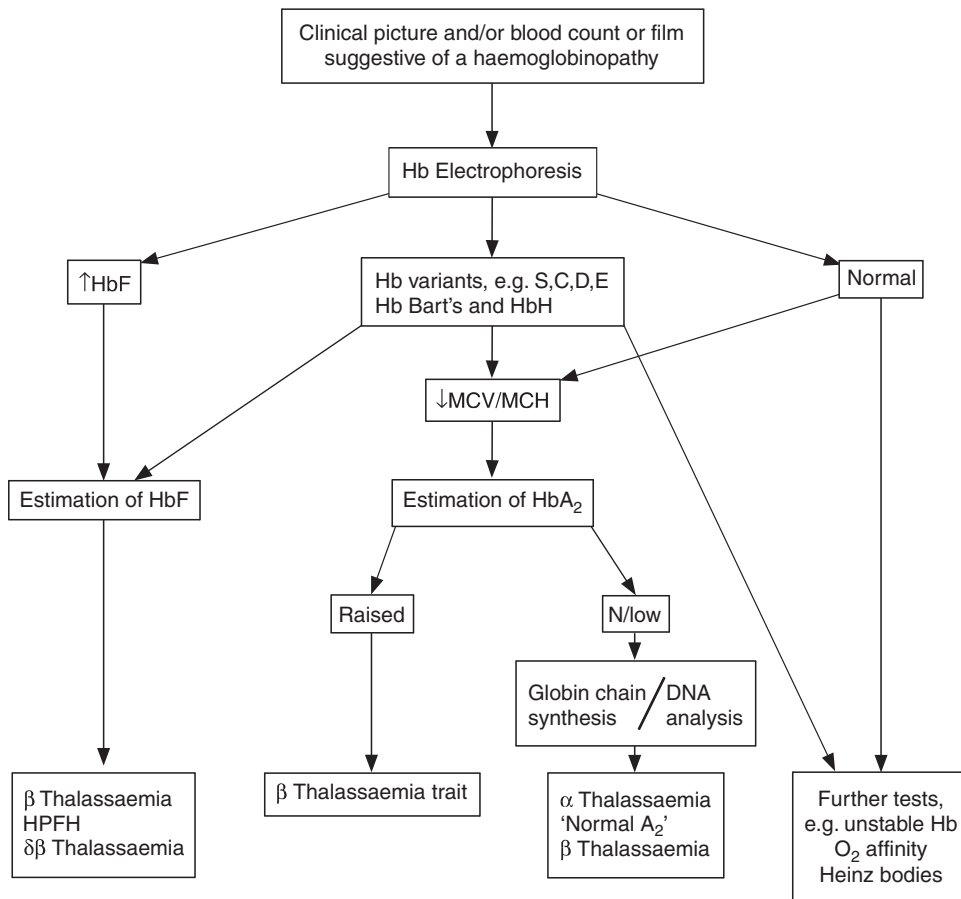

FIGURE 29.4 ■ A simple algorithm for the diagnosis of haemoglobinopathies.

a predominance of HbF, absence of HbA and variable amounts of HbA₂ (range 1.0–6.0%, mean 1.7%). In individuals with homozygous β⁺ thalassaemia or compound heterozygous β⁰/β⁺ thalassaemia, a variable amount of HbA is present. Haemoglobin F is increased and distributed heterogeneously among red cells.

Accurate quantitation of HbA₂ by HPLC or microcolumn chromatography is essential for the diagnosis of β thalassaemia trait, in which the HbA₂ is elevated, typically >3.5%. Carriers of 'normal A₂' or 'silent' β thalassaemia due to mild β gene defects or co-inheritance of a δ gene mutation in *cis* or *trans* cannot easily be distinguished from α thalassaemia by conventional screening methods and require investigation by specialized techniques, including in vitro globin chain synthesis and DNA analysis. Analysis of globin chain synthetic ratios by tritiated leucine incorporation and carboxymethylcellulose chromatography is the definitive way of identifying individuals with thalassaemia, although it is rarely used because of its laborious nature.

The α thalassaemias are characterized electrophoretically by the presence of the fast moving variants, Hb Bart's (γ4) and HbH (β4), which are most obvious in neonatal samples. In hydrops fetalis owing to homozygous α⁰ thalassaemia, Hb Bart's predominates and is found in smaller amounts in other α thalassaemia syndromes in the neonatal period. Haemoglobin H may also be detected by staining for HbH inclusion bodies. The diagnosis of clinically silent forms of α thalassaemia is often one of

exclusion, being made on the basis of the subject's ethnic origin, microcytic hypochromic red cell indices and a normal or low HbA₂ concentration in the presence of normal iron status. Definitive diagnosis can be made by DNA analysis, which can also often distinguish α⁰ and α⁺ thalassaemia.

While the majority of haemoglobinopathies can be diagnosed by haemoglobin electrophoresis, variants caused by amino acid substitutions that do not alter charge, such as those found in some unstable haemoglobins or haemoglobins with altered oxygen affinity, may escape detection. Further investigations that may be helpful in this context include assessment of haemoglobin instability and oxygen affinity. High throughput DNA analysis has made this a feasible way of screening for globin mutations in richer countries, with techniques such as multiplex ligation-dependent probe amplification allowing identification of large gene mutations which were previously only detectable using Southern blotting. Haemoglobin mass spectrometry can also be used to identify abnormal globins by measuring their mass accurately, with particular potential use in screening programmes which already use mass spectrometry.

The identification of couples at risk for major haemoglobinopathies by antenatal or preconceptional screening permits informed reproductive choice with the option of prenatal diagnosis. In most cases, this can now be accomplished in the first trimester by detection of mutant globin genes in chorionic villous DNA. In several countries,

notably Cyprus where the carrier rate for β thalassaemia reaches 12%, this has led to a marked decline in the birth incidence of haemoglobin disorders. Preimplantation genetic diagnosis is increasingly used to allow selection of unaffected embryos, although it continues to be a demanding and expensive process that is not applicable to most couples. Attempts continue to develop non-invasive prenatal diagnosis using fetal cells and DNA in maternal blood, although this is currently not technically feasible as a routine procedure for the haemoglobinopathies.

CONCLUSION

Haemoglobin is arguably the best studied of all human proteins. It is a tetramer of two pairs of globin chains. Each chain binds a molecule of haem, to which a molecule of oxygen can become reversibly bound. The affinity of haemoglobin for oxygen can be modified by various physiological factors in ways that respond to the requirements of tissues for oxygen under different circumstances.

Inherited disorders of haemoglobin synthesis can be qualitative or quantitative. More than 400 structural variants have been described, of which the most important is haemoglobin S, the haemoglobin of sickle cell disease. Quantitative abnormalities of globin chain synthesis cause the thalassaemias. Advances in diagnosis and treatment have dramatically altered the prognosis for many affected patients, although there is still a limited range of treatments available.

APPENDIX 602

THE IMMUNE SYSTEM

Introduction

The human immune system monitors the internal and external environment at a molecular level and relays information within itself and to other systems regarding the molecular nature of the environment. Within this process, the system has evolved so that certain stimuli elicit a reaction (an immune response) while others are tolerated, eliciting no response. Microbes that invade our bodies can replicate every 20 min, giving them enormous potential to evolve more virulence. Humans reproduce approximately every 20 years with considerably less potential for population adaptation. However, an immune system that uses overlapping and interwoven processes, and can evolve by somatic mutation, allows an individual to adapt to a changing microbial environment. The immune response, like any other biological process, attempts to restore homeostasis but may itself, if inappropriate or persistent, result in tissue damage and disease.

Over the last 20 years, there has been a rapid development of our knowledge of immunology, particularly at the biochemical and molecular level, in terms of the sophisticated intercellular interactions that accompany any immune response. This chapter will make no attempt to summarize this vast body of knowledge but rather aims to convey broad concepts in describing immune responses, the immune system that makes the responses and the relevance of these to clinical laboratory medicine. The spectrum of immunological diseases includes genetic

deficiencies, autoimmune diseases, allergy, malignancy, inflammation and infection. Manipulation of immune responses by inducing immune activation or suppression has great importance in many areas, including immunization and transplantation.

Immune responses

There are two major types of immune response: innate and adaptive. The innate immune response shares many components with the adaptive response but differs fundamentally in that no specific antigen recognition is required. Instead, it involves recognition of molecular sequences that are widely expressed in nature, for example on microbial cells (lipopolysaccharide) and on damaged tissue (heat shock proteins).

The adaptive response is antigen driven and requires prior antigen exposure and recognition of the antigen by T and B lymphocytes through cell surface receptors. On first contact with any antigen, the system reacts relatively slowly and transient infection may occur. Immunologically, this process is termed *immunization*. The initial response is known as the *primary immune response*: it also involves acquisition of memory of the exposure. As a result, on second contact with an antigen there is a more rapid response (the *secondary immune response*) and there is no infection: the host has acquired *immunity*. These responses involve a combination of cells, tissues and soluble mediators that are described more fully below. In order to understand immune responses, it is first necessary to consider two important terms: antigen and clonality.

Antigens

Most biological materials, including proteins, polysaccharides, glycoproteins and polypeptides can be antigens. How the antigen influences the immune system is related to its reaction with lymphocytes, which will determine whether it stimulates an immune response (i.e. it is an immunogen) or is tolerated (i.e. it is a tolerogen). For example, human albumin is tolerated by the human immune system but on injection into a rabbit, it will stimulate an immune response such that the rabbit produces antibodies to the protein. These antibodies, which react with human albumin, but not, for example, with horse albumin or with the rabbit's own albumin, are described as being specific for human albumin.

The antibodies produced are not directed against the entire molecule but to short, overlapping amino acid sequences termed epitopes. A large protein molecule such as albumin will have many hundreds of epitopes and, generally, the larger the protein, the more immunogenic it is.

Clonality

Both T and B lymphocytes have the property of antigen recognition through molecules expressed on their cell surfaces (antigen receptors). This is immunoglobulin (Ig) on B cells and the T cell receptor (TCR) on T cells. On any one cell, all the antigen receptors will be identical. Generally, this unique receptor is able to recognize one or a few epitopes. It is estimated that approximately 10^{10} different antigenic specificities may potentially be encountered during the lifetime of an individual, requiring approximately this number of unique receptors. The development of this very large number of lymphocyte receptors occurs before antigen contact by random rearrangements of the immunoglobulin and TCR genes. The molecular process by which this is achieved will be described in more detail in a later section. Immune responses are driven by the presence of antigen. Engagement of a compatible receptor with antigen provides signals for further proliferation and differentiation. The affinity of the antigen-receptor binding is crucial in determining the nature of that immune response. This is the molecular basis for the establishment of immune responses and immunological memory.

Additionally, in the B cell, the DNA that codes for the part of the Ig receptor that binds antigen is hypermutable, so that during proliferation, somatic mutations within the receptor DNA sequences occur frequently. These mutations may result in a receptor that has a higher affinity for the antigen and, as a result, the clone bearing that receptor will compete more successfully for the antigen and receive a stronger signal, so that it is preferentially selected and responds more quickly. The secreted immunoglobulin from the B cell will similarly show this higher affinity. This process is termed affinity maturation. Immunity to many potentially lethal or harmful human diseases, for example measles, polio and smallpox, is mediated by such high-affinity immunoglobulin (antibody).

The innate immune system

One of the major roles of the immune system is to neutralize and destroy invading pathogens. These pathogens – bacteria, viruses, fungi, protozoans and worms – vary in their size, typical route of entry into the body and mechanism for evading the immune system. Generally, they enter the body across the mucosal surfaces of the respiratory system and gut and across the skin; it is in these areas of the body where the innate immune system forms the first-line of defence from invading pathogens. The major components of the innate immune system are:

- mechanical barriers, e.g. intact skin, mucous membranes
- sebaceous secretions; contents include fatty and other acids (hence skin acidity)
- lysozyme (in tears)
- gut acidity
- urine acidity
- intestinal motility
- IGA (in tears, at mucosal surfaces)
- mucus
- ciliated surfaces
- normal bacterial flora
- acute phase proteins
- interferons
- other molecules (including defensins, lactoferrin, peroxidases)
- neutrophils and complement, although these overlap with the acquired immune system.

Intact mucosal surfaces give a high degree of protection against pathogens, and if breached, for example by surgery, burns or mechanical damage, significant infection can occur. The skin is relatively dry with a high salt content; sweat and sebaceous secretions contain fatty acids, triglycerides, lactic acid, amino acids and ammonia that have antimicrobial activity. Mucus and the cilia of the respiratory tract act together to trap and sweep inhaled particles towards the mouth and nose, where they can leave the body or where they can be swallowed to be inactivated by the gastric acid. The gastrointestinal tract has a combination of innate defence mechanisms such as the alkalinity of saliva and the strongly acidic conditions and enzymic activity of the stomach. Mucopolysaccharides in the secretions of the genital tract help make it inhospitable to pathogens. The eyes are bathed in tears containing the enzyme lysozyme, and the rate of tear production can increase to flush away any potential invading pathogens. Similarly, the urinary tract has a high flow rate that helps to keep it free from pathogens.

Many areas of the body are colonized with commensal organisms. It is estimated that a normal gut is colonized with 10^{14} bacteria, which form the normal (commensal) bacterial flora and produce chemicals that are antimicrobial and also compete with potentially pathogenetic organisms for essential nutrients. Commensal organisms may cause infection – usually called opportunistic infections – particularly if they get into areas where they do not normally live or if the immune system is compromised.

The innate immune system overlaps with the adaptive immune system (Fig. 30.1), with both systems using the complement cascade, cytokines, phagocytic cells, natural

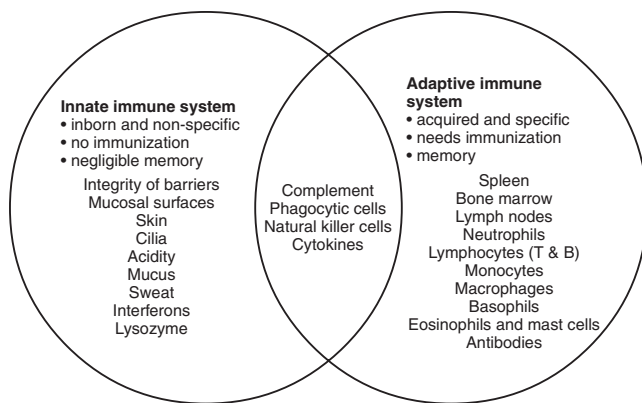

FIGURE 30.1 ■ The overlap between the innate and adaptive immune systems.

killer cells and acute phase proteins. These components can act alone in an innate response to destroy invading pathogens, but the mechanisms are non-specific and slow and are significantly enhanced by involvement of the adaptive immune system.

The adaptive immune system

An adaptive immune response involves an integrated system, in which there are three elements.

1. **Lymphoid tissue**, wherein the components of the immune system are made and where immunological processing occurs.
2. **Cells with specific functions**, including specific antigen recognition and presentation.
3. **Soluble mediators** that participate in immune reactions and can interact with other systems of the body.

The components of the adaptive immune system are summarized in [Table 30.1](#).

TABLE 30.1 The components of the adaptive immune system

Lymphoid tissue	Cells	Soluble mediators
Embryonic^a	Neutrophils	Antibodies
Yolk sac	Monocytes	Complement proteins
Fetal liver	Macrophages	Cytokines
	T lymphocytes	Acute phase proteins
Primary	Natural killer cells	Inflammatory mediators:
Bone marrow		Tryptase
Thymus	B lymphocytes	Histamine
	Basophils	Platelet activating factor
Secondary	Eosinophils	Prostaglandins
Spleen	Mast cells	Leukotrienes
Lymph nodes and lymphatics	Dendritic cells	Soluble receptor molecules
Tonsils	Cell bound recognition molecules	
Adenoids		
Lymphoid tissue in the skin and mucosa of the bronchus, gut and urogenital tract	(HLA or MHC) Cell receptor molecules	

^aAfter the early fetal development, all the cellular elements of the blood arise from haematopoietic cells in the bone marrow. HLA, human leukocyte antigen; MHC, major histocompatibility antigen.

Lymphoid tissue

Lymphoid tissue is distributed around the body ([Fig. 30.2](#)), with the blood and the lymphatics forming the lymphoid circulatory system. The bone marrow and the thymus are primary lymphoid organs, the bone marrow being the major site of production of all the cells of the immune system. The bone marrow is also the site of maturation of B lymphocytes. Immature T lymphocytes leave the bone marrow to develop further in the thymus (a bilobed organ in the upper anterior mediastinum that diminishes in size with age). The secondary lymphoid organs are found throughout the body, but particularly at junctions of the lymphatics, for example in the groin and axillae. This arrangement enables specialized antigen-presenting cells (APCs) to show antigens to an enormous number of lymphoid cells as they ‘traffic’ around the immune system. Secondary lymphoid tissue can be diffuse aggregates of cells or can be more organized into identifiable areas, for example the tonsils and Peyer patches in the gut. Lymph nodes also have an identifiable structure, with B cells residing mainly in the outer cortex and T cells mainly in the paracortex. Upon antigen stimulation, primary follicles within lymph nodes develop into secondary follicles with germinal centres. Activation of the immune system causes the cells within the lymph nodes to differentiate and proliferate, resulting in enlargement of the lymph nodes (lymphadenopathy). This is sought on physical examination of patients as a sign of increased activity of the immune system, for example in infection and malignancy. A large proportion of lymphoid cells are found in the gut and respiratory systems (gut and mucosal associated lymphoid tissue: GALT and MALT), where the antigenic burden is high.

Although specific immune responses are made within lymphoid tissues, other non-lymphoid organs have a role to play; for example, the liver is the major site of production of the complement proteins and acute phase proteins.

Cells

All cells of the body interact with the immune system. For example, any damaged nucleated cell has the capacity to make cytokines, and red blood cells have complement and antibody receptors on their surface that, owing to their enormous numbers, represent an important removal mechanism for immune complexes. Immune cells circulating in the blood are represented by the white cell population. Normally, the total white cell count of an adult is $4\text{--}11 \times 10^9/\text{L}$. This total is made up of a number of different cell types as shown in [Table 30.2](#); the differential white cell count represents the number and proportion of each of these types. Each cell type has particular functions within the immune system: the major functions are listed in [Table 30.2](#).

Each cell type has a characteristic morphology that enables it to be identified in a stained blood film examined under a microscope. [Figure 30.3](#) shows diagrams of the various types of white blood cell with their major progenitor cell types. The cell membranes are covered with molecules that enable the cells to interact

FIGURE 30.2 ■ The lymphoid organs.

TABLE 30.2 The major cells types, their approximate percentage of the differential white cell count and their major functions

Cell type	Reference range ($\times 10^9/L$)	Function
Total white cell count	4–11	
Neutrophil	1.6–7.5	Attracted to site of inflammation by chemotactic factors Most important cell type for phagocytosis and killing of bacteria Opsonization with antibody and complement enhances phagocytosis
Lymphocyte	1.5–4.0	Key role in orchestrating the immune response and producing soluble mediators of immunity
T cell (CD3+)	0.8–2.66	T helper cells (CD4+) control the development of an immune response by secreting cytokines Cytotoxic T cells (CD8+) can directly kill cells, e.g. that are infected with virus Regulatory T cells modify immune responses
B cell (CD19+)	0.1–0.6	Antibody production
Natural killer cell (CD56+, CD16+)	0.05–0.60	Can directly kill cells, e.g. infected with virus, tumour cells
Monocyte	0.1–0.8	Important phagocytic cells and can act as antigen presenting cells Cytokine production – particularly in inflammation
Basophil	<0.1	Major role is in allergic responses via release of mediators, e.g. histamine May be important in defending against parasites
Eosinophil	0.04–0.45	Some phagocytic function Major role in hypersensitivity reactions via release of variety of mediators Activation of mast cells

with their environment. They may be constitutively expressed (i.e. expressed in the unstimulated state) and this expression be increased on activation, or they may be induced when a cell is activated. Cells have many thousands of molecules of a whole variety of cell receptors on their surfaces. The cell surface molecules are classified by their cluster of differentiation (CD) numbers, with a different CD number for individual types of cell membrane protein. (The designation + after a CD number indicates that a specific antigen is expressed by that cell. For example, all T cells are CD3+; T helper cells are CD4+.) The cellular expression of these markers is used to provide a more detailed picture

of cell populations, for example whether they are immature or mature, whether activated, how they are functioning and whether they are normal or malignant. Aberrant expression of the CD markers is used to classify lymphoid malignancies while reduced expression of CD antigens can be used in the investigation of immunodeficiency, for example, CD4 counts to monitor HIV infection. The technique (known as immunophenotyping), uses specific antibodies to the CD markers and flow cytometry to count and quantify cell populations. There are approximately 400 different human proteins that have been assigned a CD number. The most important immunological markers, their major functions

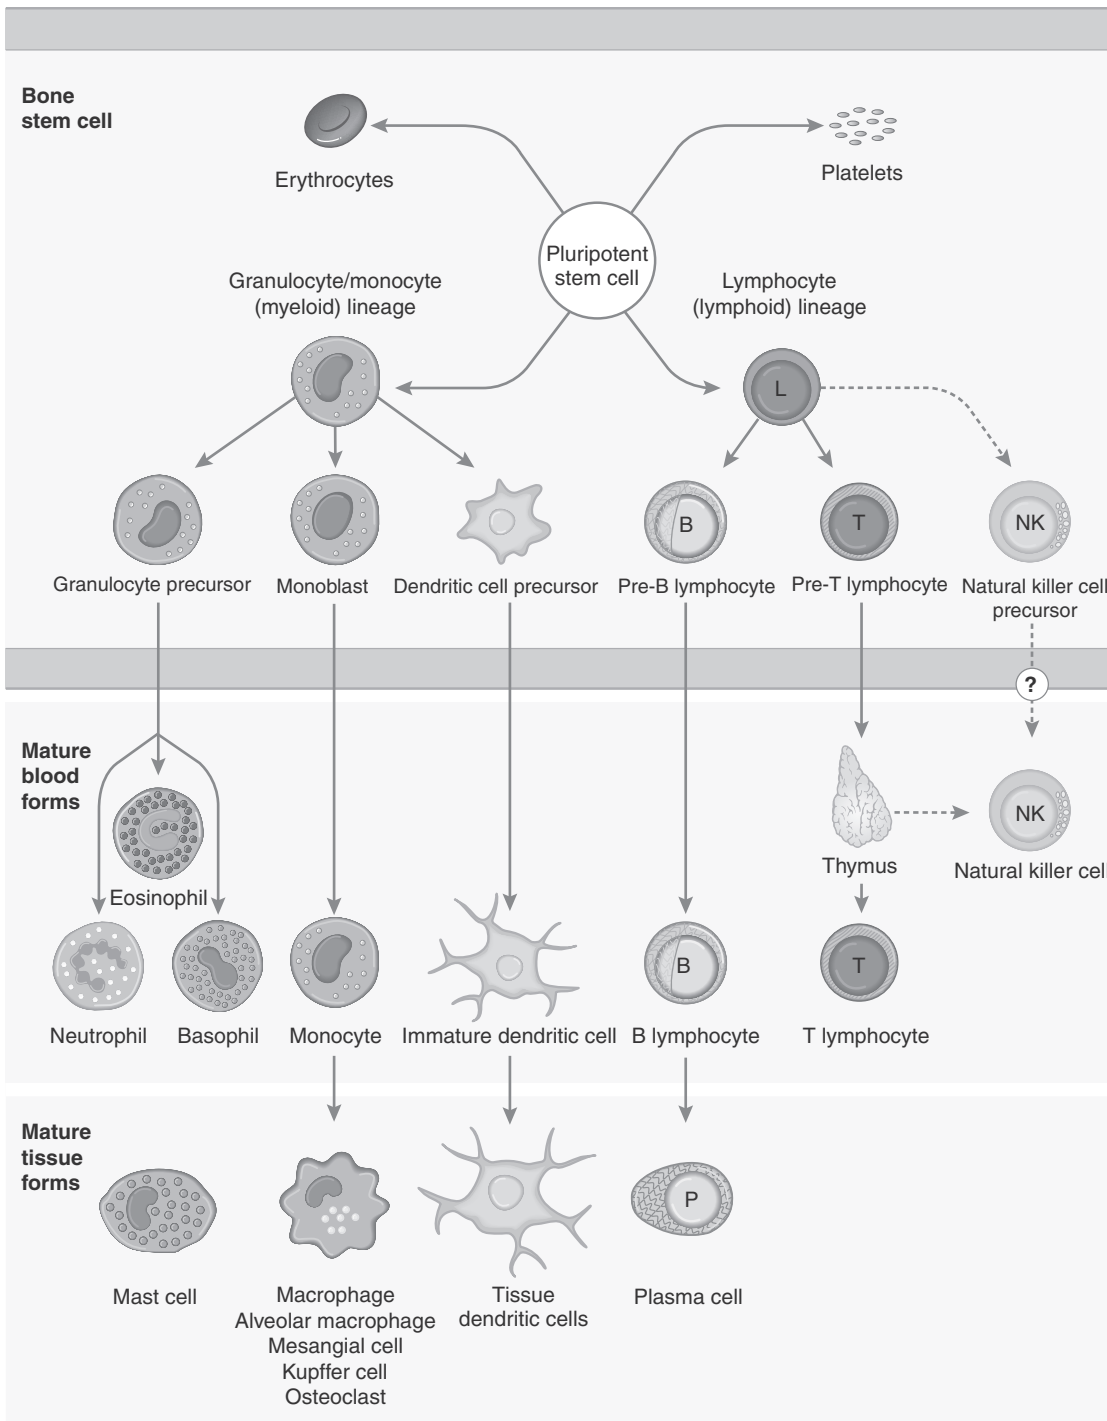

FIGURE 30.3 ■ Major types of white blood cell and their generation.

and the cells types on which they are predominantly expressed are shown in [Table 30.3](#).

The cells of the immune system arise from haematopoietic stem cells in the bone marrow. Individual stem cells respond to a number of positive or negative feedback mechanisms, for example colony stimulating factors, and are driven to proliferate and differentiate along committed pathways to give rise to populations of lymphocytes, granulocytes, APCs etc. The major processes are outlined in [Figure 30.3](#).

Neutrophils. Neutrophils, in common with basophils and eosinophils, can be shown to contain a large number of cytoplasmic granules when stained and examined by light microscopy and are thus termed granulocytes. They have a multilobed nucleus (polymorphonuclear or PMN, hence their alternative name, polymorphs) and are the most abundant white cells in the circulation. They show high expression of adhesion molecules that enable them to roll along blood vessel walls. If expression of adhesion molecules on the vascular surface is upregulated,

TABLE 30.3 The major CD phenotypes, their normal functions and cell types where they are normally expressed

Phenotype	Function of protein	Cells where expressed
CD3	Part of the T cell receptor	All T cells (pan T cell marker)
CD4	Helps T cells to hold on to antigen-presenting cells (HLA class II)	T helper cells
CD8	Helps T cells to hold on to antigen-presenting cells (HLA class I)	Cytotoxic T cells
CD19	B cell co-receptor	B cells
CD20	B cell activation and differentiation	B cells
CD45	Cell differentiation, signal transduction and lymphocyte activation	All white blood cells (leukocyte common antigen)
CD16	Binds $F_c \gamma$ RIII (binds IgG F_c)	Natural killer cells, neutrophils, monocytes
CD32	Binds $F_c \gamma$ RII (binds IgG F_c)	Neutrophils, macrophages, B lymphocytes, eosinophils
CD64	Binds $F_c \gamma$ RI (binds IgG F_c)	Monocytes, macrophages, activated neutrophils
CD89	Binds $F_c \alpha$ R (binds IgA F_c)	Monocytes, macrophages, neutrophils
CD21	CR2 (binds C3d)	B cells (some)
CD35	CR1 (binds C3b, C4b)	Neutrophils, monocytes, B cells, erythrocytes
CD25	IL-2R α chain	Activated T and B cells
CD56		Natural killer cells
CD40	Binds to CD40 ligand (CD154); B cell proliferation and class switching	B cells, antigen-presenting cells
CD11a (+CD418)	Cell adhesion (to other cells)	Leukocytes
CD11b (+CD18)	Cell adhesion (to other cells) CR3	Monocytes, neutrophils, natural killer cells
CD11c (+CD18)	Cell adhesion (to other cells) CR4	Monocytes, neutrophils, natural killer cells, some T and B cells
CD18 (+ CD11 a, b and c)	Cell adhesion (to other cells)	Leukocytes, monocytes, neutrophils, natural killer cells, some T and B cells
CD62E	E selectin cell adhesion (to other cells)	Endothelium, platelets
CD62L	L selectin cell adhesion (to other cells)	Neutrophils
CD62P	P selectin cell adhesion (to other cells)	Endothelium
	B cell proliferation and class switching	Activated T cells

IL, interleukin; HLA, human lymphocyte antigens.

for example because of tissue damage or infection, neutrophils are attracted to the site of inflammation (by chemotactic factors) and leave the blood stream and enter the tissues to engulf the invading pathogens or damaged tissue components, and destroy them, in a process termed phagocytosis.

The stages in phagocytosis are as follows.

1. **Cells move to a site of injury** or inflammation, attracted by chemicals released during the inflammatory process. Adhesion molecules, for example on the endothelium, are upregulated to hold the phagocytic cells and prevent them from moving away.
2. **At the site of injury**, the particle or microorganism, coated with antibody and complement, adheres to the phagocyte via C3b and $F_c \gamma$ receptors.
3. **The adherence of the particle to the phagocyte** results in the activation of the phagocyte's membrane, initiating a change in its shape and leading to internalization of the foreign material (phagocytosis: literally, 'eating' the particle).
4. **As the particle is taken into the cell**, it becomes surrounded with a membrane, forming a phagocytic vesicle or phagosome.
5. **The phagosome fuses with lysosomes** to form a phagolysosome, in which the microorganism is killed, and it, or other ingested material, is digested.

6. **Completely digested material** is reused by the cell; incompletely digested material is released (sometimes accompanied by potentially harmful enzymes).

If phagocytic cells are incubated in vitro with, for example, bacteria, phagocytosis will occur, but the process is significantly enhanced if the bacteria are coated with complement or antibody. This coating is called opsonization and, in simple terms, it enables phagocytic cells to adhere to the marked particles (giving the process specificity) and enables them to change shape to engulf the particles. Many cell types are capable of phagocytosis, the 'professional' phagocytic cells being neutrophils and cells of the monocyte/macrophage lineage. Many macrophages home to particular tissues where they develop highly specialized functions, e.g. Kupffer cells (in the liver), mesangial cells (kidneys), microglia (brain) and Langerhans cells (epidermis).

Basophils and eosinophils. These two cell types are also granulocytes and are particularly important in defending against multicellular pathogens, for example parasitic worms. This defence mechanism relies on the mediators in the cytoplasmic granules rather than the phagocytic functions of the cells. A close relation of the basophil, the mast cell, is tissue-based and important in allergic responses.

Monocytes. Monocytes are immature macrophages that are travelling from their site of production in the bone marrow through the bloodstream to the tissues where they will become fixed macrophages. Potentially, they are phagocytic cells but they do not seem to act as phagocytes in the bloodstream. They have receptors that recognize many bacterial products so are very effective cells in innate immunity. Engagement of these receptors stimulates release of proinflammatory cytokines such as interleukin 1 (IL-1), IL-6 and tumour necrosis factors (TNFs). These cytokines are able to drive many aspects of inflammation and specific immunity. Monocytes therefore provide a valuable second-line defence mechanism once infectious agents have breached the mucosal defences and entered the bloodstream.

Lymphocytes. The major subpopulations of lymphocytes are B and T cells. A haemopoietic stem cell first gives rise to a lymphopoietic stem cell, which in turn becomes committed to the B or T cell lineage. Lymphocytes are further divided into subsets on the basis of the presence of particular cell surface molecules (see Table 30.3). B cells (CD19+) can differentiate into antibody (immunoglobulin)-producing plasma cells in response to exposure to antigen. T cells leave the bone marrow to mature in the thymus. They undergo further differentiation to become either T helper cells (CD4+) that ultimately control the immune response, through cytokine production or cytotoxic T cells (CD8+) that have an important role in killing viruses, fungi and infected cells. Other T cell types are becoming increasingly well recognized as having important immunological roles; for example, that of regulatory T cells (T_{reg}) in the modulation of autoreactive T cells, and of Th17 (T helper) cells in inflammatory responses.

There are two main types of T helper cells (Th1 and Th2), which are defined by the cytokines they produce. Th1 cells predominantly produce IL-2, TNF α/β and γ -interferon, and drive cell-mediated immunity by cytotoxic T cells, macrophage stimulation and inflammation, and production of immunoglobulins, such as IgG1 and IgG3 by B cells. Th2 cells predominantly produce IL-4, 5, 6, 10 and 13, and are important in driving IgE responses and the growth of mast cells and eosinophils.

Natural killer (NK) cells (CD16+ and CD56+) are cytolytic cells of the lymphocyte lineage, acting in a slightly different way from the cytotoxic Tc cells.

B and T lymphocytes are at the heart of the adaptive immune response by virtue of their antigen receptors (Ig and T cell receptor, TCR). A comparison of the B and T cell receptors is shown in Table 30.4. The property of antigen binding is also shared by the human leukocyte antigens (HLA). These three sets of antigen-binding molecules are all products, or partial products, of the immunoglobulin gene superfamily; they are all composed of one or more homologous domains of approximately 110 amino acids, as illustrated in Figure 30.4.

Antigen recognition

Immunoglobulins. Immunoglobulins are proteins produced by cells of the B-lymphocyte lineage, either in a membrane-bound form as an antigen receptor, or as a secreted product that shows antibody activity. The membrane-bound and secreted forms differ only in the terminal amino acid residues that serve to anchor the protein into the membrane or allow secretion. The basic monomeric immunoglobulin unit consists of two identical heavy chains and two identical light chains arranged in a Y-shape (see Fig. 30.5). In humans, there are five possible heavy chains (γ , α , μ , δ and ϵ) that give the five immunoglobulin classes (IgG, IgA, IgM, IgD and IgE). In addition, there are four subclasses of IgG and two subclasses of IgA. There are two light chain types (κ and λ).

FIGURE 30.4 ■ The antigen presenting and binding molecules. β_2M , β_2 -microglobulin; HLA, human leukocyte antigen.

TABLE 30.4 Comparison of B cell receptor and T cell receptor

	B cell receptor (membrane-bound IgM)	T cell receptor
Similarities	Variation created by gene rearrangement Part of a protein complex including accessory chains and signalling adaptors Variable and constant domains	
Differences	Two heavy chains and two light chains Somatic hypermutation allows affinity maturation Class switching from IgM to other immunoglobulin classes Binds directly to specific antigen	Two polypeptide chains ($\alpha\beta$ or $\gamma\delta$) No somatic hypermutation No class switching Binds to specific antigen only when bound by appropriate HLA molecule

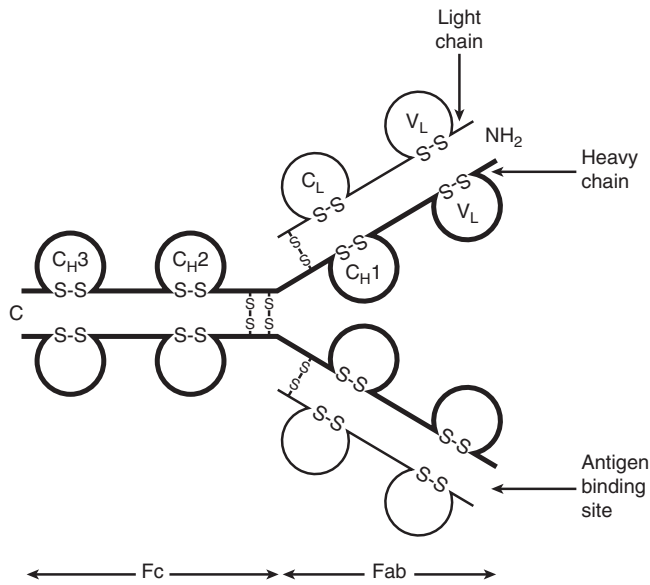

FIGURE 30.5 ■ The basic structure of an immunoglobulin molecule.

The class (or subclass) of the heavy chains and type of light chains is determined by the common amino acid sequences in areas of the molecule called the constant domains. The light chains have one constant domain and the heavy chains have three or four constant domains, depending upon the class; it is these areas that confer functionality to secreted immunoglobulin molecules. Each chain also has a single domain of great variability in the amino acid structure, called the variable domain. The heavy and light chains are arranged such that their

variable domains are adjacent, forming a groove in which antigen binding occurs.

If every antigen recognition receptor on B and T cells were encoded on a one gene/one enzyme principle, these receptors alone would require more than the total DNA present within individual cells. The enormous scope for receptors to recognize antigens is achieved by a mechanism of genetic recombination.

In humans, the gene for the production of the immunoglobulin heavy chain is located on chromosome 14. In the germ line, there are large numbers (estimated 250–1000) of variable (V) gene segments followed by small numbers of D (~ 12) and J (~ 4) gene segments. Finally, there is the constant (C) gene segment that can encode for any of the immunoglobulin heavy chains. A diagram of the immunoglobulin heavy chain gene is shown in Figure 30.6. Processing of this genetic material occurs by deletion of the introns (the non-coding DNA) and splicing together of the exons (the coding portions of the gene). One of the many V-region genes is selected and joined to one of the D-region genes, which is joined to one of the J-region genes. This VDJ sequence is then joined to the constant region genes, typically starting with the μ gene, which is the first downstream heavy chain gene in the sequence, resulting in the production of IgM. The genes for the κ and λ light chains are located on chromosomes 2 and 22, respectively, and are similar to the heavy chain gene except that they do not have a D region. Diversity of the variable region is generated by the large number of possible combinations between the V, D and J or V and J regions of the genes, variation in how these genes are spliced and by somatic mutation generated during cell development.

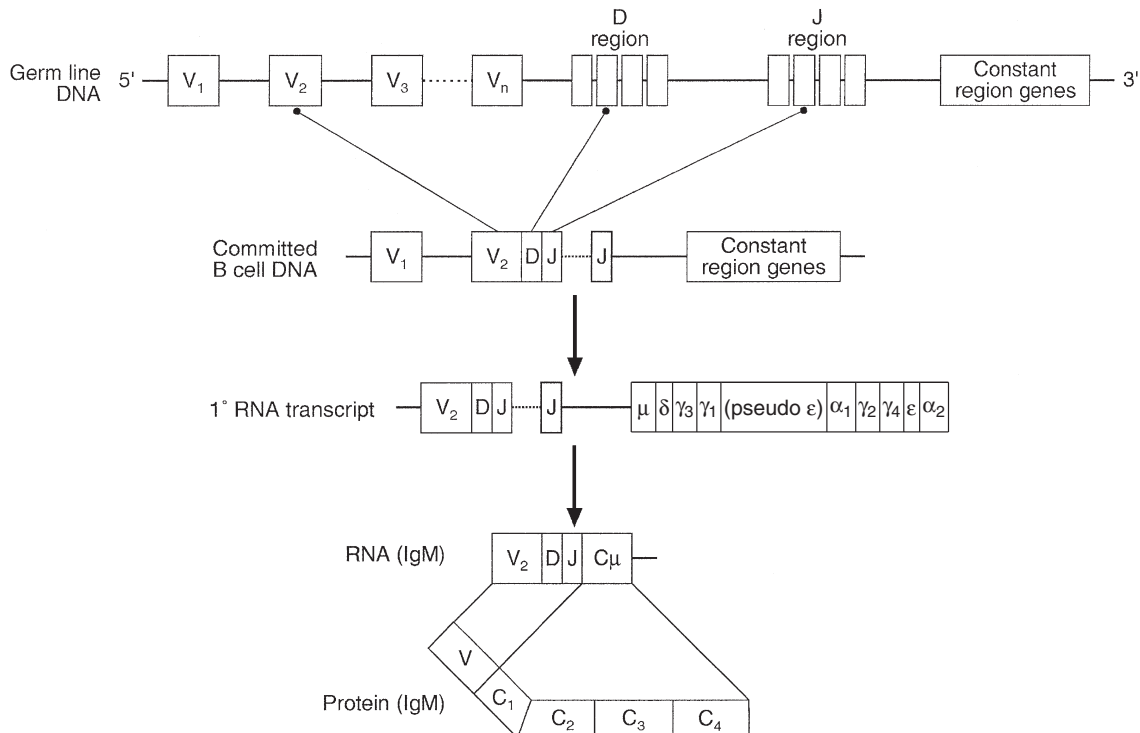

FIGURE 30.6 ■ The immunoglobulin heavy chain gene.

In any cell, there is allelic exclusion, so that only one of each pair of chromosomes coding for immunoglobulin is translated. Each cell, theoretically, has two chances for each gene to be successfully rearranged. The products of unsuccessful rearrangements are secreted by the cell and degraded or cleared by the kidneys. The immunoglobulin heavy chain gene(s) is rearranged first, followed by κ -gene rearrangement. In about 40% of cells, the κ rearrangements are abortive and the cell then proceeds to λ -gene rearrangement. A small excess of free light chains (polyclonal) is produced. The immunoglobulin molecule is then assembled and expressed on the surface of B cells. The cell is now committed to a light chain type and unique variable region specificity (also called the idiotype). The organization of the heavy chain gene enables the variable region to be spliced onto a different heavy chain by the process of 'class switching'. This occurs after interaction with antigen, when cells that show appropriate recognition of the antigen are driven to proliferate. IgM is the antibody produced in primary immune responses; IgG (or IgA or IgE), produced after class switching, is produced in secondary immune responses, as shown in Figure 30.7. Some cells will mature into memory cells and others into end-differentiated plasma cells. Plasma cells are typically non-proliferative and have little membrane-bound immunoglobulin but secrete large amounts.

IgA and IgM both occur as oligomers of the basic unit. Combination is facilitated by the addition of a short

FIGURE 30.7 ■ Antibody production in primary and secondary responses.

polypeptide chain called the J-chain. This J-chain should not be confused with the J gene segments coding for part of the variable region of the immunoglobulin molecule – the two bear no relationship. In the plasma, IgM occurs as a pentamer. IgA can occur as a dimer and this is the predominant form in secretions. A glycoprotein called 'secretory piece' is synthesized by mucosal epithelial cells and integrated into secreted IgA molecules, making them more resistant to degradation by the mucosal environment.

The major properties of the immunoglobulins are shown in Table 30.5.

Under normal circumstances, there is enormous microheterogeneity within immunoglobulin molecules. This results in polyclonal immunoglobulins, representing all classes, light chain types and a large number of different idiotypes, each produced by a different B cell clone, even to a single antigen. Monoclonal immunoglobulins, which consist of a single heavy chain class, light chain type and idiotype, result from the proliferation of a single clone of B cells. In fact, polyclonal immunoglobulins comprise very small amounts of many thousands of monoclonal immunoglobulins.

Each class and subclass of immunoglobulin has its own function or group of functions. IgG is the most abundant antibody in the circulation and also diffuses into the extravascular compartment bathing all the tissues. It is produced in secondary immune responses and is vital for immunological memory. There are four subclasses, with IgG1, IgG2, IgG3 and IgG4 being approximately 65%, 25%, 7% and 3%, respectively, of the total IgG. IgG1 and IgG3 responses mature earliest, while IgG2 and IgG4 responses mature more slowly. IgG1, IgG2 and IgG3 are all potent activators of the classical complement cascade. IgG (bound to an antigen) binds to the $Fc\gamma$ receptors I, II and III on neutrophils, macrophages etc. to facilitate and enhance phagocytosis. IgG has a half-life of approximately 21 days, but this depends upon the plasma concentration, catabolism being increased with raised IgG concentrations and decreased with low IgG concentrations.

IgA is the major immunoglobulin in mucosal secretions and is also produced in secondary immune responses. It is most important in binding and neutralizing organisms at mucosal surfaces, without interacting with other immunological systems.

IgM is the antibody of the primary immune response, culminating in the process of class switching, inducing

TABLE 30.5 The major properties of immunoglobulins

Property or function	IgG	IgA	IgM	IgD	IgE
Molecular weight (kDa)	150	160 (monomer)	900 (pentamer)	185	200
Adult plasma reference range (g/L)	6.0–16.0	0.8–4.0	0.5–2.0	0.01–0.5	<0.1
% Carbohydrate	3	8	12	13	12
Subclasses	4	2	0	0	0
Complement fixation: classical pathway	Yes	No	Yes	No	No
Complement fixation: alternative pathway	No	Yes	No	No	No
Crosses placenta	Yes	No	No	No	No
Binds to Fc receptors on phagocytes	Yes	No	Yes	No	No
Binds to Fc receptors on mast cells	No	No	No	No	Yes

the B cells to make the antibodies of the secondary responses, IgG or IgA. The large pentameric structure of IgM gives good potential for antigen binding and its high molecular weight keeps it restricted to the vascular compartment. The half-lives of IgA and IgM are independent of their plasma concentrations and are approximately five days for both.

IgD is detectable on B cells early in their development, but its concentration in plasma is normally very low. Its exact function is not known, but it is likely that it is important in processing antigens in immature B cells.

The plasma concentration of IgE is very low; it relies on its binding to the F_ε receptor on mast cells and basophils for its activity. The release of inflammatory mediators within these cells is precipitated by binding of the surface-bound IgE to a specific antigen or allergen.

T cell receptors. The T cell receptor is somewhat simpler. It is a heterodimer in which each polypeptide chain is composed of two domains, one variable and one constant. There are four possible polypeptide chains, α, β, γ and δ. A receptor is made up of a pairing of either α with β or γ with δ. In no cell are both types expressed, nor are other pairings possible (e.g. α with δ). The variable domains are similarly constructed from gene segments, as described for immunoglobulin receptors (V, D and J for β and δ; V and J for α and γ), and then spliced into the corresponding constant regions.

The T cell receptor differs from the immunoglobulin receptor in that it has no hypermutable sequences and therefore does not show affinity maturation. Also, it can only recognize antigen that is bound to an HLA (human leukocyte antigen) molecule expressed on the surface of an appropriate antigen presenting cell (APC).

Human leukocyte antigens (HLA). The major histocompatibility complex (MHC) is a group of molecules that are integral to the development of adaptive immune responses. In humans, the genes for these molecules, which are designated human leukocyte antigen (HLA), are on chromosome 6. They are expressed on the cell surface and bind peptides in an antigen-binding groove, where they are recognized by T cells via the T cell receptor. There are two types of HLA, class I and class II, summarized in Table 30.6.

HLA molecules bind antigen but they are different from the receptors on B and T cells in that there is no genetic re-arrangement. Instead, the HLA genes are highly polymorphic, i.e. their nucleotide sequences vary between individuals giving different alleles, summarized in Figure 30.8.

HLA class I molecules are widely expressed on most nucleated cells. They comprise a small non-membrane polypeptide, β₂-microglobulin (the invariant chain of MHC class I) covalently linked to a heavy chain, an integral membrane protein with external domains. The variation within MHC class I arises from polymorphisms within genes for the heavy chains. There are three loci for class I (HLA-A, HLA-B and HLA-C). Each individual inherits A, B and C from each parent and, unlike the situation with immunoglobulins and the TCR, there is no allelic exclusion: both sets of genes are translated. All types

TABLE 30.6 Comparison of HLA class I and class II

	Class I	Class II
Structure	Variable heavy chain + invariant chain (β ₂ -microglobulin)	Two variable chains, α and β
Expression	Most nucleated cells	Antigen presenting cells; may be induced on other cell types
Antigen presented	Intracellular antigen, i.e. viral, self 8–9 amino acids	Extracellular antigen, e.g. microbes or their products 14–22 amino acids
Gene loci	HLA-A, B, C	HLA-DQ, DR, DP
Responding T cell	CD8+ T cells	CD4+ T cells

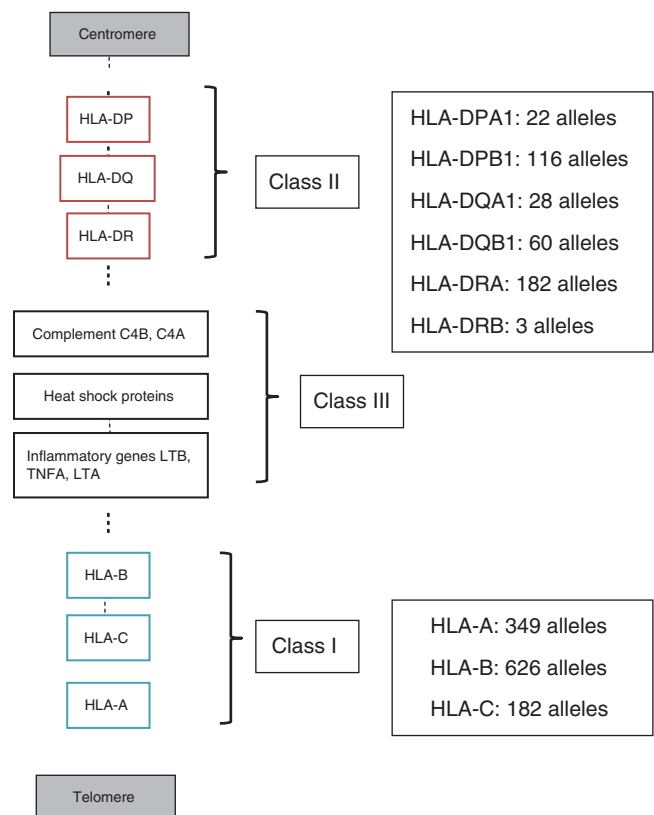

FIGURE 30.8 ■ Simplified overview of the MHC locus on human chromosome 6. The MHC locus is 4MB and encodes ~ 300 genes. Dashed lines are used to indicate that other genes lie between the ones shown.

occur on any one cell. Because of the polymorphisms, it is likely that any individual will be heterozygous at each locus; therefore six products will be formed.

HLA class II molecules are primarily expressed on immune cells, particularly those able to present antigen. They may be inducible on many other cell types. They comprise two transmembrane polypeptides (α and

β chains) of similar size. As for class I, there are three loci (HLA-DR, HLA-DQ and HLA-DP). Again, the likelihood is that these properties will result in at least six distinct receptors. The class II system is, however, more complex. During evolution, there has been replication of some loci such that it is possible to express a number of different DR and DQ types, leading to increased diversity. Even with the variations described above, it is apparent that the total number of different HLA types expressed in any one individual is relatively small compared with immunoglobulins and TCRs.

Antigen presentation

Unlike immunoglobulin and the TCR, HLA molecules are loaded with peptide antigen intracellularly during molecule assembly, so that prior 'loaded' HLA is expressed on the cell surface. Indeed, it would appear that antigen-binding is essential for stability of the molecule and that HLA without antigen is intrinsically unstable. Antigen binds in grooves formed by the folding of class I molecules and the juncture of the α and β chains in class II. The source of the antigen is different for each class. Class I molecules bind antigens synthesized intracellularly, e.g. self-peptides or viral antigens; if these antigens are able to stimulate an immune response it is via CD8⁺ T cells, resulting in destruction of the target cell. Class II molecules bind antigen that was derived extracellularly, e.g. microbes or microbial products. These antigens are internalized within the APC, where they are subjected to partial proteolytic degradation and then bound to the class II molecules for antigen presentation. These antigens are recognized by CD4⁺ T cells and stimulate an immune response.

B cells can act as antigen presenting cells. Their surface immunoglobulins are able to react with free antigen molecules, forming complexes that are taken into the cells, where the antigen is degraded into peptides. These peptides can combine with HLA class II molecules to allow antigen presentation to T cells.

Cellular immune activation

Antigen binding alone will rarely stimulate an immune response. Some very repetitive antigen sequences, for example polysaccharides, may directly stimulate B cells. To respond to most antigens, however, both T and B cells require additional signaling from cytokines or contact with other cell types mediated through accessory or co-ligatory molecules expressed on these cells. Accessory cell interactions are many and complex and the reader is referred to dedicated immunological texts for an account of these.

Complement

The complement system

The complement system consists of approximately 30 plasma proteins, normally present in inactive forms (zymogens). Activation results in the generation of a cascade of enzymes that leads to activation of the terminal cytolytic pathway (membrane attack complex). Activation can occur via two major pathways, the

classical pathway and the alternative pathway. In addition, complement can be activated through the lectin pathway and may be recruited by proteolytic activity generated by other physiological pathways such as coagulation. The system is inherently labile and subject to regulation by various proteins (see below). A simple diagram of the complement system is shown in [Figure 30.9](#). The role of the complement system as a whole is to destroy invading pathogens via the membrane attack complex and opsonization but there are many other effects of complement activation, as shown in [Table 30.7](#). During activation of the earlier components (C2, C4, C3 and C5), smaller peptides are cleaved off the zymogens. These have powerful biological activities: they are able to initiate and potentiate inflammation by increasing blood vessel permeability and attracting inflammatory and immune cells to a site of injury via a process termed chemotaxis.

The larger fragment formed on activation usually has the alphabetical annotation 'b' (e.g. C3b) and the smaller fragment, 'a' (e.g. C3a). Some authors use a line over a component name (e.g. C1 \bar{s}) to denote an active enzyme that can activate the next component; this convention is unnecessary and has not been adopted in this chapter.

Activation via the alternative pathway

The alternative pathway is initiated at the level of C3, bypassing the earlier components C1, C4 and C2, which are activated in the classical pathway. C3 spontaneously degrades in tissue fluids and is rapidly inactivated. However, on activating surfaces, including damaged tissue and components of bacterial cell walls such as lipopolysaccharides, degraded C3 is stabilized and can form an enzyme to activate further C3 and to generate an enzyme to cleave C5 and thus activate the terminal sequence of the pathway.

Activation via the classical pathway

Complexes of antigens with their antibodies (immune complexes) binding C1 activate the classical pathway. C1 is a trimolecular complex of C1s, C1r and C1q. Binding of C1 liberates an enzyme C1s (the C1 esterase), which is able to cleave C4 and C2, and an enzyme formed from a complex of the larger fragments of these two molecules can activate C3. The pathway beyond this is common with the alternative pathway.

Activation via the lectin pathway

Various components of bacterial cell walls are able to bind to a protein in the blood called mannose binding lectin (MBL); this complex is able to stimulate serine proteases that can directly activate component C4.

Regulation of the complement pathways

Many of the complement proteins have a natural cleavage site, making them inherently unstable; therefore the presence of a number of regulatory proteins is vital to stop uncontrolled activation of the cascade. Some of the control proteins circulate while others are membrane

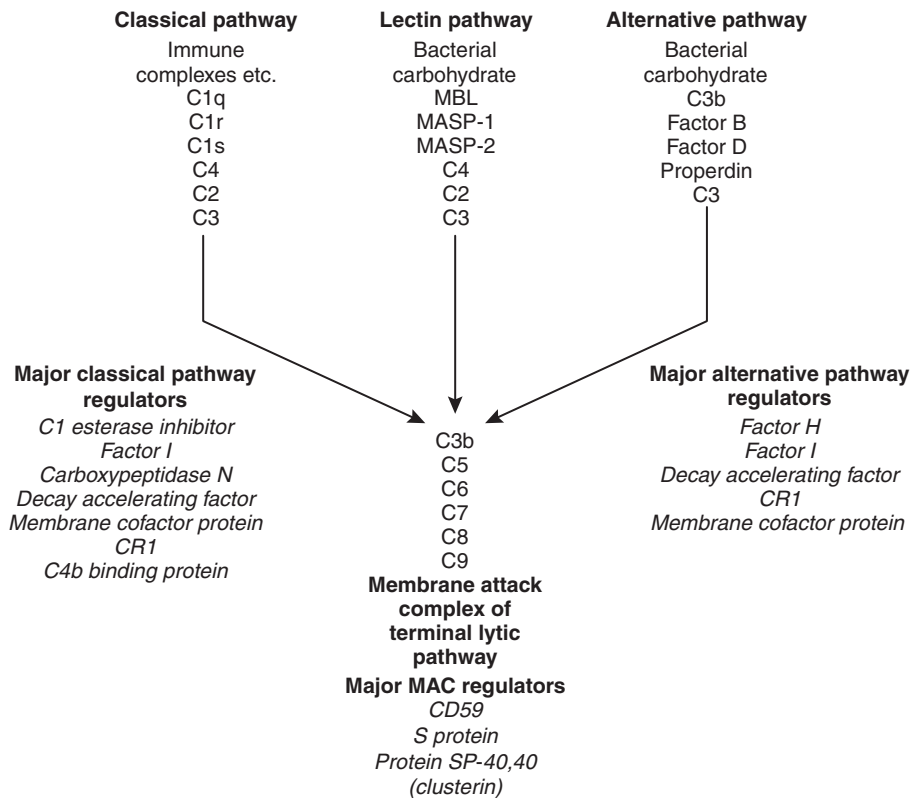

FIGURE 30.9 ■ The complement system, showing the pathways for activation and their major regulatory proteins.

TABLE 30.7 The major actions of components of the complement system

Complement components	Effect
C1q, C3, C4	Clearance of immune complexes Clearance of cell debris
C3a, C4a, C5a (anaphylatoxins)	Histamine release from mast cells Increase smooth muscle contraction Increase vascular permeability Inflammation
C3b (opsonin)	Binding of antigen–antibody complex to receptors on phagocytes, enabling effective ingestion and destruction
C5a, C3a (chemotaxins)	Recruitment of phagocytes into areas of inflammation
C5–C9 (membrane attack complex)	Cell or bacterial lysis Cell signalling

bound; some have enzyme activity, others are simple binding proteins. The important complement regulatory proteins are shown in [Table 30.8](#).

Acute phase proteins

Inflammation is a fundamental pathological process that occurs in response to tissue injury. The inflammatory response has three main stages: local reactions; destruction and/or removal of the injurious material, and repair and healing of the damaged tissue. Stimulators of

TABLE 30.8 The major control mechanisms of the complement cascade

Complement control mechanism	Activity
C1 esterase inhibitor	Protease inhibitor that blocks the activity of C1 esterase
Factor H	Binds C3b and enhances the degradative action of Factor I
Factor I	Enzyme that degrades C3b and C4b
C4b binding protein	Binds to C4 and enhances its destruction by Factor I
Protein S and SP-40,40 (clusterin)	Binds C5b67 and prevents formation of the membrane attack complex
Carboxypeptidase N	Enzyme that inactivates C3a, C4a and C5a
Decay accelerating factor	Transmembrane glycoprotein on most blood cells that binds C4b and inhibits C3 convertase
Membrane cofactor protein (CD46)	Membrane-bound C3 binding protein
Membrane attack complex inhibitory factor (CD59)	Membrane-bound protein that hinders insertion of the membrane attack complex
Complement receptor I (CRI, CD35)	High affinity receptor for C3b and C4b on surface of erythrocytes

inflammation include trauma, infection, infarction and deposition of immune complexes; these result in the release of inflammatory mediators (see [Table 30.9](#)) and the classic signs of inflammation – redness, swelling, warmth or heat, pain and loss (or impairment) of function. These

TABLE 30.9 Inflammatory mediators and their actions

Mediator	Action
Platelet activating factor, histamine, prostaglandins	Vasodilatation
Platelet activating factor, histamine, complement C3a and C5a, bradykinin, leukotrienes	Increased vascular permeability
IL-8, IL-1, and TNF α , complement C5a, leukotrienes	Leukocyte adhesion and chemotaxis
Bradykinin and prostaglandins	Pain
Enzymes (proteases) and products of neutrophil respiratory burst (free radicals)	Tissue damage
Inflammatory cytokines IL-1, IL-6 and TNF α	Hepatic production of acute phase proteins

features may be localized, but in more severe inflammation there is a widespread response and the features also include fever, leukocytosis and the production of a variety of liver-derived acute phase proteins. The functions of these proteins are summarized in [Table 30.10](#).

The acute phase proteins show diverse properties, particularly in the kinetics of their responses, as shown in [Table 30.11](#). The magnitude of response is generally related to the degree of injury, although other factors such as catabolic rate, hormonal influences and genetic variability are also important.

Cytokines

These are biological signalling peptides, whose many actions include the control of the differentiation of white blood cells and the modulation of the actions of the cells of the immune system. They include the interleukins, interferons, tumour necrosis factors and various growth factors. They are summarized in [Table 30.12](#).

In general, cytokines, like hormones, act through high-affinity cell surface receptors that can be widely distributed on many cell types or can be restricted to one or two cell types. The receptors can be up- or downregulated or induced, depending upon the prevailing conditions. Most cytokines are glycosylated and their binding to the receptors may be influenced by the configuration of the sugar residues and by the other cytokines being released in the vicinity. Most cytokines are multifunctional

TABLE 30.10 The functions of acute phase proteins

Acute phase function	Examples
Mediating	Working as parts of networks of inflammatory mediators: C-reactive protein (CRP) binds a variety of ligands and activates complement; complement components are important opsonins and chemotactic factors; fibrinogen and the clotting components form clots and fibrin matrices as a basis for repair
Inhibiting	Inhibiting protease activity and controlling pathways: α_1 -antitrypsin and α_1 -antichymotrypsin inhibit the actions of enzymes released from leukocytes during phagocytosis; C1 esterase inhibitor inhibits part of the complement system
Scavenging	Inhibiting or eliminating noxious substances produced during the inflammatory process: haptoglobin combines with free haemoglobin to form a complex that is rapidly cleared by the liver; CRP may opsonize DNA and cell membrane debris
Regulating	Modulating the immune response: α_1 -acid glycoprotein is expressed on lymphocyte cell membranes
Repairing	Control and laying down of connective tissue elements: α_1 -antitrypsin and α_1 -antichymotrypsin are deposited in a sequential fashion on the surface of newly formed elastic fibres; α_1 -acid glycoprotein promotes fibroblast growth

molecules with diverse biological actions upon a wide variety of target cells. Cytokines, in general, show significant overlap in their functions, with any one function typically being shown by a number of cytokines (pleiotropism). They mostly act locally in either an autocrine or paracrine fashion; very few, for example IL-6, show a true endocrine function. The major differences between cytokines and hormones are shown in [Table 30.13](#). Genetic deficiencies of cytokines are rare, possibly reflecting their vital role in the maintenance of health.

TABLE 30.11 Properties of the major acute phase proteins

Protein	Molecular mass (kDa)	Half-life (days)	Normal adult plasma concentration (g/L)	Magnitude of increase in concentration
Caeruloplasmin	135	2.5	0.2–0.6	} Up to 50% increase
Complement C3	185	2.5	0.7–1.7	
α_1 -Acid glycoprotein	41	2.3	0.5–1.0	
α_1 -Antitrypsin	54	4	1.4–3.2	} 2–3-fold increase
α_1 -Antichymotrypsin	68	2	0.3–0.6	
Haptoglobin	86	4	0.5–3.2	
Fibrinogen	340	4–6	2.0–3.5	} Up to 1000-fold increase
C-reactive protein	105	1	<0.005	
Serum amyloid A	12	1	<0.001	

TABLE 30.12 The major groups of cytokines

Cytokine	Major cell sources	Major immunological functions
Interleukins (ILs; over 35 interleukins have now been characterized)		
IL-1 α and β	Monocytes Macrophages Endothelial cells Fibroblasts	Activation of T and B cells, macrophages and endothelium Acute phase response and production of acute phase proteins Fever
IL-2	T cells	Activation and proliferation of T, B and NK cells
IL-4	T and B cells Macrophages mast cells	Activation of B cells Differentiation of Th2 cells Suppression of Th1 cells
IL-5	T cells Mast cells	Eosinophil recruitment, activation and development
IL-6	Monocytes Macrophages T cells Endothelial cells Fibroblasts	Activation of stem cells Differentiation of T and B cells Acute phase response and production of acute phase proteins
IL-8	T cells Monocytes Neutrophils Endothelial cells Fibroblasts	Chemoattraction and activation of neutrophils Chemoattraction of T cells and basophils
IL-10	T and B cells Macrophages	Suppression of macrophages Suppression of Th1 cells Activation of B cells
IL-12	B cells Macrophages Dendritic cells	Differentiation of Th1 cells Activation of T and NK cells
IL-13	T cells	Activation of B cells Suppression of Th1 cells
IL-15	Macrophages	T and B cell proliferation
IL-17	Activated T cells	Inflammation
IL-18	Macrophages	IFN γ production by T cells
IL-23	Macrophages Dendritic cells	IL-17 production
IL-35	Regulatory T cells	Suppresses T cell proliferation
Interferons α, β, γ		
IFN α, β	T and B cells Monocytes Macrophages Fibroblasts	Antiviral Stimulation of macrophages and NK cells Upregulation of HLA class I expression
IFN γ	T cells NK cells	Antiviral Stimulation of macrophages and endothelium Upregulation of HLA class I and class II expression Suppression of Th2 cells
Tumour necrosis factor superfamily (>50 members)		
TNF	Macrophages T and B cells Neutrophils Endothelium Mast cells	Anti-tumour Activation of macrophages, endothelium and granulocytes Upregulation of HLA class I Acute phase response and production of acute phase proteins Weight loss (cachexia)
BAFF ^b	Dendritic cells T cells	Enhancement of expression of B cell survival factors
Colony stimulating factors (G-, M-, GM-CSF)		
G-CSF	T cells	Activation and development of neutrophils
M-CSF	Macrophages Neutrophils Fibroblasts Endothelium	Activation and development of monocytes and macrophages
GM-CSF	T cells Macrophages Neutrophils Mast cells Eosinophils	Stem cell differentiation Development of neutrophils, macrophages and eosinophils
Growth factors (GF) Chemokines	Fibroblast, platelet derived, epidermal, insulin like, transforming, erythropoietin e.g. lymphotactin, monocyte chemotactic protein-1, IL8, RANTES ^a , macrophage inflammatory protein 1 α	

^aRANTES: regulated on activation, normal T expressed and secreted; Th, T helper.^bBAFF: B Cell activating factor.

TABLE 30.13 Major differences between cytokines and endocrine hormones

Property	Cytokine	Hormone
Sites of production	Many and varied	Many, but specific to each hormone
Cellular targets	Few	Many
Biological role	Fighting infection, tissue repair	Homoeostasis
Biological redundancy	High	Low
Biological pleiotropy	High	Low
Present in the circulation	Rarely	Yes
Sphere of influence	Predominantly autocrine/paracrine	Widespread and distant from site of production
Inducers	External insults	Primarily physiological changes (except stress hormones)

Many cytokines interact with each other and the effect of a cytokine may change depending upon the prevailing micro-environment. It is important to stress that cytokine synthesis, including that of the proinflammatory cytokines, is a normal response to injury. Their functions should not be thought of as exclusively harmful, resulting in tissue damage or systemic shock. In the majority of instances, cytokines act to coordinate the elimination of invading organisms or removal of damaged tissue, thus avoiding excessive stimulation of specific immunity that could lead to hypersensitivity reactions.

Inflammatory cytokines

The cytokines interleukin (IL)-1 β , IL-6 and tumour necrosis factor alpha (TNF α) are all central to the initiation of the inflammatory response. However, they do not function in isolation: other cytokines implicated in the inflammatory response include IL-8, 10, 11, 12, 17, 18, 23 and interferon γ . In addition, both defensive and injurious effects will involve the release of many mediators of inflammation such as peptides, for example the complement fragment C5a, and lipids, for example platelet activating factor. Many of these mediators act synergistically and also induce each other's production and the production of other cytokines, resulting in both positive and negative feedback control pathways. Cytokines are also responsible, either directly or indirectly, for healing and successful resolution of the inflammatory insult. Severe inflammatory responses frequently overlap with specific immune responses, as they are often induced by infection and, furthermore, the tissue damage accompanying severe trauma may lead to secondary infection.

Mechanisms of immunological damage

Immune responses are usually well controlled and host damage is minimal and reversible. Under some circumstances, resolution does not occur and an exaggerated or

persistent response leads to irreversible host tissue damage and, in extreme situations, even death. These inappropriate reactions are termed hypersensitivity reactions. These are classified into four types (I-IV), each with a different mechanism. Type I hypersensitivity reactions, central to allergic responses, may occur without involvement of any other type of hypersensitivity reaction. Most reactions, however, involve more than one type of response and do not, alone, define a pathogenetic mechanism that underlies a group of diseases. There are also other reactions that do not fit neatly into this classification, for example stimulatory reactions, such as when specific immune cells are stimulated by external agents, and when autoantibodies have a stimulatory effect, for example as occurs with thyroid receptor antibodies in Graves disease.

Hypersensitivity reactions result in the release of inflammatory mediators. Some mediators have direct effects on local, or even distant, tissues; others recruit and activate effector cells that further contribute to tissue damage.

Type I hypersensitivity

Type I hypersensitivity reactions are IgE mediated. The IgE antibodies are formed to an antigen (or allergen), with an individual's tendency towards making IgE being determined by many factors including genetic, T cell responsiveness and antigenic burden. The IgE binds to high-affinity IgE receptors on the surfaces of mast cells and basophils, and these cells are now primed to react the next time the cells come into close proximity with the allergen. The cross-linking of IgE on the cell surfaces causes rapid cellular degranulation and liberation of a number of chemical mediators. The mediators released by mast cell degranulation include the preformed molecules histamine, protease enzymes, proteoglycans (heparin) and chemotactic factors. Reaction of antigen with IgE on mast cells also stimulates synthesis and release of platelet activating factor (PAF), leukotrienes (B₄, C₄ and D₄) and prostaglandins (mainly PGD₂). The mediators of type I hypersensitivity reactions are shown in Table 30.14.

The actions of histamine depend on the site of release. In the airways, it induces smooth muscle contraction; in the skin, it causes the hallmark wheal and flare response. Widespread activation of mast cells leads to systemic effects

TABLE 30.14 Mediators of type I hypersensitivity reactions

Mediator	Pharmacological effect
Histamine	Vasodilatation, capillary permeability, bronchoconstriction
Heparin	Control of histamine release
Leukotrienes (various)	Bronchoconstriction, airway tissue oedema
Prostaglandins (various)	Potent mediators of inflammatory response
Platelet activating factor	Platelet aggregation
Tryptase	Proteolytic enzyme activates C3
Kininogenase	Kinins \rightarrow vasodilatation \rightarrow oedema
Cytokines (IL-5, IL-8, TNFs)	Chemoattractants

of circulatory shock, hypotension, collapse, chest tightness and, in the most severe cases, respiratory arrest and death: this is anaphylactic shock. Type I hypersensitivity reactions occur rapidly (within approximately 20 min of an insult) and are also called 'immediate hypersensitivity reactions'.

Type II hypersensitivity

The important characteristic of type II hypersensitivity reactions is that the antigens involved are localized to the membranes of the target cells; they may be synthesized cell products, cell membrane components or bound foreign molecules (e.g. a drug). The circulating antibodies (IgG or IgM) bind to the cell-bound antigen and activate complement. Full activation of the complement pathway results in the membrane attack complex (C5–9) being assembled on the cell surface, resulting in target cell lysis. Partial activation via C3 will also render the cell a target for phagocytosis, via C3b and IgG that bind to appropriate receptors on phagocytic cells. Activation of phagocytic cells leads to release of further tissue-damaging enzymes. The tissue damage persists for as long as antibody and antigen are present.

Some of the more important type II responses involve red blood cell antigens (including transfusion reactions and haemolytic disease of the newborn) and autoantibodies to cell surface components, for example autoimmune haemolytic anaemia (in which the target is red blood cells), idiopathic thrombocytopenia purpura (in which the target is platelets) and Goodpasture syndrome (in which the target is the kidney glomerular basement membrane).

Type III hypersensitivity

Type III hypersensitivity reactions are also termed immune complex reactions. Complexes of antigen and antibody form in the circulation and are then deposited in susceptible tissues; they may also form directly in the tissue. The latter mechanism is termed the Arthus reaction, and is typically seen with repeated insect stings, where a red swollen lesion develops after a sting. The tissue damaging mechanisms are similar to those described for the antigen-antibody complexes that form in type II responses. The response times of types II and III hypersensitivity reactions are slower than that of type I reactions; they typically develop 3–6 h after exposure to antigen. The response can also become chronic, particularly in autoimmune reactions, where antigen persists.

The clinical manifestations of type III hypersensitivity reactions relate to the tissue deposition, for example vasculitic (skin), serum sickness (systemic), nephritis (kidneys) and extrinsic allergic alveolitis (lungs).

Type IV hypersensitivity

These reactions are cell mediated. Membrane receptors on sensitized T lymphocytes recognize antigen and the cells (particularly Th1) release cytokines that in turn activate macrophages. The major mediators of the hypersensitivity response are products of activated macrophages including enzymes, coagulation factors, complement, superoxide ions, leukotrienes, prostaglandins and cytokines. The hallmark of responses to

persistent antigen is formation of granulomas that wall off the inflammatory focus.

Type IV reactions are also known as delayed type hypersensitivity reactions because symptoms occur 24–48 h after re-exposure to antigen. They are seen in response to mycobacteria (e.g. *Mycobacterium tuberculosis*) and are the mechanism underlying contact dermatitis.

Conclusion

This brief introduction has described the major components of the immune system and their interactions during immune responses. Antigens, typically encountered across mucosal surfaces, are taken up by antigen presenting cells (APCs) and processed and presented on the major histocompatibility antigen (MHC) molecules of these cells to the lymphocytes in lymphoid tissue. The lymphocytes, with their randomly rearranged receptors (TCR and Ig), traffic around the lymphoid tissue until activated by an antigen, whose three-dimensional shape can engage the receptor. Activated cells communicate via cytokines and various peptides and proteins to induce lymphocyte proliferation and maturation. Plasma cells of the B lymphocytic lineage secrete antibody that circulates, coats the mucous membranes and bathes the tissues. Re-exposure to a previously encountered antigen stimulates a rapid and specific response via antibody, complement, phagocytosis and T cell killing to provide long-lived immunity to infection. The complexity of the system makes it robust but also provides opportunities for something to go wrong and result in diseases of the immune system.

DISEASES OF THE IMMUNE SYSTEM

Introduction

Diseases of the immune system can be classified as follows:

- immune deficiency resulting from failure of the development or function of immune organs, cells or other components, either from inherited causes (primary immune deficiency) or from some other disease (secondary immune deficiency)
- allergic reactions, which may result from any of the hypersensitivity reactions previously described or from direct activation of inflammatory mediators
- autoimmune disease resulting from immune reactions against body tissues
- malignancy of organs or cells of the immune system.

In addition, severe sepsis resulting from damage to the immune system rather than direct bacterial tissue damage may be considered as an immunological disease.

These disorders will be considered in more detail in the following sections.

Immune deficiency

Development of immunity in humans

The ability to recognize antigen is present at birth, but except on the rare occasions when there has been an intrauterine infection, antigens will not previously have been encountered. The newborn will not have memory

FIGURE 30.10 ■ Serum immunoglobulin concentrations with age. IgG is actively transferred across the placenta to be gradually replaced by the IgG synthesized by the infant. The assays should be capable of reliably detecting concentrations for IgG of 1 g/L, IgA of 0.07 g/L and IgM of 0.1 g/L (after Adinolfi (ed). Immunology and development. Heinemann: London, 1969).

responses so are potentially vulnerable to infection. In the first 3–6 months of life, during which many microbes will be met, immunity is provided by maternally derived IgG, giving time for a child's own system to mature and to establish memory. Active transfer of IgG occurs from 12 weeks of gestation but the major portion is transferred after 32 weeks of gestation. A term baby should have adult plasma IgG concentrations. Premature babies will have reduced IgG concentrations and are more vulnerable to infection. Babies who grow poorly in utero may also have low concentrations. A diagram showing serum immunoglobulin concentrations from pre-term to adulthood is shown in Figure 30.10. Term babies have different immune responsiveness from adults, as shown in Table 30.15.

Deficiencies of the immune system can be due to the lack of a component (or group of components) or defective (or absent) function of a component. Owing to

TABLE 30.15 Immune responsiveness in term neonates

Components	Responsiveness
B cells	Normal numbers but immature (CD5+)
Antibodies	Able to make IgM, with good response to protein antigens but poor response to carbohydrates
Complement	Maternal IgG Classical pathway, 90% of adult; alternative pathway, 60% of adult; C8 and C9, only 20% of adult
T cells	Higher numbers than in adults and immature neonates
Cytokines	IL-2, as adult; IFN γ , 20% of adult; Th2 cytokines very low
Cytotoxicity	Tc only 30–60% of adult; NK 50% of adult

immune interactions, defects in one component may affect another. For example, T cell defects may also result in marked antibody deficiency when T helper activity is compromised.

Infection and immune deficiency

The hallmark of immune deficiency syndromes is frequent, severe or unusual infection. The pattern of infections can give an indication of the type of deficiency, although in young children, this may be difficult to judge. It is estimated that children have eight minor infections per year and it is suggested that significant infection should be regarded as one requiring antibiotic treatment. Even this can be misleading, as the threshold for prescribing antibiotics varies between practitioners. The infections typically seen in specific and non-specific immune deficiencies are summarized in Table 30.16. In general, systemic viral and fungal infections are more typical of T cell deficiencies and common respiratory tract and gut infections are more typical of B cell deficiencies. With regard to the non-specific immune system, defects in complement tend to predispose to most common bacterial infections and impose an increased risk of autoimmune disease, while defects in phagocytes are linked with most common skin infections, cutaneous abscesses and lung abscesses.

In addition to the pattern of infections, there are other factors that can be used to build up an impression of whether immune deficiency should be considered. These are listed in Box 30.1.

Investigation of patients with suspected immune deficiency

The various categorizations of immune deficiency (primary or secondary, cell mediated or humoral etc.) are made at the end of the diagnostic process, not the beginning. The investigation of patients with recurrent, atypical or severe infections, irrespective of age, should follow the same basic pattern, but the detailed investigative process needs to be tailored to the individual patient. A careful history, including the type of symptoms, age of onset of symptoms, organisms responsible (where known) and family history (particularly of immune problems) is essential. Microbiological investigations and basic tests like a full blood count and white cell differential are vital. The process aims to determine the following:

- are all the components of the immune system present?
- are all the components functional (alone or in consort)?
- can the system respond to a defined challenge?
- what is the molecular defect?

As a general guide, the simple tests, and those that are important in the more common immune deficiencies, should be done first. The more complex, functional and genetic tests should be done later in the investigation process (unless there are strong indications from the clinical manifestations or family history). Figure 30.11 shows a basic plan for the immunological investigation of a patient with suspected immune deficiency. Following

TABLE 30.16 Infections typically seen in deficiencies of the immune system

<i>Specific immune system</i>		<i>Non-specific immune system</i>	
<i>T cell deficiencies</i>	<i>B cell deficiencies</i>	<i>Complement</i>	<i>Phagocytes</i>
Common infections			
Viruses: Cytomegalovirus (CMV) Herpes Adenovirus	Bacteria: <i>Staphylococci</i> <i>Streptococci</i> <i>Haemophilus</i> <i>Neisseria</i>	Bacteria: <i>Haemophilus</i> <i>Streptococcus</i> <i>Neisseria</i>	Bacteria: <i>Staphylococci</i> Fungi: <i>Candida</i> <i>Aspergillus</i>
Fungi: <i>Candida</i> <i>Aspergillus</i> <i>Pneumocystis carinii</i>			
Protozoa: <i>Cryptosporidium</i>			
Less common infections			
Bacteria: <i>Mycobacteria</i> <i>Listeria</i> <i>Campylobacter</i>	Bacteria: <i>Campylobacter</i> <i>Salmonella</i> Enteroviruses: Polio Echoviruses	Viruses: Cytomegalovirus Herpes	Bacteria: <i>Salmonella</i>

BOX 30.1**Factors that should be considered in the evaluation of patients with possible immune deficiency**

- Increased number of infections
 - More than three infections requiring antibiotics in one winter
 - Frequent minor episodes
 - More infections than siblings
 - More infections than siblings at same age
- Severe infections
 - More than one severe bacterial infection
 - Frequent requirement for antibiotics
 - Infections that recrudescence when antibiotics are finished
- Unexpected infections
 - Opportunistic infections
 - Unexplained causative organism
 - Unusual infections
- Positive family history
 - Siblings
 - Male relatives on maternal side (for X-linked immune deficiencies)
- Unexplained bronchiectasis
- Therapy-resistant or steroid-resistant asthma
- Severe warts
- Complications of vaccination (e.g. disseminated BCG)
- Failure to thrive
- Chronic diarrhoea

this plan should make it possible to classify the type of immune deficiency.

Primary immunodeficiencies

Clinically significant primary immune deficiency is rare. Many patients suffer years of ill health before they are appropriately investigated and a diagnosis made. The classification of these disorders is by an International System (see [Further reading](#), below) based on the identified defect.

B Lymphocyte (humoral) system

IgA deficiency. This is the most common of the primary immune deficiencies, affecting approximately 1:700 of the population, and is characterized by low plasma IgA concentrations (<0.07 g/L for total IgA deficiency). Patients are often asymptomatic, although they can suffer with repeated respiratory tract and sinus infections, especially if IgA deficiency is associated with IgG subclass deficiency. No particular treatment is indicated, although, if the patient is symptomatic, a low threshold for antibiotic treatment should be adopted. Salivary IgA concentration matures at approximately six weeks of age and can be measured to give an early indication of deficiency. Patients with IgA deficiency can develop antibodies to any IgA present in blood products and this can cause transfusion reactions.

Common variable immunodeficiency (CVID). This is a primary immune deficiency, although the age of presentation can be any time from childhood to late in adulthood. It is not one clearly defined disease, rather a heterogeneous group of undifferentiated syndromes with the common feature of defective (quantitative and/or qualitative) antibody production. The most common presentation is with recurrent sinus and pulmonary infections. The critical laboratory test is quantification of immunoglobulin concentrations (with serum and urine electrophoresis to exclude myeloma). These are typically well below the lower limits of the age-related reference ranges. Patients can also have poor responses to vaccines, low CD4 counts, abnormal cell-mediated immunity and changes in the B cell subset profile. Treatment is with intravenous or subcutaneous immunoglobulin (IgG) replacement, with the dosage being calculated on the basis of body weight. Antibiotics can be given prophylactically or a low threshold adopted for their use in treatment. The IgG should be given every 2–3 weeks and trough immunoglobulin concentrations should be checked regularly, particularly in children.

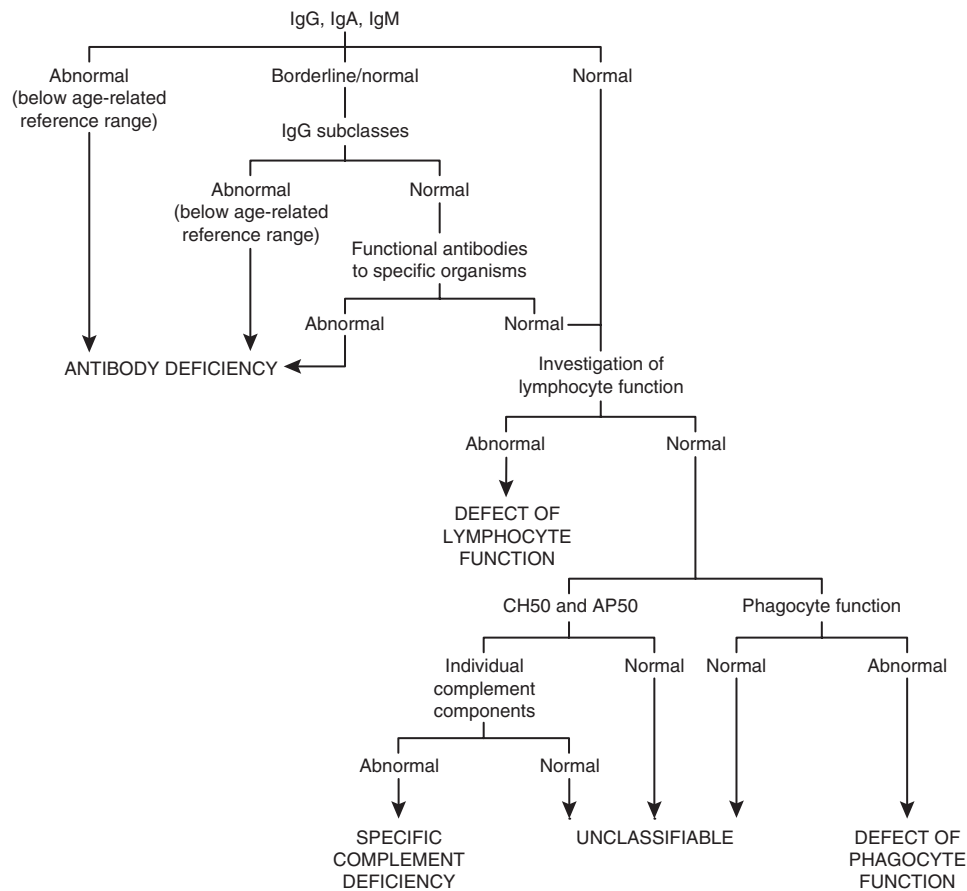

FIGURE 30.11 ■ A basic plan of investigations in suspected immune deficiency (after IUIS/WHO 1981, 1988, 2009).

X-linked agammaglobulinaemia. This condition, also known as Bruton agammaglobulinaemia, is caused by mutations in the gene for a B cell-specific tyrosine kinase (Btk). This results in no B cell development in the bone marrow, a lack of circulating B cells and profoundly low immunoglobulin concentrations. Patients present with recurrent bacterial infection from 4–5 months of age, once protective maternal IgG has disappeared. Treatment is with replacement immunoglobulin, as in patients with CVID.

T Lymphocyte (cell-mediated immunity) system

Severe combined immunodeficiencies (SCID). This is a group of deficiencies with a variety of underlying molecular defects. They are the most profound of the immune deficiency diseases and patients typically present in early infancy. The most common of the diseases is the X-linked SCID that results from a defect in the common γ -chain of the IL-2 receptor. This affects the responsiveness to IL-2, IL-4, IL-7, IL-9, IL-15 and IL-21, so that there is no T cell or NK-cell function; although B cells can be detected, they have no T cell help to make antibodies. The lymphocyte count and T and B cell numbers are the most important investigations when considering SCID; immunoglobulin concentrations are not particularly helpful (owing to the presence of maternal IgG, and the normally low IgA and IgM concentrations expected in young babies). Any baby with suspected SCID should be referred to a paediatric immunologist for investigation. Treatment is with stem cell transplantation or, more recently, gene therapy.

DiGeorge syndrome. This condition is associated with deletions in the chromosomal region 22q11. It is a clinical spectrum of developmental defects including congenital cardiac defects, dysmorphic facies (including cleft palate), immune deficiency secondary to thymic hypoplasia and hypocalcaemia due to parathyroid aplasia or hypoplasia. The abnormal development of the thymus results in reduced T cell numbers and/or function and increased susceptibility to infection. The immunological abnormalities, which are seen in approximately 25% of patients, usually improve with age.

X-linked hyper-IgM syndrome/CD40 ligand deficiency. This immune deficiency is due to a defect in the gene for a cell surface receptor called CD40 ligand (CD154). The binding of CD40 (on antigen-presenting cells and B cells) to CD40 ligand (on T cells) is vital for B cell maturation and class switching. Presentation is similar to X-linked agammaglobulinaemia but these patients are also susceptible to opportunistic infections. They typically have low plasma concentrations of IgG, IgA and IgE and increased concentrations of IgM (as high as 10 g/L). Assessment of the expression of CD40 ligand on T cells is the most important investigation. The bacterial infections can be well controlled with replacement IgG, but patients may develop infections with *Cryptosporidium*, and can develop a sclerosing cholangitis and liver failure. Rare, autosomal recessive forms of hyper-IgM syndrome also exist.

Phagocytic (polymorphonuclear and mononuclear) system

Chronic granulomatous disease. This condition, which can be X-linked or autosomal recessive, is caused by abnormalities in the NADPH oxidase system. This is critical in the respiratory burst and the production of antimicrobial free radicals in neutrophils. Patients present with recurrent abscesses or infections and granulomata. An abnormally low respiratory burst in the neutrophils is the most significant finding; this property is increasingly being investigated by flow cytometric assays. Molecular testing is used to confirm the diagnosis.

Leukocyte adhesion defect types I and II. Recruitment of neutrophils, lymphocytes and monocytes into sites of infection relies on the presence of adhesion molecules, for example CD11a/18 and selectins. Absence or deficient expression of these molecules on cell surfaces results in poor cellular adherence, migration and phagocytosis. Patients present with recurrent, life-threatening bacterial infections and impaired wound healing.

Complement system. Deficiencies of all the complement components have been identified but have varied clinical consequences. Deficiencies of C3 and C6 are particularly associated with recurrent infections. The most important initial investigation is assessment of the integrity of the whole complement system, using haemolytic assays of the classical and alternative pathways or enzyme linked immunosorbent assay (ELISA)-based total complement pathway tests. If these are abnormal, individual components can be investigated: this usually requires referral to specialized centres.

C1 Esterase inhibitor deficiency. This inherited (autosomal dominant) deficiency of the control protein C1 esterase inhibitor results in hereditary angioedema – episodes of subepithelial swelling of the skin (especially of the face, limbs and trunk), gut, larynx etc. The major laboratory findings are low C4 and C1 esterase inhibitor concentrations but normal C3 concentrations. There are rare forms in which antigenic C1 esterase inhibitor concentrations are normal but function is impaired and C4 concentrations are usually low. Measurement of C1 esterase inhibitor should also be considered in patients with apparent anaphylaxis, as the two conditions have similar features in their early stages. However, it should be noted that C4 concentrations may also be low post-anaphylaxis. C1 esterase inhibitor deficiency can also be seen secondary to B cell malignancy when the monoclonal protein interferes with the normal activity of C1 esterase inhibitor.

Transient hypogammaglobulinaemia of infancy. This condition is not strictly a primary immune disorder but is mentioned here for completeness. Some babies show a very slow maturation of their own antibody production, resulting in a lengthening of the physiological trough in concentrations after maternal IgG has disappeared. These babies show normal responses to immunization and will eventually achieve normal antibody concentrations. No particular treatment is indicated, but patients

should be monitored regularly in case antibody concentrations do not improve or they become symptomatic.

Secondary immune deficiency

Secondary immune deficiencies are significantly more common than primary immune deficiencies. They are the predominant form in adults, although they do occur in children. Investigation should concentrate on identifying the underlying process rather than identifying the nature of the defect in immunity. The causes of secondary immune deficiency are summarized in [Table 30.17](#).

There are two broad mechanisms of secondary immune deficiency: inadequate production of a component or excessive loss of a component. Iatrogenic causes of immune deficiency rarely warrant investigation as they are accepted consequences of treatment for other (usually more severe) diseases. Malnutrition is the single most common cause of immune deficiency worldwide.

The most clinically important virally induced secondary immune deficiency is that related to HIV infection. The investigation of this relies particularly on measurements of CD4+ T cell numbers and viral load. Infections with other viruses, for example Epstein–Barr virus and cytomegalovirus, may be associated with some degree of secondary immune deficiency (usually of the cell-mediated responses).

Adults with symptoms of immune deficiency without an obvious cause should be investigated for lymphoid malignancy. These conditions can affect both the cell- and antibody-mediated immunity, making the patient particularly prone to infection. The investigation of lymphoid malignancies is discussed on [p. 589](#).

Protein loss. The most frequent type of immune deficiency associated with excessive component loss is hypogammaglobulinaemia. The loss of immunoglobulins, if sufficiently marked to cause low plasma concentrations, is certain to be accompanied by the loss of albumin

TABLE 30.17 Causes of secondary immune deficiency

Cause	Examples
Immunosuppression	Corticosteroids
Chemotherapy	Cyclophosphamide, methotrexate, vincristine
Radiotherapy	Total body irradiation
Malnutrition	Protein malnutrition, vitamin deficiencies, trace element deficiencies
Infection	HIV, cytomegalovirus (CMV), Epstein–Barr virus, some bacteria, e.g. mycobacteria post-septicaemia
Malignancy	Myeloma, lymphoma, leukaemia
Loss of protein (or other components)	Nephrotic syndrome, protein losing enteropathy, loss from skin, e.g. burns
Miscellaneous	Trauma, type 1 diabetes, splenectomy, inflammatory bowel disease

(a protein of lower molecular weight and higher plasma concentration than the immunoglobulins). It is useful, therefore, to check serum albumin concentrations together with immunoglobulin concentrations when investigating this group of patients. A normal albumin concentration with low immunoglobulins would suggest suppression of production rather than excessive loss. It is also vital to remember that protein loss via the kidneys can be seen with lymphoid malignancy so serum and urine electrophoresis must be performed. Protein loss through the gut can be difficult to prove, but a raised faecal α_1 -antitrypsin concentration is good evidence that protein is being lost into the gut. α_1 -Antitrypsin is used because, as a protease inhibitor, it is relatively resistant to proteolytic degradation in the gut; nevertheless, specimens must be frozen as soon as possible after collection to minimize degradation.

Splenectomy. Patients without a spleen, for example owing to surgical removal following trauma, have an increased susceptibility to overwhelming infection with bacteria such as *Pneumococcus*, *Meningococcus* and *Haemophilus influenzae* type B. Patients who are having elective splenectomy should be vaccinated with pneumococcal, haemophilus and meningococcal A and C vaccines; asplenic patients should take prophylactic antibiotics. The measurement of specific antibody titres (approximately six weeks post-vaccination) may be indicated to confirm adequate antibody responses. Asplenic patients may not maintain optimal antibody concentrations and these should be measured every 2–3 years, depending on the clinical findings. Patients found to have suboptimal concentrations should be re-immunized.

Allergies

Various mechanisms exist, whereby an individual can have an unexpected or inappropriate response to an agent that is not typically considered to be harmful. The mechanisms of such reactions include types I–IV hypersensitivity reactions, direct pharmacological effects (e.g. from biogenic amines in certain foods), biochemical effects (e.g. due to alcohol or other drugs) and intolerances due to enzyme defects (e.g. lactose intolerance). The term *allergy* is often used by lay people to describe such reactions but this term should only be applied to type I hypersensitivity reactions mediated by IgE.

The prevalence of allergies is increasing rapidly; it is estimated that 15–20% of the population have some type of allergy. The clinical features of allergic reactions include:

- abdominal pain
- anaphylaxis
- eczema and atopic dermatitis
- bronchospasm
- conjunctivitis
- diarrhoea
- headache
- malabsorption
- pneumonitis
- pruritus

- rhinitis
- urticaria
- vomiting.

Patients may have only one symptom or a mixture of symptoms. They can range in severity from mild and inconvenient to damaging to health and, in the extreme, to life-threatening anaphylactic shock.

Investigation of patients with allergies

It is important to investigate patients with suspected allergy to provide a logical basis for exclusion of the allergen, with the objective of improving well-being and preventing severe reactions. Investigation must start with the patient's history and examination; the important points in the history are shown in Table 30.18. The exceptions are patients who complain of mild symptoms clearly related to eating one particular food, who often do not need investigation and should simply be advised to avoid that food, and patients with mild reactions to inhaled allergens, for example hay fever and seasonal rhinitis, who should attempt to avoid exposure and be treated symptomatically. However, if a patient has had a severe reaction, investigation is indicated to identify positively the causative agent. Accepted

TABLE 30.18 Important points in taking the history in a patient with suspected allergy

Point	Notes
Age	Babies and young children should be investigated by people with appropriate training. Allergy can have a wider impact in children – loss of schooling, poor health, exclusion from normal activities
Family history	A positive family history increases the likelihood of allergy in an individual
Symptoms (what symptoms and where, e.g. gut, respiratory, skin etc.)	Can help to narrow down the allergen and direct investigation
Symptoms (severity)	Severe symptoms, e.g. anaphylaxis, need rapid investigation
Symptoms – all year or seasonal	Can help to identify the allergen and direct the testing, e.g. respiratory symptoms all year round are unlikely to be due to pollen allergy
Daytime or night-time, indoors or outdoors	Can help to identify the allergen and direct the testing, e.g. symptoms at night are more likely to be due to house dust mites, feathers etc.
Frequent animal contact	Household pets, but also animals of friends and relatives etc.
Does the patient know (or believe) what causes the symptoms?	Often the patient knows what precipitates the symptoms – but they may be wrong
Has exclusion been attempted?	Patients often spontaneously avoid something that makes them unwell

TABLE 30.19 Indications for investigating patients with allergies

Reason	Notes
Severe symptoms	Anaphylactic reaction or symptoms affecting patient's overall health
Progressively worsening symptoms	Every time the patient encounters the allergen, the symptoms appear to be worse – next time it could be anaphylactic
Allergen is difficult to exclude or hidden	Foods, e.g. nuts, eggs, occupational allergens, particular tree pollens, favourite pet
Patient needs a diagnosis	Showing a patient test results may help them accept their condition and accept the reason for the proposed management, particularly if it involves dietary or other restrictions

reasons for investigating patients with allergies are shown in [Table 30.19](#).

There are two general ways of investigating allergy but they are only useful as an adjunct to a good clinical history and examination. They are skin prick testing and measurement of IgE (total and specific). Both are widely used but have advantages and disadvantages, as shown in [Table 30.20](#). In practice, both methods of investigation have a role in the allergy clinic and the allergist will use a combination depending upon a patient's age, symptoms, the putative allergens and the overall clinical picture.

Raised plasma total IgE concentrations are seen in allergic disease, parasitic infections, immune deficiencies, malignancies, liver disease and some viral infections.

With regard to allergies, there are some important caveats. While a raised total IgE concentration suggests a high risk of allergic disease, it does not directly relate to the severity of disease. An IgE concentration within the reference range (particularly in children) does not exclude significant allergy and if there are strong clinical indications, further investigation is warranted.

The IgE that has activity against a particular defined antigen is called specific IgE. The term RAST refers to the technique that was first developed to detect and quantify IgE to specific allergens and, although now scientifically outdated, the term is still commonly used. Specific IgE is reported as k_A U/L or converted to a grade based upon the concentration; both these results can be used as a guide to the patient's potential reactivity to that allergen (or group of allergens). (The subscripted 'A' refers to 'allergen'; however, the units are arbitrary in that they are calibrated against a total IgE standard rather than an allergen-specific IgE standard.) The grades corresponding to various ranges of specific IgE concentrations, and their significance, are shown in [Table 30.21](#). Like total IgE, the specific IgE does not correlate with disease activity between patients. However, in individual patients (particularly children), there is some predictive value in specific IgE concentrations, for example to predict whether a challenge test would be appropriate, so reporting specific IgE in units rather than grades is now accepted.

Anaphylaxis

Anaphylaxis is a medical emergency. It is the sudden, generalized shock and collapse that occurs when patients react to substances to which they are exquisitely sensitive. The clinical features (see [Table 30.22](#)) are induced

TABLE 30.20 Comparison of skin prick testing and specific IgE in the investigation of allergy

Property	Skin prick testing	Specific IgE
Specificity	Atopic patients may show positive skin tests to several antigens, not all of which cause symptoms	Atopic patients may show positive specific IgE to several antigens, not all of which cause symptoms
Applicability	In vivo test, so assesses the patient's response to the allergen	In vitro test, so more a test of the potential to react to an allergen
Use in children	Can be difficult in young children because they have to sit still for ~20 min	Requires a blood test but many allergens can be checked on a single specimen
Dermatological symptoms	Can be impossible in patients with extensive skin disease, e.g. eczema, dermatitis	Dermatological disease does not interfere
Risk	Must be done under medical supervision with resuscitation facilities available	As for a blood test
Convenience	Results available in the clinic within ~20 min	Samples need to be tested in the laboratory; results in days or weeks
Antihistamines	Limited use if the patient is taking antihistamines	Antihistamines do not interfere
Sensitivity	Can be insensitive for diagnosis of food allergy	Can give negative results even with highly suggestive history. Specific IgE may be negative in the first few weeks after a severe reaction
Allergens	Can be difficult if the allergen is toxic or insoluble test material often less purified and similar to native allergen	Can be used for toxic or insoluble allergens Allergens are highly purified and can show variability between different manufacturers
Standardization	Subjective with interoperator variability Saline and histamine must be used as negative and positive quality controls Results reported as wheal and flare diameter	Objective with results reported in arbitrary k_A U/L of IgE (or grades) related to the international reference preparation External QA schemes available to validate results

TABLE 30.21 Guide to the interpretation of specific IgE^a measurements

Units	Grade	Interpretation	Significance (k _A U/L)
<0.35	0	Negative	Significance of grades 1–3 varies depending on allergen
0.35–0.7	1	Weakly positive	Grade 1 to foods or moulds may be significant, but to inhaled allergens is of doubtful significance
0.7–3.5	2	Positive	Positive specific IgE ^a indicates potential to react
3.5–17.5	3	Positive	
17.5–50	4	Strongly positive	
50–100	5	Strongly positive	
>100	6	Strongly positive	

^aHistorically, specific IgE was measured by radioallergosorbent assay (RAST); this method is no longer available but the term RAST is still used as a synonym for a test for specific IgE.

TABLE 30.22 The clinical features of anaphylaxis

Organ affected	Feature
Respiratory system	Upper airway obstruction due to oedema Bronchospasm Oedema Asphyxia
Cardiovascular system	Hypotensive shock due to vascular pooling Cardiovascular collapse
Gastrointestinal system	Vomiting, nausea, diarrhoea, abdominal cramps
Skin	Erythema, pruritus, urticaria, angioedema
General	Warmth, tingling, flushing, feeling of impending doom

via an IgE-mediated mechanism (anaphylaxis), but similar, non-IgE mediated (anaphylactoid) reactions also occur. The precipitating agents are varied, with drugs, bee and wasp venoms, peanuts, latex, fish and eggs being the most common. The mediators involved are shown in [Table 30.9](#). Initial treatment should be aimed at protecting respiratory and cardiovascular function and tissue oxygenation. Adrenaline (epinephrine), antihistamines and steroids are the mainstays of treatment, together with general measures (e.g. oxygen and intravenous fluid). Long-term management must include avoidance of the precipitating allergen (which in practice may be difficult). Patients with a history of anaphylactic reactions should carry a self-injecting adrenaline device (and be instructed in its use) to administer if they inadvertently encounter the relevant allergen. In some situations, for

example sensitivity to bee and wasp venoms, desensitization can be successful.

The investigation of anaphylaxis. It is important to confirm that an apparently anaphylactic reaction is a type I hypersensitivity reaction, and to try to identify the precipitating agent. Serum tryptase is a good marker of mast cell degranulation and can be used for this purpose; the minimum number of samples required is three: at times zero (as soon after the start of the reaction as possible and preferably within 30 min), at 1–2 h post reaction and a third sample 24 h post reaction or during convalescence. Ideally, additional samples at 3, 6 and 12 h should be requested to help interpretation. The peak concentration (>50 µg/L) is reached 1–3 h after the start of the reaction; values gradually return to normal by 24 h. The timing for further investigation will be guided by the clinical situation but may involve closely supervised skin testing and/or total and specific IgE, generally with interpretation by an immunologist. Hereditary angioedema can cause symptoms very similar to those of a type I hypersensitivity reaction, so measurement of C3, C4 and C1 esterase inhibitor concentrations may be indicated.

Autoimmune diseases

The immune system is tolerant to self-antigens or makes only limited responses to them. Sometimes, this tolerance breaks down and the immune system makes a progressive response that attacks the body's own tissue, resulting in autoimmune disease. The factors that trigger such responses are not well understood; many factors are likely to be involved, for example the patient's immunological status, including their HLA types, any pre-existing inflammation and the presence of any infection. The initial damaging stage is usually cell mediated, and biopsies from affected tissue often show monocytic and lymphocytic infiltration. The production of autoantibodies can be part of the pathogenetic process or a result of a response to hidden antigens that are released as a consequence of cellular destruction. The general characteristics of pathogenetic antibodies and non-pathogenetic antibodies are shown in [Table 30.23](#). The presence and the concentration of many of these antibodies are used to help diagnose and, occasionally, to monitor autoimmune diseases.

Autoantibodies can be detected by their reaction against tissue containing the relevant antigens, using subjective methods such as indirect immunofluorescence. Samples found to be positive by these sensitive (but not very specific) methods are then analysed, using more specific and quantitative methods, for example ELISA. Automated ELISA-based 'screening' techniques are increasingly being used, although the validity in a routine setting is questionable.

It is important that detection of these autoantibodies is not considered to be a 'gold standard' test. They are, at best, markers of disease: they have significant limitations and should be used as part of a diagnostic panel rather than the presence of individual autoantibodies being regarded as diagnostic of any particular disease.

TABLE 30.23 Characteristics of pathogenetic and non-pathogenetic antibodies

Characteristic	Pathogenetic antibodies	Non-pathogenetic antibodies
Antigen distribution	Cell surface antigens, e.g. glomerular basement membrane, acetylcholine receptor, thyroid stimulating hormone receptor	Antigens within the cell
Specificity	Antibodies rarely seen in other conditions	Antibodies often seen in the absence of clinical features
Concentration	Related to disease severity	Unrelated to disease severity
	Mirrors disease activity	Unrelated to disease activity

An arbitrary distinction is often made between organ-specific and non-organ-specific autoimmune diseases, but in reality there is a spectrum of involvement ranging from only one or several organ(s) being affected to autoimmune diseases with systemic manifestations.

Autoimmune endocrine diseases

The autoimmune endocrine disorders include diseases of the thyroid, pancreatic islets, adrenal cortex, gonads, pituitary and parathyroids. More than one endocrine organ can be affected, either simultaneously or at different times during the patient's life. Autoimmune disease affecting the parathyroids or pituitary is rare, and is not discussed further in this chapter.

Thyroid. Autoimmune thyroid disease is discussed in detail in Chapter 19. It includes primary myxoedema, Hashimoto thyroiditis and Graves disease. Measurement of thyroid antibodies is of limited use. Approximately 95% of patients with Hashimoto thyroiditis have antibodies to thyroid peroxidase. There is little point in measuring them in patients with obvious hypo- or hyperthyroidism. Measurement is best reserved for patients with equivocal thyroid function test results and when thyroid disease is suspected, but there are unusual clinical findings. Thyroid peroxidase antibody measurements are not required for monitoring patients on thyroid hormone replacement. Thyroid peroxidase antibodies are also found in Graves disease, but are neither of diagnostic value nor useful in monitoring the response to treatment. They are non-pathogenetic, so their concentration does not change in relation to disease activity.

Patients with untreated Graves disease have antibodies to the thyroid stimulating hormone (TSH) receptor molecule, to which they bind, stimulating the gland and

causing hyperthyroidism. These antibodies are pathogenetic, but while the titre of antibodies correlates with thyroid gland hyperfunction, their measurement is not required routinely for diagnosis, nor is it used for monitoring treatment. The antibody is an IgG and capable of crossing the placenta and causing (transient) neonatal hyperthyroidism. A high maternal antibody titre in the third trimester indicates an increased risk of this condition. Less frequently, antibodies to the TSH receptor block the binding of TSH and cause hypothyroidism.

Pancreas. Type 1 diabetes is caused by progressive autoimmune destruction of pancreatic islet cells. Antibodies to islet cells and the enzyme glutamic acid decarboxylase can be found before clinical onset of disease and for a fairly short period early in its course, often disappearing later. There is considerable interest in how these antibodies participate in the immunological damage and whether the immune process may be susceptible to modulation. There is no clear indication for measuring these antibodies in most patients with diabetes, although they can sometimes be useful in patients with atypical clinical or laboratory findings. (More details can be found in Chapter 15.)

Adrenals. Approximately 60% of cases of Addison disease are due to autoimmune destruction of the adrenal cortex. Antibodies can be demonstrated to a number of adrenal cell components and these can show cross-reactivity to steroid-producing cells of the ovary, testis and placenta, potentially leading to gonadal failure.

Autoimmune polyendocrine syndromes (APS). These are a well-recognized group of conditions where two or more endocrine organs are affected. Table 30.24 shows how the conditions may be classified.

Autoimmune diseases of the gut. Pernicious anaemia (see Chapter 27) causes impaired absorption of dietary vitamin B₁₂. Patients develop a macrocytic anaemia and may develop neurological complications. Antibodies to gastric parietal cells and intrinsic factor are detectable in the majority of patients.

Coeliac disease is characterized by destruction of small intestinal villi, leading to malabsorption. It is triggered by an immunological response to the gliadin component of gluten (a protein in wheat and other cereals) but the endogenous antigen is endomysium, the tissue that surrounds the smooth muscle fibres of the gut. The initial response is T cell mediated but gradually antibodies (IgG and/or IgA) are made to gliadin, endomysium and tissue transglutaminase (the important antigen within the endomysium). Detection of antibodies is valuable in screening for the condition and may be sufficient for diagnosis in patients presenting with typical features (see Chapter 12, but the 'gold standard' diagnostic investigation is evidence of villous atrophy on jejunal biopsy. The UK National Institute for Health and Care Excellence (NICE) has issued a guideline on the diagnosis of coeliac disease (see: www.nice.org.uk/nicemedia/pdf/CG86FullGuideline.pdf).

TABLE 30.24 Classification of autoimmune polyendocrine syndromes

Type (syndrome)	Main clinical features	Underlying cause
Autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED) Schmidt	Candidiasis, adrenal failure, hypoparathyroidism	Mutations in the autoimmune regulator element (ARE) gene
Thyroid disease with other autoimmune disease but not Addison disease or hypoparathyroidism)	Adrenal failure, autoimmune thyroid disease, type I diabetes	Antibodies to steroid synthesis enzymes (e.g. 21 α -hydroxylase)
Undefined	Type I diabetes, pernicious anaemia, vitiligo, alopecia	Unknown
	Two or more organ specific autoimmune diseases that do not fall into categories 1–3	

Autoimmune liver diseases. The majority of cases of chronic hepatitis are due to viral infections (particularly with hepatitis B and C viruses) but approximately 20% of cases are autoimmune in origin. The distinction between autoimmune and infectious hepatitis is made mainly on the basis of the clinical features and the results of virological studies. It is important to identify the cause of chronic hepatitis, because interferon treatment (which is used for viral hepatitis) may worsen autoimmune liver disease and immune suppression (used for autoimmune liver disease) can worsen the viral disease. Unfortunately, patients with viral hepatitis sometimes make the very antibodies used in the investigation of autoimmune hepatitis.

Autoimmune hepatitis generally affects young females and is classified into types I and II. The typical age of presentation for type I is in the teenage years (~10–20 years of age), while the peak age of presentation

for type II is 7–8 years. Table 30.25 shows typical results of autoantibody measurements in autoimmune liver diseases. The antibodies are usually detected by indirect immunofluorescence. Considerable skill may be needed to interpret the immunofluorescence patterns and follow-up investigations, for example by ELISA, may sometimes be necessary. In general, high antibody titres are more closely associated with disease than low antibody titres. The hepatic autoantigens are often enzymes; for example, 2-oxoacid dehydrogenase is the specific antigen for the M2 subtype of mitochondrial antibodies that is the most specific for primary biliary cirrhosis.

Liver disease is not usually an indication for measurement of immunoglobulin concentrations, although abnormal immunoglobulin concentrations are common in liver disease, particularly when chronic. For example, patients with primary biliary cirrhosis usually have

TABLE 30.25 Investigations in liver disease, focusing particularly on the measurement of autoantibodies

Cause	Disease	Relevant finding
Infection	Hepatitis	Virus or antibody
Autoimmunity	Autoimmune hepatitis type I	Polyclonally raised IgG and IgA Smooth muscle antibodies Antinuclear antibodies Anti-soluble liver antigen Anti-liver kidney microsomal antibodies ^a
	Autoimmune hepatitis type II	Anti-liver kidney microsomal antibodies ^a Anti-liver cytosol antibodies Anti-soluble liver antigen Immunoglobulins (polyclonal raised IgG)
	Primary biliary cirrhosis	Antimitochondrial antibody ^b Immunoglobulins (predominantly polyclonal raised IgM)
Alcohol	Hepatitis and cirrhosis	Immunoglobulins (predominantly polyclonal raised serum IgA)
Drugs and toxins	Paracetamol, industrial toxins, e.g. carbon tetrachloride, polyvinyl chloride	
Genetic α_1 -antitrypsin deficiency	Prolonged jaundice in neonate	Total α_1 -antitrypsin and phenotype
Wilson disease	Varied but include fulminant hepatic failure, or cirrhosis	Urinary copper, serum copper and caeruloplasmin
Malignancy	Primary liver cancer and metastases (e.g. from bowel primary)	Tumour markers, e.g. α -fetoprotein, carcinoembryonic antigen
Obesity	Fatty liver disease	

^aLiver kidney microsomal antibodies occur only in a small number of patients with autoimmune hepatitis.

^bAntimitochondrial antibodies are virtually pathognomonic of primary biliary cirrhosis.

markedly raised polyclonal IgM concentrations; patients with alcoholic liver disease tend to have raised polyclonal IgA concentrations, and patients with persistent infections or inflammatory responses show raised polyclonal IgG and IgA concentrations. However, these patterns are non-specific and of negligible diagnostic value. Serial measurements of IgG may, however, be of value in monitoring patients with autoimmune chronic hepatitis.

Autoimmune skin diseases. The blistering skin diseases, pemphigus and pemphigoid, are caused by antibodies to components of the skin. These IgG antibodies bind to antigens in the skin, activate complement and disrupt the skin basement membrane (pemphigoid) or skin intercellular cement (pemphigus) causing intraepidermal blisters.

Autoimmune kidney diseases. Immunological damage due to the deposition on the glomerular basement membrane (GBM) of immune complexes (either to antigens of the GBM (as in Goodpasture syndrome) or formed in the circulation), is an important pathogenetic mechanism in renal disease. When the clinical features suggest a diagnosis of autoimmune kidney disease, evidence from renal biopsy often provides a definitive diagnosis. However, laboratory data can reduce the need for biopsy. The antibodies particularly implicated in autoimmune kidney disease are shown in Table 30.26. Laboratories should have protocols that have been agreed with the local renal physicians for investigating patients with renal disease, but detection of antinuclear antibody (ANA), antineutrophil cytoplasmic antibodies (ANCA) and GBM antibodies should ideally be available on an urgent basis (although, note that in immunological terms, this means results being available within 24 h of request). Patients with ANCA-associated vasculitis and GBM disease can also have pulmonary involvement (Goodpasture syndrome can manifest as haemoptysis). The vascularity of the lungs and kidneys makes them particular targets for vasculitic disease and the antibodies formed to either glomerular or alveolar basement membrane often show cross-reactivity with the other membrane. The concentrations of GBM antibodies and of antibodies to proteinase 3 (and myeloperoxidase) can be used to monitor patients' responses

to treatment and, in the vasculitides, to provide an early warning of exacerbations of disease.

Testing for renal autoantibodies is essential early in the investigation of unexplained renal impairment. Such patients should also have their serum and urine investigated for paraproteins (including Bence Jones proteinuria). The investigation of samples for cryoproteins is often forgotten but can be a vital test. The cryoproteins of relevance are not those that are seen with large monoclonal components that precipitate in the cold in vivo. Rather, they are high molecular weight immune complexes associated with infectious agents, for example hepatitis B and C viruses, which lodge in blood vessels, activating complement and causing vasculitis. This process can affect any organ, but the kidneys, with their large vascular network, are a particular target. This cryoprecipitation is a laboratory artefact, generated by storage of serum samples in the cold; the amount of precipitate can be very small, but careful isolation and investigation typically reveals monoclonal or polyclonal IgM showing rheumatoid factor activity.

Autoimmune articular diseases. These diseases are also referred to as connective tissue diseases. They are discussed in more detail in Chapter 32. There is considerable overlap between the clinical features seen in individual conditions. Autoantibodies are used as markers of the diseases; their presence contributes to, but does not establish, the diagnosis.

Rheumatoid arthritis (RA). Rheumatoid factor (RF) is an autoantibody (usually IgM) directed against the Fc portion of IgG. It is not specific for rheumatoid arthritis, also occurring in infections, malignancies, persistent inflammatory conditions and in up to 10% of healthy adults, with increasing frequency in elderly patients. A raised RF is one of the diagnostic criteria for RA but is not essential for the diagnosis. There is a correlation between higher RF concentrations and more severe disease and poorer long-term prognosis in RA; less severe disease is seen in seronegative patients. Rheumatoid factor is not of value in monitoring RA: measurement of C-reactive protein (CRP), reflecting the severity of inflammation, is superior. Changes in CRP precede both radiological and clinical changes.

TABLE 30.26 Antibody mediated renal disease

Disorder	Serological findings	Biopsy findings
Antiglomerular basement disease (Goodpasture syndrome)	Serum antibodies that react with normal basement membrane (GBM ^a)	Linear IgG, C3 along basement membrane
SLE nephritis	Antinuclear antibodies ^a (see text)	Granular IgG, IgM, C3, C4 along GBM
Vasculitis, e.g. Wegener granulomatosis	Anti-neutrophil cytoplasmic antibodies ^a (ANCA) Staining in the cytoplasm hence c-ANCA and is associated with antibodies to proteinase 3	Inflammatory – nothing specific
Microscopic polyarteritis	ANCA Staining in the perinuclear area hence p-ANCA and is associated with antibodies to myeloperoxidase	
Cryoglobulinaemia	Cryoglobulins (proteins that form a precipitate on cooling of serum)	IgG, IgM, C3 along capillary wall

^aThe indirect immunofluorescent staining patterns are shown in Figure 30.12.

FIGURE 30.12 ■ Indirect immunofluorescent patterns of: (A) homogenous and (B) speckled ANA; (C) pANCA and (D) cANCA and (E) anti-GBM antibodies.

The measurement of IgG antibodies to citrullinated peptides (anti-cyclic citrullinated peptide, CCP) is increasingly being used in investigation of patients with RA. It shows similar clinical specificity and sensitivity to RF but the presence of CCP antibodies can precede overt signs of RA. A combination of RF and

CCP antibodies is becoming important to stratify patients with RA and to direct treatment, e.g. use of anti TNF. The UK National Institute for Health and Care Excellence has issued a guideline on the management of RA in adults (see: <http://www.nice.org.uk/guidance/cg79>).

Other connective tissue diseases. The detection of antibodies to nuclear components is one of the most important laboratory tests in the investigation of patients with suspected systemic lupus erythematosus (SLE), Sjögren syndrome and scleroderma. The term ‘antinuclear antibodies’ is used to describe this diverse group of autoantibodies that react with nuclear and cytoplasmic antigens that are common to all nucleated cells. The antigens typically have functions in the cell cycle, or in transcription and translation.

Antinuclear antibodies. Antinuclear patterns are detected by indirect immunofluorescence using either frozen sections of animal tissue or cultured human cancer cell lines, most commonly the epithelial cell line HEp-2. This is usually a very sensitive test and specimens that test positive for antinuclear antibodies then need testing for one of the nuclear antigens by specific methods. These specific tests use purified or partially purified antigens. There is a move towards using combined specific tests instead of the subjective immunofluorescence assays, but these methods are not yet widely accepted as potential replacements.

The pattern of the immunofluorescence reaction gives some indication of the antigen specificity because of the different distribution of antigens within the nucleus and cytoplasm. Figure 30.13 shows a diagram of a nucleus with the distribution of the important antigens. The more frequently identified and clinically useful antibodies are listed in Table 30.27. Specificities other than those listed rarely have clinical significance, are usually present at low concentrations and can be found non-specifically in many infectious and inflammatory conditions.

Antibodies to double-stranded DNA. Antibodies to single-stranded (ss) DNA are frequently present in SLE but can also be demonstrated in many other inflammatory conditions and in infections. Antibodies to double-stranded (ds) DNA are one of the important diagnostic criteria in SLE. The most frequently used methods for the quantification of anti-dsDNA are ELISAs, but the immunofluorescence assay using *Critidia luciliae* is usually a more specific (although less sensitive) assay. High antibody concentrations to

dsDNA are associated with renal complications of SLE and quantification of dsDNA antibodies is useful (together with C3 and C4 concentrations) to monitor the disease and response to treatment.

Antibodies to extractable nuclear antigens. Numerous antibodies to various nuclear or cytoplasmic protein antigens (commonly termed the extractable nuclear antigens or ENAs) are detectable in connective tissue disorders (see Table 30.27). They may be of diagnostic value but, in contrast to antibodies to dsDNA, there is negligible value in using these tests for monitoring disease activity.

Antinuclear antibodies in pregnancy. Antinuclear antibodies are of the IgG class and can therefore be transported across the placenta to the fetus. Antibodies to dsDNA can cause a transient, self-limiting, neonatal lupus syndrome. Antibodies to the Ro antigen cross-react with the fetal heart tissue and can cause neonatal heart block.

Antiphospholipid antibodies. These are a group of antibodies that are associated with an increased tendency for thrombosis. The most clinically relevant are

antibodies to cardiolipin, β_2 -glycoprotein 1 and 'lupus anticoagulant'. They may occur in some patients with SLE but can also be found in patients with recurrent miscarriages, unexplained transient ischaemic attacks, strokes or thrombotic events.

LYMPHOID MALIGNANCIES

Lymphocytes go through a complex process from the start of their lives as naïve lymphocytes to end-differentiated, functional lymphocytes. The complexity of the process means that there are many opportunities for a cell to undergo a malignant transformation that may result in malignant disease. The classification of lymphoid malignancies is based upon the normal physiological pathways and the place in this pathway where the malignant transformation has occurred. The leukaemias are malignancies of cells whose mature forms are normally found in the blood, while the lymphomas are tumours of the non-recirculating lymphoid cells. The diagnosis and management of lymphoid malignancy is predominantly the remit of haematologists. Flow cytometric analysis of peripheral blood for panels of CD markers is important as are cytological examinations of either lymph node or bone marrow biopsies. The detection of the products of monoclonal B cells, monoclonal proteins, is, however, a vital test in the investigation of patients with suspected B cell malignancy (the category that includes myeloma). There are no specific biochemical investigations for the diagnosis and management of malignancies of the T cell lineage, and the subsequent discussion therefore focuses on malignancies of B cells.

B lymphocytes and monoclonal proteins

Early B lymphocytes, with their randomly rearranged B cell receptors (IgM), leave the bone marrow and traffic around the lymphoid tissue, searching for appropriate antigens. Once a lymphocyte meets an antigen, there is a process of maturation to secrete high-affinity antibody (after class switching) and to maintain a memory response. Plasma cells are end-differentiated B cells that reside in the bone marrow and secrete immunoglobulins. There is normally considerable microheterogeneity in the immunoglobulin molecules. This results in polyclonal immunoglobulins, representing all classes and light chain types, with a large number of different idiotypes produced by a large number of different B cell clones. A monoclonal immunoglobulin of a single heavy chain class, light chain type and idio type, results from the proliferation of a single clone of B cells. Monoclonal B cells, especially those that have undergone malignant transformation, do not necessarily produce normal, intact immunoglobulin: in approximately 20% of patients with myeloma, they produce only monoclonal free light chains (detectable in the urine as Bence Jones protein, BJP). Almost all variations on the normal immunoglobulin molecules are possible: monoclonal monomeric (7S), instead of the normal pentameric IgM, may be secreted, monoclonal fragments, for example free heavy chains,

half molecules and truncated molecules can all occur; so, too, can combinations of immunoglobulin fragments and intact monoclonal immunoglobulins. The class of immunoglobulin produced by the tumour can give a clue to the place in the B cell development where the malignant transformation occurred. For example, tumours of early B cells often secrete monoclonal IgM, while tumours of end-differentiated B cells tend to secrete IgG or IgA.

Monoclonal proteins or fragments appear as homogeneous, compact bands on electrophoretic separations. These bands should be called monoclonal proteins but are often called paraproteins, M components or M proteins. Monoclonal proteins detectable in serum are most often intact immunoglobulins; if there is renal damage these proteins can leak into the urine. Low molecular weight fragments and monoclonal free light chains (BJPs) can pass readily through normal glomeruli and appear in the urine in the absence of renal damage but may also be detectable in the serum.

Clinical significance of monoclonal proteins

The finding of a monoclonal protein in the serum and/or urine can be associated with both malignant and benign conditions, as indicated in [Table 30.28](#).

In malignant diseases, paraproteins are sensitive tumour markers (see below), but their presence in (apparently) non-malignant diseases limits their specificity. However, immunoglobulin fragments are rarely found in non-malignant monoclonal B cell expansions and their presence is thus highly suggestive of malignant B cell proliferation. The clinical features associated with paraproteinaemia can be due to the effects of the underlying tumour or to the properties of the monoclonal protein. Features related specifically to paraproteins are listed in [Table 30.29](#). Some paraproteins also show autoantibody activity, for example against other

TABLE 30.28 Conditions associated with the production of monoclonal proteins

Category	Condition
Malignant	Multiple myeloma, plasmacytoma, Waldenström macroglobulinaemia, lymphoma (of B cell origin), chronic lymphocytic leukaemia
Non-malignant (asymptomatic)	Benign Transient Monoclonal gammopathy of unknown significance (MGUS)
Non-malignant (symptomatic)	Amyloidosis Cryoglobulinaemia and immune complex disease Primary cold agglutinin disease

There are also dermatological and neurological diseases where the incidence of paraproteinaemia is greater than can be accounted for by coincidence. Amyloidosis with neurological and dermatological manifestations can occur as a complication of malignant diseases.

TABLE 30.29 Clinical manifestations of the physicochemical properties of paraproteins

Condition	% of patients with paraproteins	Main Ig classes
Hyperviscosity syndrome	8	IgG3, IgA and, particularly, IgM
Amyloid deposition	8	Bence Jones
Renal tubular obstruction	6	Bence Jones
Thromboembolism	5	IgG
Immune complex disease	4	IgM, IgG
Monoclonal cryoglobulinaemia	2	IgM, IgG
Fanconi syndrome	1	Bence Jones

immunoglobulins (e.g. rheumatoid factor) in immune complex disease and cryoglobulinaemia, against the I red cell antigen in primary cold agglutinin disease, and against myelin-associated glycoprotein in peripheral neuropathy.

Monoclonal proteins can also occur secondarily to infection and as part of immune reconstitution post-transplantation; in these situations, they are generally transient, disappearing over weeks or months. Monoclonal proteins may also be found in patients without any overt clinical signs of malignancy; this is particularly true in the elderly.

Prevalence of monoclonal proteins

The prevalence of monoclonal proteins is dependent on the population being considered. In symptomatic populations (e.g. hospital patients), paraproteins are predominantly associated with B cell malignancy, of which myeloma is the most common. In asymptomatic populations, the prevalence depends on the sensitivity of the electrophoresis used to detect the paraprotein and the characteristics of the group that is screened. The incidence of paraproteins rises with age; a survey of over 9000 apparently healthy individuals showed paraproteins in 0.1% of those aged 20–30 years, in 0.6% by age 60 years and in 6% of subjects aged 90–99 years.

Laboratory investigation of paraproteins

The detection, typing and quantification of monoclonal components in serum and urine are essential laboratory investigations in the diagnosis and monitoring of both malignant and non-malignant monoclonal B cell expansions. A serum paraprotein and/or urine BJP is a highly sensitive tumour marker for certain B cell malignancies, particularly myeloma (>95%) and Waldenström macroglobulinaemia (100%). In these conditions, the monoclonal component is indeed a diagnostic feature. However, they are not entirely specific for these conditions and can be found in other B cell malignancies and non-malignant diseases (see [Table 30.28](#)). It is important to note that the detection of a monoclonal protein does not necessarily

BOX 30.2 Findings that should prompt the investigation of serum and urine for a monoclonal immunoglobulin

Symptoms

- Backache (especially localized or with local tenderness)
- Lassitude
- Recurrent infection

Clinical syndromes

- Renal impairment
- Nephrotic syndrome
- Peripheral neuropathy
- Hyperviscosity syndrome
- Carpal tunnel syndrome
- Malabsorption

Radiological findings

- Osteolytic lesions
- Pathological fractures

Haematological findings

- Normochromic, normocytic anaemia
- Raised erythrocyte sedimentation rate (ESR)

Biochemical findings

- Raised serum total protein
- Raised serum globulin (total protein minus albumin)
- Proteinuria
- Abnormal results of renal function tests
- Subnormal immunoglobulin concentrations
- Hypercalcaemia

indicate that the patient has myeloma or, indeed, any malignant transformation of B cells, nor does the absence of a paraprotein completely exclude the presence of myeloma or B cell malignancy.

The presence of a monoclonal immunoglobulin may be suspected from the patient's clinical presentation or from results of other investigations. The findings that should, in the absence of another explanation, prompt investigation for paraproteinaemia, are shown in [Box 30.2](#).

Identification of paraproteins

The detection of monoclonal proteins is one of the two clear indications for the measurement of serum IgG, IgA and IgM concentrations and protein electrophoresis; these investigations should be done as a logical group of tests for optimum interpretation; this approach is in line with the consensus recommendations of the International Myeloma Workshop Consensus Panel (see [Further reading](#), below). Protein electrophoresis is the only reliable method for the detection of paraproteins in serum and urine. Abnormal bands (in the serum), once detected by electrophoresis, can be quantified by scanning densitometry or directly from the capillary zone electrophoresis trace. Immunofixation should be used to type the monoclonal band; this will confirm clonality and identify the heavy and light chains.

Automated capillary zone electrophoresis (CZE) systems are becoming the most common method for serum

protein electrophoresis, although agarose gel based methods are still in frequent use. Capillary zone electrophoresis techniques for urine protein electrophoresis are available but sample preparation is complex and the methods not sufficiently robust for routine practice. Serum proteins are separated by electrophoresis at pH 8.6; both agarose and CZE systems generate five major zones. Figure 30.14 shows the typical mobility of the major serum proteins. Agarose separations should be long enough (3–4 cm) to allow good separation of zones and show a good spread of the β - γ zone, which is achieved by properties of the agarose gel and buffer system that produce high endosmotic flow. The majority of serum paraproteins migrate in the β or γ zones, although they may be found anywhere on the electrophoretic separation between the α_1 zone and the post- γ region. Monoclonal heavy chains may show as diffuse zones running very anodally in the α_2 - β region of the electrophoretic separation; IgD paraproteins can also form a diffuse zone in the β - γ region. Representative examples of serum protein electrophoretic patterns are shown in Figure 30.14.

Paraproteins may be missed if they are present at low serum concentrations (<5.0 g/L), when their mobility coincides with other bands such as β -globulins, or where there is no suppression of normal background immunoglobulin concentrations. This is most often seen with low-concentration IgM or IgA paraproteins. Therefore, whenever there is a raised concentration of IgA or IgM with no clear increased staining in the β - γ region that would indicate a polyclonal increase, immunofixation should be done, as it should be also if there is a high clinical index of suspicion of B cell malignancy but an apparently normal electrophoresis. IgD paraproteins and free heavy chains are susceptible to post-synthetic degradation, which results in diffuse paraprotein bands on electrophoresis, and these may be missed if present at low concentrations or if the operator is expecting to see a narrow band rather than a diffuse zone. Precipitation of paraproteins on cooling of blood samples (monoclonal cryoglobulins) and subsequent removal with the clot, can also result in failure to detect a significant paraprotein. There are a number of proteins that can be mistaken for monoclonal proteins in electrophoresis separations.

FIGURE 30.14 ■ Representative serum electrophoresis patterns. Tracks 1 and 10 are dilutions of normal serum. Dots to the right of some of the tracks indicate bands that require immunofixation for further investigation.

These include:

- allotypic variants, e.g. of α_1 -antitrypsin, may result in two bands in a normally homogeneous region
- a haptoglobin–haemoglobin complex as a result of in vitro haemolysis, causing splitting of the normally homogeneous α_2 zone
- acute phase proteins, e.g. C-reactive protein, increases, which may result in additional bands being present
- fibrinogen in plasma or inadequately clotted samples, which results in an additional band in the fast γ region
- lipoproteins, which may give distinct bands in the β region in agarose systems
- haemoglobin, which migrates in the β region.

Urine should be examined in every patient in whom B cell malignancy is being considered. This is especially important if there is suppression of the serum immunoglobulins or if there is renal impairment, and it should be done even where no serum monoclonal component is detected. It is also important to monitor the amount of BJP during a patient's follow-up, even when BJP is not detected at presentation, because it can appear later in the course of the disease ('Bence Jones escape').

The presence of BJP provides strong evidence of malignancy, although it can occur in apparently benign conditions. The International Federation for Clinical Chemistry (IFCC) recommends a sensitivity for the detection of BJP of 10 mg/L: high-sensitivity electrophoresis of urine is therefore essential. This can be achieved by using very sensitive stains when electrophoresis is performed on unconcentrated urines, or by concentrating urines at least 100-fold. The concentration devices separate the water, ions and low molecular weight peptides from higher molecular weight constituents across a semipermeable membrane. The molecular exclusion of these membranes should be between 11.5 kDa and 13.0 kDa. Some concentration systems are static; others require centrifugation to achieve separation. Urine concentrates should then be analysed alongside serum in the agarose systems. Ideally, a trace of albumin should be visible in every urine sample; failure to detect any albumin on the electrophoretic separation should prompt further concentration and re-analysis. The renal damage associated with Bence Jones proteinuria often results in complex patterns; immunofixation improves both specificity and sensitivity, so is very useful to help resolve these patterns. Representative examples of urine protein electrophoretic patterns are shown in Figure 30.15. Low concentrations of BJP can be seen with a significant glomerular proteinuria in patients with light chain renal amyloidosis. Any urine with a marked glomerular proteinuria should be investigated by immunofixation, even in the absence of a band suggestive of BJP.

Several proteins can be mistaken for monoclonal protein in urine electrophoresis separations, particularly where there is an element of tubular proteinuria. They include the following:

- α_1 -microglobulins
- lysozyme (migrating in the slow γ region)
- degraded fragments of protein of glomerular origin

FIGURE 30.15 ■ Representative urine electrophoresis patterns. Tracks 1 and 10 are dilutions of normal *serum*; all urine samples contain a trace of albumin. Significant bands that require immunofixation for further investigation are indicated by dots to the right of the respective tracks.

- seminal fluid proteins (very rare)
- β_2 -microglobulin (can produce a prominent band when present in high concentrations).

Measurement of serum free light chains is now routinely available. A combination of serum protein electrophoresis and free light chain measurement has been suggested as a suitable screening protocol for B cell malignancy. This approach is now being used in some laboratories and is further discussed on p. 596.

Typing of monoclonal immunoglobulins in serum and urine

Immunofixation. Once a paraprotein band has been detected, it is important to identify the heavy and light chain components. The major indications for immunofixation are to:

- confirm clonality of a band detected by electrophoresis
- test for α , γ or μ heavy chains and κ and λ light chains (routinely)
- test for δ and ϵ heavy chains when a serum shows monoclonal light chains without a corresponding α , γ or μ heavy chain
- exclude monoclonal components being present at low concentrations, even where no band is apparent

on electrophoresis but when there are appropriate clinical indications, e.g. amyloid

- exclude the presence of monoclonal IGA or IGM if there are raised concentrations without β - γ fusion (the appearance when these bands lose their separate identities)
- investigate the possibility of an apparent paraprotein in serum or urine being caused by a high concentration of another protein (e.g. fibrinogen, complement components, β_2 -microglobulin) (using antisera specific to these proteins)
- detect minimal residual disease or complete remission following haematopoietic stem cell transplantation for myeloma when no monoclonal component is seen on the electrophoretic separation.

When monoclonality has been confirmed, determination of the paraprotein type may provide useful additional information about the underlying tumour and prognosis. The distribution of heavy chain classes in B cell dyscrasias is shown in Table 30.30. The light chain distribution of the common paraproteins is similar to that of normal polyclonal immunoglobulins, with a predominance of κ over γ (about 2:1). IgD paraproteins are usually of γ light chain type, although κ may be found, and the few IgE paraproteins that have been reported have all been of κ light chain type.

The electrophoresis pattern may change during the course of a patient's disease or treatment. For example, some patients may start producing BJP after having not done so at the time of diagnosis. Complete disappearance of a paraprotein is rare but is occurring increasingly with treatment regimens using high-dose chemotherapy and bone marrow transplantation. An oligoclonal banding pattern is often seen in patients after stem cell transplantation and it is important to distinguish this from the original paraproteinaemia.

Immunofixation enhances the sensitivity of gel electrophoresis both by removing background staining and selectively increasing the amount of protein (by adding antibodies) in the band of interest. Representative examples of serum and urine immunofixation patterns are shown in Figures 30.16 and 30.17, respectively. The choice of antisera is paramount: problems with this technique are often related to the use of poor antisera. This is

TABLE 30.30 Paraprotein types in B cell dyscrasias

Monoclonal type	All paraproteins (%)	Myeloma (%) ^a	Waldenström macroglobulinaemia (%)	Other B cell diseases (%) (NHL/CLL ^b)	MGUS (%)
IgG	53	53 ^c (40)	–	40	60
IgA	22	22 ^c (22)	–	10	35
IgM	11.4	0.5 (19)	100 ^e	50	5
IgD	1.3	1.51 ^{c,d} (14)	–	–	–
IgE	<0.001 ^e	0.1 (30)	–	–	–
BJP only	11.6	21 (5.4g/24h)	–	–	(+)
Biclonal	1.5 ^f	Unknown	–	–	–
Non-secretory	–	1	–	–	–

^aValues in brackets = typical serum concentrations in g/L (except BJP); ^bNHL, non-Hodgkin lymphoma; CLL, chronic lymphatic leukaemia; both are tumours of B cell origin. ^cCan also show Bence Jones protein; ^dusually γ light chain; ^eusually κ light chain; ^fdoes not include intact monoclonal Ig with BJP or multiple bands of the same paraprotein type.

FIGURE 30.16 ■ Representative immunofixation of a serum sample containing an IgGλ paraprotein.

FIGURE 30.17 ■ Representative immunofixation of a urine specimen containing a λ Bence Jones protein.

especially true for the antisera to free κ and λ light chains. Such antisera are available but often react poorly. The antisera most widely used for immunofixation react with both free and bound immunoglobulin heavy and light chains. The presence of free light chains can be inferred if no heavy chain reaction is present. Immunofixation is not a quantitative method; antisera often show greater binding to free than to bound light chains.

A major problem with immunofixation of urine is distinguishing between monoclonal light chains and light chain fragments generated from normal immunoglobulin catabolism, which result in a 'ladder-like' pattern, particularly in the immunofixation reaction with antiserum to κ light chains. This 'κ banding' pattern is most often seen in elderly patients with inflammatory conditions. Examples of BJP and κ banding are shown in Figures 30.17 and 30.18.

Immunofixation techniques are not applicable in automated CZE systems; therefore, the technique of immunosubtraction has been developed for these systems. Immunosubtraction techniques work well for large monoclonal proteins but can lack sensitivity for small paraproteins and are inflexible; for example no reagents are available for typing IgD or IgE paraproteins or other non-immunoglobulin proteins.

In rare circumstances, the presence of free heavy chains may need to be confirmed. This is done by an adaptation

FIGURE 30.18 ■ Representative immunofixation of a urine specimen showing κ banding (lane 5) (immunofixation will vary between manufacturers, in particular, the extent of separation).

of gel electrophoresis called immunoselection, or by molecular weight and immunoblotting methods that are best referred to expert laboratories.

Quantitation of monoclonal components

The concentration of a monoclonal component does not, in general, predict tumour mass. However, in individual patients, concentration does reflect tumour mass and is therefore an essential component in both the initial investigation and the assessment of the response to treatment of patients with B cell malignancies. Table 30.30 shows the average paraprotein concentration at presentation with myeloma with respect to the paraprotein type.

The only reliable method of paraprotein quantitation is to measure the percentage of the monoclonal protein (by scanning densitometry or from CZE read-out), with respect to the total electrophoretic separation or to the globulin fraction. The stains used in protein electrophoresis show differential dye binding between albumin and globulin; the more precise estimation of paraprotein is therefore derived from the percentage of relative dye binding of the paraprotein band compared with the total globulin fraction rather than the total protein. The CZE measuring system uses a UV detector system that overcomes the differential dye binding and also limits problems of non-linear dye binding at high paraprotein concentrations. Serum total protein is most often measured by biuret-based methods. A useful check is to take the sum of the paraprotein and albumin concentrations and add 10–15 g/L (to account for the other serum proteins): the result should be approximately equal to the measured serum total protein.

It is possible to quantitate reliably a serum paraprotein down to a concentration of 1 g/L, provided there is suppression of the background immunoglobulins. Monoclonal proteins with electrophoretic mobility in the β region can be difficult to measure. However, the concentration of the β-globulins is relatively constant. Therefore, when a paraprotein band migrates with β-globulins, the total band can be measured: significant changes in that concentration are likely to be due to changes only in the concentration of the monoclonal

component. When it is possible to delineate a monoclonal peak for the purposes of measurement, densitometric quantitation should be reported; however, once the concentration has fallen to an extent that the peak cannot be clearly seen, immunochemical quantitation should be used. The concentration of monoclonal components can reach values in excess of 140 g/L, although this is rare. In this situation, falsely low concentrations can be seen because the paraprotein concentration has exceeded the capacity of the detection system; the monoclonal peak on the CZE tracing may appear with a flat or split top. The frequency of monitoring the concentration of monoclonal proteins will depend upon a patient's clinical condition and treatment regimen. Cumulative reporting of paraprotein studies is invaluable in monitoring patients with myeloma and other paraproteinaemias.

Quantitation of BJP in urine is generally more difficult than quantitation of monoclonal proteins in serum. Urine volume can be very variable, being influenced by factors such as fluid intake, renal function, state of hydration and time of day. Quantitation of BJP should start with the densitometric scan of the stained electrophoretic separation in a similar way to that used for serum paraproteins. The band can be expressed as a percentage of the total protein, but this can give misleading information, especially if the general background proteinuria is increased, making the percentage of BJP relatively lower. This percentage BJP can be used with the urine albumin or creatinine concentration to give the quantity of BJP expressed per gram of albumin or millimole of creatinine. It can also be used with the total protein concentration to generate a concentration in g/L and this result can be used with the 24h urine volume to generate a 24h excretion. There are both practical and analytical issues, with no one method being ideal for all situations. Most importantly, a consistent approach should be adopted so that it is reliable to compare results on the same patient during the course of the disease.

Cryoproteins

Cryoproteins are proteins that aggregate on cooling of the serum or plasma and usually redissolve on warming to 37 °C; immunoglobulins and fibrinogen can all show this property.

Cryofibrinogen is an unusual finding resulting from misdirected synthesis or by post-synthetic modifications of fibrinogen. It can also be (artefactually) induced by heparin; thus collection into EDTA, citrate or oxalate is essential. Cryofibrinogen will only be visible in plasma samples while cryoprecipitating immunoglobulin should be visible in both serum and plasma stored at 4 °C. Cryofibrinogenaemia typically produces skin lesions or thrombophlebitis migrans and patients are managed by dermatologists or haematologists.

Cryoprecipitating immunoglobulins are classified into types I, II and III, based on whether they are mono- or polyclonal, their approximate concentrations and other properties; details of this classification are shown in [Box 30.3](#). Individual cryoproteins show particular

BOX 30.3 Classification and characteristics of cryoproteins

Type I cryoglobulins

- Monoclonal immunoglobulin, often present at high concentrations (>30 g/L)
- Account for ~25% of all cryoproteins
- Occur predominantly with IgM paraproteins (6% of all macroglobulinaemia)
- Especially associated with lymphoma
- Can be seen with monoclonal IgG (particularly of the IgG3 subclass)
- Only occasionally with monoclonal IgA
- Significant cryoprecipitation can occur with low concentrations (~5 g/L)
- Cryoprecipitation occurs most readily in the microvasculature of the colder peripheries (fingers, toes, earlobes, nose); rapid precipitation (24h incubation is usually adequate for their detection)

Type II cryoglobulins

- Monoclonal component (usually IgMκ), usually present at low concentrations (<5 g/L) showing rheumatoid factor activity with polyclonal IgG
- Most often associated with viral hepatitis (hepatitis B and C); can occur with other infections, e.g. mycoplasma pneumonia; can be seen in autoimmune diseases and in lymphoproliferative diseases
- Precipitate slowly (need 72 h incubation)

Type III cryoglobulins

- Polyclonal rheumatoid factor (IgM) and polyclonal IgG or IgA; most often in association with autoimmune rheumatic diseases and persistent infections and only occasionally with lymphoproliferative diseases
- Precipitate slowly (need 72 h incubation)

Cryofibrinogen

- Fibrinogen that precipitates in the cold – collect into EDTA, citrate or oxalate

thermal profile characteristics that influence their clinical significance. Monoclonal proteins that precipitate at temperatures close to 4 °C may not cause any significant problems, but those that precipitate close to room temperature frequently precipitate in the plasma in vivo and are more likely to become clinically manifest, irrespective of relative concentrations.

The clinical features associated with types II and III cryoproteins are linked more to their ability to deposit in tissue as immune complexes rather than to their tendency to precipitate in the cold. Types II and III cryoproteins are both associated with neuropathy, vasculitis and nephropathy.

Immune complex or cryoprotein deposition in tissues is likely to cause activation of the classical complement cascade. Low concentrations of complement (particularly C4) are a good marker of active immune complex disease; measurement of these components is an important part of the investigation of possible cryoproteinaemia. Careful specimen collection and handling are vital. Both serum and plasma samples should be collected, transported and

separated at 37°C. Failure to do this may result in significant cryoproteins being lost in the blood clot during centrifugation.

β_2 -Microglobulin

In conditions in which there is increased cell turnover, for example malignancy (particularly lymphoid), acquired immune deficiency syndromes and inflammatory conditions, plasma β_2 -microglobulin concentrations increase. This protein is cleared from the plasma by glomerular filtration followed by proximal tubular reabsorption and catabolism; plasma concentrations therefore reflect cell turnover and renal function. They have been shown to be an important prognostic indicator in myeloma.

α -Interferon, used in maintenance treatment of some β -Cell malignancies, induces marked increases in plasma β_2 -microglobulin concentrations, and this should be taken into consideration when using β_2 -microglobulin for the assessment of tumour response during α -interferon therapy.

B cell malignancies

Myeloma

Plasma cell disorders have been classified into monoclonal gammopathy of unknown significance (MGUS), smouldering (asymptomatic) multiple myeloma and symptomatic multiple myeloma, based on the presence and concentration of a monoclonal protein, number and morphology of bone marrow plasma cells and end organ damage (hypercalcaemia, renal insufficiency, anaemia, bone lesions attributable to the plasma cell proliferation disorder). Myeloma is the commonest of the malignant causes of paraproteinaemia. The most frequent presenting features are bone pain (in 70% of patients), hypercalcaemia (30%), fever (15%), renal failure (10%) and infection (10%). It is predominantly a disease of the elderly, with a peak incidence between 75 and 80 years.

The three major diagnostic features are the identification of a monoclonal protein in serum or urine, the presence of neoplastic cells in the bone marrow and the destruction of bone. The significance of these and other laboratory investigations is shown in Table 30.31.

As indicated in Table 30.30, IgG, IgA and BJP account for the majority of paraproteins in myeloma. IgD paraproteins occur occasionally, usually with λ light chains. IgM paraproteins are rare in myeloma; IgE paraproteins are extremely rare in any B cell malignancy. The paraprotein concentration at presentation does not predict survival; patients with Bence Jones and IgD paraproteins often present when the paraproteins are present only at relatively low concentrations (they also tend to present at an earlier age) but have shorter survivals than myeloma patients with IgG or IgA paraproteins, even though the concentrations at presentation are often higher in the latter. Bence Jones protein (with or without intact monoclonal immunoglobulin) is seen in over 80% of patients with myeloma; it is rarely found in benign conditions.

The natural history of myeloma is generally one of progression. No treatment can be regarded as curative,

TABLE 30.31 Investigations in myeloma

Investigation	Typical results and their significance
Diagnosis (two of these three are required for a diagnosis of myeloma)	
Serum and urine for presence of paraprotein	Narrow band on electrophoresis shown to be monoclonal by immunofixation
Bone marrow biopsy	Abnormal number and morphology of plasma cells
Skeletal X-ray survey	Lytic lesions (punched out appearance)
Management and prognosis	
Serum calcium	Hypercalcaemia (with normal alkaline phosphatase), due to bone destruction
Serum creatinine and urea	Raised concentrations in renal impairment; ^a the presence of renal impairment is associated with a poor prognosis
Serum albumin	Low concentrations associated with high tumour burden and poor renal function
Full blood count and film	Anaemia, rouleaux formation (due to hyperviscosity), increased background staining (due to paraprotein)
Erythrocyte sedimentation rate (ESR)	High
Non-paraprotein immunoglobulins in serum	Low concentrations due to immune suppression that may predispose to infection
Serum β_2 -microglobulin	High concentrations are associated with high tumour burden and turnover and/or renal impairment and a poor prognosis
Serum paraprotein concentration	In individual patients, correlates with tumour mass so used to monitor response to treatment
Serum free light chains	Particularly useful in non-secretory myeloma and amyloid

^aCauses of renal impairment include deposition of immunoglobulins in the glomeruli, precipitation of light chains causing tubular obstruction, amyloid and hypercalcaemia.

although significant remission may be obtained with newer treatments regimens that may include chemotherapy, steroids, autologous stem cell transplant, bisphosphonates and the newer biologics, lenalidomide, bortezomib and thalidomide. Hypercalcaemia can be a particular problem and cause severe dehydration and/or exacerbate renal failure; it is treated with rehydration and bisphosphonates. Monoclonal protein concentrations that exceed 30 g/L can cause hyperviscosity: this is seen particularly with IgA and IgG3 paraprotein which have a tendency to aggregate. The effects of hyperviscosity can be ameliorated by plasmapheresis. Spinal cord compression requires urgent treatment with dexamethasone, followed by radiotherapy; the latter can also be helpful when localized bone pain is a problem. Infections (often associated with secondary immune deficiency) must be treated promptly. The anaemia may respond to erythropoietin.

Solitary plasmacytoma

In addition to the disseminated form in multiple myeloma, plasma cell tumours may occur as apparently solitary lesions in either bone or soft tissue. Paraprotein concentrations may be very low and intensive urine concentration ($\times 300$) may be necessary to reveal small traces of BJP. Immunofixation of serum, even in the absence of a visible band on electrophoresis, is also worthwhile as the high sensitivity of this technique may reveal a low concentration of paraprotein, which then acts as a valuable marker. Localized treatment by surgery or radiotherapy will frequently result in disappearance of the paraprotein. Patients should be followed up at three-monthly intervals for the first year, six-monthly for the second year and then annually, as there is always a risk that progression to disseminated disease will occur and this may take as long as 20 years from detection of the solitary tumour. Extramedullary deposits may also occur in myeloma, particularly with IgD and Bence Jones type.

Waldenström macroglobulinaemia

IgM myeloma is very rare; IgM paraproteins are more often seen with a heterogeneous group of lymphoproliferative diseases of the B cell lineage such as Waldenström macroglobulinaemia (WM), lymphoma and chronic lymphocytic leukaemia. Waldenström macroglobulinaemia is characterized by the presence of an IgM paraprotein and pleiotropic lymphoid proliferation in the bone marrow. It is generally a disease of elderly men. The presenting symptoms and laboratory investigations in WM are shown in Table 30.32. The malignant cells proliferate

only slowly and are relatively non-invasive; it tends to be the high paraprotein concentration and its effects that account for the presenting features. Hyperviscosity (responsible for the headaches and visual disturbance) is associated with paraprotein concentrations over 30 g/L. Bence Jones protein does occur in WM patients but tends to be at lower concentrations and less damaging than in myeloma.

Lymphomas, chronic lymphocytic leukaemia and heavy chain diseases

A paraprotein (most often IgM) is found in 10–20% of patients with non-Hodgkin lymphoma (NHL) and 5–15% of patients with chronic lymphocytic leukaemia (CLL). These tumours arise from cells early in the B cell maturation and the monoclonal protein concentration is usually low. The tumours are diagnosed by biopsy and histological examination of lymphoid tissue and by immunophenotyping of blood and lymph node biopsy material.

Certain B-lymphoproliferative disorders are associated with synthesis of heavy chains or heavy chain fragments in the absence of light chain synthesis; most often the fragments consist of heavy chains with deletion of the variable and first constant region domain. Free heavy chains are more susceptible to enzymatic degradation than intact immunoglobulin; they undergo considerable post-synthetic modification and migrate in electrophoretic separations as rather diffuse zones, anywhere between the α_1 and fast γ zone. Low concentrations of the heavy chain paraprotein may be missed on examination of the electrophoretic separation. The presence of heavy chains can be indicated by immunofixation when reaction with heavy chain, but not light chain, antiserum is seen. Identity is confirmed by an immunoselection technique whereby the serum is electrophoresed through an agarose gel layer containing antiserum to light chains where any complete immunoglobulin will be trapped; free heavy chains pass through the light chain 'trapping' layer then move into a second layer containing antiserum to the appropriate heavy chain (α , γ or μ) and precipitate as they travel through this layer to form a 'rocket'. The rocket is usually directly visible but can be stained with protein stains if necessary. It is essential that a positive heavy chain sample and a myeloma protein of the same class are included as controls in the heavy chain immunoselection technique. Bence Jones protein is unusual in α - and γ -chain diseases and is more often seen with μ -chain disease. Immunosuppression of non-paraprotein immunoglobulin is frequent in the heavy chain diseases.

α -Chain disease represents the most distinct clinical entity among the heavy chain diseases. The disease is a lymphoma, usually of the gut, and is alternatively known as Mediterranean type lymphoma. It is interesting in that the initial diffuse infiltration appears benign and complete remission can be achieved in some patients with oral antibiotics. However, untreated, the condition progresses to frank malignancy. The diagnosis depends on the finding of α -chains in the serum. Gut biopsies show villus

TABLE 30.32 Clinical features and results of investigations in Waldenström macroglobulinaemia

Clinical feature	% of patients
Weakness and fatigue	41
Hepatosplenomegaly	40
Lymphadenopathy	36
Bleeding tendency	31
Weight loss	18
Neurological	12
Visual disturbances	10
Infection	8
Bone pain and arthralgia	4
Raynaud phenomenon	3
Investigation	Typical results
Serum and urine for presence of paraprotein	Narrow band on electrophoresis shown to be monoclonal on immunofixation
Bone marrow biopsy	Increased number of lymphocytoid cells
Plasma viscosity	Increased
Lymph node biopsy	Well preserved architecture with lymphocytoid infiltrate
Haematology investigations	Anaemia, clotting disorders, rouleaux formation, high ESR

atrophy and plasma cell infiltration of the lamina propria. Clinical features include a malabsorption syndrome and diarrhoea.

γ -Chain disease is not characterized as a distinct clinical entity but has a varied clinical and pathological picture ranging from apparently non-malignant proliferation, for example systemic lupus erythematosus, to aggressive lymphoma. An association with autoimmune diseases has been recorded in about 25% of published cases, most frequently with rheumatoid arthritis and autoimmune haemolytic anaemia and, in a few cases, malignant NHL that was not diagnosed until many years after the autoimmune disorder.

μ -Chain disease is extremely rare and most often a variant of CLL.

Monoclonal gammopathy of unknown significance (MGUS)

A clearer definition of MGUS is gradually emerging as a serum monoclonal protein present at a concentration <30 g/L, clonal bone marrow plasma cells $<10\%$ and no end-organ damage (e.g. hypercalcaemia, renal insufficiency, anaemia or bone lesions). Nevertheless, the finding of a paraprotein without any symptoms poses a problem, and a relatively frequent one, given that sensitive electrophoretic techniques are so readily available and there are few constraints on requesting such investigations. Benign disease can be indistinguishable from malignant disease early in its course. No single feature can help differentiate these two entities, but monoclonal protein concentration, the presence and degree of any immune suppression and the presence of BJP can give some guide. Thus, in general, benign disease is seen with serum paraprotein concentrations below <10 g/L (not applicable for IgD or BJP only): higher concentrations, and particularly values >30 g/L, suggest malignancy. Non-paraprotein immunoglobulins are suppressed in 75% of myeloma patients at presentation. The presence or absence of BJP is the most important distinguishing feature; myeloma should be considered in any patient with BJP in the urine at a concentration of >10 mg/L. The International Myeloma Working Group suggests that the measurement of serum free light chains can help to stratify patients with MGUS. The risk of progression of MGUS to an overt malignancy has a cumulative probability of 10% at 10 years (approximately 1% per year). The follow-up time in patients with MGUS should be determined by the clinical findings and the patient's age. A general guide would be to examine the paraprotein in serum and urine at three-monthly intervals for the first year, six-monthly for the second year and, if no progression occurs, annually thereafter. If any other features of B cell malignancy occur, full investigation is required.

Transient paraproteinaemia

Transient paraproteins are usually small IgG or IgM bands (~ 1 – 2 g/L); however, they may be >10 g/L. They typically occur during infections, often in patients with compromised immune systems, for example patients with CLL or with iatrogenic immune suppression for

organ transplantation. Transient paraproteins may persist for over one year but most disappear within a few months.

Serum free light chains (SFLC)

Methods for the quantification of serum free light chains are now widely available, with more manufacturers producing reagents. The assays use antibodies directed against the 'hidden' epitopes of free light chain molecules at the interface between the light and heavy chains of intact immunoglobulins. The general concerns about the immunochemical quantification of a monoclonal protein are as applicable to SFLC as they are to the quantification of intact monoclonal IgG, IgA or IgM. However, there are additional concerns about the FLC assays with respect to their linearity, performance in external quality assurance schemes, reproducibility between laboratories and quantification of the proteins. Nevertheless, there is clear value to these measurements in patients with light chain amyloidosis and in non-secretory myeloma where the serum monoclonal protein may be undetectable by other methods. They are being used as 'stringent' criteria for remission in some trials investigating new treatment regimes in myeloma. There are also publications promoting their use to stratify risk in myeloma, other B cell dyscrasias and MGUS.

Amyloidosis

Amyloidosis is a heterogeneous group of clinical conditions characterized by the systemic or localized deposition of fibrils derived from a variety of protein precursors and having characteristic histological appearance. It can be systemic or localized, and both types can be acquired or hereditary (Table 30.33). This table also indicates the nature of the deposit and precursor proteins, where known. In addition to the precursor proteins, amyloid deposits can contain sulphated glycosaminoglycans and serum amyloid P component, which is a normal circulating protein in human plasma.

The tendency for monoclonal immunoglobulin to form amyloid fibrils (AL) can occur as a secondary complication of B cell malignancies. Amyloidosis occurs in 6–15% of patients with myeloma and is more common when the major paraprotein is free light chains. When amyloid fibrils are found in the absence of myeloma (previously classified as primary idiopathic amyloidosis), 90% of patients have a demonstrable serum paraprotein or Bence Jones proteinuria, albeit often at low concentrations; in addition, there is frequently a degree of hypogammaglobulinaemia and a slight increase in plasma cells in the bone marrow. Progressive amyloid deposition is the most serious clinical complication in these patients as they do not tend to progress to overt malignancy.

The clinical features of peripheral neuropathy, cardiomyopathy, purpura, macroglossia and carpal tunnel syndrome are similar in both the malignant and benign conditions and both have similar age distribution (mean 55–62 years), with males more frequently affected than females.

TABLE 30.33 Amyloidosis

	Disease/association	Fibril	Precursor	
Systemic	Acquired	Paraproteinaemia	Monoclonal Ig light chain	
		Chronic inflammation/infection	SAA	
		Haemodialysis	Raised plasma β_2 M	
		Senile type	Plasma PA	
	Hereditary	Neuropathic		
		Type I (Portuguese, Japanese, Swedish, Jewish)	PA	Plasma PA
		Type II (Swiss, German, Indiana-Maryland)	PA	Plasma PA
		Type III + nephropathy (Irish, Scottish, English, Iowa)	Apolipoprotein A1	
		Type IV (Finnish)	?	
		Nephropathic		
Familial Mediterranean fever	AA	SAA		
Others (Ostertag, Muckle–Wells)	?			
Cardiomyopathic	PA	Plasma PA		
Localized	Acquired	Cerebral (Alzheimer, senile dementia, Down syndrome)	Precursor encoded on chromosome 21	
		Endocrine (APUDomas)	Calcitonin	
		Nodular deposits		
		Primary cutaneous		
	Hereditary	Ocular deposits	AL	Monoclonal Ig light chains
		Cerebral	?	? Keratin
		Icelandic type	?	
		Dutch type	Cystatin C	Cystatin C
			B-protein	Precursor encoded on chromosome 21
		Cutaneous	?	

APUD, amine precursor uptake and decarboxylation; ASc₁, an amyloid protein derived from prealbumin; β_2 M, β_2 -microglobulin; PA, prealbumin; SAA, serum amyloid A protein.

While the detection of a serum or urine paraprotein is an important finding in AL amyloidosis, the diagnosis depends on demonstration of amyloid fibrils in biopsy material. Tissue, usually rectal mucosa or abdominal fat, is stained with Congo red: the presence of characteristic apple green birefringence under polarized light is diagnostic. The National Amyloidosis Centre can localize amyloid deposits using gamma camera photographs after injection of radiolabelled serum amyloid P material. Increasingly, serum free light chain measurements are used to monitor patients but other biochemical markers (e.g. the cardiac biomarkers troponin-T (cTnT) and N-terminal pro-B-type natriuretic peptide (NT-proBNP) in cardiac amyloid) are equally important.

INFECTION AND SEPSIS

All bacteria are recognized as foreign and cause inflammation on entry into tissues. This is achieved by various mechanisms, many of which are innate. In addition, many components of bacteria are able to stimulate inflammatory or immune responses, and some of these are shown in Table 30.34.

Infection with a small bacterial load, particularly if confined to a local site, will cause cytokine production, a controlled inflammatory response and recruitment of immune cells. The outcome will be the resolution of the infection, the repair of any damage to surrounding tissue and wound healing. If the bacterial load is

TABLE 30.34 Proinflammatory bacterial components and their modes of action

Component	Mode of action
Carbohydrates in cell walls (O-antigen of lipopolysaccharide (LPS))	Activation of complement via alternative pathway
Endotoxin (Gram-ve organisms)	Engage macrophage receptors (CD14) to induce inflammatory cytokine production (mainly IL-1, IL-6 and TNF α)
Peptidoglycan (Gram +ve organisms)	Activate T cells, production of immune cytokines
Superantigens, e.g. enterotoxin of <i>Staphylococcus aureus</i>	
Exotoxins, e.g. anthrax lethal toxin	Enzymic properties induce cytokines via various mechanisms

greater, the bacteria and/or the cytokine response may not be confined and may extend to produce a generalized systemic response. If this is unabated, it will eventually lead to septic shock, the condition in which vital tissues are inadequately perfused with blood, with progressive deterioration of circulation and falling blood pressure leading inevitably to death if untreated. Because the inflammation progresses through cascades of host-mediated reactions, once the inflammatory

response has been initiated, stopping it becomes increasingly difficult – even removal of the bacteria may not affect the outcome.

Diagnosis and monitoring of infections

The diagnosis of infection is based on clinical findings, but microbiological investigation is often required to identify the organism responsible and information about antibiotic resistance may help guide treatment. However, there are situations when the clinical signs of infection may be masked, for example in patients who are immunosuppressed. In these situations, markers of acute phase response and, in particular, measurement of C-reactive protein (CRP) concentrations may be useful to give an independent marker of the presence of infection or inflammation and to monitor the response to treatment.

C-reactive protein and markers of the acute phase response

Measurement of the erythrocyte sedimentation rate (ESR) is one of the oldest ways of detecting the acute phase response. It is still frequently requested but has important limitations, including its slow response and insensitivity to small changes in disease activity. Plasma viscosity measurements have also been used to monitor the acute phase response but suffer from the same limitations as the ESR.

C-reactive protein is produced by the liver on stimulation with the inflammatory cytokines IL-6, IL-1 and TNF α . There is a rapid increase in CRP concentrations, with changes detectable as quickly as 6 h after the inflammatory insult, with a half-life of 19 h. C-reactive protein is the most widely measured acute phase protein, with raised concentrations occurring in both bacterial infections and inflammation. A raised CRP concentration is unequivocal evidence of an inflammatory response. However, viral infections do not usually cause a raised CRP and neither do some autoimmune diseases, for example SLE and scleroderma. Minimal inflammation causes a significant increase in CRP concentration but most analytical methods lack the sensitivity to detect this. There are also marked variations in quoted reference ranges, for example, <0.1 mg/L, <1 mg/L and <10 mg/L. The concentration of CRP is related to the extent and severity of inflammation, with concentrations of 10–40 mg/L occurring in mild inflammation, 40–200 mg/L in acute inflammation and bacterial infections, and >300 mg/L in extensive trauma and severe sepsis. In patients with bacterial infections, daily measurement of CRP may be useful to monitor response to treatment. Appropriate antibiotic therapy should result in the CRP falling by approximately 50% every 24 h. If the fall in CRP is slower than this, it suggests that the antibiotic regimen may not be appropriate. Patients with severe systemic inflammatory responses, for example the critically ill, often have infection on top of a marked inflammatory response, and in these situations, a fall in CRP of >20% in 24 h is consistent with successful treatment of the infection,

TABLE 30.35 Clinical applications of C-reactive protein measurements

Disease category	
? Unwell	Raised CRP concentration is unequivocal evidence of inflammation. Normal CRP concentration does not exclude significant inflammation
Bacterial infection	Major elevations normally seen in bacterial infections Useful to monitor response to antibiotic treatment
Viral infections	Only minor elevations seen – unless complicated by secondary bacterial infection
Fungal infections	Only minor elevations with localized infections; marked elevations when systemic
Transplantation	Raised concentrations reported during organ rejection episodes – but also in infection Raised concentrations help to distinguish bacterial infections from graft-versus-host disease (GVHD) in bone marrow
Chronic inflammatory states	Raised concentrations in many inflammatory conditions, therefore diagnostically useful Useful to monitor disease progression and treatment (RA particularly) Useful to detect intercurrent infection (SLE particularly)

whereas a rise in CRP of >20% in 24 h is consistent with a new infection. In chronic inflammatory diseases, for example rheumatoid arthritis, a falling CRP concentration precedes clinical and radiological improvements in disease.

Some laboratories are measuring CRP using assays with improved sensitivity (0.1–5 mg/L, so-called ‘highly-sensitive CRP’) for use as a marker of chronic low-grade inflammation to predict risk of coronary heart disease and progression of unstable angina. The combination of high analytical imprecision and high biological variation at low concentrations makes this difficult in a ‘one-off’ analysis, but if the analytical systems improve, CRP may become more widely applicable in predicting risk of cardiovascular disease. The major clinical applications of CRP measurement are shown in [Table 30.35](#).

Procalcitonin (PCT) is a peptide that undergoes post-translational proteolysis into the mature hormone calcitonin. High plasma PCT concentrations are seen in patients with severe bacterial and fungal infections but also during the acute phase response post surgery. There is considerable interest in the possible use of this protein as a marker of acute sepsis, particularly in neonates, but it has not been shown to be clearly superior to CRP.

TRANSPLANTATION

Transplantation of organs or tissues is a complex procedure undertaken to restore a damaged or missing function, or to replace a lost, removed or absent 'tissue'. Transplants may be autologous (within same person, e.g. stem cell transplant post-chemotherapy), syngeneic (identical genetics, i.e. from a twin) or allogeneic (from a different person). Table 30.36 shows the major types of transplantation currently performed in the UK, and some of the requirements applicable to each type of transplant. (General information about transplantation can be found at: www.histocompatibilityandimmunogenetics.com)

Immunological issues in transplantation include rejection due to the graft being recognized by the immune system as foreign, graft-versus-host disease (GvHD) and infection secondary to the immune suppression required to prevent or control rejection or GvHD (see Box 30.4). The key issue, however, remains rejection of the graft. This can happen by three different mechanisms, shown in Box 30.5. The risk of rejection or GvHD can be reduced by matching the donor and recipient for ABO blood group and HLA type. This is particularly important for renal and stem cell transplants. A longer-term complication of modulating the immune system to accommodate transplanted tissue is an increased risk of malignancy.

Organ transplantation

Patients waiting for an organ transplant are registered, together with their HLA type, on a waiting list. As potential donors become available their HLA type is compared with those of the patients on the waiting list. Potential donor-recipient matches need to be further investigated using a specific test of the reactivity of the recipient's serum against the donor. This is particularly to check whether the recipient has any pre-formed antibodies to the donor that could cause hyperacute rejection. Transplant patients usually need long-term immunosuppression to prevent graft rejection; the most common immunosuppressants with their modes of action are shown in Table 30.37.

TABLE 30.36 Organ transplantation in the UK, April 2011–March 2012

Organ/tissue	Number in UK
Kidney	2801
Heart/lung	321
Liver	791
Pancreas	249
Cornea	3520
Intestine	22
Stem cell transplantation (prepared from peripheral blood, umbilical cord or bone marrow)	Not available

Taken from NHS Blood and Transplant Activity Report 2011–2012: www.organdonation.nhs.uk

BOX 30.4 Immunological complications of transplantation

1. **Rejection:** controlled by HLA and blood group matching and immunosuppression. For 'solid' organ transplantation, the aim is to prevent the recipient immune system from attacking the transplanted organ. With stem cell transplantation, the recipient's immune system will have been destroyed by conditioning, thus reducing the risk of rejection.
2. **Graft versus Host Disease (GvHD):** the main cause of morbidity and mortality post-stem cell transplantation. Donor immune cells attack the recipient, particularly in the skin, gut and liver. The severity depends on the degree of HLA matching but the risk is reduced by T cell depletion of the stem cell preparation before infusion into the donor. Some T cells may have a graft versus leukaemia (GvL) effect, which can be beneficial.
3. **Infection secondary to immune suppression:** Suppressing the immune system to prevent rejection or GvHD increases the risk of infection. Suspected infections must be treated promptly with broad spectrum antibiotics, antiviral or antifungal drugs. In stem cell transplantation, conditioning causes profound myelosuppression, so cell counts, particularly of neutrophils and platelets, are monitored closely as immune reconstitution by the donor stem cells takes place. Additional infection control measures are used, including nursing the patient in air-filtered isolation room and providing specially sterilized food until the neutrophil count is $>0.5 \times 10^9$ cells/L. Prophylactic antibiotics, antivirals and anti-fungals may also be used to minimize the risk of infection with organisms such cytomegalovirus (CMV), Epstein-Barr virus (EBV), adenovirus, *Candida* and *Aspergillus*.

BOX 30.5 Types of rejection

- **Hyperacute rejection:** this is caused by the recipient having pre-formed antibodies to the donor's cells. This can be due to previous blood transfusion, multiple pregnancies or transplantation and the antibodies can be to blood group or HLA antigens. The antibodies bind to their antigenic target in the graft blood vessels as the graft is perfused by the recipient's blood. This activates the complement cascade, damages the blood vessels, activates platelets and causes blockage of the graft microvasculature, resulting in graft failure in minutes to hours. The risk can be minimized by HLA typing and pre-transplant cross-matching.
- **Acute rejection:** this is caused by recipient T cells recognizing donor antigen presented by antigen-presenting cells in the draining lymph nodes of the graft. The T cells attack the graft, resulting in graft failure within days-weeks. Production of anti-donor antibodies may also be a consequence of this process compounding the damage by an antibody-mediated response. Compatible HLA typing minimizes the risk of acute rejection but the immune suppression is focused on preventing it.
- **Chronic rejection:** the cause is poorly understood but there is gradual (over months to years) occlusion of blood vessels resulting in local tissue necrosis and ultimately graft rejection. Cellular and antibody mechanisms are both thought to contribute.

TABLE 30.37 Major immunosuppressive drugs and their actions

Drug	Action	Comments
Ciclosporin A	Inhibits T cell activation	Nephrotoxic, so minimize use in renal transplant Serum concentrations monitored
Tacrolimus (FK506)	Inhibits T cell activation	Nephrotoxic, so minimize use in renal transplant Serum concentrations monitored
Sirolimus (rapamycin)	Inhibits cell proliferation by blocking cell cycle	
Steroids	Suppress expression of inflammatory genes, e.g. cytokines	
Azathioprine	Purine analogue that inhibits proliferation	
Mycophenolate mofetil (MMF)	Inhibits proliferation by targeting inosine monophosphate dehydrogenase	

TABLE 30.38 Sources of stem cells

Source of stem cells	Cord blood	Peripheral blood	Bone marrow
Preparation	None	GCSF is used to mobilize stem cells from bone marrow into blood – small risk of malignancy	None
Collection	Painless; would be wasted otherwise	Minimal discomfort; no hospital stay or anaesthesia	Painful collection Requires hospital admission General anaesthesia
Storage	Can be stored, so readily available when required	Collected on day of transplant, so requires coordination	Collected on day of transplant, so requires coordination
Yield (CD34+ cells/kg)	Approx. $0.5-1 \times 10^6$	Approx. 7×10^6	Approx. $2-3 \times 10^6$
Function	Does not confer immunity as immunologically naive – reduced risk of GvHD but lack of GvL	Can confer immunity	Can confer immunity

GCSF, granulocyte colony stimulating factor; GvHD, graft-versus-host disease; GvL, graft-versus-leukaemia.

Stem cell transplantation

This is the re-population of the bone marrow to rescue and restore an immune system ablated as a result of high dose chemo- or radiotherapy or to treat genetic diseases. Stem cells are undifferentiated cells that are capable of self-renewal and differentiation into more specialized cells. Stem cells can be harvested for transplant from cord blood or bone marrow but are now most commonly obtained from peripheral blood (see Table 30.38). The relative ease with which stem cells can be collected from peripheral blood and safely stored has made autologous (from the patient) peripheral blood stem cell transplant (PBSCT) a common 'rescue' treatment following high dose chemotherapy, e.g. for malignancy. Allogeneic (from a donor) stem cell transplants may be required to treat haematological malignancies, e.g. leukaemias, and bone marrow disorders such as thalassaemias, aplastic anaemia and severe combined immunodeficiency.

There are registers for people willing to be bone marrow or stem cell donors, which contain details of their HLA types. When a patient requires an allogeneic stem cell transplant (and a suitable family member is not available), their HLA type is used to search donor

databases to try to find an appropriate match. If a donor is identified, their HLA type is double-checked and the potential recipient's sample cross-matched with the potential donor. The transplant typically involves 'conditioning' with chemotherapy or radiotherapy to eradicate disease (depending on the reason for transplant) and the recipient's functioning bone marrow. The donor stem cells are infused like a blood transfusion; they 'home in' to the bone marrow where they start to develop and multiply. The patients are immunosuppressed to prevent rejection and GvHD. The main immunological complications of PBSCT are shown in Box 30.5.

CONCLUSION

The immune system is complex and the diseases associated with abnormalities of the immune system can affect almost every part of the body. The common symptoms where the immune system is involved are shown in Table 30.39, together with the appropriate investigations and relevant disease. The list is not exhaustive but covers the most important immunological investigations.

TABLE 30.39 Clinical features and investigations in immunological diseases

Organ or clinical feature	Investigation(s)	Disease, pathological process or comments
Recurrent infections	Immunoglobulins (IgG, IgA and IgM)	Primary immune deficiency, e.g. common variable immunodeficiency (CVID) Secondary immune deficiency, e.g. B cell malignancy (+ urine for BJP)
	CRP	To support diagnosis and monitor response to treatment
	Complement (CH50)	Complement deficiency – Neisserial infections, meningitis
Liver	α_1 -Antitrypsin	α_1 -Antitrypsin deficiency (especially in neonates)
	Antinuclear antibodies	Autoimmune hepatitis
	Smooth muscle antibodies Mitochondrial antibodies	Autoimmune hepatitis Primary biliary cirrhosis (M2 variant, IgM concentrations usually raised)
Kidney	Antinuclear antibodies	Systemic lupus erythematosus (SLE)
	Antinuclear cytoplasmic antibodies	Vasculitis
	Glomerular basement membrane antibodies	Goodpasture syndrome (GBM disease)
	Serum immunoglobulins and serum and urine electrophoresis	B cell malignancy (with renal damage due to AL amyloid, cast formation etc.)
	Cryoglobulins	Immune complex deposition in the kidneys causing renal impairment
Respiratory system	C3 and C4	Immune complex disease and nephritis (SLE, cryoproteins etc.)
	Total and specific IgE	Allergy
Anaphylaxis	Antinuclear cytoplasmic antibodies	Vasculitis
	GBM antibodies	Goodpasture syndrome (GBM disease)
	α_1 -Antitrypsin	COPD
Skin	Serum tryptase	Type I hypersensitivity
	Total and specific IgE	Allergy
Skin	C1 esterase inhibitor, C3 and C4	Hereditary angioedema
	Antibodies to skin basement membrane and intercellular cement	Pemphigus and pemphigoid
	Cryoglobulins (with serum and urine paraprotein studies)	Deposition of cryoproteins in the skin because of their precipitation in the cold Deposition of immune complexes in the skin causing vasculitis
	C1 esterase inhibitor, C3 and C4	Hereditary angioedema
	Antinuclear antibody	Urticaria SLE Systemic sclerosis
Gut	Total and specific IgE	Allergy
	Total and specific IgE	Food allergy
	C1 esterase inhibitor, C3 and C4	Hereditary angioedema
	Immunoglobulins (IgG, IgA and IgM)	Immune deficiency
	Endomysial antibodies (or anti-tissue transglutaminase antibodies)	Coeliac disease
Bone and joint pain	Serum and urine paraprotein studies	Myeloma
	Rheumatoid factor	Rheumatoid arthritis (CRP for monitoring)
	Anti-cyclic citrullinated peptide (CCP) antibodies	Earlier predictor of rheumatoid arthritis
Thyroid	Antinuclear antibodies	SLE
	Anti-thyroid peroxidase antibodies	Present in autoimmune hypothyroidism
Pancreas	TSH receptor antibodies	Present in Graves disease
	Glutamic acid decarboxylase antibodies	Present in type I diabetes
Anaemia	Islet cell antibodies	Present in type I diabetes
	Serum and urine paraprotein studies	Myeloma
	Endomysial antibodies (or anti-tissue transglutaminase antibodies)	Coeliac disease
	Gastric parietal cell antibodies and intrinsic factor antibodies	Pernicious anaemia

APPENDIX 30.1: IMMUNOLOGICAL INVESTIGATIONS

Quantitative assays should be calibrated against available international reference preparations; be sensitive, specific, precise and where available, validated by adequate performance in external quality assurance (QA) schemes. It is important to mention these factors because there is a trend towards moving immunoglobulins and complement measurements from dedicated immunoassay analysers to main clinical chemistry analysers and we must not compromise our ability to detect immune deficiencies or the overall quality of the assays by losing precision and sensitivity. It is also worth remembering that babies and children will be a group of patients often investigated for immune deficiency and saving any 'left-over' samples for further analysis can be very useful.

Quantification of total immunoglobulin concentrations

Methods for the quantification of serum IgG, IgA and IgM concentrations are readily available. Quantification of serum immunoglobulin concentrations should be accompanied by serum protein electrophoresis and, in adults, by urine protein electrophoresis.

There is marked variation in immunoglobulin concentrations with age, and results must be interpreted using appropriate age-related reference ranges and the potential impact of transfusion of any blood products, maternal IgG and prematurity.

IgG subclasses

The IgG1 and IgG3 subclass concentrations mature first, with IgG2 and IgG4 concentrations maturing more slowly. There is considerable debate among immunologists about the value of IgG subclass measurements. It is likely that many IgG subclass requests are of negligible value; e.g. a patient with a low total serum IgG will have low IgG concentrations of subclasses. There may be a small number of

patients where the subclass measurements may be useful but increasingly, quantitative specific antibody responses are being used.

Quantification of specific antibody responses

These assays quantify the antigen-specific IgG. Ideally, every individual should be vaccinated against tetanus and should have measurable IgG concentrations to tetanus. There are assays for IgG to *Haemophilus influenzae* B, *Pneumococcus* and tetanus but the assays can be variable and the external QA programmes show marked variability in performance. Analysis of pre- and post-vaccination samples helps to limit the effect of inter-assay variability. Patients with a low specific antibody concentration should be re-vaccinated and the concentrations re-checked 4–6 weeks later. Unfortunately, antibody production and concentration are not necessarily good correlates of immunological protection so the interpretation of the results needs particular care.

Quantification of IgE

Reliable assays for IgE are becoming increasingly available on immunoassay analysers. It is interesting to note that in the investigation of immune deficiency (e.g. hyper IgE syndrome), immunologists now tend to look for raised IgE concentrations (into many thousands of kU/L) rather than low concentrations.

Complement

It is possible to quantify all the complement components but only C3 and C4 assays are readily available. Concentrations of other proteins, e.g. C1 esterase inhibitor can be easily measured but tend only to be available in more specialized centres. The functional assays are also vital in the investigation of immune deficiencies; these are variations on total haemolytic complement assays (for the classical and alternative pathways).

Enumeration of cell numbers

The total white cell count and differential is a vital investigation that will include total lymphocyte count and total neutrophil count but it cannot, for example, distinguish T lymphocytes from B lymphocytes. The various white cell types can be defined using flow cytometric assays that look at the size and granularity of the cells and the binding of fluorescent conjugated antibodies to the cell surface markers. The assays are usually done in immunology or haematology departments. Table 30.3 shows the common CD antigens, many of which are used in the investigation of suspected immune deficiency. Reference ranges are age-related and the results reported as either percentages or as absolute numbers.

Functional assays

There are immune deficiencies, where the various cell types are present but they lack any functional ability. Assays of lymphocyte function are laborious and complex and

typically rely on the proliferation of cells after stimulation with mitogens, antigens or stimulation via specific receptors. These assays are often run over 3–5 days, so need careful planning, and the interpretation of the results needs great expertise, therefore they are only done in specialized centres.

Neutrophil function tests

Neutrophil function tests are also complex and like lymphocyte function tests, the cells need to be alive for them to work. The most common analysis is for detection of the neutrophil respiratory burst, either by a flow cytometric assay (using dihydrorhodamine) or by looking at

neutrophils under the microscope after being incubated with the redox dye, nitroblue tetrazolium.

Autoantibodies

The analytical problems with autoantibody testing are many and include the source, type and preparation of antigen, the method used and variation between each patient's antibodies. Autoimmune serology, in comparison with general clinical biochemistry, is poorly standardized and this is compounded by large numbers of companies producing kit reagents for these tests. External quality assurance schemes are in place but they can make scary reading for a laboratory scientist!

APPENDICES 635

BONE BIOLOGY

The principal role of the skeleton is a structural one, maintaining body shape, providing protection for internal organs and, together with the neuromuscular system, making locomotion possible. It also has an important secondary role in mineral homeostasis, functioning as a reservoir for calcium ions in particular. Metabolic bone diseases can affect both these functions.

Anatomy of bone

Macroscopic

The anatomist classifies bones as being either flat (e.g. skull, scapula, mandible, ilium) or long (e.g. the limb bones). Flat bones result from intramembranous ossification; long bones predominantly from endochondral ossification. A long bone consists of a shaft (diaphysis) broadening at either end into an epiphysis. The transitional zone between the diaphysis and the epiphysis is termed the metaphysis. On sectioning a long bone, two patterns of organization of bone tissue are found. The

elements of bone can be packed together without intervening marrow spaces to form cortical or compact bone, or they can form an interlacing meshwork of trabeculae referred to as cancellous or trabecular bone. The diaphysis of the long bone consists mainly of cortical bone, whereas the metaphysis and epiphysis have a greater quantity of trabecular bone, enclosed within a thin cortical envelope. Some 80% of the weight of an adult human skeleton consists of cortical bone. However, the surface-to-volume ratio of trabecular bone is very much higher than that of cortical bone and it is metabolically much more active.

Microscopic

At a microscopic level, bone consists of matrix (~35% by volume), mineral (~60%) and cells (<5%). The matrix is predominantly type I collagen fibres, usually organized in layers within which the fibres are parallel to one another. In adult bone, the fibre orientation varies from one layer to the next and this is referred to as lamellar bone. If deposited along a flat surface, the lamellae will be parallel to that surface, but in cortical bone they are

concentrically oriented around a central blood vessel to form the Haversian canal system. When bone formation is rapid (e.g. during growth or fracture healing) collagen fibres may be laid down with more random orientation, producing woven bone.

The mineral phase of bone is hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$). This forms spindle-shaped crystals, which are found in association with the collagen and ground substance. Their orientation is usually parallel to that of the collagen fibres.

There are two general cell types in bone: osteoblasts and osteoclasts. Both are found on the bone surface at sites of active remodelling. Osteoblasts are also thought to be the precursor of two cell types that are more widespread: bone lining cells, which are found over inactive bone surfaces, and osteocytes, which are found in lacunae scattered throughout bone. They are thought to be osteoblasts that have been engulfed by the bone that they have formed. They have long cell processes, which are in contact with similar processes arising from other osteocytes or with those of the bone lining cells. The cell processes lie in an interconnecting network of canaliculi that extends throughout bone tissue. The bone lining cells and osteocytes thus delineate an extracellular fluid (ECF) space that is in contact with the bone surface. This space has a volume of 1–1.5 L and a surface area of several thousand square metres. This is the site of mineral exchange between ECF and bone. The size and nature of this exchange is unknown but the fluid within this space, the bone ECF, has an ionized calcium concentration of only 0.5 mmol/L – less than half of that elsewhere in the ECF.

Bone matrix proteins

Collagen

Almost 90% of the protein in bone matrix is type I collagen, which is synthesized by osteoblasts. It is a large molecule (MW >300 000 Da) with a trimeric helical structure. Type I collagen is initially synthesized in the rough endoplasmic reticulum (RER) as a precursor molecule (type I procollagen) that combines two $\text{pro}\alpha 1(\text{I})$ and one $\text{pro}\alpha 2(\text{I})$ peptide chains (coded by *COL1A1* and *COL1A2*, respectively) in a triple helix. $\text{Pro}\alpha 1(\text{I})$ and $\text{pro}\alpha 2(\text{I})$ have similar structures with a core triple helical domain of 1014 amino acids composed of uninterrupted Gly-X-Y tripeptide repeats, where Gly is glycine and X and Y are often proline or lysine, flanked by propeptides at both N- and C-terminal ends. During and after translation, the three chains undergo extensive modification. Prolyl-4-hydroxylase converts virtually all Y-position proline residues to 4-hydroxyproline, an alteration that is essential for thermal stability of the assembled trimer. In the absence of this modification the trimer melts (that is the individual chains unfold from the stable triple helix, at about 27°C, whereas with full hydroxylation, the melting temperature is about 42°C). Some Y-position lysine residues within the triple helical domain are hydroxylated by the enzyme lysyl hydroxylase-1, and glucose and galactose groups added by glycosyltransferases (Fig. 31.1). Hydroxylation of these triple helical residues is part of the pathway to form

stable complex intermolecular crosslinks that provide the tensile strength in tissues. Most of these modifications are completed during translation and occur on the individual chains. If there is a delay in triple helix folding, the process can continue and the physical properties of the chains and molecules are altered and contribute to an osteogenesis imperfecta phenotype.

The three chains that form a [$\text{pro}\alpha 1(\text{I})_2 \text{pro}\alpha 2(\text{I})$] trimer interact through regions in the carboxyl-terminal propeptide of each chain. The full length chain must be maintained in an unfolded state while the carboxyl-terminal propeptides fold, associate, and then begin the process of triple helix formation. Propagation of the collagen triple helix requires a number of enzymes and molecular chaperones to ensure correct folding and trimerization. These include peptidyl disulfide isomerase (PDI), which also forms part of the prolyl 4-hydroxylase complex, and is likely to involve prolyl peptidyl cis-trans isomerase B (also known as cyclophilin B). This protein can act on its own, to assist in the folding around prolyl residues, such as those in the carboxyl-terminal propeptide adjacent to cysteine residues, and as part of a complex that includes two additional proteins, cartilage-related protein and prolyl 3-hydroxylase, to modify certain triple helical prolines. The function of this last process is not yet entirely clear but when the complex is missing, the propagation of the triple helix is altered and modification of the chains increased.

Disulphide bonds between the carboxyl-terminal region of the chains act to secure the three chains in a trimer, a process requiring protein-disulphide isomerase. Lysine residues outside the major triple helical domain of type I collagen, needed for the formation of mature intermolecular crosslinks, are hydroxylated by lysyl hydroxylase-2. These complex modifications, which are necessary for correct folding, assuring thermal stability of the triple helix and crosslink formation between collagen molecules once they are secreted into the matrix, need to take place in an orderly and timely sequence, and various chaperone proteins, including HSP47 and FKBP65, help regulate this process. Procollagen trimers are then transported via the Golgi network and packaged into membrane-bound organelles where lateral aggregation, the initial phase of fibril formation, occurs. As secretion occurs, the procollagen molecules are further processed into mature type I collagen molecules by proteolytic cleavage of the N- and C-terminal propeptides (by the enzymes ADAMTS-2 (a disintegrin and metalloproteinase with thrombospondin motifs 2) and BMP1 (bone morphogenetic protein 1), respectively). Finally, the trimers are assembled into collagen fibrils and fibres and anchored in those positions by intermolecular lysine-derived crosslinks in a process that is begun by modification of specific residues by lysyl oxidase. These cross-links are initially reducible, but as tissue maturation proceeds, they are converted into non-reducible compounds including hydroxylysylpyridinoline (derived from three hydroxylysine residues) and the less abundant lysylpyridinoline (derived from two hydroxylysine residues and one lysine residue). The latter (also known as deoxypyridinoline) is present in the body almost exclusively in bone tissue and dentine, where it accounts for 21% of the total mature cross-links.

Glc, glucose; Gal, galactose; Man, mannose; GlcNac, N-acetylglucosamine. *Lower panel:* view along the axis of the triple helical structure of the collagen backbone, with every third amino acid a glycine residue forming the inner circle.

Non-collagenous proteins

The non-collagenous proteins of bone (proteoglycans, glycosylated proteins, RGD (arg-gly-asp)-containing glycoproteins and γ -carboxylated proteins) account for only 10–15% of bone protein mass but, because of their very much smaller size, are as common as collagen in bone on a molar basis. Most are synthesized by osteoblasts, but a number are produced elsewhere in the body and arrive in bone via the circulation. The latter proteins, which include albumin and platelet-derived growth factor, are usually negatively charged and become bound to hydroxyapatite. The most abundant of the bone-derived non-collagenous proteins are osteocalcin, also known as bone Gla-protein, and osteonectin, both of which have a high affinity for bone mineral.

Osteocalcin is synthesized by osteoblasts as a 75-amino acid precursor known as pro-osteocalcin. The amino-terminal propeptide includes the substrate recognition site for the vitamin K-dependent γ -carboxylase enzyme which γ -carboxylates three glutamic acid residues (17, 21 and 24) in the central region of the osteocalcin molecule, following which the amino-terminal propeptide is cleaved, leaving the 49-residue osteocalcin molecule.

The γ -carboxyglutamic acid residues are strongly calcium binding and allow the molecule to bind to hydroxyapatite. The process of γ -carboxylation seems to be impaired in the elderly.

The physiological role of osteocalcin is uncertain, but it probably contributes to the regulation of bone remodelling, since deletion of the osteocalcin gene in mice leads to increased bone density. Its synthesis is regulated by 1,25-dihydroxyvitamin D (1,25(OH)₂D, calcitriol) and cortisol, and it is incorporated into bone matrix, being especially abundant in cortical bone.

Recently, its uncarboxylated form has been implicated in the regulation of intermediary metabolism, including fat mass, glucose tolerance and insulin secretion. The relevance to human physiology of these findings in genetically modified mice remains to be determined.

Other bone proteins

Several proteoglycans, macromolecules that contain acidic polysaccharide side chains, are present in bone. In the early stages of bone formation, versican, a dermatan sulphate proteoglycan, and the glycosaminoglycan, hyaluronan, are present and may act to delineate areas that are destined to become bone. Subsequently, two chondroitin

TABLE 31.1 Major glycoproteins containing the arginyl-glycyl-aspartate (RGD) cell-attachment motif in skeletal tissue

Protein	Proposed function
Thrombospondins	Cell attachment, bind heparin, collagens, thrombin, fibrinogen, plasminogen
Fibronectin	Binds to cells, collagen, fibrin, heparin, gelatin
Vitronectin	Cell attachment, binds collagen and plasminogen
Fibrillin	Regulation of elastic fibre formation
Osteopontin	Binds to cells, inhibits mineralization, regulates cell proliferation and tissue repair
Bone sialoprotein	Binds cells, may inhibit mineralization
BAG-75	Binds calcium, ?cell attachment
Dentin matrix phosphoprotein 1	Osteocyte-derived, regulates osteocyte maturation and FGF23 production

sulfate proteoglycans, decorin and biglycan, are expressed and may influence cellular proliferation and differentiation in the newly forming bone. Fibromodulin, osteoglycin and osteoadherin are other proteoglycans that are expressed in bone matrix, but their functions are less well characterized.

The major glycoproteins present in bone are alkaline phosphatase (ALP), which is highly expressed on the osteoblast cell surface, and osteonectin, a phosphorylated glycoprotein that is also present in several other tissues that undergo rapid remodelling. In bone, osteonectin may regulate both cellular activity and matrix mineralization.

At least eight non-collagenous glycoproteins expressed in bone contain the arginyl-glycyl-aspartate (RGD) tripeptide as the consensus cell-attachment sequence (Table 31.1). Some are specific to bone (e.g. bone sialoprotein), but most are more ubiquitously expressed (e.g. fibronectin, osteopontin, thrombospondins, vitronectin). Although the role(s) of each individual protein in skeletal physiology is(are) uncertain, it seems very likely that they collectively serve to promote attachment of bone cells to bone matrix (and perhaps thereby regulate their function). The components of the matrix–cell interactions are clearly dependent upon the maturational stage of the remodelled bone. Three matrix non-collagenous proteins, matrix Gla-protein, protein S and osteocalcin (bone Gla-protein), undergo post-translational γ -carboxylation, a process that enhances calcium binding. These proteins may function physiologically as inhibitors of mineral deposition.

Cellular elements of bone

Osteoblasts

Osteoblasts are the cells responsible for the synthesis and maintenance of bone matrix. They are derived from pluripotent mesenchymal progenitor cells that also give rise

to adipocytes, chondrocytes and myocytes. Expression of the transcription factors *cbfa1* and *osterix* is critical for commitment to the osteoblast lineage, while expression of peroxisome proliferation activating receptor- γ (PPAR- γ) favours adipocytic over osteoblastic differentiation.

A key molecular event in osteoblast proliferation, and perhaps survival, is signalling through the wnt-low density lipoprotein-related receptor 5 (LRP5)- β -catenin pathway. In this system, secreted wnt proteins bind to and activate LRP5 on the cell surface, which in turn activates a series of intracellular events that result in translocation of cytoplasmic β -catenin to the nucleus, where it activates transcription of genes critical for osteoblast growth and function. The pathway is further regulated by secreted proteins that inhibit wnt-induced activation of LRP5, such as sclerostin, Dickkopf (DKK) and frizzled. Thus, humans carrying mutations of components of this signalling pathway that decrease nuclear translocation of β -catenin have decreased bone mass and fractures as a result of impaired bone formation (e.g. *WNT1* and most *LRP5* mutations), while constitutive activation of the pathway (e.g. *LRP5* mutations affecting one particular extracellular domain or *SOST* mutations) increases bone mass. Other LRP family members are also important in bone physiology. Mutations affecting one particular region of the extracellular domain of LRP4 result in impairment of the ability of sclerostin to inhibit bone formation, and thereby cause increased bone mass (sclerosteosis type 2).

Mature osteoblasts are metabolically very active and intimately involved in bone formation. They synthesize many of the matrix proteins referred to above. They have very high levels of alkaline phosphatase (ALP) activity associated with their cell membranes. This enzyme is necessary for normal bone mineralization to take place. Osteoblasts express receptors for parathyroid hormone (PTH) and $1,25(\text{OH})_2\text{D}$, as well as a number of cytokines, growth factors and sex hormones. Osteoblasts also play a key role in regulating osteoclastic bone resorption, ensuring that the components of bone remodelling, formation and resorption are coupled. A critical mechanism by which osteoblasts regulate bone resorption is via the RANK–RANKL–OPG system (see below).

Osteocytes

Osteocytes and bone lining cells are terminally differentiated osteoblasts derived from mature osteoblasts that are no longer involved in active bone formation, and have become entrapped within the canaliculi of the bone matrix that they have produced. This process of osteocytogenesis is probably an active one, requiring cleavage of matrix proteins: mutations of the metalloproteinase MT1-MMP lead to osteocytes with fewer and shorter dendritic processes. As osteocytogenesis occurs, the osteoblast changes from a cuboidal cell to a typical osteocytic morphology, characterized by a stellate appearance and numerous cytoplasmic projections that permit the cell to communicate with cells on the bone surface and other osteocytes living within adjacent bone. Concurrently, the genetic signature of the cell changes from a typically osteoblastic one to that which reflects a mature osteocyte, in particular the expression

of *DMP1*, *SOST* and *FGF23*. Osteocytes play a key role in the regulation of bone remodelling. At sites of skeletal microdamage, osteocytes undergo apoptosis and release apoptotic bodies expressing RANKL (see below), promoting the recruitment of osteoclasts to the area to initiate remodelling to allow repair of the damaged bone. Osteocytes also produce and release sclerostin, an endogenous inhibitor of osteoblast differentiation and function that acts to inhibit wnt-induced activation of LRP5. They also act as mechanosensory cells in bone, perhaps in tandem with osteoblasts lining the bone surface, with which they communicate. Finally, osteocytes are critically important for bone mineralization, by regulating phosphate metabolism at a whole organism level, principally by production of the phosphaturic hormone fibroblast growth factor 23 (*FGF23*), a process that involves the osteocyte products phosphate-regulating endopeptidase (*PHEX*) and dentine matrix phosphoprotein 1 (*DMP1*).

Osteoclasts

Osteoclasts are the cells that resorb bone. They are derived from cells of the monocyte/macrophage series. They are multinucleated and are usually found singly or in small numbers within resorption lacunae of their own making. They have large numbers of mitochondria and lysosomes. Activated osteoclasts possess a 'ruffled' border, adjacent to the bone being resorbed. The ruffled border is delimited by a 'sealing zone' at which the osteoclast is attached to the underlying bone. Bone resorption occurs as a result of the secretion of protons and proteolytic enzymes into the space between the ruffled border and the bone surface. Among these enzymes are tartrate-resistant acid phosphatase (a useful histological marker of osteoclasts) and cathepsin K.

Osteoclast development and function are regulated by osteoblast and osteocyte-derived cytokines, in particular osteoprotegerin (*OPG*) and receptor activator of nuclear factor- κ B ligand (*RANKL*), which are members of the tumour necrosis factor (*TNF*) receptor superfamily. *RANKL* expressed on the osteoblast and osteocyte surface binds to, and activates its receptor – receptor activator of nuclear factor- κ B (*RANK*) – which is expressed on the surface of osteoclast precursors. *RANKL* is also shed from the cell surface, and this soluble form of the protein may confer osteoclastogenic activity distant from the cell of origin, in particular the osteocyte. Interaction between *RANKL* and *RANK* promotes osteoclastogenesis. Osteoprotegerin is a secreted osteoblast product that acts as a decoy receptor for *RANKL*, and thereby functions as an endogenous inhibitor of osteoclastogenesis. Thus, the relative levels of expression by the osteoblast of *RANKL* and *OPG* determine the rate at which osteoclastogenesis occurs. Many of the systemic factors that alter bone resorption, such as *PTH* and $1,25(\text{OH})_2\text{D}$ (which increase osteoclast function) and sex hormones (which decrease it), do so by changing osteoblastic production of *RANKL* and/or *OPG*. An exception is calcitonin, whose receptor is expressed on osteoclasts, and which therefore inhibits bone resorption directly.

A number of other critical cellular and molecular events are now recognized to underpin osteoclastic

bone resorption. The intracellular tyrosine kinase *c-src* regulates osteoclast motility and aspects of cytoskeletal function that are critical to formation of a functional resorption space; the $\alpha_v\beta_3$ integrin (vitronectin receptor) plays a key role in osteoclast attachment to bone; the cysteine protease cathepsin K and the type 7 transmembrane chloride channel (*ClCN7*) are each required for proteolytic degradation of bone matrix.

Bone remodelling and its regulation

In mature bone, there is a continuous process of removal and replacement of pockets of old bone. This is termed *bone remodelling* and is shown in schematic form in Figure 31.2. The process occurs at discrete sites on the bone surface and, in the mature skeleton, is probably an adaptive response to skeletal microdamage. Bone remodelling is achieved by teams of osteoclasts and osteoblasts acting within the anatomical structure known as the basic multicellular unit (*BMU*). Osteocytes play a critical role in initiating bone remodelling, and probably also in regulating the coordination of formation and resorption within the *BMU*. Thus, apoptotic osteocytes in an area of skeletal microdamage produce *RANKL* that directs osteoclastogenesis and initiation of bone remodelling to the damaged bone. At that site, the osteoclasts excavate a resorption pit, the depth of which is determined by the number and activity of the osteoclasts present. The motile osteoclasts are then replaced by osteoblasts, which proceed to fill the resorption pit with bone matrix. Mineralization of this new bone then occurs, lagging behind matrix synthesis by a period of about three weeks. Once the resorption pit has been filled, the osteoblasts either undergo apoptosis, return to their quiescent state as bone lining cells or survive as osteocytes within the bone lacunae.

An increase in bone turnover is characterized by a faster bone remodelling cycle initiation rate, rather than an increase in the duration of the cycle. The histological consequence of such an increase is that a greater proportion of bone surface is involved in remodelling at any one time. The time required to complete a full cycle of resorption and formation (σ) is in the order of 6–12 months. Inhibiting bone resorption, for example with pharmaceutical agents, rapidly reduces the initiation rate of new remodelling cycles, but those cycles already initiated go to completion. Thus there is a period ('a transient') of duration σ , when the bone formation rate exceeds the resorption rate. This ends when all those cycles initiated before the inhibition of bone resorption took place have completed their formation period. The bone formation rate at this stage will have fallen to match the new, lower, resorption rate.

Bone resorption and formation are thus very closely linked in normal bone and also in many metabolic bone disorders. As outlined earlier, the osteoclasts and osteoblasts clearly 'communicate' with each other. Osteoblastic regulation of osteoclast function is mediated in large part by the *RANK*–*RANKL*–*OPG* system, but the nature of the osteoclast-derived signal(s) that recruits and activates osteoblasts is not yet fully characterized. Osteocyte-derived sclerostin, an inhibitor of osteoblast differentiation, probably contributes to the regulation

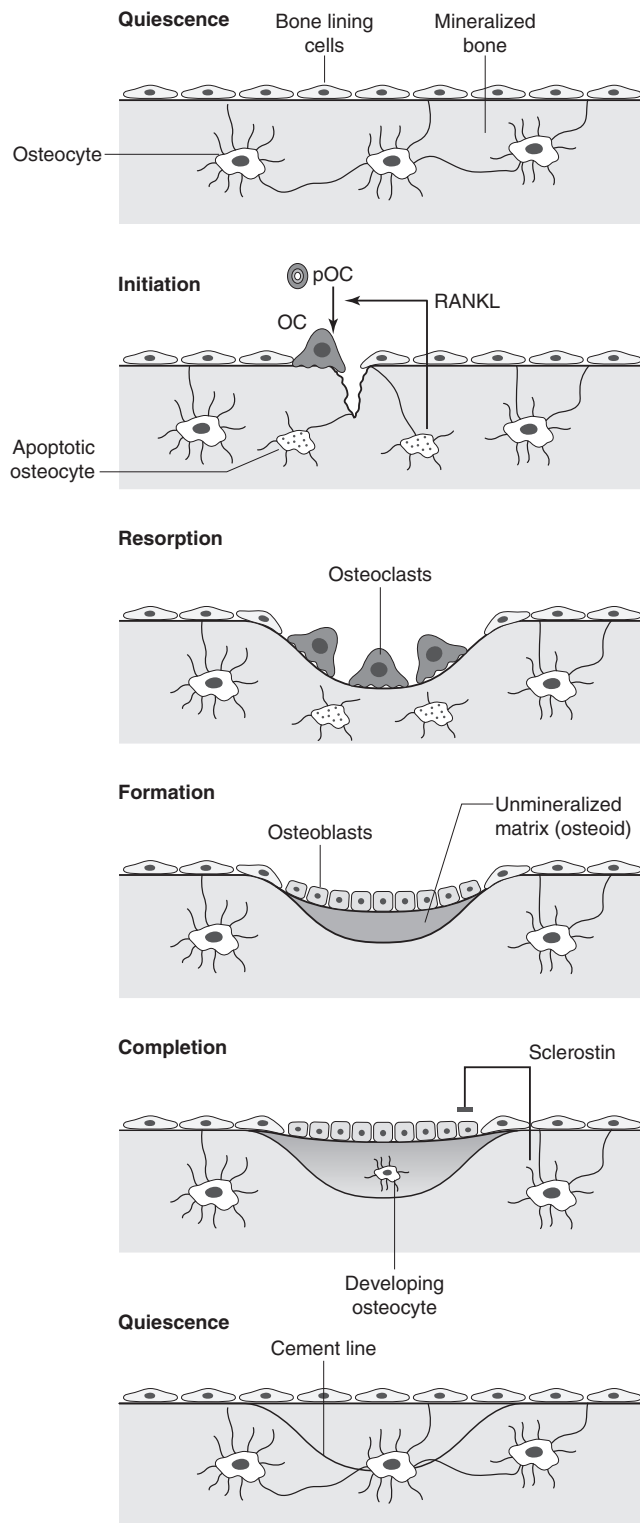

FIGURE 31.2 ■ The bone remodelling cycle. Bone remodelling is initiated in response to skeletal microdamage, sensed by adjacent osteocytes which undergo apoptosis and produce the osteoclastogenic cytokine, receptor activator of nuclear factor- κ B ligand (RANKL). Osteoclastic resorption of the damaged bone ensues, after which mature osteoblasts progressively fill the resorption cavity with osteoid, and coordinate its subsequent mineralization. Some of the osteoblasts develop into osteocytes within the lacunae of the newly formed bone. Sclerostin is produced by osteocytes adjacent to the remodelling space: it signals inhibition of bone formation and a return to a quiescent state. In skeletal homeostasis, the amount of new bone formed equals that resorbed during each remodelling cycle. OC, osteoclast; pOC, pre-osteoclast. (Courtesy of Dr Andrew Grey.)

of the bone formation component of the remodelling cycle. Matrix-associated growth factors that are released from resorbed bone, such as transforming growth factor β (TGF β), bone morphogenetic proteins (BMPs) and platelet-derived growth factor, may also constitute part of this signal. Finally, genetic evidence suggests that communication from osteoclasts to osteoblasts occurs via members of the ephrin (Eph) family of signalling proteins, specifically osteoclast-expressed ligand ephrin-B2 signalling through the osteoblast-expressed receptor EphB4 to activate osteoblast differentiation and bone formation.

During growth, the amount of bone deposited exceeds that which is removed and there are also changes in the size and configuration of bones (modelling). In senescence, because of factors including sex hormone deficiency, reduced physical activity and various endocrine and inflammatory diseases, the balance of formation and resorption is reversed and bone is lost. Age-related bone loss affects both cortical and trabecular bone, but early after the menopause, bone loss is particularly rapid from the axial skeleton, which has a greater proportion of trabecular bone.

A large number of factors have been found to influence bone remodelling (discussed in Chapter 6).

Biochemical markers of bone turnover

Bone turnover is a term referring to both osteoblastic bone formation and osteoclastic bone resorption. These processes can be assessed by bone histomorphometry, skeletal scintigraphy and by analysing the kinetics of intravenously administered isotopes of calcium. There are numerous biochemical markers of bone turnover, representing either products of bone cells or degradation products from the breakdown of bone collagen (Box 31.1). The number of potential markers available has increased considerably in recent years. In a small number of rare conditions (e.g. hypophosphatasia, osteopetrosis, Bruck syndrome and mild osteogenesis imperfecta), a specific pattern of bone turnover markers can be helpful in diagnosis. However, the main use of markers is to establish whether a high bone turnover state exists. High bone turnover, with its various adverse consequences, is a feature of many of the more common metabolic bone disorders, and a key target of currently available therapies.

Markers of bone formation

Alkaline phosphatase. Alkaline phosphatase is widespread in human tissues. Enzymes with this activity are coded for by genes at three separate loci, their respective products being referred to as intestinal, placental and bone/liver/kidney (or tissue non-specific) ALP. The latter gene is located on chromosome 1p36. The gene transcript has a number of glycosylation sites, and the bone, liver and kidney isoenzymes differ in their carbohydrate side chains.

The major limitation of total ALP as an index of bone formation is its multiple tissues of origin and hence its lack of sensitivity at low values. In health, plasma ALP activity is principally derived from the liver and osteoblasts in approximately equal proportions. If the activity of other

BOX 31.1 Biochemical markers of bone turnover
Formation markers
Blood

- C-telopeptide of collagen cross-links (CTX)

*P1NP and CTX have been endorsed by the International Osteoporosis Foundation for use in clinical trials of osteoporosis treatments.

hepatic canalicular cell enzymes is normal, then elevated total ALP activity usually reflects osteoblastic activity (or, more precisely, the number of active osteoblasts). If uncertainty persists in determining the origin of increased plasma ALP, then isoenzyme studies may be undertaken. The bone and liver isoenzymes have differing stabilities to heating (the bone fraction being more sensitive to heat inactivation) and different mobilities on electrophoresis. Immunoassays for bone-specific ALP use isoform-specific monoclonal antibodies; even so, there is up to 20% cross-reactivity with the liver isoform in these assays. Thus very high plasma activities of liver ALP, as occur in hepatobiliary disease, can still interfere with the measurement of bone-specific ALP. The activity of the bone isoenzyme has a diurnal variation in plasma, with peak values occurring around midnight and being some 25% higher than early morning values. Although the half-life in plasma of the bone isoenzyme is very short (~2 days), in metabolic bone disorders changes in ALP activity reflect slower processes – the acceleration or deceleration of the remodelling cycle – so the rate of change of plasma ALP is also much slower.

The marked elevation in plasma ALP activity seen in childhood and adolescence is due to an increase in the bone fraction. The plasma ALP activity closely parallels the growth velocity curve (Fig. 31.3). A significant (40–50%) rise in plasma ALP activity occurs at the menopause because of accelerated bone turnover. Plasma activity of the enzyme can also be increased after major fractures and reflects the increased cellular activity associated with healing. After hip fracture, for example, ALP activity reaches a peak at around four weeks, with values approximately double those on admission to hospital. Total plasma ALP activity is increased during pregnancy because of the appearance of the placental isoenzyme.

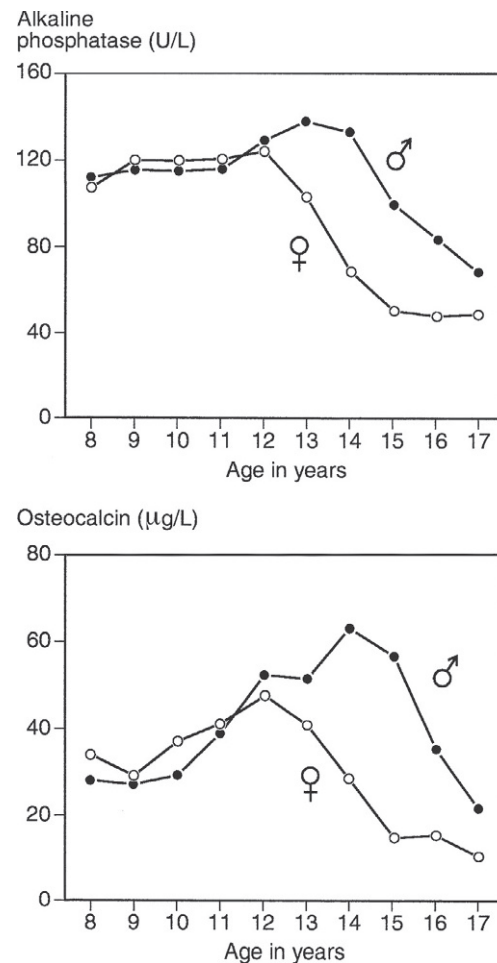

FIGURE 31.3 ■ Bone turnover markers during growth. Mean values of plasma alkaline phosphatase (ALP) and osteocalcin in males (closed circle) and females (open circle) through childhood and adolescence. Peak values are reached at an average age of 12 years in girls and 14 in boys, coinciding with peak growth velocity. As growth velocity falls, both these indices decline toward adult values. (Data from Round JM 1973 Plasma calcium, magnesium, phosphorus and alkaline phosphatase concentrations in normal British school children. *British Medical Journal* 3: 173–140, and Johansen JS, Riis BJ, Podenphant J, Skakkeboek NE, Christiansen C 1987 Plasma bone Gla protein: a specific marker of bone formation. In: Christiansen C, Johansen JS, Riis BJ (eds). *Osteoporosis*, vol 2. Copenhagen: Osteopress ApS: 677–681.)

The entity of *familial benign hyperphosphatasia* is characterized by asymptomatic high ALP activities (predominantly of intestinal isoform) and dominant inheritance, but with no clinical evidence of bone disease. *Benign transient hyperphosphatasemia* is a condition characterized by high concentrations of both bone and liver isoenzymes, first identified in children but now recognized in adults (see Chapter 13).

There are a number of causes of low ALP activities (*hypophosphatasemia*), including vitamin C deficiency, hypothyroidism, starvation, zinc or magnesium deficiency, Cushing syndrome, Wilson disease and the genetic disorder, hypophosphatasia (discussed below).

Osteocalcin. Osteocalcin is produced by osteoblasts, and is generally regarded as a marker of bone formation, but it seems to be involved in the process of mineralization

rather than matrix production. Plasma concentrations of intact osteocalcin are markers of bone formation, and circulating concentrations generally correlate well with histological measures of bone formation rate. Around 25% of circulating osteocalcin consists of intact osteocalcin, the remaining immunoreactivity comprising N-terminal, mid-region, mid-region-C-terminal and C-terminal fragments. When bone is resorbed, osteocalcin fragments are released, and the plasma concentrations of these fragments may thus reflect bone resorption. These fragments are cleared predominantly by the kidneys, so there is considerable immunological heterogeneity in plasma osteocalcin in patients with renal impairment. These factors may limit the usefulness of osteocalcin as a marker of bone formation.

Osteocalcin has a particular advantage in having greater sensitivity than ALP in the detection of low rates of bone formation. As with plasma ALP activity, plasma osteocalcin and growth rate are closely correlated (see Fig. 31.3), and there is a two-fold rise in plasma osteocalcin concentration at the menopause. Plasma osteocalcin concentrations fall markedly during pregnancy. Cord blood concentrations are two to three times higher than adult values. The half-life of intact osteocalcin in the circulation is about 5 min.

Plasma osteocalcin concentrations exhibit a diurnal variation with the peak in the early morning being about 15% higher than the nadir value, which occurs in the afternoon. Concentrations may also be depressed (by about 10%) by alcohol intake and are markedly suppressed (by about 50%) by glucocorticoids. Plasma concentrations rise when osteoblasts are stimulated by the administration of 1,25(OH)₂D.

Procollagen 1 extension peptides. Antibodies have been raised to both the soluble C-terminal and N-terminal propeptides of procollagen, which appear in the circulation after cleavage from the newly formed collagen molecule. Their concentrations in the plasma thus reflect osteoblastic collagen synthesis. As they are not filtered by the kidney, variations in renal function should not affect their plasma concentrations. Degradation of the proteins takes place in hepatic endothelial cells (through the mannose 6-phosphate receptor in the case of procollagen 1 carboxy-terminal extension peptide (P1CP), and by scavenger receptors in the case of procollagen 1 amino-terminal extension peptide (P1NP)).

Procollagen 1 carboxy-terminal extension peptide is usually measured by enzyme linked immunosorbent assay (ELISA). It has a diurnal variation, with peak concentrations occurring at 04.00–08.00 h, and the nadir in the afternoon. There may be some contribution to circulating P1CP from non-osseous sources.

Procollagen 1 amino-terminal extension peptide has been more widely studied. It appears to be a more dynamic marker than P1CP or other formation markers. The peptide is stable, and the available assays are precise and responsive to common interventions in metabolic bone diseases. It is now regarded as the marker of choice to assess osteoblast activity. Of the various assays available for P1NP, some measure the intact propeptide (intact P1NP) while others (total P1NP) also detect a smaller antigen in serum. In many clinical situations, these assays give similar information, but renal insufficiency increases the

concentrations of the smaller antigen, influencing both the apparent concentration of P1NP and assay calibration.

Markers of bone resorption

Hydroxyproline. Hydroxyproline is a major component of fibrillar collagen of all types, comprising ~14% of the total amino and imino acid content. It is produced by the post-translational modification of proline by the enzyme 4-prolyl hydroxylase. In plasma, hydroxyproline exists in protein-bound, peptide-bound and free forms. Most hydroxyproline is oxidized in the liver but a small proportion (~10%) is excreted in the urine. Approximately 90% of collagen-derived hydroxyproline excretion is in the form of peptides resulting from collagen degradation, with the remainder in the form of fragments of the N- and C-terminal procollagen peptides cleaved during collagen synthesis. When bone resorption is increased, urinary hydroxyproline excretion rises, because of the increased rate of catabolism of type 1 bone collagen. When bone turnover is low, urinary hydroxyproline is not a reliable index of bone resorption, since the other sources (for example C1q complement component) can contribute up to 50% of the total urinary hydroxyproline.

Like all urinary collagen breakdown products, hydroxyproline excretion can be measured in a 24 h urine collection or, more conveniently, in fasting, second voided morning samples, expressed as a ratio to the creatinine concentration. Dietary sources of hydroxyproline (e.g. gelatin) need to be eliminated immediately before and during the collection. The major limitations of hydroxyproline estimation as an index of bone resorption are interference from sources other than type 1 collagen, its lack of sensitivity at low concentrations, its day-to-day variability and its partial origin from bone formation.

Glycosylated hydroxylysine. Hydroxylysine – another amino acid unique to collagen-like peptides – is produced by the post-translational modification of lysine residues. These amino acids can then undergo further modification by glycosylation – giving rise to galactosyl-hydroxylysine and glucosylgalactosyl-hydroxylysine. The former predominates in the type 1 collagen of bone. Galactosyl-hydroxylysine is not significantly metabolized before excretion in the urine (10% in free form, 90% peptide bound), and the urinary concentrations are not affected by diet, so it is a good marker of bone resorption. It can be measured by HPLC, but the assay is technically demanding.

Collagen cross-links. The amino acids hydroxylysylpyridinoline and lysylpyridinoline (also known as pyridinoline and deoxypyridinoline, respectively) are created by the covalent cross-linking that takes place when mature collagen molecules stabilize after forming the triple helical structure (Fig. 31.4). Since the cross-links are formed only in extracellular collagen fibrils, they appear in the circulation and the urine only as degradation products of mature matrix and do not reflect new collagen synthesis. In contrast to hydroxyproline, neither pyridinoline nor deoxypyridinoline occur in the collagen of normal skin. Pyridinoline is present in other connective tissues, notably cartilage and tendon, whereas the

FIGURE 31.4 ■ Molecular structure of pyridinoline cross-links. R1 and R2 are telopeptide sequences and R3 a helical fragment sequence; for free crosslinks, R1, R2 and R3 are: $-\text{CH}(\text{COOH})\text{NH}_2$.

less abundant deoxypyridinoline is more specific to bone and dentine.

In urine, both pyridinoline and deoxypyridinoline are present as both free amino acid derivatives (~40%) and as oligopeptide-bound fractions (~60%). The free forms can be measured directly, but the conjugated form has to be hydrolysed before assay. After acid hydrolysis, total urinary pyridinoline and deoxypyridinoline can be measured by HPLC, but ELISA immunoassays for the free amino acids or peptides containing the cross-links are now available.

The pyridinoline:deoxypyridinoline molar ratio in urine is similar to that found in bone (7:2), and the urinary excretion rate of the cross-links agrees well with radioisotopic and histomorphometric measures of bone resorption. The cross-links do not undergo further metabolism once released, and their rate of excretion is not influenced by dietary intake or moderate renal impairment. Random urine measurements (expressed relative to creatinine concentration) correlate closely with 24h estimates. The elderly tend to have relatively greater excretion of the larger peptide-bound forms, and a correspondingly

smaller proportion of the free pyridinoline and low molecular weight peptide forms.

Urinary pyridinoline and deoxypyridinoline concentrations appear to be good markers of bone resorption, and more sensitive than hydroxyproline in distinguishing small increases in bone resorption from normal. For example, when normal premenopausal and postmenopausal women are compared, hydroxyproline excretion in the latter group is about 50% above that of premenopausal women, whereas for urinary pyridinoline and deoxypyridinoline, excretion is increased by 100%.

Collagen telopeptides. Collagen cross-links form mainly between the short non-helical peptides at both ends of the collagen molecule (the N- and C-terminal telopeptides), which link via pyridinium or pyrrole compounds to the helical portion of an adjacent collagen molecule (Fig. 31.5). During collagen breakdown, N- and C-terminal telopeptide fragments, still attached by the pyridinium cross-link to the helical fragments of the nearby molecule, are released into the circulation and are cleared by the kidneys. Within the C-telopeptides of type I collagen is an aspartyl-glycine motif that can undergo β -isomerization to isoaspartyl-glycine. This process is believed to be linked to protein ageing, with younger bone having a greater proportion of the non-isomerized α -C-telopeptides, and older bone having a greater proportion in the β -isomerized C-telopeptide form. Various immunoassays have been developed to detect epitopes specific to particular fragments.

The urinary N-telopeptide (NTX) assay is an ELISA based on a monoclonal antibody that recognizes a conformational motif in the $\alpha 2$ -chain that is linked to a pyridinium cross-link. Although it does not recognize the pyridinoline or deoxypyridinoline cross-link itself,

FIGURE 31.5 ■ Intermolecular cross-linking in type I collagen and the location of the peptide sequences of the N-terminal (NTX) and C-terminal (CTX) immunoassays.

it is specific for the cross-linking site of bone collagen. The assay requires no hydrolysis. The measurement is usually performed on a second void, morning urine sample, and the results are expressed as bone collagen equivalent, corrected for urinary creatinine concentration. A serum assay has also been developed, which correlates well with urinary concentrations.

Immunoassays for the C-terminal telopeptide cross-linked region of type I collagen (CTX) have also been developed. The monoclonal antibody recognizes an octapeptide sequence of the $\alpha 1$ chain containing the lysine in the C-terminal telopeptide that is involved in intermolecular cross-linking. Immunoassays that are specific for either α -CTX or β -CTX have been developed, and can measure these fragments in both serum and urine. Serum β -CTX is generally regarded as the marker of choice for assessing bone resorption. It should be measured fasting at 08.00–09.00 h, since it shows diurnal variation and is suppressed by food.

Tartrate-resistant acid phosphatase. The acid phosphatases are lysosomal enzymes that hydrolyse phosphomonoesters at low pH, releasing phosphoric acid. They are produced in a number of tissues, including bone, prostate, platelets and erythrocytes. Five isoenzymes are detectable in plasma. The different acid phosphatase isoenzymes differ in tissue of origin, chromosomal origin, molecular size and electrophoretic mobility. Based on the latter, the plasma isoenzymes have been classified as types 1–5. According to their sensitivity to inhibition by L(+)-tartrate, the isoenzymes are further classified as tartrate sensitive (TSAP) and tartrate resistant (TRAP).

Prostatic acid phosphatase (type 2b) activity is typically raised in plasma in carcinoma of the prostate. Type 5 acid phosphatase is produced by macrophages (TRAP5a) and osteoclasts (TRAP5b). TRAP5a activity in plasma is elevated in Gaucher disease and hairy cell leukaemia.

Tartrate resistant 5b differs from TRAP5a by not having sialic acid residues. It can be measured in serum by a variety of kinetic assays or by immunoassay. Measurement has some value in the diagnosis of osteoclast-rich forms of osteopetrosis. In most forms of this disorder, the number of osteoclasts in bone is actually increased – although they are ineffective at resorbing bone – and plasma activities of TRAP5b are increased. In most other bone disorders, TRAP5b plasma concentrations correlate well with other indices of bone resorption and with histological measurements of osteoclastic activity. Unlike other resorption indices, TRAP5b reflects osteoclast number and/or activity, rather than matrix breakdown. It may find a particular role in situations where these are dissociated, such as in examining the actions of drugs that inhibit osteoclast activity without reducing their number (e.g. cathepsin K inhibitors). Plasma acid phosphatase concentrations are also increased in bisphosphonate-induced osteosclerosis.

New markers. It is now possible to measure circulating cathepsin K concentrations. Preliminary reports indicate that these are higher in subjects with fractures, and are related to other turnover markers. Assays are also available for circulating osteoprotegerin, soluble RANKL, and sclerostin. These factors all act locally in bone, and the relevance

of circulating concentrations to judging their bioactivity in the bone micro-environment remains to be determined. These new markers are used mainly for research purposes at present, and their clinical utility is uncertain.

Variation in bone turnover markers. Many of the markers described are now widely used in research, and are finding a place in the management of some metabolic bone diseases. In general, they correlate well with assessments of turnover based on histomorphometry or calcium kinetic studies. The newer assays are more specific to bone and, in some cases, are more sensitive to perturbations, but their usefulness is limited by the day-to-day biological variability (as well as analytical imprecision). Stability is also an important issue for some analytes. In general, plasma markers of bone resorption show less day-to-day variability than urinary markers. Urinary resorption markers are usually measured on fasting second void urine samples to minimize the effect of diet and results expressed as a ratio to creatinine concentration. Thus, artefact can arise if muscle mass is significantly altered from normal.

Most markers of bone turnover show significant diurnal variation with highest values in the early morning hours and lowest values during the afternoon or night. The amplitude of this variability is around 15–30%. Therefore, resorption markers are best assessed in the early morning, after overnight fasting.

Bone turnover may also vary with the menstrual cycle: formation markers are higher in the luteal phase, whereas resorption markers are higher during the follicular phase. The amplitude of these changes is ~10%. After the menopause, there is an increase in bone turnover – resorption markers increase by 30–50% within 12 months of the menopause, and there are similar, but later, increases in formation markers. A less marked increase in bone turnover markers is also seen in men after the age of 50 years. Compared with adult values, all turnover markers are much higher during childhood and puberty, because the skeleton is growing and modelling, as well as remodelling (see below). It is thus important that age-appropriate reference ranges are used for all these assays.

Bone markers increase by ~50% two to four weeks after a fracture, and can take six to nine months to return to normal.

OSTEOPOROSIS

Osteoporosis is a reduction in bone density to the point that fractures occur as a result of the minor trauma that is a normal part of everyday life. At the microscopic level, osteoporotic bone is normally mineralized but reduced in volume. There is a generalized thinning of trabecular elements with the total loss of some trabeculae, greatly reducing the strength of bone (Fig. 31.6) and a reduction in cortical width in long bones. This loss of the normal microarchitecture emphasizes the need for prevention of bone loss, since restoration of the lost structure is unlikely to be achievable with pharmacological agents.

Osteoporosis can also be defined using bone mineral density (BMD) criteria. Thus, osteoporosis is defined as a BMD T-score less than –2.5, a BMD that is more

FIGURE 31.6 ■ Low-power scanning electron micrographs of iliac crest biopsies at the same magnification. (A) Taken from a healthy 47-year-old woman; (B) from an osteoporotic woman of 75 years. In comparison with (A), there has been thinning of the trabeculae with loss of some trabecular elements and discontinuity (arrowed) of some of those which remain. (From Dempster D W et al. 1986 A simple method of correlative light and scanning electron microscopy of human iliac crest bone biopsies. *Journal of Bone and Mineral Research* 1:21–25, with permission.)

than 2.5 standard deviations below the mean value in the young healthy population. Using this diagnostic criterion, ~50% of women have osteoporosis by the age of 80 years. Osteopenia is defined as a BMD T-score that is 1–2.5 standard deviations below the mean value in the young healthy population. Low bone mineral density is an important predictor of future fractures. Loss of BMD is sometimes pathological, but more frequently occurs as a normal part of ageing. With age, the efficiency with which osteoblasts refill resorption cavities is reduced, and there is also an increase in bone resorption associated with hypogonadism.

The important clinical consequence of osteoporosis is fracture. Common osteoporotic fractures include those of the hip, forearm, vertebral body, humerus, ribs and pelvis, while digital, skull, facial and fibular fractures are generally not osteoporotic in origin. The epidemiology of osteoporotic fractures reflects the importance of age and sex in the pathogenesis of the disease. The incidence of vertebral and hip fractures increases exponentially in later life in both men and women, although fracture rates at these sites in men increase about 10 years later (at age 75) than those in women.

Causes of osteoporosis

Box 31.2 sets out a list of risk factors for, and causes of, osteoporosis. Some of these (for example age and family history) are not modifiable. Whether or not an individual will develop osteoporosis depends on two factors: the peak bone mass, typically attained by age ~20 years, and the rate of loss of bone in later life. Probably the strongest influence on peak bone density is genetic – there is a

BOX 31.2 Risk factors for osteoporosis

Physiological

- Heredity: race, stature, family history
- Leanness
- Nutritional: very low calcium intake, hypovitaminosis D
- Inactivity
- Age

Pathological

- Endocrine: hypogonadism, hyperthyroidism, Cushing syndrome, primary hyperparathyroidism, adult growth hormone deficiency
- Gastrointestinal: partial gastrectomy, malabsorption
- Nutritional: prolonged undernutrition, e.g. anorexia nervosa
- Chronic liver disease
- Drugs: glucocorticoids, ciclosporin, thiazolidinediones, anticonvulsants, heparin, alcohol, tobacco
- Inflammatory disorders: rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease
- Haematological: myeloma, monocytic leukaemia, mastocytosis

close relationship between an individual's BMD and that of his parents, and bone density is reduced in the children of patients with osteoporosis.

Because of the evidence for a strong heritable component to peak BMD, there has been intense interest in identifying genes that regulate skeletal health. Thus, a large number of genome-wide association studies (GWAS) have been performed in recent years. These analyses have identified more than 20 genes that are associated with

alterations in BMD. Several of these genes cluster into four biological pathways: the vitamin D endocrine pathway, the oestrogen endocrine pathway, the wnt- β -catenin signalling pathway and the RANKL-RANK-OPG pathway. However, collectively these genes account for only a few percent of the variability in BMD. So, at present, it seems unlikely that genetic testing will improve the predictive power of algorithms used to identify patients at high fracture risk. Genetic factors may also underlie the significant racial differences in bone density and fracture incidence. Individuals of African or Polynesian ancestry have higher bone mass than Europeans and Asians.

Body weight is an important influence on bone density, with heavier people having greater bone mass, and lower fracture risk than those who are thin and/or underweight. The relationship between body weight and bone density is probably mediated in several ways, including mechanical loading of bone, the skeletal actions of hormones affected by nutritional status, and the actions of adipokines produced by adipose tissue.

Despite continued argument as to what constitutes an adequate calcium intake at different stages of life, the impact of calcium intake on bone density and fracture risk is probably slight at intakes >10 mmol (400 mg)/24 h (populations in Asia and Africa appear to maintain satisfactory bone health on intakes of <10 mmol/24 h). Vitamin D insufficiency (plasma 25-hydroxyvitamin D <50 nmol/L), or deficiency (<25 nmol/L), which is common in the contexts of skin pigmentation and sunlight deprivation, may contribute to reduced bone mass.

There has been extensive study of the relationship of physical activity to bone density. Cross-sectional studies are subject to various biases, but most prospective intervention studies indicate that this variable contributes only moderately to the differences in bone density that exist in postmenopausal women. However, prospective studies do indicate that weight-bearing exercise increases bone mass in the pre-pubertal skeleton.

Age has an important effect on bone density in both sexes, and also contributes to skeletal fragility, independently of BMD. In the proximal femur, loss of BMD begins in both sexes in the third and fourth decades, whereas in women BMD in the lumbar spine is probably stable until the perimenopause.

The loss of sex hormones has a deleterious effect on bone mass at whatever time it occurs. In both men and women it is oestradiol deficiency that appears to be critical. Men with inactivating mutations in the genes encoding either the aromatase or the oestrogen receptor have low BMD, despite the presence of normal or high testosterone concentrations. In women, late menarche and episodes of amenorrhoea with oestrogen deficiency reduce bone mass in much the same way as early menopause. Amenorrhoea with oestrogen deficiency can arise from a number of causes (Box 31.3). In the underweight, the low body weight itself has an effect on bone density. Adipose tissue is an important site of oestrone production, and high fat mass is associated with higher circulating concentrations of a number of bone anabolic factors including insulin, amylin and leptin. Cigarette smoking accelerates the metabolism of oestrogens to biologically inactive forms, is associated with reduced body weight

BOX 31.3

Causes of amenorrhoea and oestrogen deficiency in young women that are associated with reduced bone density

Ovarian failure

- Premature menopause
- Oophorectomy
- Chemotherapy

Hypothalamo-pituitary dysfunction

- Weight-related amenorrhoea
- Hyperprolactinaemia
- Drugs: long-acting gonadotrophin-releasing hormone agonists, depot medroxyprogesterone acetate contraception

and early menopause and may directly inhibit osteoblastic function: consequently, BMD tends to be lower in smokers than in non-smokers.

Various pathological conditions can also have significant effects on BMD (see Box 31.2). Alcohol appears to act as an osteoblast toxin and high intakes are also associated with both liver disease and hypogonadism. Glucocorticoids cause bone loss through inhibition of osteoblastic and osteocytic activity, intestinal calcium absorption and renal tubular calcium reabsorption. Glucocorticoids may directly or indirectly stimulate both hyperparathyroidism and bone resorption and, in men, are associated with reduced plasma testosterone concentrations.

Investigation and diagnosis

In recent years, there has been a move to characterize osteoporosis as a disease, principally so that it will be taken seriously by doctors, patients and regulatory authorities. However, this can be counterproductive to an understanding of the nature of the condition, since the process of bone loss is universal. Therefore, the key issue is often not so much one of diagnosis (required in the context of a disease), but one of assessing fracture risk, and then determining which interventions are cost-effective for a given level of risk. Fracture risk can be assessed from clinical risk factors (discussed above) and measurement of BMD.

Clinical risk factors for fracture

The risk factors of greatest importance include age, weight, family history and smoking. However, the most powerful predictor of future fractures is a past history of fracture. The presence of a deformed vertebra on a lateral spine or chest X-ray increases future fracture risk as much as five-fold, and a similar effect is seen with a past history of fractures at other sites. Therefore, treatment is sometimes indicated following fracture, even if the BMD is not particularly low.

Bone densitometry

There is a continuous, inverse, relationship between fracture risk and BMD. The best validated methodology for assessing BMD is dual-energy X-ray absorptiometry

(DEXA). Using this technology, a difference in bone density of one population standard deviation (about 10%) is associated with a two-fold difference in fracture risk. Most sites of bone density measurement give comparable prediction of global fracture risk. However, fracture at a given site is best predicted by bone density measurement at that site: for example, hip bone density predicts hip fracture risk better than measurements elsewhere. The sites most commonly assessed are the hip and spine. The fact that hip fractures are numerically the most important osteoporotic fractures argues in favour of using the hip as the preferred measurement site. However, the precision of measurement is greater in the spine, and the trabecular bone of the spine is more rapidly responsive to both disease and to therapeutic interventions. With advancing age, the value of vertebral scans diminishes because of artefacts associated with degenerative joint and disc disease. Because of these conflicting issues, it is common practice to measure bone density in both the lumbar spine and proximal femur. In the past, the forearm was a common site for measurement because that was all that was technically feasible. Modern densitometers can also measure the forearm, but there is no reason to prefer it to the spine and hip when these measurements are available.

Absolute values of bone density are not comparable between different anatomical sites, measurement techniques and make of densitometer. This problem has been addressed by reporting bone densities in terms of the young healthy population range, using standard deviation units (T-scores). The DEXA-based 'definition' of osteoporosis can be used as the threshold for intervention. However, it does not take into account the fact that clinical risk factors are multiplicative with the risk estimated from bone density measurement. For example, a T-score of -2.5 in an 80-year-old woman with a history of vertebral fracture is associated with a considerably higher risk of fracture over the next year than is the same density in a 50-year-old woman with no fracture history.

It is now standard practice to combine clinical risk factors with BMD in algorithms that produce estimates of absolute fracture risk. Examples, freely available via the internet, include the WHO-sponsored FRAX and the Garvan Fracture Risk Predictor. A 10-year hip fracture risk of $>3\%$ or an osteoporotic fracture risk of $>15\text{--}20\%$ are typically taken as indications for pharmaceutical intervention, but these thresholds are obviously influenced by the cost and safety of the interventions, balanced against their effectiveness. Of the other modalities available for assessment of BMD, computerized tomography (CT) scanning is rarely used because of the higher radiation exposure involved and ultrasound-based methods (e.g. of the os calcis) have not been as extensively validated.

Biochemical investigation

The investigations necessary in a patient who has osteoporosis will depend upon the extent to which the low bone mass can be accounted for by information already available. Thus, in an elderly subject or someone who has received long-term high-dose glucocorticoid therapy, there may be very little need for further investigations. However, in a younger individual whose bone density is

clearly subnormal without apparent cause, a more extensive investigation for an underlying abnormality is appropriate. The investigation thus depends on the clinical context (see Box 31.2). Measurements of sex hormone concentrations (particularly in men), thyroid, renal and liver function tests, plasma and urinary cortisol, plasma calcium, albumin and phosphate, 25-hydroxyvitamin D (25(OH)D), serum and urine protein electrophoresis, coeliac disease markers, serum tryptase (to diagnose mastocytosis) and full blood count may be appropriate.

There remains much debate about the utility of measuring bone turnover markers in the management of osteoporosis (Table 31.2). The potential uses include both prognosis (prediction of fracture, selection of patients for treatment, prediction of response to treatment) and therapeutics (selection of treatment, monitoring adherence to, and effectiveness of treatment). At present, there is little convincing evidence for use of biochemical markers in most clinical settings, but these are active areas of research and more data will emerge.

There has been concern that long-term suppression of bone turnover with potent bisphosphonates might increase the risk of osteonecrosis of the jaw and subtrochanteric femoral fractures. While the significance of these issues continues to be debated, 'drug holidays' after 5–10 years of bisphosphonate therapy are now commonly recommended; bone turnover markers have a role in deciding when treatment should be reintroduced.

There is limited value in measuring 24h urine calcium in patients with osteoporosis. The urine calcium excretion reflects an interaction of dietary calcium intake, fractional intestinal absorption, bone resorption and renal tubular reabsorption, and it is not possible to tease these apart without other investigations. The calcium:creatinine ratio in a fasting, second-voided urine sample in the morning is a poor guide to the rate of bone resorption, but does permit calculation of indices of renal calcium handling – though these are seldom needed in managing osteoporosis.

TABLE 31.2 Potential uses of bone turnover markers in osteoporosis

Clinical question	Utility of test
Diagnosis of osteoporosis or prediction of bone mass	None
Prediction of fracture and selection of patients for therapy	Possibly useful, but not yet validated
Selection of type of therapy	Theoretically appealing, not yet validated
Monitoring adherence to treatment	Useful
Monitoring effectiveness of therapy	Possibly useful, in conjunction with bone mass measurement
Predicting change in bone mass on treatment	Reasonable correlation in some studies
Determining duration of 'drug holiday' in patients on long-term antiresorptive therapy	Useful

In a few centres, the efficiency of intestinal calcium absorption is measured. However, there are practical difficulties in the performance of these tests (see Chapter 6) and there is no clear evidence that this approach is a useful guide to treatment selection or improves treatment outcomes.

Other investigations

The clinical history should include an assessment of recent and past dietary calcium intake. The presence of fractures should be confirmed radiologically and the radiographs scrutinized for evidence of other abnormalities, particularly the possibility of malignancy. Isotope scanning is also useful in detecting metastases. Bone biopsy is needed rarely, to diagnose pathologies such as osteomalacia or mastocytosis, and is reserved for patients with atypical presentations in whom there is a high index of suspicion of some other underlying abnormality (Appendix 31.1).

Treatment

Treatment of osteoporosis involves a number of strategies, all of which are aimed at reducing the individual's future risk of fracture. They can be divided into lifestyle changes (many of which are applicable to the whole population), oral calcium and vitamin D supplementation (in subjects with low intakes) and pharmacological measures. The latter are more expensive and more likely to be associated with side-effects, so are reserved for those with a moderately high absolute risk of fracture. In addition, minimization of exposure to drugs (particularly glucocorticoids) that are toxic to the skeleton is important.

Lifestyle modifications

Lifestyle interventions that can be recommended to all patients include maintenance of ideal body weight throughout life, maintenance of normal sex hormone concentrations from puberty until the late forties (as evidenced in women by regular menstruation), regular weight-bearing exercise, avoidance of smoking and avoidance of high alcohol intake. Exercise may be particularly important during childhood and adolescence, when the skeleton is very responsive to the loads placed upon it. Vigorous exercise interventions in postmenopausal women produce changes in bone density of only a few percent, but regular exercise, by increasing fitness, may also decrease an individual's risk of falling.

Calcium and vitamin D

While the fundamental building block of bone is collagen, calcium is also an important constituent, and its supply in the diet has been suggested to be a limiting factor for bone growth and maintenance. The average calcium intake in Western postmenopausal women is 17.5–22.5 mmol (700–900 mg)/24h, and there is evidence that increasing this by a further 25 mmol (1 g)/24h slows postmenopausal bone loss by ~50%, though calcium supplementation alone is not able completely to prevent

postmenopausal bone loss. Fracture risk appears to be reduced by ~10% with calcium supplements. However, the trials which suggest this fracture prevention also demonstrate an increase in risk of myocardial infarction of about 25% and of stroke of about 15%, effectively negating any potential benefit. These risks have not been demonstrated with *dietary* calcium intake, so modest augmentation of the diet may be a safer course to follow than the use of mineral supplements.

Vitamin D deficiency is extremely common among the frail elderly as a result of low levels of exposure to sunlight. If severe, it sometimes accelerates bone loss and it may also contribute to muscle weakness, increasing the risk of falls. If suspected, it can be confirmed by measurement of serum 25(OH)D. The current consensus is that optimum plasma concentrations of this compound are at least >50, and probably >70 nmol/L, although some authorities advocate concentrations as high as 100 nmol/L. Vitamin D deficiency can be prevented or treated with oral calciferol (at least 500–1000 U/day or, more conveniently, 50 000 U/month). There is evidence from randomized controlled trials in markedly deficient frail elderly subjects, that the provision of calcium and calciferol supplementation reduces hip fracture risk by more than a quarter. The use of the potent metabolites of vitamin D, such as calcitriol, is more expensive, more likely to cause hypercalcaemia or hypercalciuria and is of uncertain clinical benefit.

Pharmacological management

Bisphosphonates. The pharmacological management of osteoporosis is currently dominated by the bisphosphonates. These are relatively simple phosphate salts that have a very high affinity for the surface of bone but are very poorly absorbed from the gastrointestinal tract. Thus, only 1–2% of an oral dose is absorbed, about half of which is rapidly deposited on the bone surface, the balance being excreted unchanged in the urine. When osteoclasts resorb bone, they ingest the bisphosphonate and are effectively poisoned by it. This reduces the amount of bone resorption (bone resorption markers fall by 50–80%) with a consequent redressing of the imbalance between bone formation and resorption. Bisphosphonate remains present on the bone surface for many years and is gradually incorporated into the structure of the bone, so that it can inhibit remodelling cycles that occur years after the time of dosing. Thus, bisphosphonates have a long duration of action and intermittent administration is effective. Zoledronate, for instance, can be given as infrequently as once every 2–3 years by intravenous infusion and produces changes in bone density comparable to or greater than those seen after weekly oral dosing with alendronate.

The low oral bioavailability of bisphosphonates is a critical issue in their use. They must be taken fasting, with water alone, if they are to be absorbed at all. Aminobisphosphonates, such as alendronate and risedronate, can cause oesophagitis and gastric ulceration, so patients should not lie down for 30–60 min after oral dosing, since this may permit reflux of the tablet into the oesophagus. This does not appear to be such a problem for the less potent, non-amino bisphosphonate, etidronate.

A common phenomenon after first exposure to intravenous (and occasionally oral) nitrogen-containing bisphosphonates is an 'acute phase response' of fever, myalgia and headache that lasts 24–48 h. This is mediated by the release of TNF α and interleukin (IL)-6 from peripheral blood T cells. While sometimes unpleasant, the reaction is transient, and tends not to recur with subsequent doses.

Potent bisphosphonate use in postmenopausal women results in an increase in bone density comparable to that produced by hormone replacement therapy. Bone resorption is reduced by more than one half, and the risk of hip, spine and forearm fractures is lowered by ~50%. While there are a number of trials assessing the effects of bisphosphonates on fracture risk over periods of three to four years, there are only limited data available from longer-term studies. The available data suggest that anti-fracture efficacy is maintained with long-term use.

Of the currently available bisphosphonates, the evidence for anti-fracture efficacy is strongest for alendronate (most conveniently given as a weekly dose), risedronate (weekly) and intravenous zoledronate (annually), each of which has been demonstrated to prevent both vertebral and non-vertebral fractures in osteoporotic and glucocorticoid-treated patients and in men as well as postmenopausal women. Thus, these bisphosphonates are currently the first choice therapy in all forms of osteoporosis.

Following discontinuation of bisphosphonates, bone resorption rises to some extent, but even several years after discontinuation of long-term use of alendronate and zoledronate, bone turnover markers do not return to baseline. The same is true of bone density, which declines only slowly after withdrawal of these agents. This prolonged duration of action is a consequence of the long residence time of bisphosphonates in bone, and it raises important (as yet unanswered) questions about the optimal duration of continuous therapy. There is general agreement that these agents should be used continuously for periods of up to five years. Beyond that, some experts reduce the dose, whereas others opt either for no change or for a period off treatment. There is no clear evidence at present to determine what is optimal. Risedronate and ibandronate have a more rapid offset of effect, and will often require re-institution of therapy within 6–12 months of treatment cessation.

Hormone replacement therapy. Hormone replacement therapy (HRT) was the most widely used intervention for the prevention and treatment of osteoporosis for many years, but was displaced by the aminobisphosphonates, because of their demonstrated anti-fracture efficacy, and because the Women's Health Initiative produced a marked change in attitudes to hormone replacement therapy. On the one hand, it clearly demonstrated that HRT reduces the incidence of fractures, including hip fractures. On the other, it raised concerns regarding safety, particularly with respect to cardiovascular and cerebrovascular disease, breast cancer and venous thromboembolism. Public and professional enthusiasm for the use of HRT in the management of osteoporosis waned, because the older age group in whom osteoporotic fracture risk is high is the same group in whom vascular disease is a major concern.

If early postmenopausal women require interventions for osteoporosis, HRT may still be a reasonable option, although the balance of risks and benefits of HRT in younger (<50 years) postmenopausal women is uncertain, and the bisphosphonates are also suitable for use in this context. The cardiovascular and skeletal effects of transdermal oestrogen preparations have not been assessed in large randomized studies. Unlike the bisphosphonates, oestrogen effects on bone disappear within months of treatment discontinuation, so long-term reductions in fracture risk are unlikely to occur.

Selective oestrogen receptor modulators. Selective oestrogen receptor modulators (SERMs) are a newer class of pharmaceuticals with mixed oestrogen agonist/antagonist activities that vary from tissue to tissue. Thus, the prototypic SERM, raloxifene, acts as an oestrogen agonist on bone, but as an antagonist in the breast and endometrium. Raloxifene reduces bone resorption and increases bone density, but is less potent than either oestrogen or bisphosphonates in this regard. It decreases the incidence of vertebral fractures but it has not been shown to have any effect on non-vertebral fractures. It substantially reduces the incidence of breast cancer, and does not significantly influence risk of vascular disease. Basodoxifene has similar effects and is being developed for co-administration with oestrogen, thus augmenting its bone effects, while the anti-oestrogen actions of the SERM block the proliferative effects of the oestrogen on breast and endometrial cells. Lasofoxifene is the only SERM to be shown to reduce risk of non-vertebral factors, but it is not clear that this drug will reach the market.

Parathyroid hormone. Parathyroid hormone (PTH) preparations, either PTH(1-34) (teriparatide) or PTH(1-84), were the first anabolic therapies to be approved for treatment of osteoporosis. When given as a daily injection, they produce substantial increases in BMD at skeletal sites containing predominantly trabecular bone, with less marked increases in cortical BMD, and reductions in fracture incidence that tend to be greater than are seen with other currently available agents. PTH use is restricted to a period of 1.5–2 years because of the high incidence of osteosarcoma in rat toxicology studies, although this problem has not been an issue in human use. Unlike the antiresorptive agents, it causes sustained *increases* in markers of both formation and resorption. Practices for combining PTH with antiresorptives vary; co-administration with alendronate may blunt its anabolic effects, though this appears not to be the case for combination with zoledronate. The anabolic effects dissipate rapidly after treatment discontinuation, so locking in gains in BMD with subsequent antiresorptive therapy is important.

Other pharmacological treatments. The divalent cation strontium (in the form of strontium ranelate) has been shown to prevent both vertebral and non-vertebral fractures, though effects on hip fracture were only seen in *post hoc* analyses. The mechanism of action of strontium on bone is not understood, but some of the increase in

BMD it produces is artefactual, resulting from replacement of calcium ions by the heavier strontium ions in the hydroxyapatite. BMD measurements in strontium-treated patients, should be adjusted for skeletal strontium content.

Denosumab is a monoclonal antibody against the osteoclastogenic factor, RANKL. It produces profound reductions in both bone resorption and bone formation, resulting in increases in BMD and decreases in fracture rates comparable to those resulting from the use of potent bisphosphonates. It is given by six-monthly subcutaneous injection but there is a rapid loss of effect 6–8 months after an injection, with an overshoot in bone turnover during this time. Therefore, maintaining continuity of treatment is very important to achieve anti-fracture efficacy.

Cathepsin K is the principal osteoclastic enzyme involved in the degradation of type I collagen. It is therefore an obvious target for an antiresorptive agent. Several early studies in this area were abandoned because of insufficient specificity of the investigation compounds. The cathepsin K inhibitor odanacatib, has demonstrated sustained year-on-year increases in bone density in phase 2 studies. A large phase 3 study to determine anti-fracture efficacy is nearing completion. Tartrate resistant 5b concentrations are not suppressed (as osteoclasts remain numerous on the bone surface, although their bone resorbing activity is markedly curtailed) and the suppression of bone turnover markers with odanacatib is less marked than seen with other antiresorptive agents; in particular the suppression of bone formation appears to diminish after 2–3 years. Discontinuation of treatment is accompanied by a rapid rise in bone turnover markers.

In recent years, the wnt-LRP5 pathway has emerged as a critical regulator of bone formation. Activity of this pathway is regulated by sclerostin, an inhibitor secreted by the osteocyte. A number of studies are exploring the efficacy of monoclonal antibodies directed against sclerostin as bone anabolics. Phase 1 and 2 studies suggest that these could be the most effective bone anabolic drugs yet developed; results of phase 3 trials are awaited.

In the past, sodium fluoride and calcitonin were widely used to treat osteoporosis but good evidence of anti-fracture efficacy is lacking for both and fluoride interferes with normal bone mineralization. As a result, both agents have dropped out of common usage.

Biochemical responses to treatments

Antiresorptive agents such as HRT, SERMs and the bisphosphonates produce an early (within weeks) reduction in indices of bone resorption, followed by a slower fall in indices of bone formation (Fig. 31.7). Similar effects are observed in hypogonadal men treated with testosterone replacement. These effects are sustained for the duration of therapy and, in the case of potent bisphosphonates, which have long skeletal retention times, may persist for considerable periods of time (months or years) after therapy is stopped. The most potent currently available bisphosphonates may reduce markers of bone resorption by up to 80% from baseline levels. Denosumab can produce even larger decreases in bone resorption, most patients having undetectable resorption markers in

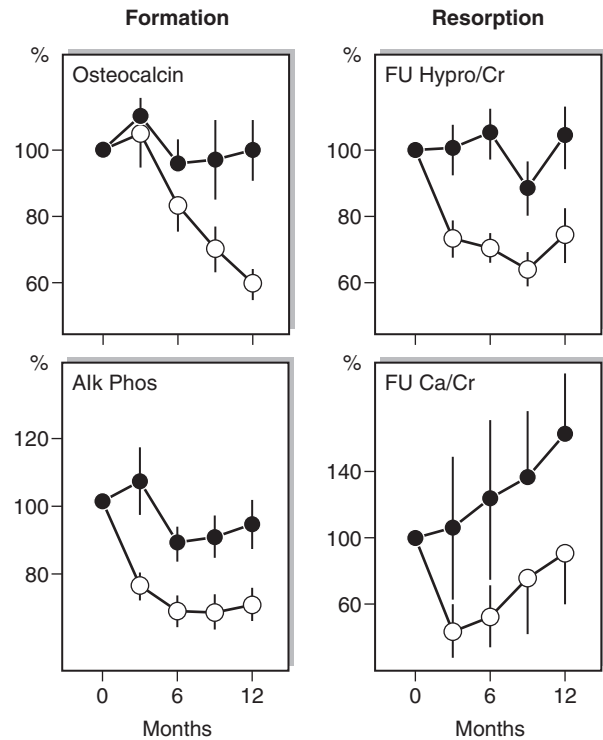

FIGURE 31.7 ■ Changes in mean (\pm SD) biochemical indices of bone formation and resorption in postmenopausal women receiving either placebo (closed circle) or a regimen of continuous oestrogen and progesterone (open circle). The group receiving active treatment show significant suppression of both bone resorption and formation. There is a tendency to reach a plateau in these indices as a new steady state is reached. Note that the variance in fasting urine calcium/creatinine ratios (FU Ca/Cr) is considerably greater than that in fasting urine hydroxyproline/creatinine (FU Hypro/Cr). (Data from Christiansen C, Riis BJ 1990 17 β estradiol and continual norethisterone: a unique treatment for established osteoporosis in elderly women. *Journal of Clinical Endocrinology & Metabolism* 71:836–841.)

the first weeks after injection. In contrast, the cathepsin K inhibitor odanacatib only reduces resorption markers by about 50%, with smaller declines in formation markers. Plasma calcium and phosphate concentrations can also fall during the early phase of antiresorptive therapy but usually recover without specific intervention.

Intermittent PTH treatment produces biochemical changes characterized by an initial increase in markers of bone formation (P1NP, e.g. typically doubling), reflecting primary activation of osteoblasts. A smaller increase in osteoclastic activity follows as a secondary, coupled phenomenon. Plasma 1,25(OH)₂D concentration increases by ~25% and there may be small falls in 25(OH)D. Plasma calcium concentration may increase and plasma phosphate decrease during treatment because PTH also stimulates renal tubular calcium reabsorption and phosphaturia (directly) and intestinal calcium absorption (indirectly). Occasionally, a reduction in PTH dose may be required because of mild hypercalcaemia. Early data with anti-sclerostin antibodies demonstrate large early increases in formation markers and, surprisingly, some inhibition of bone resorption markers. Over a period of months, both changes tend to revert towards baseline values.

Treatment with strontium produces inconsistent changes in markers, smaller in magnitude than most agents discussed above. Notably, strontium interferes in many routinely available assays for calcium concentration.

Growth hormone replacement in adults who are deficient improves bone mass, primarily by stimulating cortical bone accretion. Growth hormone treatment induces an early increase in bone resorption markers, and later increases (~two-fold) in bone formation markers that reach a peak after a year of treatment, and then gradually decline. The peak in osteocalcin is delayed relative to the other formation markers.

OSTEOMALACIA

Osteomalacia is the term used to describe the disorder arising from defective mineralization of bone. It is a histological diagnosis, based on the volume of unmineralized osteoid, its extent over bone surfaces, its thickness and the rate of mineralization, as assessed by tetracycline labelling. If a mineralizing defect is a diagnostic possibility in an unusual case, then biopsy should be undertaken (Appendix 31.1). In adults, the radiographic appearances are generally non-specific, showing generalized osteopenia or (in severe cases) vertebral collapse. Looser zones (short radiolucent lines through the cortex, at right angles to the shaft) are very suggestive of osteomalacia, but occur in only a minority of patients.

When osteomalacia arises before growth is complete, the clinical and radiographic features differ from those seen in adulthood, and the condition is termed rickets. The histological processes occurring in osteomalacia and rickets are similar. In order for newly formed osteoid to mineralize, adequate supplies of mineral (calcium and phosphate) must be available and the function of the osteoblasts that regulate the mineralization process must be normal. The causes of osteomalacia are conveniently categorized into those where there is inadequate supply of mineral and those where osteoblast function is defective. The former group may be further categorized into those where inadequate calcium supply is the critical factor (calciopenic) and those where inadequate phosphate supply is critical (phosphopenic). Calciopenic forms are frequently associated with abnormalities of vitamin D metabolism. Biochemical investigations can suggest that osteomalacia is present and indicate possible aetiologies, but cannot prove its presence. However, the biochemical findings in calciopenic and phosphopenic forms of osteomalacia are often very characteristic, so that bone biopsy is not necessary in routine cases.

Calciopenic osteomalacia

The major causes of calciopenic osteomalacia are summarized in Box 31.4.

Vitamin D deficiency

Rickets and osteomalacia were endemic in the UK and many other European countries from the 17th century until the mid-20th century. Crucial scientific observations

BOX 31.4 Causes of calciopenic osteomalacia

Low 25(OH)D, normal 1,25(OH)₂D synthesis

- Low calcium intake
- Binding of dietary calcium by phytate and other factors
- Lack of exposure to sunlight
- Post-gastrectomy
- Malabsorption syndromes (small intestinal disease, hepatobiliary disease, pancreatic disease)
- Anticonvulsants
- Mutation in gene for 25-hydroxylase (*CYP2R1*)

Normal 25(OH)D, reduced 1,25(OH)₂D synthesis

- Chronic kidney disease
- Vitamin D-dependent rickets type I

Normal 25(OH)D, normal 1,25(OH)₂D synthesis

- Vitamin D-dependent rickets type II

made in post-war Vienna in 1919–1922 established the role of vitamin D in the aetiology of privational osteomalacia. Although it was clearly demonstrated at that time that it was possible to cure privational rickets by exposing children to sunlight, as well as by the administration of a fat-soluble food factor, the dominance of nutritional theory led to the active factor being termed a vitamin, that is, an obligatory food component that the body cannot synthesize. It is now clear that under the influence of ultraviolet light, the skin can synthesize vitamin D₃ (cholecalciferol), the precursor of the prohormone 25(OH)D, and that dietary sources of vitamin D (mainly vitamin D₂, ergocalciferol) are critical only when exposure to sunlight is significantly limited.

Diminished exposure to ultraviolet light through industrial pollution and the practice of infant swaddling may have been important during the years that rickets was endemic, and would account for its greater prevalence in more northerly cities in the UK. In the present day, vitamin D-deficient osteomalacia is observed most commonly in individuals who are sunlight deprived because of skin pigmentation, whose cultural practices involve sunlight deprivation, the malnourished and the institutionalized elderly. Osteomalacia occurring in patients with malabsorption syndromes or after partial gastrectomy is not so easily explained, but does suggest that a nutritional factor is important. This factor is most probably calcium.

Reduced intake of calcium, or impaired calcium absorption, initially causes a small fall in plasma ionized calcium concentration and compensatory secondary hyperparathyroidism. As a consequence of this, a greater proportion of 25(OH)D is metabolized to 1,25(OH)₂D – the active hormone – rather than to inactive metabolites such as 24,25(OH)₂D₃ and 25,26(OH)₂D₃. In the short term, the increased 1,25(OH)₂D production, by increasing fractional absorption of calcium from the intestine, corrects the hypocalcaemia at the expense of modest hyperparathyroidism. However, 1,25(OH)₂D has an additional effect upon the hepatic metabolism of 25(OH)D, accelerating the metabolic clearance of 25(OH)D to its inactive dihydroxylated forms (see Fig. 6.3, p. 97). In the chronic situation, the sustained increase in 1,25(OH)₂D

production eventually depletes the available 25(OH)D pool. Once the concentrations of 25(OH)D have fallen beyond a critical point, 1,25(OH)₂D synthesis itself may become insufficient to sustain adequate calcium absorption, so that there is overt hypocalcaemia. Plasma phosphate is also reduced because of diminished intestinal absorption and the renal effects of hyperparathyroidism. With insufficient calcium and/or phosphate available for mineralization, osteomalacia follows.

Osteomalacia and low plasma 25(OH)D concentrations are also found in some patients on long-term anticonvulsant therapy. Hepatic enzyme induction by the anticonvulsant drugs and accelerated clearance of 25(OH)D are important, but the people most likely to develop this syndrome are institutionalized patients who also have limited exposure to sunlight. Intestinal calcium transport can be impaired directly by phenytoin. A patient from Nigeria with severe rickets/osteomalacia and a very low serum 25(OH)D concentration was found to be homozygous for an inactivating mutation in the gene *CYP2R1*, that encodes the enzyme mainly responsible for 25-hydroxylase activity.

Osteomalacia in people of South Asian origin is multifactorial. As well as diminished dermal synthesis of vitamin D, the traditional diet has a high content of calcium-binding factors such as phytate, which limit the bioavailability of dietary calcium. In groups with a high prevalence of osteomalacia, the disease may be exacerbated by lack of sunshine in winter and at times of increased vitamin D requirements: infancy, adolescence and pregnancy.

The clinical features of privational osteomalacia in adults include bone pain, proximal myopathy and fractures. Bone pain and myopathy are often overlooked and their severity only appreciated when a cure has been effected. The aetiology of the myopathy is unknown. It is not a feature of hypocalcaemia, and does not invariably occur in other types of osteomalacia. In children, rickets may additionally result in difficulty with walking, growth retardation, bowed legs and enlargement of the costochondral junctions.

Defects in 1,25-dihydroxyvitamin D synthesis or action

Osteomalacia and rickets can result from deficiency of the renal 1 α -hydroxylase enzyme and thus failure to synthesize 1,25(OH)₂D, or from defective action of 1,25(OH)₂D, owing to abnormalities of the receptor. Deficiency of the renal 1 α -hydroxylase enzyme can be acquired, as in chronic kidney disease (CKD, see below), or can occur as a rare autosomal recessive disorder known as vitamin D-dependent rickets (VDDR) type I. Clinically, these children develop florid rickets in the first two years of life. The syndrome of VDDR type II is also a rare autosomal recessive disorder, often associated with alopecia totalis, but otherwise with a clinical picture similar to VDDR type I. It is caused by an abnormality in the receptor for 1,25(OH)₂D, arising from mutations either in the DNA-binding or the hormone-binding domain, and there is target organ resistance to the hormone. Acquired resistance to 1,25(OH)₂D has been seen in untreated coeliac disease, where the intestinal mucosa is very abnormal and the absorption of calcium and phosphate impaired.

Laboratory investigation

The relevant laboratory investigations are summarized in Table 31.3. It is important to note that the plasma calcium concentration may be normal in the early phase of privational vitamin D deficiency. Hypophosphataemia due to hyperparathyroidism and reduced intestinal phosphate absorption can occur in any type of calciopenic osteomalacia. However, there are occasional patients with an apparent renal resistance to the effects of PTH who do not become hypophosphataemic when deficient in 25(OH)D. These patients have marked hypocalcaemia and hyperphosphataemia with increased plasma ALP activities.

All bone turnover markers, apart from plasma osteocalcin, are increased in vitamin D deficiency osteomalacia. When assessing plasma phosphate and ALP concentrations, it is important to bear in mind the normal age-related ranges for these indices. The key diagnostic investigation in privational

TABLE 31.3 Typical biochemical and histological findings in calciopenic and phosphopenic forms of osteomalacia and rickets

FGF, fibroblast growth factor; HPT, hyperparathyroidism; N, normal; OM, osteomalacia.

vitamin D deficiency is measurement of serum 25(OH)D concentration. Measurement of 1,25(OH)₂D is indicated in infants with rickets who have no medical or social risk factors for privational vitamin D deficiency and who are hypocalcaemic despite normal plasma 25(OH)D concentrations.

Responses to therapy

Vitamin D deficiency should be treated with calciferol. Single high-dose treatment (300 000–600 000 units orally in an adult) may be more effective than low-dose long-term replacement and reduces problems of adherence to therapy. Patients with chronic conditions can be given weekly or monthly treatment with smaller doses, or annual prophylaxis in mid-autumn. There is a marked tendency for spontaneous improvement in the spring and summer. Attention needs also to be directed to underlying problems such as malabsorption. Vitamin D therapy is ineffective if the dietary calcium content is very low.

Effective therapy is followed by changes in the plasma biochemistry. Plasma calcium concentration rises and hyperparathyroidism is corrected. A marked rise in plasma phosphate concentration occurs after initiation of therapy and peaks at 3–5 weeks; thereafter plasma phosphate gradually declines, reaching the concentration which is normal for that individual after about 6–9 months. Plasma 1,25(OH)₂D concentration is also supranormal during this period, but there is no clinical need to measure 1,25(OH)₂D in this circumstance. Plasma ALP activity often flares during the first two to three weeks but then declines exponentially with a half-time of 50–100 days. A similar early increase in plasma concentrations of procollagen 1 extension peptides can also be seen. Osteocalcin concentrations also rise transiently, and peak about two weeks after treatment is started.

Vitamin D-dependent rickets type I is best treated with oral calcitriol (50 ng/kg per day) or alfacalcidol (100 ng/kg per day). Vitamin D-dependent rickets type II may respond to a combination of calcium supplementation and treatment with very high doses of calcitriol (60 µg/kg per day) or alfacalcidol (100 µg/kg per day).

Any patient being treated continuously with *pharmacological* doses of any form of vitamin D is at risk of vitamin D toxicity, and plasma calcium concentrations need to be monitored and dosages adjusted accordingly. Toxicity is particularly liable to occur as bone disease heals and therapeutic requirements fall.

Phosphopenic osteomalacia

In this group of conditions, the low plasma phosphate concentration is the main factor underlying the osteomalacia. Very rarely, this may result from the ingestion of phosphate-binding antacids, but most commonly it is due to renal tubular dysfunction and phosphaturia (manifest as a low TmP/GFR, see Table 31.3). The disorders can be classified into genetic and acquired forms and by whether or not there are other associated renal tubular defects (aminoaciduria, bicarbonate loss with systemic acidosis, glycosuria and hypokalaemia: the Fanconi syndrome). The most frequently encountered forms are listed in Box 31.5, and their aetiology discussed in Chapter 6.

BOX 31.5 Osteomalacia and rickets resulting from renal tubular phosphate loss

Isolated phosphate leak

Hereditary

- X-linked hypophosphataemic rickets – X-linked dominant (307800 – *PHEX*)
- Autosomal dominant hypophosphataemic rickets (193100 – *FGF23*)
- Hypophosphataemic rickets with hypercalciuria – autosomal recessive (241530 – *SLC34A3*)
- X-linked hypophosphataemic rickets (Dent disease) – X-linked recessive (182309 – *CLCN5*)
- Hypophosphataemic rickets – autosomal recessive (241520 – *DMP1*)

Acquired

- Tumour-associated: mesenchymal cell tumours, polyostotic
- Fibrous dysplasia, neurofibromatosis
- Drug-associated: imatinib, ifosfamide, saccharated ferric oxide

Generalized tubular disorders (Fanconi syndrome)

Hereditary – many different types with dominant, recessive or X-linked inheritance, such as:

- Cystinosis (219800 – *CTNS*)
- Wilson disease (277900 – *ATP7B*)
- Tyrosinaemia, type I (276700 – *FAH*)
- Oculocerebrorenal syndrome/Dent disease-2 (300555 – *OCRL*)
- Hereditary fructose intolerance (229600 – *ALDOB*)
- Fanconi–Bickel syndrome (227810 – *GLUT2*)

Acquired

- Renal tubular acidosis (type 1 and type 2)
- Heavy metal toxicity: lead, cadmium, mercury, platinum, uranium
- Drugs: out-dated tetracycline, cisplatin, 6-mercaptopurine, amphotericin, trimethoprim, pentamidine, toluene
- Dysproteinaemias: myeloma, light chain disease, amyloidosis
- Autoimmune-mediated: systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis
- Interstitial nephritis, renal transplantation

Numbers in brackets after genetic disorder indicate numbering on Online Mendelian Inheritance in Man (OMIM); the gene for each disorder is in italics.

The presentation of the inherited syndromes is usually in infancy with a clinical picture similar to that of rickets due to privational vitamin D deficiency. The most common form of inherited hypophosphataemic rickets, the X-linked type, is exceptional in that myopathy is absent and that marked ligamentous calcification can occur. Male children are more severely affected than females and short stature is a prominent feature.

Adult onset hypophosphataemic osteomalacia is usually associated with mesenchymal tumours (oncogenic osteomalacia) that are often difficult to identify because of their small size. These tumours secrete phosphatonins, such as FGF23, that act on the renal tubules to induce phosphaturia. If a tumour is solitary and can be removed

surgically, then complete resolution of the osteomalacia occurs. Tumours can be identified by either magnetic resonance imaging (MRI) or scintiscanning using isotope-labelled somatostatin or sestamibi, but in a significant minority of cases even these sophisticated techniques may be inadequate. Plasma concentrations of FGF23 are usually increased, and fall after successful resection of the tumour.

Heavy metal nephropathy or light chain deposition in the renal tubules can cause an acquired form of the Fanconi syndrome with hypophosphataemic osteomalacia.

Laboratory investigation

The occurrence of rickets or osteomalacia in an individual without evidence of vitamin D deficiency should prompt consideration of phosphopenia as a cause. A key, and often overlooked, investigation is measurement of the plasma phosphate which, if low, should prompt evaluation of renal phosphate handling. The typical laboratory findings are listed in Table 31.3. The critical biochemical features that distinguish osteomalacia caused by hypophosphataemia due to a renal phosphate leak from that caused by vitamin D deficiency are:

- normal plasma 25(OH)D concentration
- low TmP/GFR, which persists after treatment of the bone disease
- absence of hyperparathyroidism.

Plasma FGF23 measurements are helpful in the diagnosis of oncogenic osteomalacia and some of the genetic disorders. Plasma calcitriol concentrations are usually low in hypophosphataemic osteomalacia that is the result of excess FGF23 activity, but high in conditions such as Dent disease or hereditary hypophosphataemic rickets with hypercalciuria, where the primary defect lies in renal tubular phosphate transporters.

Special tests are required for the diagnosis of the rare inherited and acquired metabolic disorders in which hypophosphataemic osteomalacia is part of a more generalized Fanconi syndrome.

Treatment

When hypophosphataemic osteomalacia occurs with inappropriately low concentrations of calcitriol (usually in the context of increased FGF23 activity) then it is best treated with phosphate supplements and 1 α -hydroxylated vitamin D derivatives. Commercial preparations of sodium dihydrogen phosphate, are available but the precise form of phosphate is not important. Phosphate (total 30–120 mmol/day) has to be given frequently through the day to be effective, because of its rapid loss through the kidneys. Phosphate therapy alone induces hyperparathyroidism, so vitamin D therapy, which offsets this and enhances intestinal phosphate absorption, is also used. These patients are vitamin D resistant, so if calciferol (vitamin D₂) is used, pharmacological doses are required and there is a danger of prolonged vitamin D toxicity. Alfacalcidol or calcitriol are therefore preferred to the parent compound. The histological responses to alfacalcidol or calcitriol also seem to be superior to those seen with calciferol. The therapy should aim to keep plasma

phosphate around 1.0 mmol/L (measured 1–2 h after a dose), but to avoid hypercalciuria and hypercalcaemia. There is an increased risk of metastatic calcification, particularly in the kidney. The risk of nephrocalcinosis is related primarily to the amount of phosphate given, and its occurrence suggests that the dose of phosphate should be reduced (or stopped in the X-linked form when growth is complete). Healing of the bone disease is accompanied by a fall in plasma ALP activity.

Hereditary hypophosphataemic rickets with hypercalciuria is caused by mutations in the renal tubular phosphate transporter NaPi2c. FGF23 concentrations are not increased and plasma calcitriol is appropriately raised (given the hypophosphataemia). The bone disease can be cured with phosphate alone. In some conditions, the Fanconi syndrome responds to treatment of the underlying disorder (e.g. Wilson disease).

Antacid-induced hypophosphataemic osteomalacia is treated by withdrawal of antacids and the short-term prescription of phosphate supplementation.

Osteomalacia and acidosis

Longstanding metabolic acidosis is also associated with osteomalacia. The clinical situations in which this occurs most commonly are types 1 and 2 renal tubular acidosis and patients with bladder resection and ureterosigmoidostomy. The physiological basis of the osteomalacia is incompletely understood. At high [H⁺], the renal 1 α -hydroxylase enzyme is inhibited, so the increase in plasma 1,25(OH)₂D concentrations induced by phosphate depletion is less than expected. However, metabolic acidosis reduces TmP/GFR and, in the short term, stimulates 1,25(OH)₂D synthesis. The mechanism of induction of osteomalacia may thus be similar to that seen in simple vitamin D deficiency. In keeping with this, plasma 25(OH)D concentrations have been reported to be low in many of the published cases of osteomalacia associated with ureterosigmoidostomy. In type 2 renal tubular acidosis, the hypocalcaemia and hypophosphataemia accompanying the Fanconi syndrome could also be important contributory factors. Treatment with alkali alone (sodium bicarbonate) can improve the osteomalacia, but in the limited studies published, has not produced complete healing.

Defective osteoblast function and osteomalacia

Osteomalacia can arise from either congenital or acquired abnormalities of osteoblast function. The acquired forms relate to aluminium or the use of high-dose etidronate in the treatment of Paget disease. In both these conditions, osteoblast numbers are reduced, plasma ALP activity is low and the osteomalacia is resistant to treatment with vitamin D.

Fluoride therapy, or endemic fluorosis, produces a mineralization defect despite abundant osteoblasts being present.

Hypophosphatasia. This is a rare familial disorder with autosomal recessive inheritance arising from mutations in the tissue non-specific ALP gene (*ALPL*). There are varying degrees of clinical severity, depending on the

TABLE 31.4 Clinical syndromes of hypophosphatasia

Presentation	Clinical features
Perinatal	Stillbirth or neonatal death; absence of mineralized skeleton
Infantile	Diagnosed <6 months; rickets, flail chest, hypercalcaemia/hypercalciuria, pyridoxine-responsive seizures
Childhood	Premature loss of primary teeth, rickets, hypercalcaemia/hypercalciuria
Adult	Middle age; recurrent stress fractures; pathological fractures
Odontohypophosphatasia	Premature loss of primary teeth only

types of mutation and the residual activity of the enzyme. The clinical presentation can vary from a lethal perinatal form through to a relatively benign disorder presenting in adulthood (Table 31.4). Heterozygous carriers can be asymptomatic or have a mild form of the disease. In the childhood form, the diagnosis is made usually after the age of six months of age because of orthopaedic abnormalities that resemble rickets. Other features include premature loss of the deciduous teeth, premature closure of the cranial sutures and growth retardation.

The characteristic biochemical findings are reduced plasma ALP activity (both total and bone ALP) with concomitant increases in endogenous substrates of the enzyme. These include plasma pyridoxal 5'-phosphate, inorganic pyrophosphate and phosphoethanolamine. An elevated plasma pyridoxal 5'-phosphate concentration is specific to hypophosphatasia (provided the patient is not taking vitamin B supplements), but urine phosphoethanolamine excretion can be modestly increased in a variety of other disorders. Severely affected children may have hypercalcaemia and hypercalciuria. Plasma phosphate concentrations also tend to be above average for age (due to an increase in the TmP/GFR), and PTH concentrations relatively low. Antenatal diagnosis of the severe form is possible by measurement of amniotic fluid ALP.

The bone shows osteomalacia with reduced osteoblast numbers. Treatment options are limited, but there are case reports of improvement of bone disease with parathyroid hormone treatment, and in severe infantile disease with bone marrow transplantation. The most promising treatment for severe hypophosphatasia is enzyme-replacement therapy, using a fusion protein (named *asfotase alfa*) that comprises the TNSALP ectodomain, the constant region of the human IgG1 Fc domain and a deca-aspartate motif.

CHRONIC KIDNEY DISEASE – MINERAL AND BONE DISORDER

Bone diseases complicating CKD emerged as major problems with the development of dialysis programmes, which permitted the prolonged survival of patients with

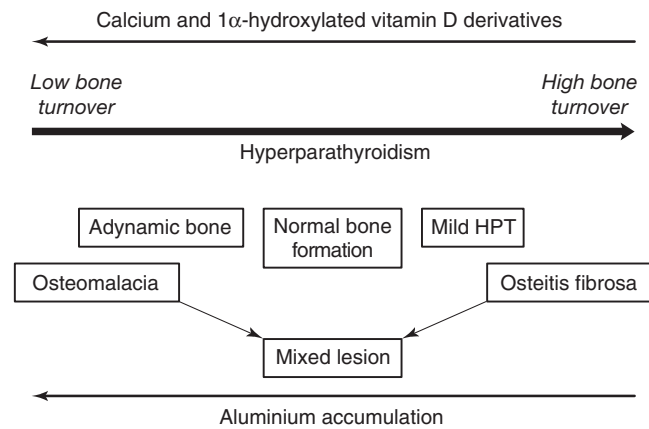

FIGURE 31.8 ■ Chronic kidney disease mineral and bone disorder is a dynamic process. The main influences determining the nature of the bone histology are the degree of hyperparathyroidism (HPT) and the degree of aluminium accumulation in bone. Hyperparathyroidism can be suppressed to varying degrees by the manipulation of dietary and dialysate calcium and the use of 1 α -hydroxylated vitamin D derivatives, or by parathyroidectomy. Aluminium accumulation also favours low bone turnover and, in significant quantities, can cause osteomalacia.

established renal failure. The major aetiological factors are disturbances of the parathyroid hormone–calcitriol axis and skeletal retention of aluminium. Renal bone disease is not uniform in its features because the effects and interactions of these factors differ at various stages of its evolution. The disease can be modified substantially by a variety of treatments, from changes in dialysate composition, diet or drugs to renal transplantation. Chronic kidney disease – mineral and bone disorder (CKD-MBD), previously called renal osteodystrophy, can be regarded as a dynamic process that is affected by both patient characteristics and a number of pathophysiological and iatrogenic factors. These are illustrated in Figure 31.8.

Aetiology

Parathyroid hormone–calcitriol–FGF23 axis

Mild hyperparathyroidism can be detectable when the glomerular filtration rate falls to <50 mL/min. The hyperparathyroidism is secondary to a modest fall in plasma ionized calcium, resulting from a reduction in intestinal calcium absorption that, in turn, is due to a decline in the production of 1,25(OH)₂D because of reduced renal 1 α -hydroxylase activity. This arises initially not because of the loss of functioning nephrons, but because of phosphate retention. Plasma phosphate concentrations are not increased and may even be low because of secondary hyperparathyroidism, but there is saturation of the intracellular phosphate pool that ‘senses’ phosphate requirements. The high intracellular phosphate is responsible for the reduction in renal 1 α -hydroxylase activity and therefore 1,25(OH)₂D synthesis. Rising FGF23 concentrations in response to phosphate retention may mediate this early reduction in 1 α -hydroxylase activity: increases in plasma FGF23 concentrations seem to precede the development of hyperparathyroidism. Reduction in the intake or the intestinal absorption of phosphate at this early

stage reverses all these abnormalities: $1,25(\text{OH})_2\text{D}$ concentration in the blood rises, intestinal calcium absorption increases and hyperparathyroidism is suppressed.

As kidney disease progresses, the disturbances in the PTH- $1,25(\text{OH})_2\text{D}$ axis become more marked. When the glomerular filtration rate falls to <30 mL/min, hyperphosphataemia develops, as the number of functioning nephrons becomes too low to cope with the phosphate load, despite lowering of the TmP/GFR. Progressive nephron loss and metabolic acidosis further impair $1,25(\text{OH})_2\text{D}$ synthesis. Hypocalcaemia develops and hyperparathyroidism worsens, so by this stage, bone histology in most subjects will show signs of hyperparathyroidism that cannot be reversed by restricting the intake and absorption of phosphate.

Untreated, ~40% of patients reaching established renal failure will have significant parathyroid bone disease, as judged by the presence of marrow fibrosis on bone biopsy. If there is coincident vitamin D deficiency, then florid osteomalacia with hyperparathyroidism can arise.

The interactions between PTH and $1,25(\text{OH})_2\text{D}$ are complex. $1,25(\text{OH})_2\text{D}$ modifies PTH secretion indirectly through its actions on plasma ionized calcium, but it can also act directly on the parathyroids and inhibit the transcription of pre-pro-PTH mRNA. In established renal failure there are fewer receptors for $1,25(\text{OH})_2\text{D}$ in the nuclei of the parathyroid cells, as well as reduced circulating concentrations of $1,25(\text{OH})_2\text{D}$. The loss of this direct effect upon the parathyroids is an important factor in the development of parathyroid hyperplasia. An additional effect of importance is the change in the 'set point' for PTH secretion. This is defined by the concentration of plasma ionized calcium that will suppress PTH secretion by 50% as calculated from calcium infusion experiments. Calcitriol deficiency shifts the set point to the right, that is, a higher ionized calcium has to be achieved before PTH secretion is suppressed.

Aluminium retention

Aluminium retention was recognized as a significant cause of skeletal disease in the late 1970s, when an unusual type of osteomalacia became endemic in haemodialysis units in certain geographical locations, such as Newcastle-upon-Tyne. Aluminium sulphate is added to water as a flocculent during the purification process in order to precipitate organic matter. The quantity of aluminium required for this process varies with environmental factors, so the concentration in tap water may range from 5–30 $\mu\text{mol/L}$. When the dialysate aluminium content is >2 $\mu\text{mol/L}$, there is a substantial transfer from dialysate to plasma. Aluminium is normally excreted by the kidneys, so, in a patient with no renal function, it accumulates in various tissues, including the brain, bone and the parathyroids. The aluminium content of the dialysate can be reduced to <2 $\mu\text{mol/L}$ by reverse osmosis treatment and it is now standard to use dialysates prepared this way. The oral ingestion of aluminium hydroxide as a phosphate-binding agent can also contribute to aluminium loading.

In bone, aluminium is taken up at the bone-osteoid interface and has a marked toxic effect upon osteoblasts, inhibiting the rate of new matrix synthesis and, at higher

doses, inhibiting mineralization. Aluminium can also accumulate in the parathyroids, and patients with severe aluminium-related disease often have low plasma PTH concentrations.

Clinical features

Hyperparathyroidism in the early stages of CKD-MBD is asymptomatic, but with advanced disease, bone pain and proximal myopathy are the predominant symptoms. Because of its insidious onset, it tends to be under-reported and patients may only notice that they have had it when adequate treatment is given and the pain relieved. Fractures are rare in parathyroid disease, but in adolescents and children, horrifying deformities can develop very rapidly as a result of the erosion and weakening of the metaphyses of the long bones. Hyperparathyroidism can impair the effectiveness of erythropoietin therapy.

The full-blown syndrome of aluminium-induced osteomalacia comprises generalized skeletal pain, frequent fractures and disabling proximal myopathy. With very high total body aluminium loads, hypochromic anaemia and dementia ('dialysis dementia') may occur. Because of increased awareness of aluminium, this presentation is uncommon nowadays. Milder degrees of aluminium-related bone disease and a mixed form of aluminium and parathyroid disease are recognized. These forms of disease give rise to fewer symptoms. Aluminium accumulates more readily in the bones of children and adolescents with CKD than in older patients, and also more readily in the bones of patients with CKD secondary to type 1 diabetes.

In recent years, changes in the therapy for CKD-MBD, and changes in dialysis techniques resulting in more active suppression of hyperparathyroidism, have meant that the more florid forms of CKD-MBD have become less common. A consequence of therapeutic measures to suppress hyperparathyroidism has been the emergence of a low turnover state called 'adynamic bone disease'. The clinical sequelae are not clear, but there are suggestions that the risk of fracture is higher and that, in children, growth may be impaired. The strategy of maintaining higher plasma calcium concentrations to suppress hyperparathyroidism also increases the ECF [calcium] \times [phosphate] product, and thus the risk of metastatic or vascular calcification. With an increasing number of older patients being taken onto dialysis programmes, osteoporosis with a high incidence of fractures has also emerged as a significant clinical issue.

Investigations

Biochemical measurements in serum are useful in assessing renal bone disease, but even with the help of radiographic assessments they cannot always provide an unequivocal account of events in bone. CKD-MBD is still, therefore, the commonest indication for bone biopsy, which remains the reference standard for other tests.

Calcium. Plasma calcium concentration (either total or ionized) is usually normal in early renal impairment but

BOX 31.6 Aetiology of hypercalcaemia and hyperphosphataemia in dialysis-treated patients

Hypercalcaemia (>2.7 mmol/L)

- Use of calcium-containing phosphate binders
- Therapeutic vitamin D toxicity
- Severe hyperparathyroidism
- Aluminium bone disease and mixed bone disease
- High dialysate calcium concentrations

Hyperphosphataemia (>2.0 mmol/L)

- Inadequate dialysis regimen
- Inadequate phosphate-binder therapy
- Poor adherence to dietary restrictions
- Therapeutic vitamin D toxicity
- Severe hyperparathyroidism

falls as renal function deteriorates (glomerular filtration rate <30 mL/min). Dialysis partially corrects the hypocalcaemia. In long-term dialysis patients, hypercalcaemia may develop and can arise from one or more of a number of causes (Box 31.6). With the move away from using aluminium-based to calcium-based phosphate binders, the prevalence of hypercalcaemia in dialysis-treated patients has increased.

Phosphate. Plasma phosphate concentration is normal or reduced in early renal disease, but hyperphosphataemia occurs when renal impairment is advanced. In dialysis-treated patients, hyperphosphataemia is inevitable and it is almost impossible to maintain 'normal' plasma phosphate concentrations (0.8–1.4 mmol/L). Phosphate should be kept in the range 1.4–2.0 mmol/L, although even this can be difficult. Phosphate concentrations <1.4 mmol/L can contribute to impaired bone mineralization, whereas at >2.0 mmol/L there is a risk of metastatic calcification (see Chapter 6). Failure to maintain plasma phosphate below this concentration can be due to a variety of reasons (see Box 31.6).

Parathyroid hormone. After secretion of the intact molecule, PTH undergoes cleavage into amino-terminal and carboxy-terminal fragments. The latter are metabolized and excreted predominantly by the kidney, so that immunoassays that are not specific for the intact molecule or the amino terminal are liable to detect high concentrations of circulating PTH, whether or not glandular secretion is increased (see Chapter 6). It may be difficult to interpret a single measurement of plasma PTH in an individual. Nonetheless, in population studies the patients with the most severe parathyroid bone disease have the highest plasma PTH concentrations, irrespective of the assay used, and plasma PTH correlates well with histological indices of bone resorption (and formation). The newer assays for 'intact' PTH perform well in established renal failure but these assays also measure a large PTH fragment (probably PTH 7-84). New two-site chemiluminescence and immunoradiometric assays specific for PTH 1-84 are increasingly used in patients with renal impairment.

FGF23. By the time patients reach dialysis, plasma FGF23 concentrations are extremely elevated (commonly ~1000 times normal). This may reflect delayed clearance as well as increased production of FGF23, but almost all the circulating FGF23 seems to be biologically active. The prognostic value of FGF23 measurements in patients with CKD is beginning to be explored, but at present there is no indication for its routine measurement.

Alkaline phosphatase. The bone isoenzyme is neither dialysable nor filterable by the kidney, so its plasma concentration (and thus activity) is not modified by variations in renal function. Plasma alkaline phosphatase activity is increased when bone turnover is high and, in general, reflects the degree of hyperparathyroidism. If the plasma PTH concentration is clearly elevated, a high ALP is strongly predictive for high-turnover renal bone disease. Aluminium deposition affects osteoblast function so that plasma ALP activity is often normal, or only slightly above the reference range, in aluminium-related disease. The activity of ALP gives no indication of the severity of this type of bone disease.

Other markers of bone turnover. The markers of bone resorption based on urine measurements are obviously of limited use in CKD. Markers such as osteocalcin, hydroxyproline, pyridinoline, deoxypyridinoline and cross-linked C-telopeptide of type I collagen (ICTP) are wholly or partially cleared by the kidneys, so in CKD their plasma concentrations are greatly increased because of accumulation of inactive fragments. In population studies, correlations with histological indices of bone resorption or formation can be demonstrated, but in practice they are of little diagnostic value in individual patients. Concentrations of the formation markers PINP and P1CP are not so affected by CKD, but correlate less well than ALP with histological indices. Tartrate-resistant acid phosphatase 5b is unaffected by CKD and correlates with histological measures of bone resorption. It is elevated in high-turnover bone disease.

Aluminium. Provided that care is taken in the collection and laboratory handling of specimens to avoid contamination, aluminium concentrations in plasma reflect the recent level of exposure to this element. Because of the rapid uptake of aluminium into tissues, plasma concentrations do not reliably indicate the total body burden. The desferrioxamine test was developed in an attempt to measure the total body aluminium load. Desferrioxamine mobilizes aluminium from bone and other tissues, so after its intravenous administration to dialysis patients, plasma aluminium concentrations increase (see Appendix 31.2 for protocol). The increment in plasma aluminium correlates reasonably ($r=0.6-0.7$) with the degree of aluminium loading as assessed by bone biopsy, but the test has insufficient sensitivity and specificity to be used on its own. However, an increment of >7.5 $\mu\text{mol/L}$ in the presence of low plasma PTH is very suggestive of aluminium loading and an indication for bone biopsy to establish the extent of aluminium accumulation. A recommended protocol for surveillance

for aluminium overload in dialysis patients is to measure serum aluminium every 4–6 months, seeking to maintain plasma concentrations at $<1.9 \mu\text{mol/L}$.

Radiology, scintigraphy and densitometry. Radiology is useful in the diagnosis of parathyroid bone disease. Subperiosteal erosions of the phalanges and/or the distal ends of the clavicle are virtually pathognomonic. Other radiographic manifestations of hyperparathyroidism include osteosclerosis (commonly in the spine) and, more rarely, periosteal new bone formation. Aluminium-related disease has no specific X-ray findings, but pathological fractures and radiolucency of bones are typical if there is osteomalacia. Spinal bone density measurements are often increased in hyperparathyroid bone disease and reduced in aluminium-related disease, but these measurements are not of diagnostic value. The scintigraphic changes of hyperparathyroidism add little to the information from other diagnostic modalities.

Bone histology. Bone biopsy after double tetracycline-labelling, with the preparation of undecalcified sections for quantitative histomorphometry, remains an important investigation. Severe hyperparathyroidism can be demonstrated satisfactorily by radiographic and biochemical means, but mineralization defects, low bone turnover and aluminium loading are difficult to quantitate accurately without biopsy. Florid forms of aluminium-related disease are now uncommon, but a mixed form of bone disease with hyperparathyroidism and aluminium retention together, which can only be diagnosed by biopsy, is recognized. Bone histomorphometry permits classification of an individual into one of several diagnostic categories described according to the parameters of turnover (low, normal or high), mineralization (normal or abnormal) and volume (low, normal or high). CKD-MBD remains one of the commonest indications for bone biopsy (Appendix 31.1).

Treatment

Hyperparathyroidism

Vitamin D derivatives. Abnormalities of vitamin D metabolism are critical in the genesis of hyperparathyroidism, and vitamin D, its metabolites or derivatives are successful in reversing hyperparathyroidism at least in the short term. All forms of vitamin D are effective, but forms that require 1α -hydroxylation (such as calciferol or $25(\text{OH})\text{D}$) have to be given in pharmacological doses in order to achieve the desired effects. The 1α -hydroxylated forms, $1,25(\text{OH})_2\text{D}$, alfacalcidol ($1\alpha\text{OHD}_2$) or doxercalciferol ($1\alpha\text{OHD}_2$) are effective at much lower doses and are preferred. Their main advantages are their very quick onset and cessation of action: if vitamin D toxicity occurs with these compounds, it reverses rapidly. Although this is a distinct advantage, toxicity can also arise abruptly. Intestinal calcium and phosphate absorption are increased, the $[\text{calcium}] \times [\text{phosphate}]$ product in plasma increases and, with it, the risk of metastatic and vascular calcification. This can accelerate the decline in

renal function in patients with moderate CKD who have not yet reached dialysis and increases the risk of cardiovascular disease.

How well hyperparathyroidism is suppressed depends mainly on the increment in plasma calcium that can be safely attained. Patients who have high or high-normal plasma calcium concentrations at the outset of therapy are therefore likely to tolerate only low dosages. $1,25(\text{OH})_2\text{D}$ may be given intravenously (usually thrice weekly). The object is to obtain transiently high plasma $1,25(\text{OH})_2\text{D}$ concentrations and to maximize the directly suppressive effects of $1,25(\text{OH})_2\text{D}$ upon PTH synthesis. However, the degree of suppression of hyperparathyroidism obtained by this method remains closely correlated with the increment in plasma calcium. In patients with established hyperparathyroidism, successful treatment with vitamin D derivatives is accompanied by reductions in plasma PTH concentration and ALP activity. Alkaline phosphatase may rise in the first few weeks of therapy, but then declines exponentially with a half-time of around 50 days. As healing takes place, vitamin D toxicity is likely to occur, so dosage reductions are required. All patients taking vitamin D derivatives require monitoring of plasma calcium, phosphate and ALP.

There is increasing use of an emerging group of bioactive vitamin D analogues with supposedly less marked calcaemic activity than calcitriol (e.g. paricalcitol and maxacalcitol). It is hoped that these agents may allow more effective control of parathyroid gland hyperplasia with less hypercalcaemia, although as yet there is little evidence that they are superior to calcitriol, alfacalcidol or doxercalciferol.

Phosphate metabolism. Control of plasma phosphate is important in slowing the development of hyperparathyroidism and is approached by dietary restriction, the use of phosphate-binding agents and adequate dialysis. The concentration of calcium in the dialysate can also be manipulated to influence hyperparathyroidism.

Parathyroidectomy. Parathyroidectomy is very effective in patients with severe hyperparathyroidism and produces a quicker and more complete resolution of parathyroid bone disease than can be achieved with alfacalcidol or calcitriol. With the abrupt cessation of PTH-driven bone resorption after surgery, there follows a period when bone formation remains very rapid, before it, too, slows to match the new, lower resorption rate. During this period, calcium and phosphate are taken up very rapidly from the blood into bone and profound hypocalcaemia (and hypophosphataemia) can occur – the ‘hungry bone syndrome’. This can be so severe as to cause hypocalcaemic fits. Patients undergoing parathyroidectomy are therefore treated pre- and postoperatively with 1α -hydroxylated forms of vitamin D and may require intravenous or oral calcium. After parathyroidectomy, plasma ALP activity may show an early rise but then suppresses rapidly, with a half-time of around 23 days, as bone disease heals. The more rapid suppression of ALP after parathyroidectomy than after alfacalcidol or calcitriol reflects the more rapid reduction in PTH.

Hyperparathyroidism can recur after parathyroidectomy and there is continuing debate over the choice of procedure – subtotal or total parathyroidectomy – and, in the subtotal procedure, about the size of the remnant and whether to leave it in situ or to transplant it to the sternomastoid or forearm muscles. One concern about the rapid suppression of parathyroid hormone, whether by parathyroidectomy or by the use of 1α -hydroxylated vitamin D compounds, is the ease with which aluminium is retained in bone when turnover is very slow. The aluminium–osteomalacia syndrome can certainly be precipitated by parathyroidectomy, hence the importance of making sure the bone is free of aluminium before undertaking this procedure.

Calcimimetic agents. An important development in the treatment of hyperparathyroidism secondary to CKD has been the use of cinacalcet, an allosteric agonist of the ionized calcium-sensing receptor that is expressed on parathyroid cells. With cinacalcet treatment, reductions of ~40% in PTH concentrations are reached after about three months of treatment, and are maintained for at least two years. Reductions in plasma calcium and phosphate of 6–8% are seen and the [calcium] \times [phosphate] product decreases by ~15%.

Aluminium toxicity

Aluminium toxicity is treated by withdrawing all parenteral sources of aluminium and stopping aluminium-containing phosphate binders. The chelating agent desferrioxamine effectively removes aluminium from bone and other tissues. In order to minimize the risk of desferrioxamine-related cerebral, auditory and visual side-effects, and siderophore-mediated opportunistic infections, the chelator should be used at low doses (5 mg/kg) and administered only once weekly – typically for 4–6 months. In patients not requiring dialysis, most of the aluminium–desferrioxamine complex is excreted in the urine and can be monitored by urinary aluminium measurements. Prolonged desferrioxamine treatment can result in iron depletion.

Bone disease after renal transplantation

In the first two weeks following successful renal transplantation, plasma FGF23 concentrations fall very rapidly and $1,25(\text{OH})_2\text{D}$ concentrations rise. Hyperparathyroidism resolves slowly after transplantation and may be expressed as post-transplant hypercalcaemia. Hyperparathyroidism, persistent FGF23 elevation and steroid treatment all contribute to hypophosphataemia in transplant recipients (see Chapter 6). Bone resorption, stimulated by hyperparathyroidism, may be high after transplantation, but corticosteroids, given for immunosuppression, suppress bone formation. Transplant recipients may thus lose bone and become osteoporotic. The suppressive effect of steroids on osteoblasts means that the markers of osteoblast function, ALP activity and osteocalcin are not reliable guides to bone resorption in these circumstances.

BONE DISEASE IN PRIMARY HYPERPARATHYROIDISM

Bone disease was one of the complications of primary hyperparathyroidism that led to the recognition of this disorder in the 1920s, but in Western countries florid parathyroid bone disease is now uncommon. The availability of plasma calcium measurements on modern biochemical analysers has identified a large population with asymptomatic hyperparathyroidism, and early surgery in symptomatic patients probably accounts for the infrequency of severe skeletal manifestations.

Clinical, biochemical and histological features

Since bone is one of the target tissues for PTH, it is not surprising that the bones of almost all patients with hyperparathyroidism show some histological evidence of increased parathyroid activity. In asymptomatic or mildly affected individuals, this amounts only to increases in the extent of active formation and resorption surfaces. This is reflected in modest increases in biochemical markers of bone turnover. Mild primary hyperparathyroidism causes a preferential loss of cortical bone, and may be associated with an increased fracture risk. Both antiresorptive therapy and surgical correction of the disease prevent progressive bone loss.

Much less commonly, patients with primary hyperparathyroidism manifest overt parathyroid bone disease (osteitis fibrosa) characterized by marked increases in osteoclastic bone resorption and increases in bone formation rate, with a resulting increase in osteoid surface extent and marrow fibrosis. Patients experience generalized bone pain, often worse when standing, bone tenderness and proximal myopathy. Radiographic signs can be helpful, subperiosteal erosions being pathognomonic of parathyroid bone disease. Spinal osteosclerosis can occur in primary hyperparathyroidism, but is seen less frequently than in uraemic hyperparathyroidism. Cystic lesions filled with osteoclasts, and marrow fibrosis ('brown tumours'), are a feature of bone disease in severe primary hyperparathyroidism and can be sites of pathological fracture.

The presence of bone abnormalities tends to be associated with more aggressive disease with a shorter duration of symptoms, higher plasma concentrations of calcium and PTH and larger, more rapidly growing brown tumours. Occasionally primary hyperparathyroidism can enter an accelerated phase with a marked increase in the rate of bone resorption and disequilibrium hypercalcaemia (acute parathyroid crisis).

Vitamin D insufficiency occurs commonly in patients with primary hyperparathyroidism, and is probably associated with larger parathyroid adenomas and higher rates of bone turnover. Accelerated hepatic metabolism of $25(\text{OH})\text{D}$ may contribute to the lower vitamin D concentrations in this situation. Maintenance of vitamin D sufficiency may restrain the progression of the parathyroid disease. In patients with mild hyperparathyroidism and low plasma $25(\text{OH})\text{D}$, supplementation with vitamin D

does not usually exacerbate the hypercalcaemia and may, indeed, lower PTH and bone turnover.

Treatment

Most patients with mild primary hyperparathyroidism do not require specific therapy. All patients with severe primary hyperparathyroidism or osteitis fibrosa require parathyroidectomy to correct the disease, but these patients are at risk of developing the 'hungry bone syndrome' with postoperative hypocalcaemia and hypophosphataemia. This can be ameliorated by treatment for 1–2 weeks prior to surgery with low doses of 1 α -hydroxylated vitamin D derivatives. Following successful surgery, plasma calcium concentrations fall, but there can be secondary hyperparathyroidism as the remaining normal parathyroid glands respond to the fall in plasma calcium. The changes in plasma calcium following surgery are therefore a better immediate guide to the success of the procedure than changes in plasma PTH concentration. Nonetheless, intraoperative measurement of PTH can provide useful information as to whether the abnormal parathyroid tissue has been resected – a fall of >50% in the PTH concentration within 20 min of parathyroid gland removal is highly predictive of long-term surgical cure. Plasma ALP may flare in the 1–2 weeks following surgery, and then falls in a similar manner to that seen after parathyroidectomy in uraemic hyperparathyroidism. The biochemical markers of bone resorption fall early after successful surgery.

PAGET DISEASE OF BONE

Epidemiology

Although Paget disease of bone is, next to osteoporosis, the metabolic bone disorder most frequently encountered in general medical practice, it is in many ways quite mysterious. The disease is characterized by extreme metabolic disturbance of one (monostotic) or more (polyostotic) bones in the skeleton, while the uninvolved bones are quite normal. This patchy, asymmetrical distribution of disease within the skeleton is unexplained, as is its striking geographical distribution. It is most common in people of European origin living in temperate zones and is common in the UK, the USA, Australia, New Zealand and western Europe. It has been described in African-Caribbean peoples living in the UK and in African-Americans, but it is rare in groups native to areas where it is common among whites, such as native North Americans, Australian aborigines and the Maori of New Zealand. Even in countries where the disease is widespread, there are well-documented variations in prevalence. For example, in the UK, the prevalence in parts of Lancashire is two to three times greater than elsewhere. Families with many members affected, and a dominant pattern of inheritance, are not uncommon.

Aetiology

The cause of Paget disease is unknown, but both genetic and environmental factors appear to be important. In about

a third of patients with a positive family history (and a much lower proportion of patients without a positive family history), Paget disease is associated with mutations in the gene *SQSTM1*. This gene encodes the p62 protein, which forms part of the scaffold linking the RANK receptor on osteoclasts to the nuclear transcription factor NF- κ B. The majority of Paget disease-associated mutations identified to date (currently numbering ~30) have been in the ubiquitin-binding domain of the molecule. Patients with *SQSTM1* mutations tend to have disease that is more extensive, more symptomatic and is of earlier onset than in patients without such mutations. This is particularly the case with mutations that result in truncation of the p62 protein. The commonest *SQSTM1* mutation is P392L which is found all around the world. Haplotype evidence suggests this is a founder mutation distributed by European colonists. The rare dominantly inherited syndrome of inclusion-body myopathy, Paget disease and frontotemporal dementia (OMIM 605382) is associated with mutations in the *VCP* gene, encoding the valosin-containing protein. This protein is also a component of the scaffold linking RANK to NF- κ B.

Genome-wide association studies of patients negative for *SQSTM1* mutations have indicated that polymorphisms at a number of genetic loci are statistically associated with Paget disease. Several of the candidate genes encode proteins known to be important in osteoclast physiology, such as M-CSF, a cytokine essential for osteoclast differentiation, DC-STAMP, a cell surface protein essential for the formation of multinucleated osteoclasts and RANK, a receptor essential for osteoclast differentiation and bone resorption.

Recent epidemiologic data indicate that in the past 40 years, there has been a significant reduction in the prevalence of Paget disease in high-prevalence regions such as the UK and New Zealand, and that extensive polyostotic involvement has become less common. These observations suggest that in addition to genetic influences an important environmental factor is involved in the causation of Paget disease. Research has concentrated on a potential viral cause as the environmental agent. Both measles and canine distemper virus have been suggested as culprits, but the laboratory evidence is inconclusive.

Natural history

Many people have the disease without symptoms, as shown by the frequent incidental finding of either an isolated elevation in plasma ALP activity in 'routine' blood tests or pagetic changes in bone when radiographs are taken for other indications. Radiographic surveys have shown that in endemic areas of the world, the prevalence increases with age, and suggest that disease before the age of 40 is rare. It appears to arise more or less simultaneously at several skeletal sites. In some patients, distinct phases can be discerned. Bone lysis and progression of lytic lesions may predominate, particularly in the skull and long bones: this is presumed to be early disease. In the later stages, in some patients, osteoclast activity dies out, the bones become intensely sclerotic and ultimately osteoblast activity declines too, leaving abnormal but metabolically quiescent bone. What proportion of patients go through this cycle and how long it takes are not known. The majority

of patients have mixed disease with similar increases in both resorption and formation of bone. Observations of plasma ALP activity in untreated subjects show an unpredictable variation from year to year, with an overall tendency to rise with time until it becomes stabilized within a range characteristic for an individual.

Pathology

Paget disease is characterized by massively increased turnover in affected bones. It is thought to be primarily a disorder of osteoclasts. The number and size of the osteoclasts are greatly increased and they contain numerous large nuclei. Resorption surfaces are increased in extent. The coupling of bone resorption to formation is, however, more or less maintained, and many of the histological features of Paget disease relate to the massive increase in bone formation. Osteoblast numbers, the extent of bone-forming surfaces and the rate of new bone formation are all increased. At very high rates of bone formation, collagen fibres are not laid down in the usual orderly lamellar pattern, but more randomly, resulting in new bone of abnormal structure (visible as a mosaic pattern under polarized light), known as 'woven bone'. This bone has a larger volume than lamellar bone, hence pagetic bone shows an increase in trabecular bone volume. Collagen fibres are also secreted by osteoblasts into the marrow space, giving rise to marrow fibrosis.

Clinical features

Bone pain is a common feature. Pagetic bone pain is characteristically chronic and persistent rather than episodic, worse at rest and relieved by movement. It responds rapidly to antipagetic therapy. Because pagetic bone is soft and readily deforms, secondary osteoarthritis is very common. This is particularly so in the hip joints (from pelvic or femoral involvement). Pathological fractures of long bones (particularly in areas where lysis dominates) are common. Pagetic bone is very vascular and the high blood flow causes an elevation of skin temperature over the affected bone. In severe polyostotic disease in the elderly, the quantity of blood shunted through bone may precipitate heart failure. Spinal disease can cause a reversible myelopathy through a vascular steal phenomenon. Involvement of the otic capsule causes deafness. The most feared complication is the development of osteosarcoma, but fortunately this is rare. Osteosarcoma appears to arise from somatic mutations.

Investigations

Radiology

The radiographic appearances of bone reflect the histological events. There are areas of focal bone resorption (lytic lesions). In long bones and in the skull, flare-shaped lytic fronts can progress through bone: typical rates of progression are 0.8–1.2 cm/year. The increased bone formation is reflected by loss of the normal trabecular pattern, sclerosis and an overall enlargement of bone dimensions. Deformity, arthritis and fracture are common secondary events visible

on radiographs. Incomplete cortical 'fissure' fractures of the convex surface of deformed long bones often precede completed fractures. Isotope scanning is the best method of determining the extent of the disease.

Biochemical tests

Bone turnover markers. Biochemical tests are very useful in monitoring the progress of Paget disease and its response to therapy. The markers in use are not specific to the disease, but are simply markers of increased rates of bone formation and resorption. The concentrations of plasma ALP and other markers reflect both the extent and the activity of the disease. Hence the greatest values are seen in patients with widespread active polyostotic disease. In such patients, the turnover markers are elevated to a greater extent than in any other metabolic bone disorder. In patients with monostotic disease, bone turnover markers need to be interpreted with caution; although increased for that individual, they may not be outside the reference range.

All bone turnover markers are increased proportionately apart from osteocalcin, which is not increased to the extent expected from ALP measurements. Because of its rapid turnover, much of pagetic bone is 'young' and thus has a greater proportion of the linear, non-isomerized α -C-telopeptide collagen cross-links, and a smaller proportion of the β -isomerized C-telopeptides typical of older bone. This is reflected in the results of assays for α -CTX and β -CTX – patients with Paget disease having a greater than usual proportion of the former.

Alternative methods of monitoring disease activity can be employed. Over the lower limb and the forearm, skin temperature is a useful guide to disease activity, provided the disease is unilateral so that there is a normal limb for comparison. The skin temperature at the same point on opposite limbs in normal subjects does not differ by more than 0.5°C. The skin overlying a tibia affected by lytic Paget disease can be up to 4°C warmer than the unaffected limb opposite. Alternatively, the uptake of isotope on a bone scintiscan gives a measure of disease activity.

Since bone resorption and formation are closely linked, there is, not surprisingly, a strong correlation between plasma ALP activity and bone resorption markers in the untreated state. It is arguable as to whether, in the presence of symptoms, signs and radiographic evidence of Paget disease, it is necessary for diagnostic purposes to measure resorption markers if the plasma ALP is elevated and other liver-derived enzymes are normal. The smaller coefficient of variation in ALP measurements at times when disease activity is stable (~10%), compared with that of urine resorption markers, is an additional argument in favour of using the former as the main index of disease activity. A potential advantage of measuring resorption markers is the earlier detection of relapse after treatment, but the greater imprecision of the resorption markers means that in practice there is little advantage over measuring formation markers.

In response to treatment with potent bisphosphonates, the bone markers that appear to perform best (i.e. show the greatest changes) are total ALP, bone ALP and PINP. The latter probably performs best in terms

of pre-treatment values being clearly elevated in disease of limited extent, and showing the greatest changes with treatment and on relapse of disease. Using the same criteria, the best performing resorption marker is the urine N-telopeptide/creatinine ratio.

Plasma and urinary calcium. Plasma and urinary concentrations of calcium (and phosphate) are usually normal in Paget disease, but patients with very extensive and active disease are prone to develop hypercalciuria and even hypercalcaemia if immobilized. This results from increased bone resorption and a relative fall in bone formation, detectable by an increase in bone resorption markers and a fall in ALP activity.

Responses to treatment

There is no cure for Paget disease, but the metabolic activity of the affected bone can be reduced by the use of inhibitors of bone resorption – nowadays bisphosphonates are used almost exclusively. The main indication for treatment is bone pain. In practice, it can be difficult to distinguish pagetic from arthritic pain, so a trial of therapy may be given. Prompt (and prolonged) relief after treatment suggests that Paget disease was the main cause of pain. Myelopathy secondary to vascular steal is an indication for immediate treatment. Bisphosphonates

are commonly give in preparation for joint replacement surgery, where one of the bones concerned is involved with Paget disease, in the hope that this will reduce the vascularity of the bone and make the surgery easier. There is, as yet, no clear evidence that aggressive treatment to reduce bone turnover to normal prevents fracture or the development of late complications such as deafness or arthritis, though it is probable (comparing radiographic series from the pre-bisphosphonate era and now) that deformity can be prevented.

In response to bisphosphonate treatment, there is an early fall in urine resorption markers reflecting the reduction in osteoclastic activity. This rapid fall is complete by four days after intravenous treatment. Bone formation falls secondarily to this, so that the decline in plasma ALP lags behind that of bone resorption markers by several months. Ultimately, a new steady state is reached where resorption and formation are matched (Fig. 31.9). When the treatment is with oral bisphosphonates, a similar pattern is seen. Both bone resorption and bone formation markers fall in a monoexponential manner with a half-time of around two weeks, but the response of the formation markers lags behind by two to three weeks.

During the period early after initiation of therapy where resorption has fallen but formation remains high, there is a considerable uptake of calcium and phosphate into bone, thus some degree of secondary hyperparathyroidism is

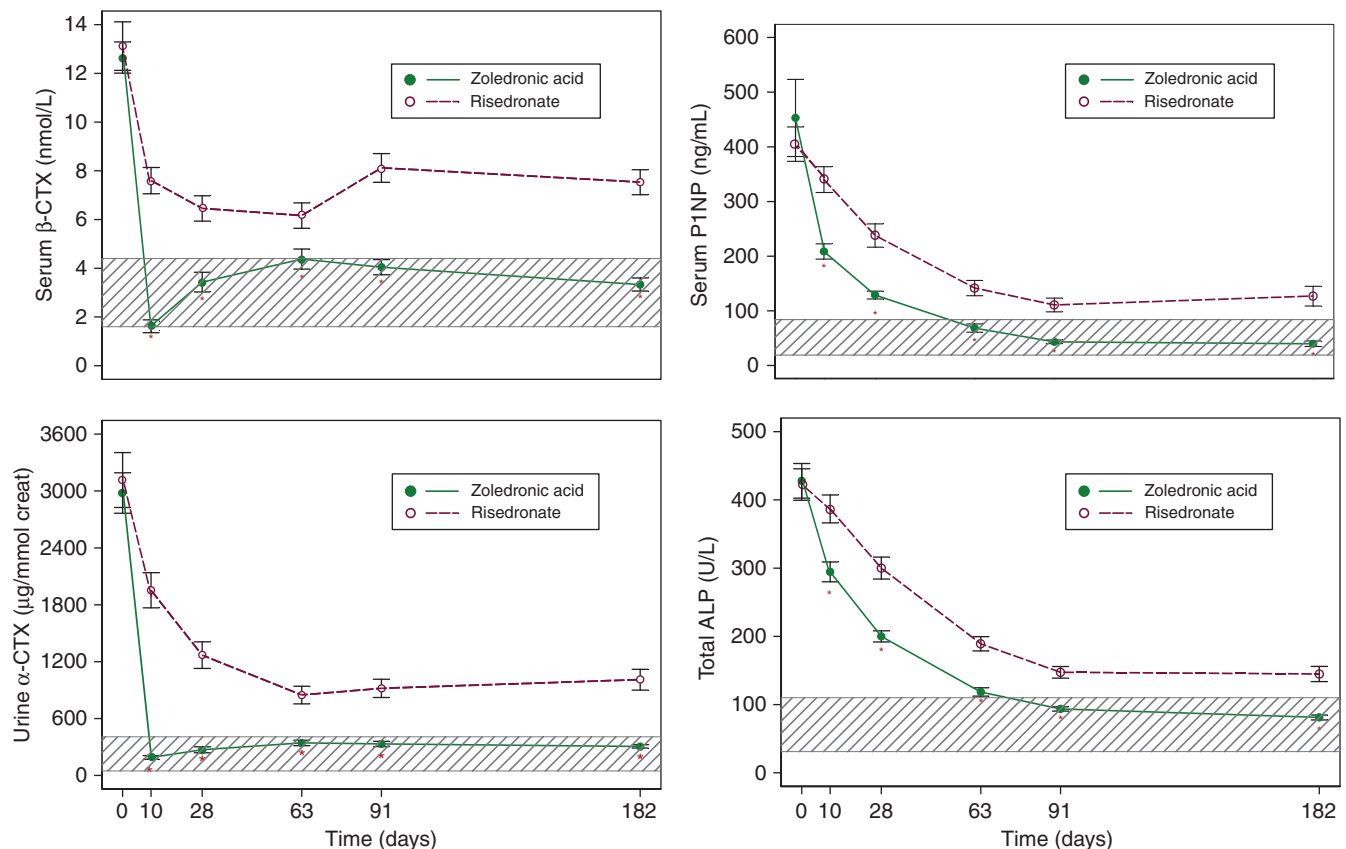

FIGURE 31.9 ■ The treatment of Paget disease. Effects of a single infusion of zoledronate 5 mg or oral risedronate 30 mg/day for two months on bone turnover in patients with Paget disease. The very rapid drop in bone resorption markers (serum β -CTX and urine α -CTX) is followed by a slower fall in the formation markers (serum P1NP and ALP). Zoledronate produces a more profound and sustained suppression of bone turnover. Hatched areas indicate normal reference intervals. (Based on data from Reid et al. 2005 in *N Engl J Med* 353: 898–908.)

usual. Following intravenous bisphosphonates, this is evident some 2–4 weeks after the infusions but it is not of any great consequence in most patients. Plasma osteocalcin concentrations may actually increase by 30–40% within the first two weeks of treatment, probably because the secondary hyperparathyroidism stimulates an increase in $1,25(\text{OH})_2\text{D}$ synthesis and this, in turn, stimulates osteocalcin production. Osteocalcin concentrations do subsequently decline with the fall in bone formation. Because of these disparate responses and the poor correlation with ALP in the untreated state, plasma osteocalcin measurements are not used in the management of Paget disease.

Treatment with calcitonin produces reductions in both plasma ALP activity and urinary hydroxyproline excretion to an average of 50% of the pretreatment values, within six months of starting treatment. Continued use of calcitonin produces no further improvement – the ‘plateau’ phenomenon – and discontinuation of treatment is followed by prompt relapse.

The bisphosphonates have made the use of calcitonin and other treatments obsolete, since they are far more effective and have fewer side-effects. A large number of bisphosphonates have been used. The more recently developed, such as zoledronate, are substantially more potent and have a long duration of action. Patients whose turnover markers suppress to the lowest values are likely to remain in biochemical ‘remission’ the longest. For example, if plasma P1NP is suppressed to $<40\ \mu\text{g/L}$ six months after treatment with intravenous zoledronate, then $>90\%$ of patients will remain in biochemical remission 6 years later. If P1NP suppresses only to the 60–80 $\mu\text{g/L}$ range, then only $\sim 60\%$ will remain in remission. If treatment is discontinued, all patients seem ultimately to relapse – although in patients with limited disease, treatment with potent bisphosphonates can produce remissions of ten years or more.

Relapse is first detectable biochemically by an increase in markers of bone resorption. Retreatment when a relapse has occurred produces a further suppression of bone turnover markers, but it is proportionately smaller, so the previous nadir is reached but concentrations are not usually reduced much further. The bisphosphonates, though effective orally, are poorly absorbed from the gut, so short intravenous regimens are frequently employed. The more potent amino-bisphosphonates (such as pamidronate, ibandronate and zoledronate), when given intravenously for the first time, often provoke an acute febrile reaction.

Etidronate, the first bisphosphonate to be developed, has a toxic effect upon osteoblasts and impairs mineralization when given in high doses ($>10\ \text{mg/kg}$ per day) for >3 months. Etidronate also has a much greater effect on the TmP/GFR than the other bisphosphonates, so that hyperphosphataemia is not uncommon during treatment. It is little used nowadays as the newer bisphosphonates are significantly more effective and longer lasting.

BONE TURNOVER AND BONE DISEASE IN CHILDREN

In infants, children and adolescents, bone turnover, as assessed by biochemical markers, is at much higher levels than in healthy adults. In general, the concentrations

TABLE 31.5 Bone turnover abnormalities in paediatric bone diseases

Disorder	Abnormalities
Prematurity	Bone ALP and osteocalcin relatively reduced, but increase after several weeks
Malabsorption/ malnutrition	All turnover markers relatively reduced
Growth hormone deficiency	Relative reduction in formation markers – which increase with growth hormone treatment
Glucocorticoid use	Relative reduction in both formation and resorption markers
Vitamin D deficiency	Increased ALP and P1NP, but osteocalcin relatively low: resorption markers increased

reflect growth velocity. [Figure 31.3](#) illustrates age-related changes in ALP and osteocalcin: the mean values at peak growth velocity are 3–5-fold higher than mean adult values. For P1NP, mean values at peak growth velocity are 6–10-fold higher than mean adult values. Turnover markers cannot accurately predict the accrual of bone during growth. The interpretation of bone marker data in individual children is difficult as the growth rate, nutritional status, sex, age, pubertal stage and renal function of the child all need to be taken into account.

There is relatively little information about very early life, but in healthy infants the urine marker of bone resorption NTX is low at birth, increases dramatically in the first ten days of life, remains very high for the next three months of life and then decreases to values similar to those at birth and one year of age.

Because new bone formed during growth is necessarily immature, the α -CTX isomer of the C-telopeptide predominates when this index is measured. Abnormalities in bone markers can be seen in various acquired and genetic disorders that affect bone directly or indirectly, and these are occasionally of diagnostic value ([Tables 31.5](#) and [31.6](#)).

GENETIC BONE DISEASES

There are numerous genetic bone diseases. The discussion below refers only to those conditions not covered above, for which there is a clear role for the clinical biochemistry laboratory in diagnosis (see [Table 31.6](#)).

Osteogenesis imperfecta

The term osteogenesis imperfecta (OI) encompasses a group of genetic disorders usually defined by recurrent fractures, low bone mass and skeletal fragility. Most cases are dominantly inherited and result from mutations in the genes encoding type I collagen (*COL1A1* and *COL1A2*). The condition is not synonymous with type I collagen abnormalities, as a number of genetic disorders affecting type I collagen or its post-translational modification that have skeletal phenotypes are not usually included in the

TABLE 31.6 Biochemical abnormalities in genetic bone diseases

Disease	Gene	Effects	Biochemical findings
Osteogenesis imperfecta*			
Haploinsufficiency	<i>COL1A1</i>	Insufficient type I collagen produced	Low plasma P1NP and P1CP concentrations
'Type VI'	<i>SERPINF1</i>	?	Low plasma concentrations of pigment epithelium-derived factor (PEDF)
Bruck syndrome and Kuskokwim disease	<i>PLOD2</i> <i>FKBP10</i>	Impaired telopeptide cross-linking	Reversal of usual pyridinoline: deoxypyridinoline molar ratio in urine from ~9:1 to ~1:7
Ehlers–Danlos syndrome*			
kyphoscoliotic type (VIA)/Nevo syndrome	<i>PLOD1</i>	Lysyl hydroxylase deficiency	Reversal of usual pyridinoline: deoxypyridinoline molar ratio in urine from ~9:1 to ~1:7
Osteopetrosis			
Autosomal recessive (severe)	<i>TCIRG1</i>	Impaired acidification of extracellular compartment of the osteoclast	Increased TRAP
Autosomal recessive or dominant (severe)	<i>CICN7</i>		Increased TRAP and BB fraction of creatine kinase
Autosomal recessive with renal tubular acidosis (RTA)	<i>CAII</i>		RTA
Autosomal recessive (intermediate) Pycnodysostosis	<i>PLEKHM1</i> <i>CTSK</i>	Impaired vesicular trafficking Cathepsin K deficiency	Increased TRAP Cathepsin K concentrations low, ICTP/CTX ratio increased
Osteosclerosis			
Progressive diaphyseal dysplasia	<i>TGFB1</i>	Mutations affect latency-associated peptide of TGFβ1 ↑TGFβ1 activity	ALP and other bone turnover markers modestly increased
Sclerosteosis and Van Buchem disease	<i>SOST</i>	Inactivating mutations in sclerostin	ALP and other bone turnover markers modestly increased
Juvenile Paget disease	<i>TNFRSF11B</i>	Osteoprotegerin deficiency	ALP and other bone turnover markers very high
Familial expansile osteolysis	<i>TNFRSF11A</i>	Activating mutations of RANK	ALP and other bone turnover markers increased significantly
Polyostotic fibrous dysplasia	<i>GNAS1</i>	Activating somatic mutations in G _s α	ALP and other bone turnover markers increased significantly

*Note: Only variants with distinctive biochemical findings are listed. Please refer to text for explanation of abbreviations.

OI rubric. These include Caffey disease, and the type VI and VII variants of the Ehlers–Danlos syndrome. In addition, some genetic disorders of skeletal fragility included in classifications of OI are the consequence of mutations in key osteoblast genes (*LRP5*, *WNT1* and *SP7*) that code for proteins concerned with matrix homeostasis, and are not directly related to collagen metabolism and matrix structure.

More than 200 mutations in the collagen genes *COL1A1* and *COL1A2* that cause OI have been identified. All the mutations result in decreased synthesis and secretion of normal type I procollagen. When no abnormal procollagen is synthesized, the phenotype is generally mild: this is the commonest form of the disease, arising where a mutation in one of the *COL1A1* genes produces a null allele (haploinsufficiency). When abnormal molecules are synthesized in addition to normal type I collagen, the phenotype can range from very mild to lethal, depending on the nature and location of the mutation.

The diagnosis of OI is predominantly based on clinical assessment (including family history) and imaging. Biochemical tests are helpful with excluding differential diagnoses, but with a few exceptions are not generally specific. Ultrasound and radiographic examinations are useful for intrauterine diagnosis of severely affected fetuses. The quantity and some structural characteristics of type I collagen produced by cultured skin fibroblasts can be assessed in vitro.

The usual biochemical indices of metabolic bone disease are normal in osteogenesis imperfecta, though resorption markers are often increased when the patient is immobilized. In patients with haploinsufficiency, the bone formation markers plasma procollagen C-terminal peptide and procollagen N-terminal peptide (which are derived from type I collagen) are often relatively low compared to the other formation markers such as bone ALP.

The genetic bases of a number of *recessively-inherited* OI variants have been identified. The majority of the genes involved code for proteins that regulate the post-translational modification of type I collagen, and there are some instances where specific biochemical tests can help. In patients with Bruck syndrome (OI with contractures), where there is defective cross-linking of collagen (owing to mutations in *FKBP10* or *PLOD2*) the usual ratio of pyridinoline to deoxypyridinoline in urine is reversed. Another recessive OI variant results from mutations in *SERPINF1* that encodes pigment epithelium-derived factor (PEDF), a secreted glycoprotein of as yet uncertain function in bone. Pigment epithelium-derived factor can be measured in normal serum and is undetectable in the serum of patients with this OI variant.

Bisphosphonate treatment is now widely used in children with more severe forms of osteogenesis imperfecta. During growth, osteoclasts remove bone from the endosteal surface of the diaphysis and the primary

spongiosa in the metaphysis, as part of the modelling process. Bisphosphonates inhibit this osteoclastic resorption, with the end result that cortices are thicker and trabecular number is increased. Bone pain is reduced, the bones are stronger and fracture less frequently. The benefit of bisphosphonates in children and adults with milder forms of osteogenesis imperfecta is less certain.

High bone mass

High bone mass disorders are classified according to whether there is excessive bone formation (osteosclerosis) or a failure of bone resorption (osteopetrosis).

Osteopetrosis

Osteopetrosis is further categorized according to whether there are normal or increased numbers of osteoclasts: osteoclast-rich (the majority of cases) or osteoclast-poor. Osteoclast-rich osteopetrosis arises because of mutations in a number of genes encoding proteins important in generating and excreting hydrogen ions onto the bone surface sealed beneath the osteoclast. The genes usually involved are *TCIRG1*, *CICN7*, *PLEKHM1* or *CAII*. Osteoclasts are typically abundant, but their capacity to resorb bone is impaired. Severe osteopetrosis typically becomes manifest during infancy. The bone marrow space is occluded so the infant develops leukoerythroblastic anaemia with bruising and bleeding and extramedullary haematopoiesis. Growth is poor and blindness and deafness occur because of cranial nerve entrapment. The radiographic features are diagnostic. The plasma calcium concentration may vary and seems to reflect the dietary calcium intake. Restriction of dietary calcium may precipitate tetany, presumably because of defective osteoclastic bone resorption. Urinary calcium excretion is often low. Plasma total and tartrate-resistant acid phosphatase activities are increased, although ALP is normal. This condition can be cured by successful bone marrow transplantation, which permits colonization of the host marrow by normal osteoclast precursors.

Carbonic anhydrase II deficiency, resulting from mutation in the *CAII* gene, is a congenital disorder comprising osteopetrosis, renal tubular acidosis and cerebral calcification. Although haematopoiesis is not affected, cranial nerve entrapment may be a feature. The laboratory findings include a metabolic acidosis and greatly reduced activity of the enzyme carbonic anhydrase II in erythrocytes. This enzyme is widely distributed and is found, among other places, in normal osteoclasts.

The osteoclast-poor forms arise from inactivating mutations in *TNSF11* (encoding RANKL) or *TNFRSF11A* (encoding RANK). Children with the latter also have hypogammaglobulinaemia and commonly develop severe but transient hypercalcaemia after bone marrow transplantation.

Progressive diaphyseal dysplasia

This osteosclerotic condition results from mutations in the gene encoding TGF β . It is characterized by new bone formation, affecting predominantly the diaphyses of the long bones and the skull. The clinical features may

include difficulty in walking, muscle wasting and leg pain. Laboratory findings of note are increased plasma ALP activity and other bone turnover markers.

Familial or idiopathic hyperphosphatasia (juvenile Paget disease)

This is a very rare, recessively inherited disease that results from deletion of, or inactivating mutations in, the gene for osteoprotegerin (*TNFRSF11B*). The onset is in infancy with skeletal abnormalities including dwarfism, bone fragility, a large head and anterior bowing of the limb bones. The bone shows greatly increased cellular activity. The characteristic biochemical changes are very high levels of plasma ALP activity and all other bone turnover markers.

Other disorders

Familial expansile osteolysis and related disorders

These rare, dominantly inherited conditions result from activating mutations in the signal peptide domain of RANK. Painful, progressively worsening expansile lytic lesions develop in bone. The characteristic biochemical changes are a sustained rise in plasma ALP activity and all other bone turnover markers.

Fibrogenesis imperfecta ossium

Fibrogenesis imperfecta ossium is a disorder of bone matrix in which collagen is laid down in a haphazard fashion. The onset is after the age of 50 years and it presents with severe bone pain and tenderness. The plasma ALP activity is consistently elevated.

Polyostotic fibrous dysplasia

Polyostotic fibrous dysplasia is characterized by well-circumscribed areas of marrow fibrosis that replace bone and give the radiographic appearance of cysts, through which pathological fractures may occur. Plasma ALP and urinary hydroxyproline are variably increased, depending on the extent of the disease. The major biochemical interest in this disorder is its association with endocrine diseases such as thyrotoxicosis, acromegaly, Cushing syndrome, precocious puberty and hypophosphataemic osteomalacia (McCune–Albright syndrome). The endocrine disorders are the consequence of constitutive (non-ligand-dependent) activation of the adenylate cyclase second messenger system. They arise from somatic mutations in the gene for the α subunit of the stimulating guanine binding protein ($G_s\alpha$), which forms a critical part of the adenylate cyclase activating system, linking the receptor to the second messenger.

CONCLUSION

Bone is a metabolically active tissue. In mature bone, there is a continuous cycle of bone resorption and replacement. Osteoblasts are responsible for the synthesis

of bone matrix and osteoclasts for bone resorption. The important role of osteocytes is increasingly recognized. Normal bone formation, metabolism and repair depend on the coordinated activity of these cells and the integrity of the homeostatic mechanisms for calcium and phosphate, which primarily involve parathyroid hormone, FGF23 and vitamin D.

Metabolic bone disease can be due to intrinsic abnormalities of the cellular elements of bone or to abnormalities of the homeostatic mechanisms for calcium and phosphate.

The commonest metabolic bone diseases are osteoporosis – a generalized reduction in bone density due to an imbalance between the rates of bone formation and resorption, which can have several causes, of which oestrogen deficiency in postmenopausal women is particularly important; osteomalacia, a defect of mineralization related either to a lack of calcium or phosphate or to defective osteoblast function; CKD-MBD, a complex bone disease occurring in patients with chronic kidney disease, and Paget disease, a condition of unknown aetiology characterized by greatly increased osteoclastic activity and disordered new bone formation.

Biochemical measurements are of considerable importance in the diagnosis of metabolic bone diseases and in the assessment of the response of patients to treatment.

APPENDIX 31.1: INDICATIONS FOR DIAGNOSTIC TRANSILIAC BONE BIOPSY

- Excessive skeletal fragility in unusual circumstances (e.g. in a young adults).
- When a mineralizing defect is a diagnostic possibility.
- Characterization of bone lesion in CKD-MBD.
- Diagnosis and assessment of response to treatment in vitamin D-resistant osteomalacia and related disorders.
- When a rare metabolic bone disease is suspected.

To get maximum information from a biopsy, fluoro-chrome labelling of bone is advised. Tetracycline (250 mg q.d.s.) or demeclocycline (150 mg q.d.s.) should be administered by mouth for two days, 18 and 17 days before the biopsy, and again five and four days before the biopsy. Tetracyclines are taken up into the mineralization front and 'double labelling' permits calculation of bone formation and mineralization rates. The biopsy should be collected into phosphate-buffered formalin or 70% alcohol and not decalcified. An experienced bone histomorphometrist is needed to interpret the biopsy.

APPENDIX 31.2: PROTOCOL FOR DESFERRIOXAMINE TEST IN DIALYSIS PATIENTS

Desferrioxamine (DFO) 5 mg/kg body weight is administered i.v. (in 100 mL 5% dextrose during the last 60 min of a dialysis session in haemodialysis patients). The plasma aluminium concentration is determined before this session and before the subsequent session (i.e. approximately 44 h after DFO administration).

An increment in plasma aluminium >7.5 µmol/L suggests aluminium accumulation in bone. When coupled with a low concentration of PTH (<15 pmol/L with an intact PTH assay), it is indicative of a high total aluminium burden, and has a sensitivity of 87% and specificity of 95% for the diagnosis of aluminium-related bone disease.

If the plasma PTH is >65 pmol/L, patients are not prone to the effects of aluminium at the bone mineralization front.

CONCLUSION 645

INTRODUCTION

While biochemical abnormalities themselves are responsible for few articular disorders, clinical biochemistry plays an important part in the diagnosis, treatment and monitoring of many of these conditions.

This chapter starts with a description of the articular system and its diseases, which will put the role of biochemistry in these conditions into perspective.

Crystal synovitis, as seen in gout and pseudogout, is the only common articular condition caused by an underlying biochemical abnormality. This is described in some detail along with examination of synovial fluid, the one biochemical investigation that is primarily the province of the rheumatologist.

Some diseases with a primary biochemical abnormality like diabetes, alkaptonuria, endocrine conditions and haemochromatosis have articular manifestations and also warrant discussion.

Immunological abnormalities are at the root of an important group of rheumatic diseases, the connective tissue diseases. Autoantibody formation is a major disease manifestation and, in some hospitals, tests to identify and measure autoantibodies are performed in the biochemistry laboratory. These tests are described briefly.

THE ARTICULAR SYSTEM

The joint is the pivotal structure of the articular system. Joints can be considered as discontinuities in the skeleton that permit controlled mobility. They have different structures depending on their functional requirements.

When no movement is needed, the joint is bound together by tough fibrous tissue (e.g. the skull 'sutures'). In cartilaginous joints, the bone ends are joined by compressible fibrocartilage and reinforced by a surrounding tough fibrous tissue (as in the symphysis pubis and the manubriosternal joint) and permit only a limited amount of movement. This type of joint tends to be located centrally. If a moderate or wide range of movement is required, a space must exist between the bone ends, forming a discontinuous 'synovial' joint. Most of the peripheral joints fall into this category.

The most important joints from a clinician's point of view are the peripheral ones, which enable our arms and legs to move through such a wide range, our hands to be endowed with such dexterity and strength and our feet to carry us so uncomplainingly when we stand, walk, run and jump.

While synovial joints have the same basic structure and physiology, individual joints have evolved differently, depending on their situation and what is expected of them. For example, the knee, ankle and finger joints, which move mainly in one plane, are 'hinge' joints, while the hip and shoulder, which move in all directions, are ball and socket joints. Of course, to carry out even the simplest of tasks, like opening a door or walking up a step, we have to coordinate the movement of several joints, not to mention contracting and relaxing the muscles on either side of the joints.

The archetypal synovial joint is an enclosed space with a negative pressure (Fig. 32.1). The bone ends that move against each other (the articular surfaces) are covered with articular cartilage. This is made up of proteoglycans and collagen, combined in such a way as to allow it to absorb

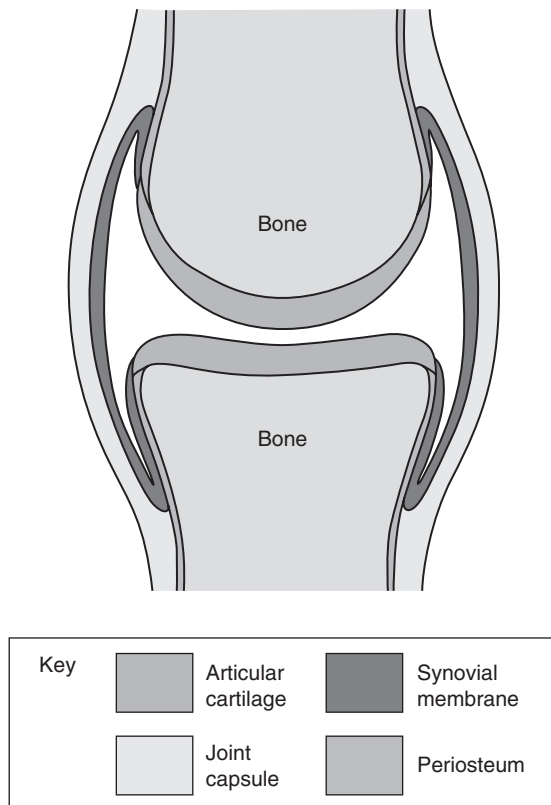

FIGURE 32.1 ■ A typical synovial joint.

huge forces of pressure like a shock absorber, while providing a shiny surface for smooth, low-friction movement. A healthy joint is lubricated by a small amount of synovial fluid (0–4 mL). This is an ultrafiltrate of plasma with additional components secreted by the synovium. The most important of these is hyaluronate, a linear repeating disaccharide with a molecular weight of some 10^7 Da. This provides the fluid with its viscoelastic properties without which the cartilage would fail and smooth movement would be impossible. Cartilage and synovial fluid together maintain coefficients of friction of <0.02 .

The bone ends are enclosed by the tough joint capsule which is lined by the synovial membrane, a structure only a cell or two thick (Fig. 32.1). Synovial cells phagocytose intra-articular debris, secrete many components of synovial fluid and possess immunological functions.

While we talk of ‘articular disorders’, it is not really possible to consider the joint in isolation. Each joint depends on other structures like ligaments, tendons, muscles and bone for its function and stability. Bone and muscle disease are dealt with in separate chapters.

DISORDERS OF THE ARTICULAR SYSTEM

There are over 100 rheumatic disorders with different underlying causes, different treatments and different outcomes. These conditions can be broadly divided into non-inflammatory diseases, of which osteoarthritis is the most important, and inflammatory conditions such as rheumatoid arthritis (RA), ankylosing spondylitis and systemic lupus erythematosus (SLE or lupus).

Osteoarthritis (OA)

The most common form of articular disease is osteoarthritis, in which the articular cartilage becomes fissured and gradually wears away. The joint tries to heal itself by forming bony out-growths on the sides of the joints (osteophytes). Trauma to a joint predisposes to OA, as do some rare biochemical disorders like alkaptonuria. However, in most cases, apart from an inherited tendency and increasing frequency with age, the cause cannot be identified. For many years, OA was thought to be due to degeneration or ‘wear and tear’. Recently, we have appreciated that a degree of inflammation is often present if sought and that calcium pyrophosphate and basic calcium phosphate crystals are frequently found in osteoarthritic joints (see below).

At present, we have no treatment to influence this process. The knee and hip are often affected and, if the pain and limitation to mobility are severe enough, the orthopaedic surgeon will remove the joint and replace it with an artificial one, usually with very gratifying results.

Inflammatory arthritis

The other major class of articular disease is inflammatory arthritis. This consists of a group of systemic immunological diseases that focus their attention on the synovium of the joint. Rheumatoid arthritis (RA) is the archetypical form of inflammatory arthritis. In RA, there is an imbalance between the proinflammatory and anti-inflammatory cytokines that favours the induction of autoimmunity (an immune reaction against one’s own tissues), chronic inflammation and joint damage. The synovium becomes inflamed, resulting in pain, tenderness, heat and stiffness in the joint as well as a systemic reaction consisting of malaise and fatigue. An acute phase reaction ensues, which can be detected and monitored by measurement of plasma C-reactive protein (CRP) concentration or the erythrocyte sedimentation rate (ESR). In what may well be a separate process, in time the synovial cells increase in size and number, the synovium becomes thickened and develops the changes of chronic inflammation with infiltration by macrophages and lymphocytes. There are also alterations in the small blood vessels. In addition, the amount of synovial fluid in the joint increases in quantity, which adds to the swelling and dysfunction of the affected joint. A number of different cytokines associated with the rheumatoid process can be found in the synovial tissue and fluid; these include tumour necrosis factor alpha (TNF α), interleukins one (IL-1) and six (IL-6). There are also abnormalities of the T and B cell lymphocytes. If left to its own devices, the thickened synovium will spread over the cartilage and erode it and the neighbouring bone. This results in joint damage, deformity and disability.

Non-steroidal anti-inflammatory drugs, e.g. diclofenac, ibuprofen and naproxen are used less frequently than they once were. Although they often provide symptomatic relief, they increase the risk of cardiovascular events, can cause chronic kidney disease and have no influence on the long-term outcome of the disease.

Of more concern in the long term, is the chronic inflammation that results in joint damage and disability. Until about 20 years ago, there was little that we could do to slow or even stop the inexorable progress of this destructive process, meaning that many people with RA became very disabled with joint deformity and pain. However, there have been dramatic improvements in our drug treatment of this most unpleasant condition. We have learnt that we need to diagnose the condition as early as possible. This enables treatment with one or more disease modifying anti-rheumatic drugs (DMARDs) (e.g. methotrexate, leflunomide, sulfasalazine), to be started as soon as possible. As a rule, these drugs rapidly bring the arthritis under control, but different drugs suit different people so sometimes a degree of trial and error is required. DMARDs are taken for long periods and can cause side-effects such as liver damage or bone marrow suppression, and regular blood tests (full blood count, ESR, CRP and liver function tests) are used to monitor their safety as well as the activity of the disease.

More recently, the treatment of RA has been transformed by the introduction of so-called 'biologics' (monoclonal antibodies designed to counteract the effects of cytokines or alter the function of T or B cell lymphocytes). They are expensive and need to be taken long term, so at present they are used in the cases where DMARDs have been unsuccessful. However, in time, they may become the first-line in treatment of RA. Biologics in common use include agents against TNF α (e.g. etanercept) and anti IL-6 (tocilizumab), as well as B cell depleters (rituximab) and T cell blockers (abatacept). This is a field of active research with the potential to transform the treatment not only of RA but of many other immunological diseases.

Other examples of chronic inflammatory arthritis include ankylosing spondylitis, which mainly affects the small joints of the spine, the arthritis associated with psoriasis and the 'reactive' arthritis one sees in response to certain intestinal or genitourinary infections.

The connective tissue diseases

The connective tissue diseases (CTDs) are a fascinating group of conditions in which, for reasons we do not understand, the normal fine balance of the immune system gets disturbed, causing the body to react against itself. In health, the immune system consists of series of counterbalancing mechanisms that marshal defences against alien material like bacteria, viruses or foreign tissue, while not reacting in this way against itself. The identification of foreign tissue (the antigen) is the first step in the process and is followed by a series of defensive reactions including manufacturing antibodies. In CTDs, the person's ability to recognize their own tissue goes awry and they form antibodies against their own tissue (autoantibodies). In some cases, these are responsible for the clinical manifestations of the disease; in others they are a peripheral effect of the underlying disease process. Theories of the pathogenesis of autoimmune diseases are discussed in Chapter 30.

Systemic lupus erythematosus (SLE) mainly affects younger women and can involve one or more of the

bodily systems. It is characterized by the formation of autoantibodies against the cell's nucleus, or part of the nucleus, which are believed to be responsible for many of the manifestations of the disease.

Joint pain is common, although it is unusual to see joint damage such as occurs in RA. SLE can result in a variety of manifestations in other systems, for example various rashes, haemolytic anaemia and glomerulonephritis leading to renal impairment, as well as cerebral, lung and heart problems. Some of these can be life threatening.

Autoantibodies against cell nuclei (antinuclear factor, ANF) are present in the plasma in almost every patient with SLE. However, they are also frequently present in other CTDs and in a proportion of healthy people. Antibodies to specific components of the nucleus are more specific. For example, antibodies against double-stranded DNA are strongly suggestive of SLE.

Management depends on the systems affected. The joint and skin manifestations can often be controlled with hydrochloroquine and/or low doses of prednisolone. More severe cases require the use of high doses of corticosteroids with immunosuppression using cyclophosphamide, azathioprine or mycophenolate mofetil.

Other CTDs are associated with autoantibody formation, although in these cases the disease is not believed to be caused by specific antibody-antigen complexes as in SLE. Examples of these conditions include Sjögren syndrome, polymyositis, scleroderma and primary biliary cirrhosis.

For details and associated immunological abnormalities, see [Table 32.1](#). [Table 32.1](#) is, of necessity, an oversimplified guide to some of the more important signs and symptoms seen in the CTDs, with their associated antibodies. There is often a crossover of antibodies in the various diseases and the antibodies are by no means seen in every case.

Aches and pains

If we move from the laboratory to the clinic or surgery, 'articular disorders' take on another perspective. About one-fifth of the patients in a GP's surgery will complain of musculoskeletal symptoms, such as aches, pain, stiffness or disability. Only a proportion of these patients will have a demonstrable disease or significant anatomical abnormality. Some will have abnormalities associated with the way they move their musculoskeletal system ('mechanical' pain), while in other cases, no abnormality can be identified. This does not mean the symptoms are imagined, but in the absence of an abnormality, attempts to diagnose and 'cure' a disease will, of course, be futile. Doctors are trained to diagnose diseases and then treat them. Too many doctors are uncomfortable when they are not able to make a diagnosis. This may provoke them to order unnecessary investigations in these often anxious patients, thus exposing both parties to the dangers of false positives, laboratory or clerical error and misinterpretation of the results.

As a rheumatologist, each week the author sees one or two patients referred as a consequence of an inappropriately performed blood test. These patients usually have mechanical or unexplained musculoskeletal symptoms

TABLE 32.1 The connective tissue diseases, their common clinical features and frequently associated autoantibodies

Disease	Clinical features	Autoantibodies
SLE	Rashes, joint pains, glomerulonephritis, haemolytic anaemia, leukopenia, neuropsychiatric lupus, pericarditis, pleurisy, vasculitis, fatigue	Anti-nuclear factor Anti-double-stranded DNA Anti-Sm Anti-Ro Anti-La
Scleroderma	Thickened skin, Raynaud phenomenon, pulmonary hypertension, calcinosis, pulmonary fibrosis	Anti-nuclear factor Anti-centromere
Sjögren syndrome	Dry eyes, dry mouth, joint pains, fatigue, Raynaud phenomenon	Anti-nuclear factor Anti-Ro Anti-La
Polymyositis	Muscle weakness and wasting, joint pains, pulmonary fibrosis, fatigue	Rheumatoid factor Anti-nuclear factor Anti-Jo-1 Anti-synthetase
Dermatomyositis	Proximal muscle weakness and wasting, rashes, joint pains, pulmonary fibrosis	Anti-nuclear factor
Wegener granulomatosis	Vasculitis, sinusitis, pulmonary infiltration, glomerulonephritis, rashes	Anti-Mi2 cANCA
Microscopic polyangiitis	Glomerulonephritis, joint/muscle pains, rashes, lung infiltration	pANCA
Primary biliary cirrhosis	Jaundice, itching, joint pains, Raynaud phenomenon	Antimitochondrial

cANCA, cytoplasmic anti-neutrophil cytoplasmic antibody; pANCA, perinuclear anti-neutrophil cytoplasmic antibody; SLE, systemic lupus erythematosus.

and their doctors have performed a batch of tests with vague rheumatological connotations, presumably to reassure themselves or to be seen to be doing something for the patient. The problem is that these tests are often positive in healthy people, especially at low levels. For example, low titres of ANF are widespread, and it is common for a number of anxious young women to be referred with aches and pains, 'weakly positive ANF' and a sheaf of internet misinformation about how fatal SLE is. Informed of their 'positive' test, they have often had to wait several months for their referral appointment, in fear and trepidation, and come prepared to hear the worst. False positive rheumatoid factor tests, high plasma urate concentrations and slightly raised ESRs produce a steady stream of worried well people with fears they have rheumatoid arthritis, gout or inflammatory disease, respectively. Inappropriate tests are not only of concern to the biochemist and accountant. They cause a mass of unnecessary work for the clinician, but the real victims are the unfortunate patients who have to endure long periods of unnecessary strife, stress and uncertainty.

Crystal arthritis

Just as crystals form *in vitro* when the concentration of a solute is sufficiently high to allow nucleation and growth, so do they form *in vivo*. Crystals are sometimes found in joint fluid. These include monosodium urate (MSU), calcium pyrophosphate (CPP), basic calcium phosphates, cholesterol and oxalate crystals. The body's response to crystals varies. In some cases, the presence of crystals in a joint provokes a severe inflammatory reaction, but researchers have found crystals in joint fluid from asymptomatic patients. Different crystals tend to favour different sites. Monosodium urate is preferentially deposited in cartilage and synovium, CPP in articular

fibrocartilage and basic calcium phosphates in tendons and hyaline cartilage. The formation of crystals is influenced by physical factors such as temperature and hydrogen ion concentration (pH), but it is a complex process and what follows is a practical simplification.

Hyperuricaemia and gout

Gout is the best known form of crystal arthritis and is caused by MSU crystal deposition in articular tissues. The term hyperuricaemia is used to describe excessive uric acid or urate in the blood as defined by solubility in plasma at 37 °C; that is, >0.42 mmol/L in males and >0.36 mmol/L in females. While there is a relationship between MSU crystal deposition and hyperuricaemia, it is by no means absolute. Hyperuricaemia without attacks of gouty arthritis is common, and sometimes, particularly during an acute attack, plasma uric acid concentrations are normal.

Uric acid is the end-product of purine metabolism (Fig. 32.2). Purines are components of nucleic acids and of nucleotides that are involved in energy transformation and phosphorylation reactions and act as intracellular messengers. They are derived from diet, the breakdown of nucleotides and from *de novo* synthesis. Purines are metabolized to urate via hypoxanthine and xanthine, the final step being catalysed by xanthine oxidase. The kidneys excrete two-thirds of the urate, the remainder being removed via the bowel, where it is broken down into carbon dioxide and ammonia by bacterial action. The amount of urate pooled in the body depends on the relationship between the input from diet, the breakdown of nucleotides and *de novo* synthesis versus the output via kidney and bowel. Hyperuricaemia results from excess production of urate or reduced excretion, or sometimes both mechanisms. The average uric acid pool size is 7.2 mmol in men

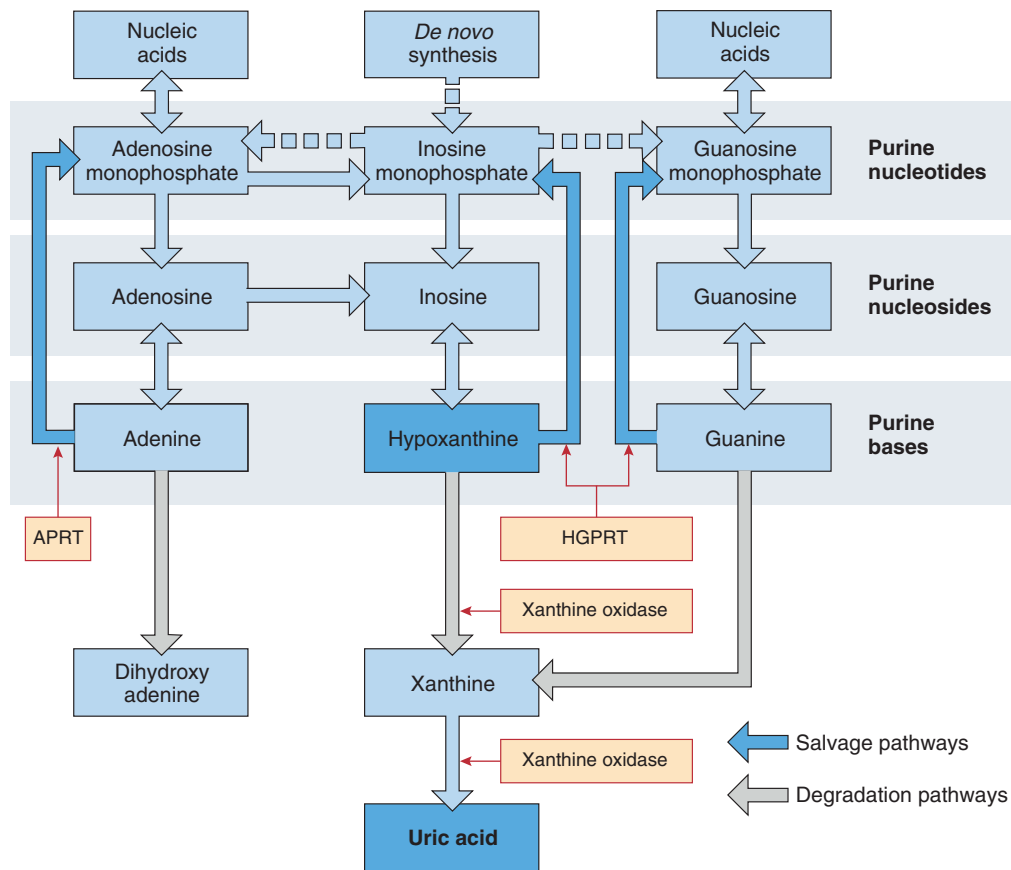

FIGURE 32.2 ■ A simplified diagram of the pathways of purine nucleotide metabolism and uric acid synthesis in humans. APRT, adenine phosphoribosyl transferase; HGPRT, hypoxanthine-guanine phosphoribosyl transferase. (From Marshall W J, Bangert S K, Lapsley M 2008 Clinical Chemistry, 7th ed. Edinburgh: Elsevier, with permission.)

and 3.6 mmol in women. Two-thirds is turned over each day. The uric acid pool of people with gout is increased to 12–24 mmol; those with deposits of urate (tophi) may have a pool as large as 180 mmol.

Gout tends to run in families and is frequent in certain races, such as the New Zealand Maori. This points to an inherited abnormality in urate metabolism, but while there are well-defined enzyme defects resulting in hyperuricaemia, for example hypoxanthine-guanine phosphoribosyl transferase deficiency, the cause of the Lesch–Nyhan syndrome (see p. 640), these are rare. In most cases, we can only divide people with gout into those who undersecrete uric acid from the kidney (85%) and those who synthesize an increased amount.

Gout commonly affects middle-aged males; it is most unusual in premenopausal women. Hyperuricaemia, family history, obesity, hypertension, age, alcohol consumption and renal insufficiency are risk factors for gout. Several drugs, particularly diuretics, low-dose aspirin and ciclosporin, and lead poisoning, may provoke gout by causing hyperuricaemia. Conditions with high purine turnover, such as leukaemia and lymphoma and their treatment with cytotoxic drugs, can cause gout and sometimes acute urate nephropathy by increasing the urate load.

Asymptomatic hyperuricaemia. Asymptomatic hyperuricaemia is the first stage of gout. This is seen on

at least one occasion in as many as 10% of adults, the majority of whom never experience an attack of gout. In the past, we have ignored asymptomatic hyperuricaemia, but it is looking increasingly likely that it is a risk factor for acute coronary syndromes and it is also linked with obesity, type 2 diabetes, hypertension and hyperlipidaemia.

Acute gout. Acute gout usually strikes the first metatarsophalangeal joint (the bunion joint in the big toe) at night. Crystal formation is more likely at colder temperatures and this joint is cooler than more proximal ones of a similar size. The joint rapidly becomes severely painful, swollen, red and exquisitely tender to touch. The weight of the bedclothes is unbearable. There is often a systemic reaction with fever, an acute phase reaction and a leukocytosis. While acute gout most commonly attacks the great toe (70% of cases), the instep, the ankle or knee can be affected. Examination of synovial fluid drawn from an affected joint will show many MSU crystals. Left to itself, acute gout usually subsides over ten days or so.

While some patients never have another attack, there are usually further sporadic attacks. These may become more frequent and may involve several areas at a time (polyarticular gout) as the urate load increases and the disease progresses. In time, upper limb joints such as the fingers, wrists and elbows become affected.

Chronic tophaceous gout. In the later stage of untreated disease, the patient may have continuous inflammation of many joints with associated pain, tenderness and immobility. In addition, crystals of urate are deposited in masses of chalky material called tophi, which sometimes ulcerate and discharge through the skin. These are often seen over joints and bony prominences such as the points of the elbows. They can occur in the joint and inside bone causing permanent damage, pain, deformity and disability. Urate crystals are often the focus for renal stone formation. At this stage, gout is a miserable business.

Diagnosis. When gout presents in the classic manner, the diagnosis is obvious. However, infection in a joint also makes it hot, red and painful and sometimes it can be difficult to differentiate between crystal arthritis and infection. Because both conditions cause fever, leukocytosis and an acute phase reaction, the only reliable way to make the diagnosis is to aspirate fluid from the joint and examine it for crystals (using polarizing light microscopy, see Fig. 32.3) and for bacteria (Gram stain and culture). Rarely, the two conditions coexist, so both tests should be performed.

For the reasons mentioned above, plasma urate concentrations are not helpful in diagnosis, although very high values are convincing and sometimes influence decisions about drug treatment.

Treatment. There are three strands to the treatment of gout. Immediate action is required to counteract the severe inflammation that is producing such pain and disability. In straightforward cases, anti-inflammatory drugs, such as diclofenac or naproxen, can rapidly achieve this. Colchicine, which stabilizes lysosomal membranes, can be used when anti-inflammatory drugs are inadvisable, for example in patients with kidney or stomach conditions. These drugs settle the inflammation but have no effect on crystal formation or the underlying problem of the increased urate load. The second strand to treatment is to

try to persuade the patient to modify his lifestyle. More exercise, less alcohol, improved diet and weight loss are the goals. They are more easily achieved in some than in others.

The third strand of treatment is to reduce the urate load. This will have built up over years and so will take time to reduce. Reduction is usually achieved by the use of allopurinol, a potent purine xanthine oxidase inhibitor, which blocks the conversion of xanthine to urate. Xanthine is soluble and is excreted renally. The decision to start allopurinol should be influenced by the frequency of the attacks of acute gout, the presence of tophi and/or chronic polyarticular gout and very high urate concentrations. Allopurinol gradually leaches away the high urate load and, in time, urate concentrations become normal and tophi are absorbed. There is a danger of allopurinol provoking an acute flare of gout when it is first used, so it should not be started until the acute attack has been controlled. Once treatment with allopurinol has been established, urate concentrations should be checked. The target is a value of <0.3 mmol/L and the dose of allopurinol should be titrated accordingly.

The treatment of uncomplicated gout is simple and rewarding if patients can be persuaded to take their tablets regularly. Male patients often seem to find it difficult to continue their medication when they feel well and this is by far the commonest cause of failure of treatment. However, treating complicated gout can be challenging. These patients often have chronic kidney disease, cardiac disease, peptic ulcers and are taking warfarin, all of which are relative contraindications to the use of anti-inflammatory drugs. They often require diuretics (which may provoke gout) to control heart failure and gout is frequently a problem in transplant patients because of the use of the hyperuricaemia-inducing anti-rejection drug, ciclosporin. In these cases, injecting corticosteroid into the affected joint controls the acute inflammation. If several joints are affected, systemic adrenocorticotrophic hormone (ACTH) or corticosteroids are necessary.

FIGURE 32.3 ■ Sodium urate (needle shaped, A) and calcium pyrophosphate (rhomboid, B) crystals viewed microscopically. Under polarized light, the former are negatively, the latter positively, birefringent.

Lowering urate concentrations with allopurinol has been the mainstay of the treatment of gout for the past 40 years. It is inexpensive and in most cases is very effective. However, drug reactions do occur and there has been a need for other urate lowering agents. Recently, febuxostat, a non-purine selective xanthine oxidase inhibitor, has been introduced and is showing great promise. It does not inhibit enzymes involved in purine and pyrimidine metabolism, as does allopurinol and may in time become the drug of first choice.

All mammals apart from humans and Dalmatian dogs possess the enzyme urate oxidase (uricase) which oxidizes urate to allantoin. This is 5–10 times more soluble than uric acid and so is more effectively excreted by the kidney. However, urate oxidase was lost in early human evolution. The reasons for this are not clear but it has been proposed that its loss was an advantage because uric acid is a powerful antioxidant and scavenger of free radicals that might protect against oxidative damage and so prolong life and decrease the risks of cancer. As a result, humans are prone to gout. The selective inbreeding of Dalmatian dogs has produced a striking white animal with black spots but also one without urate oxidase. Hence, the Dalmatian's tendency to the development of gout and the formation of urate renal stones, which can be treated with allopurinol.

Until recently, this interesting information was of peripheral interest. However, researchers have investigated the use of urate oxidase to treat hyperuricaemia in humans. There are two preparations. Rasburicase, a recombinant form from the fungus *Aspergillus flavus*, is used to prevent acute urate nephropathy, which can occur when large tumour loads are treated with chemotherapy (tumour lysis syndrome, see p. 114). However, its very short circulating life and the fact patients sometimes develop antibodies to the drug limits its use. These disadvantages led to the development of PEG-uricase, a recombinant porcine urate oxidase, to which multiple strands of polyethylene glycol (PEG) of average molecular weight 10 000 Da have been attached. This greatly prolongs its circulating life and it is non-immunogenic. However, it has to be given intravenously at two-weekly intervals and can cause flares of gout and infusion reactions. At present, its use is reserved for patients with gout that is difficult to control who cannot take standard treatment. It may be noted that accurate measurement of urate in patients treated with this drug is difficult, as it continues to act *in vitro*.

Calcium pyrophosphate deposition (CPPD)

This is the other common form of crystal arthritis. It is not as frequent as gout and is less well understood. Calcium pyrophosphate crystals are preferentially deposited in articular cartilage where calcification can be seen on X-rays (chondrocalcinosis). Affected joints can become acutely inflamed in a way that resembles gout (hence CPPD's other name of pseudogout). The knee and the wrist are most frequently affected. An acute phase reaction is common and, again, finding CPP crystals in the joint fluid makes the diagnosis. In some cases, there is chronic involvement of several joints, which can cause diagnostic confusion with other inflammatory articular diseases.

Calcium pyrophosphate deposition becomes more common with age. Symptomless chondrocalcinosis is often seen on X-rays of the elderly. Attacks are sometimes triggered by trauma unrelated to the joint (of which surgery is an excellent example), and rheumatologists are often asked to see elderly postoperative patients in the surgical wards with a hot, swollen, 'infected' wrist or knee. Almost invariably, pseudogout is responsible.

Familial CPPD is well recognized, and kindred from many different countries have been described. These patients present in their twenties and usually have severe destructive joint disease. In some families, a genetic abnormality on the short arm of chromosome 5p has been identified.

Calcium pyrophosphate deposition is associated with several metabolic diseases described in other chapters. Definite associations have been established with haemochromatosis, hyperparathyroidism, hypomagnesaemia, hypophosphatasia, alkaptonuria and Wilson disease. In these cases, the onset is often at a younger age (under 55 years) and the disease is more severe than is seen in uncomplicated cases. A link with thyroid disease is now disputed.

As yet, we have little understanding of the underlying biochemical processes at play in this group of conditions. Our 'first aid' style of treatment, with anti-inflammatory drugs and corticosteroid injection of affected joints, reflects this.

Basic calcium phosphate deposition disease

Basic calcium phosphate (BCP) crystals include hydroxyapatite, octacalcium phosphate and tricalcium phosphate. They are often difficult to identify, which is why we still have so much to learn about these conditions. Basic calcium phosphate crystals are sometimes deposited in the tendons or in soft tissues outside the joints, where they can give rise to intense pain. This tends to occur in younger females and affects the shoulder, wrist and even the great toe, when gout may be incorrectly diagnosed. Injection of corticosteroid into the lesion often results in dramatic improvement. Mercifully, the pain usually settles down over a week or two and the calcification seen on X-ray is often resorbed within six weeks. Basic calcium phosphate crystal deposition has also been implicated in an unusual condition that causes large effusions and joint resorption in the shoulders of elderly women (Milwaukee shoulder).

There is increasing interest in these crystals because they appear to be closely involved in the process of osteoarthritis (OA). Basic calcium phosphate crystals can be found in the synovial fluid of as many as 60% of joints severely affected by OA. It is uncertain whether this is related to the cause of OA or is a downstream effect of the OA process. However, in tissue culture, BCP crystals stimulate mitogenesis and the production of metalloproteinases, which cleave cartilage matrix. This suggests BCP crystals may be involved in the cartilage breakdown seen in OA, and researchers are starting to look at the effects of agents such as phosphocitrate, which inhibit the formation of BCP crystals.

Other crystals found in synovial fluid

Other crystals can be found in synovial fluid. These include cholesterol and oxalic acid crystals. These latter occur in primary oxalosis and in patients with established renal failure on dialysis, in whom the crystals can provoke a chronic polyarthritis in the small joints of the hand.

ARTICULAR INVOLVEMENT IN ENDOCRINE AND METABOLIC DISEASES

Diabetes mellitus

Over 30% of diabetic patients have potentially disabling hand or shoulder disorders. Capsulitis of the shoulder (frozen shoulder) is particularly common in diabetes. It causes severe, disabling shoulder pain, which settles after a few months but leaves the patient with very limited mobility at the shoulder joint. The range of movement usually improves over the months. Sometimes a corticosteroid injection will help the pain, but limited movement remains a problem.

Many patients with diabetes develop changes in the connective tissues of the hands. Dupuytren contracture, a condition in which there is thickening of the palmar fascia and increasing contracture of fingers, is common in diabetes. In what seems to be a different process, called diabetic cheiroarthropathy or diabetic hand syndrome, the skin and underlying tissues become thickened, resulting in a limited range of movement of the hand and finger joints. Often the finger tendons are affected. These changes are sometimes mistaken for rheumatoid arthritis but there is no joint damage or acute phase reaction. Biopsy shows excessive fibrosis and increased deposition of dermal collagen. It has been suggested that increased tissue glycation may result in diminished collagen breakdown. Perhaps a similar sort of process is taking place in the frozen shoulders of diabetic patients.

Peripheral nerve damage is a frequent complication of diabetes. In some cases, the nerve supply to the joints is affected so that the usual sensations of joint position and joint movement are lost. Repeated trauma can take place within such a joint without the patient being aware and this can rapidly result in painless destruction and bony resorption of large areas of bone around the affected joint. This is called a Charcot joint. It occurs almost exclusively in the foot and is a major problem. However, although evidence of damage to small nerve fibres is usually present in this condition, other factors are undoubtedly involved. Charcot arthritis occurs more frequently in type 1 diabetes. The reason for this is not clear.

Other endocrine disorders

Several endocrine disorders can cause muscle and joint pains and need to be considered in the assessment of the patient with aches and pains. Only rarely will they be found to be responsible, but early diagnosis and treatment will often relieve the patient's symptoms and can

prevent further suffering and tissue damage. As ever with uncommon conditions presenting in unusual ways, the important thing is to think of the diagnosis.

Both hypo- and hyperthyroidism can result in joint pains and a variety of muscular symptoms. Hyperparathyroidism is a cause of bone pain and aching joints as well as chondrocalcinosis and pseudogout, while joint pains, degenerative arthritis, joint laxity and muscle weakness can result from effects of acromegaly on bone, joints and soft tissue. Hypercortisolism sometimes presents in the rheumatology clinic with back pain (from osteoporotic fractures) and muscle weakness.

Haemochromatosis

As described in Chapter 14, liver disease and diabetes in a male with slate grey skin is the classic presentation of haemochromatosis. However, the alert rheumatologist will discover the occasional patient with this condition presenting in the clinic with articular disease. This can happen in two ways. We have already discussed how haemochromatosis is associated with chondrocalcinosis and pseudogout. In addition, haemochromatosis itself is responsible for a characteristic form of arthritis involving the metacarpophalangeal joints of the index and middle fingers. X-rays show loss of joint space and characteristic hook osteophyte formation in these joints. There is no inflammatory reaction, but iron studies show the characteristic picture of haemochromatosis. The synovium contains much iron. Venesection unfortunately makes little difference to the joint symptoms, but does prevent further harm to the pancreas and liver. It is also important to screen the patient's relatives so that those who have inherited the disease can be identified and treated before damage occurs.

Alkaptonuria

This rare, autosomal recessive disorder is caused by a deficiency of the enzyme homogentisic acid oxidase. This results in a build-up of homogentisic acid, an intermediary product in the metabolism of phenylalanine and tyrosine. The excess homogentisic acid is oxidized and polymerized and forms a blackish pigment, alkapton, which is deposited in cartilage and can be easily seen in the cartilage of the ears. More importantly, it is also deposited in articular cartilage, which becomes more susceptible to mechanical stress and degeneration. Arthritis of the hips, knees and shoulders develops early. Alkapton is also deposited in the intervertebral discs in the spine, which become calcified. This produces a characteristic X-ray appearance and predisposes to mechanical back problems. The diagnosis is made by identifying homogentisic acid in the urine.

LABORATORY TESTING IN ARTICULAR DISEASE

Anaemia in rheumatoid arthritis

Anaemia is common in RA. When the disease is active, there is frequently a normochromic, normocytic anaemia. This is called 'the anaemia of chronic disease'

(see Chapter 27) and it will resolve if the activity of the arthritis can be controlled. Iron is present in the bone marrow but cannot be utilized in erythropoiesis.

Some RA patients require an anti-inflammatory drug to keep their pain and stiffness at bay. These drugs have a tendency to cause erosions and ulcers in the stomach, duodenum or small bowel, resulting in blood loss, iron deficiency and a hypochromic microcytic anaemia.

Separating iron-deficiency anaemia and the anaemia of chronic disease in these patients is often tricky and is made more difficult by the behaviour of ferritin in inflammatory diseases. Ferritin is one of the several proteins that are acute phase reactants, and for this reason, its plasma concentration is usually raised when RA is active. Measurement of plasma ferritin concentration is considered to be the best test of iron deficiency (see Chapter 27), but in RA, the result should be interpreted with caution. Usually a concentration of $<12 \mu\text{g/L}$ is taken as diagnostic of iron deficiency, but in RA, rheumatologists take a concentration of $<30 \mu\text{g/L}$ to indicate iron deficiency. However, iron deficiency can exist with higher concentrations of ferritin. The presence of microcytosis favours the diagnosis of iron deficiency, but sometimes examination of bone marrow for iron stores is the only reliable way to differentiate between iron-deficiency anaemia and the anaemia of chronic disease.

The acute phase response

The acute phase response is discussed in detail in Chapter 30. Traditionally, rheumatologists have used the ESR to diagnose and then monitor an acute phase response. This is, of course, an indirect measure of a series of acute phase proteins and immunoglobulins and is particularly influenced by plasma fibrinogen concentrations. Measurement of CRP concentration is gradually superseding the ESR and is believed to correlate better with disease activity in RA. In SLE, CRP concentration is often normal; indeed, a raised value in this condition is said to suggest infection rather than increased disease activity. In truth, most rheumatologists like to use both CRP and ESR.

These simple investigations are of great help to a rheumatologist. One of our main tasks when confronted with a new patient is to differentiate between the inflammatory and non-inflammatory types of arthritis. This is not always easy and the CRP and/or ESR often provide the answer. The activity of rheumatoid arthritis waxes and wanes over time and this is reflected in the acute phase response, as is the success or otherwise of drug treatment.

Examination of synovial fluid

An acutely swollen hot joint can be a result of infection, crystals or the irritative effects of blood on the synovium. The only reliable way to determine which is responsible is to aspirate the joint fluid. Blood will be apparent to the naked eye. Gram-staining will show bacteria and polarizing light microscopy will demonstrate crystals (Fig. 32.3) and whether they are negatively (gout) or positively (CPP) birefringent. The chances of identifying crystals are increased if the specimen is centrifuged and the deposit examined at the earliest opportunity. Sometimes it

is only possible to obtain a tiny amount of fluid. If expressed on to a microscope slide at the bedside and covered with a cover slip to avoid evaporation, this can yield vital information when examined in the laboratory.

Rheumatoid factor

Rheumatoid factors (RFs) are antibodies directed against the Fc portion of human IgG and are present in 75–80% of patients with RA. At present, it is believed that RF is produced as a downstream product of the rheumatoid process rather than being central to the disease process. Rheumatoid factors also occur in other connective tissue diseases, chronic infections such as tuberculosis and hepatitis C and conditions associated with hyperglobulinaemia, such as hyperglobulinaemic purpura, sarcoidosis and cryoglobulinaemia. They are found in low titres in 5% of the population, occurring more frequently with advancing age.

A positive RF is strong confirmatory evidence of RA. In a patient with polyarthritis it has a sensitivity of 70% and a specificity of 80%. However, in an unselected population its predictive value is low (20%). Very high titres of RF are associated with severe disease and are a marker of poor prognosis.

Most laboratory methods identify IgM antibodies, although IgA and IgG antibodies of uncertain clinical significance do exist. For many years, rheumatoid factor was detected by techniques using flocculation or agglutination of IgG-coated particles or cells. The Rose Waaler test, the standard method for many years, used sheep red blood cells coated with rabbit IgG, which agglutinate in the presence of RF, while the flocculation of latex beads coated with human IgG forms the basis of the RA latex test. The sheep cell tests are more specific. However, heterophile antibodies reacting directly against sheep cells sometimes give rise to false positives. Because of this, sera are usually tested on uncoated and coated sheep red cells in parallel. Laser nephelometry, enzyme linked immunosorbent assay (ELISA), immunofluorescence and radioimmunoassay can also be used to measure rheumatoid factors.

Other autoantibodies are seen in RA. In recent years, it has become standard practice to measure antibodies to cyclic citrullinated protein (anti-CCP) as well as RF. These are measured by peptide-based ELISA. The test has a sensitivity of 74% and a specificity of 94%. It may eventually supersede the time-honoured RF test but most rheumatologists use both tests at present.

Other autoantibody tests

Autoantibodies are produced in the connective tissue diseases (see above) and some cases of vasculitis. These are sometimes diagnostic, but most autoantibodies occur in several of these conditions and in healthy people. These tests are valuable in confirming a suspected diagnosis and negative tests are useful in helping to rule out diagnoses. However, because they occur in a proportion of normal people, they should not be used for screening purposes or in cases without clinical features suspicious of connective tissue disease (see p. 639). For some years, autoantibodies have been identified by indirect immunofluorescence

using Hep-2 cells. In this age of automation, there is a move to streamline the process of identifying anti-nuclear antibodies. In some laboratories, automated multiplex immunoassay is used to screen for a mixture of common nuclear antigens. Positive specimens are then examined by direct immunofluorescence, which remains the gold standard. At this stage, the presence of anti-nuclear factor (ANF) is a non-specific indicator that a connective tissue disease may be present (see Table 32.1). The next step is to determine to which part of the nucleus the antibody reacts, by using highly specific tests, including enzyme linked immunoabsorbent assay (ELISA) and indirect immunofluorescence. Anti-double stranded DNA, anti-Sm, anti-Ro, anti-La, anti-centromere, anti-Jo1, anti-Mi2 and anti-mitochondrial antibodies can be identified in this way, each of which, as shown in Table 32.1, is associated with different connective tissue diseases.

CONCLUSION

In spite of the fact that biochemical abnormalities themselves are responsible for few articular diseases, we have seen how clinical biochemistry plays an important part in the diagnosis, treatment and monitoring of rheumatological conditions. Many of the chapters in this book refer to medical specialties that primarily focus on biochemical disorders, or conditions with major biochemical consequences. However, there are some, such as rheumatology, for which this is not the case. It is instructive to examine the different ways in which biochemical tests are useful in such a setting, using articular disorders as an example:

1. Confirming a diagnosis:
 - finding urate crystals in synovial fluid makes the diagnosis of gout
 - finding raised iron and ferritin concentrations in haemochromatosis arthritis and demonstrating the presence of increased iron on liver biopsy confirms the diagnosis
 - finding homogentisic acid in the urine confirms the diagnosis of alkaptonuria.
2. Categorizing class of arthritis:
 - in a patient with arthritis or possible CTD, demonstrating an acute phase response by raised CRP and/or ESR supports the diagnosis of an inflammatory disease, while a normal CRP/ESR favours a diagnosis of osteoarthritis, a mechanical disorder or 'unexplained symptoms'
 - the presence of ANF suggests one of the connective tissue diseases.
3. Supporting a diagnosis:
 - when a diagnosis is suspected, a positive sensitive test is strong support for that diagnosis, for example a positive rheumatoid factor and/or CCP in suspected RA or a raised urate in gout.
4. Excluding a diagnosis:
 - normal iron studies virtually exclude the diagnosis of haemochromatosis.

5. Monitoring the activity of a disease:
 - the activity of inflammatory arthritis waxes and wanes spontaneously. This can be monitored by regular CRP/ESR measurements.
6. Monitoring the effect of treatment:
 - similarly, the CRP/ESR can be used to monitor the effectiveness of drug treatment in controlling the activity of inflammatory arthritis.
7. Monitoring for drug toxicity:
 - regular blood testing is used to monitor for drug toxicity. For example, two-monthly liver function tests are performed routinely on the many patients with RA, who are taking the potentially hepatotoxic drug methotrexate.
8. Monitoring for the complications of a disease:
 - glomerulonephritis and renal failure are fairly frequent complications of SLE. Hence regular tests of renal function and urine tests are part of the routine follow-up of these patients.
9. Specialty-specific idiosyncrasies:
 - each specialty or disease has its own idiosyncrasies, for example the conflicting effect of iron deficiency and the acute phase response on ferritin concentrations in patients with RA and anaemia.

These examples show how powerful biochemical investigations can be, when performed for a defined reason. However, we have also demonstrated that, when used inappropriately, they have the power to inflict harm and distress on the unfortunate victim. We must recall Hippocrates' dictum 'primum non nocere' (first do not harm) at all times.

APPENDIX 659

INTRODUCTION

Diseases affecting striated muscle are important causes of morbidity and mortality. They are common in clinical practice, and patients may be seen by a variety of clinical specialists, including neurologists, rheumatologists, orthopaedic surgeons and paediatricians. Investigating suspected muscle disease requires a combination of clinical and laboratory skills, including biochemical, genetic and pathological investigations, each assuming a different importance depending on the nature of the disorder. In some, biochemical studies play a minor role whereas in others, particularly the metabolic myopathies, biochemical investigations are crucial.

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF MUSCLE

Skeletal muscle accounts for approximately 40% of total body weight and between 30% and 40% of total body oxygen consumption, even at rest. It is, therefore, an extremely important tissue in metabolic terms. Muscle is composed of multinucleated fibres that contain the contractile apparatus upon which movement depends. Although similar in structure, muscle fibres vary and three main types have been defined using metabolic and functional criteria (Fig. 33.1 and Table 33.1). Most skeletal muscles contain all three fibre types, although the proportions vary considerably depending on the function of the particular muscle.

The main function of muscle is to generate force in a controlled manner. This force, in the form of contraction (shortening), is produced in muscle fibres by the

interaction of actin and myosin (Fig. 33.2), a process that is highly energy dependent. The energy required for muscle contraction comes from the hydrolysis of ATP, and maintenance of ATP concentration is critical. Any interference with ATP generation will inevitably impair the ability of muscle to produce force. ATP concentration is maintained by one of two mechanisms: ATP can be regenerated either from the energy storage molecule phosphocreatine or from ADP, or produced directly during glycolysis and mitochondrial oxidation. Regeneration is rapid, while the second process takes longer.

Phosphocreatine is present in large quantities in muscle (the other major site is brain) and acts as a reservoir of

FIGURE 33.1 ■ Cross-section of normal muscle showing the histochemical reaction for ATPase activity. The three fibre types can be easily identified: type I (dark), type IIa and type IIb. (Photograph courtesy of Dr M A Johnson.)

TABLE 33.1 Muscle fibre types

Fibre type	Electrical properties	Metabolic properties	Histochemical properties
Type I	Slow twitch	Oxidative	Heavily stained ATPase after preincubation at acid pH (e.g. pH4.6)
Type IIA	Fast twitch	Oxidative/glycolytic	Lightly stained ATPase after preincubation at pH4.6
Type IIB	Fast twitch	Glycolytic	Lightly stained ATPase only after preincubation at pH4.3

The three main fibre types are differentiated on muscle biopsy by the calcium-activated myosin ATPase. Type I fibres are dependent upon oxidative metabolism, contain the most mitochondria and are particularly important for endurance exercise. Type II fibres contain a higher proportion of glycolytic enzymes and are important in rapid movement. Regenerating fibres have an intermediate staining pattern and are referred to as type IIC fibres.

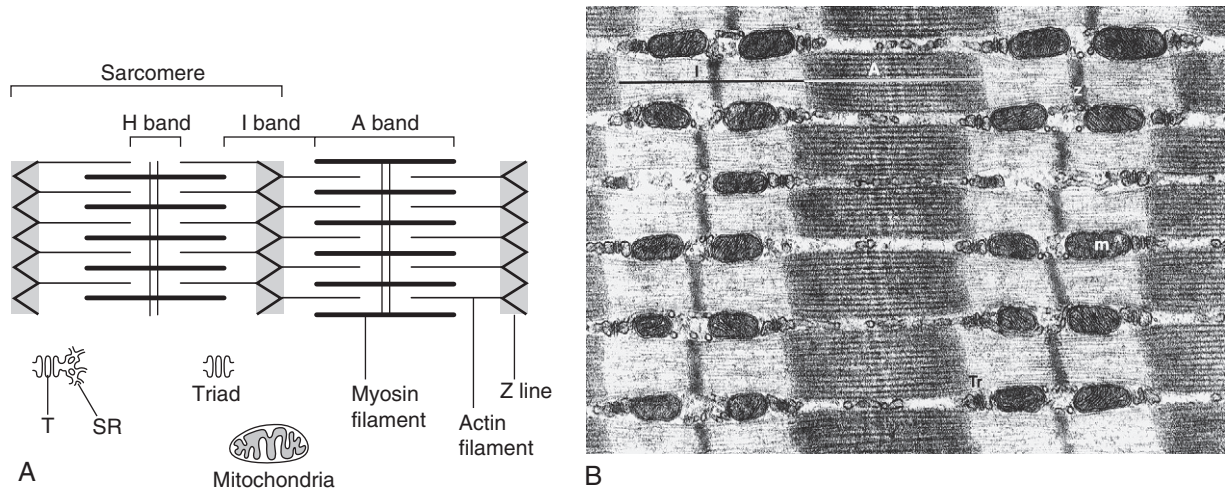

FIGURE 33.2 ■ The structure of skeletal muscle. (A) Diagrammatic representation of the structural components within a single muscle fibre. Thin filaments (actin) are anchored to the Z line. Thick filaments are composed of multiple myosin molecules, each of which has a hinged end that can interact with the thin filament. The T tubule is a continuation of the sarcolemmal membrane, which interacts with the sarcoplasmic reticulum at specific sites (triad). The signal for contraction is transmitted along the sarcolemma to the T tubule, which in turn causes release of calcium from the sarcoplasmic reticulum (SR). Calcium release stimulates contraction. (B) Electron micrograph of normal muscle. This shows the bundles of myofilaments with Z lines (z), thin (I band) and thick (A band) filaments. Triad (Tr) and mitochondria (m) are identified. high-energy phosphate groups that it can donate to ADP in the following transphosphorylation reaction, catalysed by the enzyme creatine kinase:

The concentration of ATP does not fall significantly until nearly all of the phosphocreatine has been converted to creatine. A second transphosphorylation reaction, catalysed by adenylate kinase, seems to have a minor role in ATP production. The AMP formed is broken down further by AMP deaminase.

ATP can also be generated directly by glycolysis and the oxidative catabolism of carbohydrate and lipid fuels. These processes are slow compared with transphosphorylation, but nevertheless are essential for ATP generation. The breakdown of carbohydrate by glycolysis (Fig. 33.3) has a vital role in skeletal muscle since it permits ATP

production under anaerobic conditions. When oxidative metabolism of pyruvate is impaired, for example during ischaemia, which includes high intensity activity, or in the presence of a defect of the respiratory chain, increasing amounts of lactate may be produced.

While small amounts of ATP can be generated by glycolysis in the cytosol, significantly greater amounts are produced by the oxidative breakdown of metabolic fuels (pyruvate, ketone bodies, fatty acids) that occurs within mitochondria. Long chain fatty acids, either from intracellular lipid stores or imported from the bloodstream, are first activated to their acyl-CoA esters before being transported into the mitochondrial matrix by the concerted action of carnitine palmitoyltransferase I, carnitine/acylcarnitine translocase and carnitine palmitoyltransferase II (Fig. 33.4). Short and medium chain fatty acids enter the mitochondria as the free acids and are activated to their acyl-CoA esters in the mitochondrial matrix. Inside the mitochondria, fatty acyl-CoA esters undergo β -oxidation, a series of four reactions that results in the production of acetyl-CoA and a chain-shortened fatty acid (Fig. 33.5); there are two or three enzymes with overlapping substrate specificities for each of these steps. Reducing equivalents

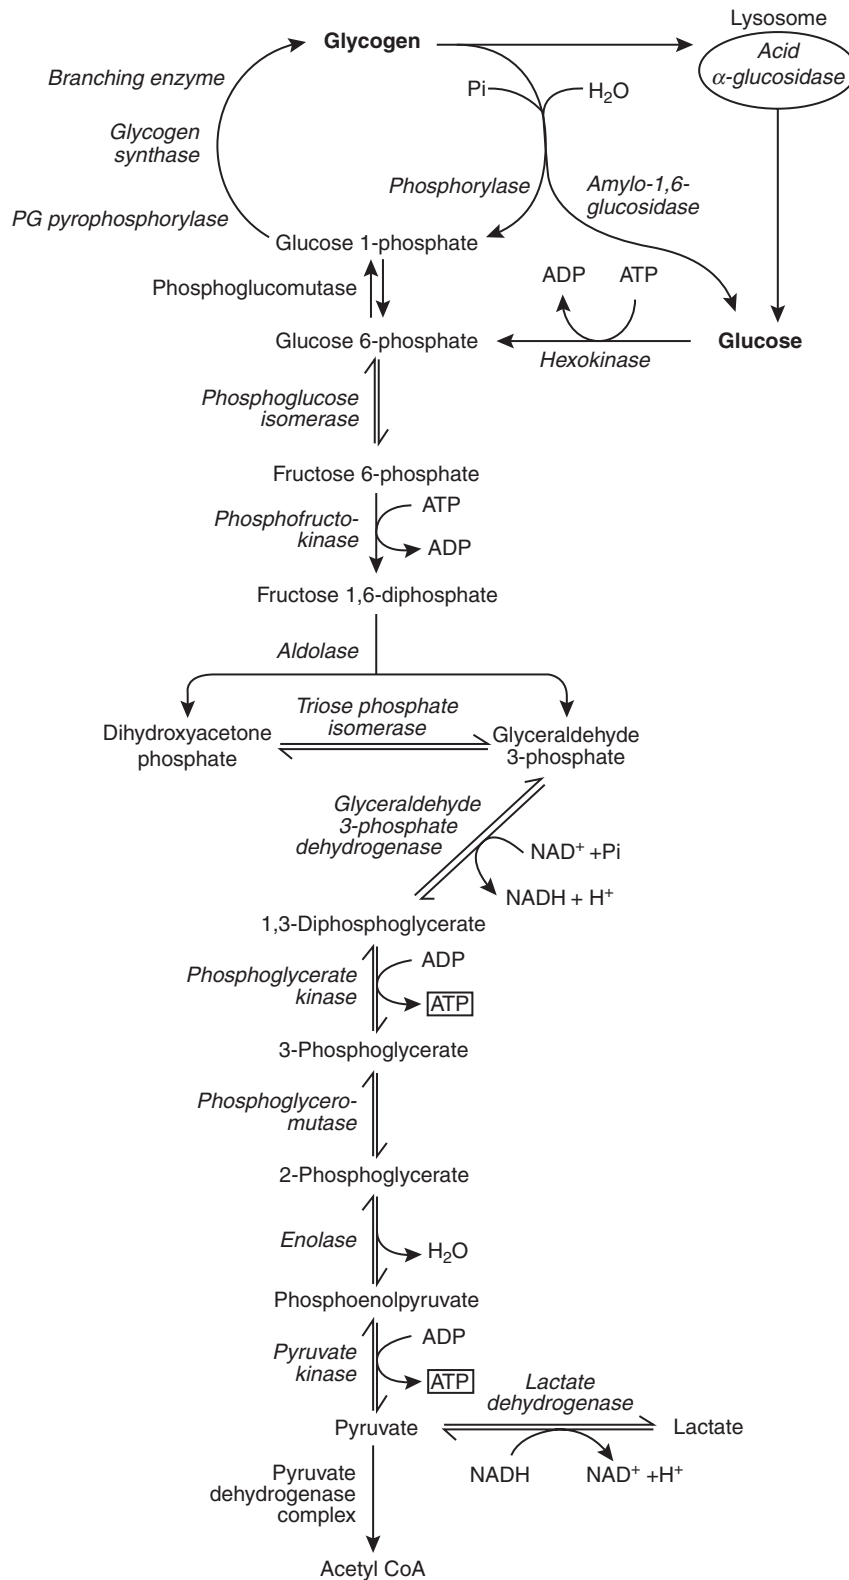

FIGURE 33.3 ■ Glycogen breakdown and glycolysis. Under anaerobic conditions, when further oxidation of acetyl-CoA is impaired, pyruvate is metabolized to lactate. This will also occur in defects of pyruvate dehydrogenase complex (PDC) and of the respiratory chain, and is due to the failure to reoxidize intramitochondrial NADH, which in turn inhibits PDC. NADH formed during glycolysis (and other substrate oxidation) is reoxidized by complex I of the mitochondrial respiratory chain (see Fig. 33.7).

FIGURE 33.4 ■ Transport of fatty acids across the inner mitochondrial membrane. Short and medium chain fatty acids do not require a specialized transport mechanism to cross the membrane. Long chain fatty acids are first acylated in the cytosol. Carnitine palmitoyltransferase (CPT I) on the outer side of the inner membrane converts the fatty acyl-CoA to an acylcarnitine ester and this is transported across the membrane linked to the export of carnitine. Inside the matrix, CPT II converts the acylcarnitine back to the fatty acyl-CoA, which is broken down by β -oxidation.

generated by the process of β -oxidation are transferred to the respiratory chain. The acyl-CoA dehydrogenases transfer reducing equivalents to electron transfer flavoprotein (ETF) and thereafter to ETF dehydrogenase, which directly reduces ubiquinone of the respiratory chain (see Fig. 33.7). The 3-hydroxyacyl-CoA dehydrogenases reduce NAD^+ to give NADH, which transfers its reducing equivalents to complex I of the respiratory chain. Acetyl-CoA generated either from carbohydrate or fatty acid oxidation is metabolized further by the tricarboxylic acid cycle (Fig. 33.6). The oxidation of fatty acids and glucose, as well as the subsequent metabolism of acetyl-CoA, generates more reduced cofactors (NADH and FADH_2) that are re-oxidized by the respiratory chain, and the energy released by this process is conserved as ATP (Fig. 33.7).

The balance of muscle metabolism depends on the state of activity, diet and the influence of various hormones (particularly insulin, thyroxine, glucocorticoids). At rest, muscle predominantly oxidizes fatty acids to generate the energy for ATP synthesis. During exercise, the proportion of energy derived from carbohydrate or lipid depends on the degree and duration of this exercise and on the degree of physical fitness. High-intensity exercise at close to maximum oxygen uptake relies almost exclusively on carbohydrate metabolism, and glycogen depletion coincides with exhaustion. During moderate-intensity exercise for prolonged periods, there is a switch from carbohydrate to lipid metabolism.

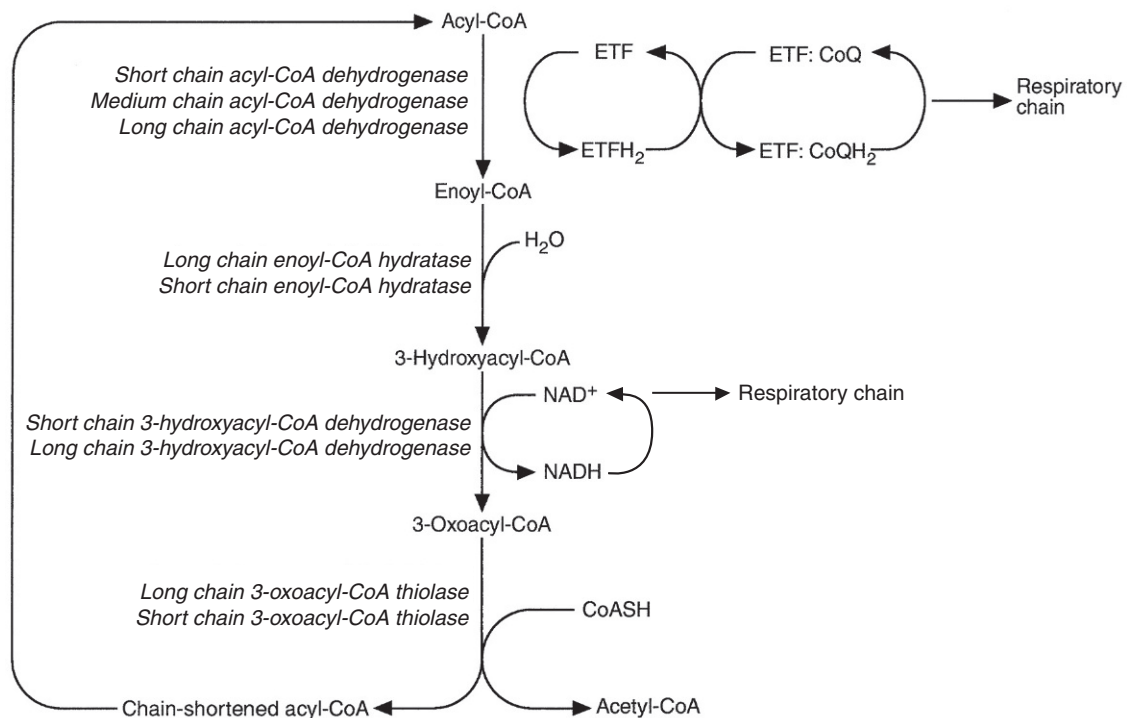

FIGURE 33.5 ■ Mitochondrial β -oxidation of saturated fatty acids. ETF, electron transfer flavoprotein; CoQ, coenzyme Q.

FIGURE 33.6 ■ The production and further metabolism of acetyl-CoA.

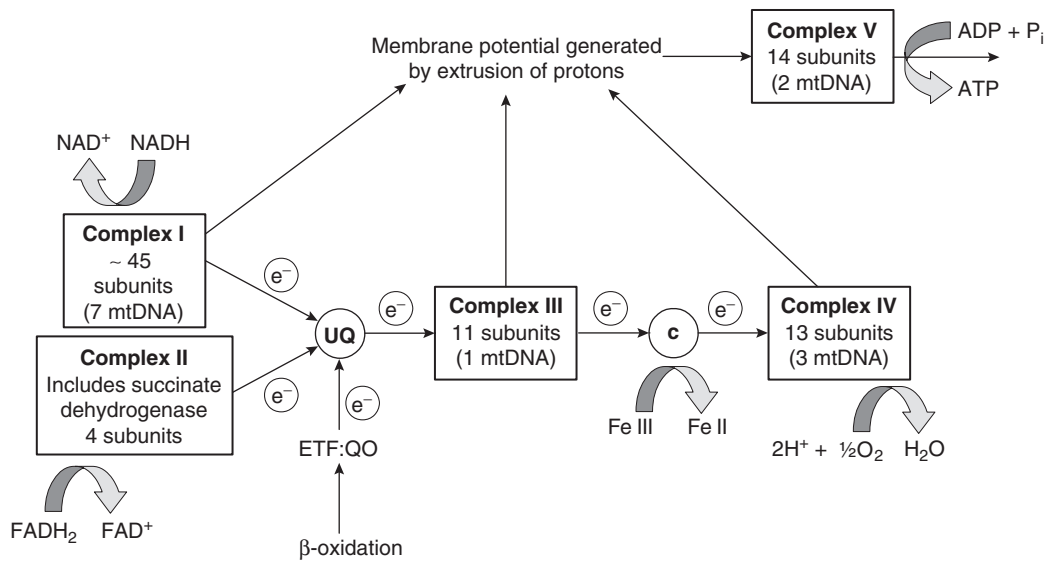

FIGURE 33.7 ■ Components of the mitochondrial respiratory chain. NADH is reoxidized by complex I, while FADH₂ donates electrons via complex II and ETF dehydrogenase (ETF:QO) donates electrons directly to ubiquinone (UQ). Electron transport generates sufficient energy at three sites (complexes I, III and IV) to pump protons out of the matrix, producing an electrochemical gradient. This gradient is discharged by ATP synthase (complex V) and the energy released used to drive the phosphorylation of ADP to ATP. c, Cytochrome c; e⁻, electron.

DISEASES OF MUSCLE AND THEIR INVESTIGATION

There are a large number of different disorders of muscle, and while our classification includes the main categories (Box 33.1), more comprehensive lists are available (see Karpati et al. in Further reading, below). A detailed description of the clinical features associated with the different types of muscle disease is outside the scope of this chapter, but is discussed in several texts on muscle disease. The clinical features depend upon the age of the

patient and the type of disease. For instance, a child with Duchenne muscular dystrophy will experience difficulty rising from sitting or lying and may have frequent falls. Such problems will prompt the parents to seek advice. In adults, the main forms of presentation are weakness, fatigue and pain. Less commonly, muscle wasting, swelling or twitching of the muscle or a skin rash may be a first symptom. In the genetically determined disorders, the weakness is usually gradually progressive and often follows a characteristic pattern. In other myopathies, there may be associated stigmata, for instance joint disease or skin rash

BOX 33.1 Classification of muscle disease (excluding disorders of motor nerves and the neuromuscular junction) with examples

Non-metabolic, genetically determined myopathies

- Muscular dystrophies
 - Duchenne, Becker
 - Limb girdle types
 - Facioscapulohumeral
 - Others
- Congenital muscular dystrophy/myopathy including central core disease (association with malignant hyperpyrexia)
- Disorders of muscle membrane/myotonic syndromes
 - Myotonic dystrophy type I and II
 - Myotonia congenita
 - Periodic paralyses: hyperkalaemic and hypokalaemic

Trauma to muscle by external agents

- Physical
 - Crush syndrome
 - Ischaemic damage
- Toxic
 - Drugs: steroids, chloroquine, fibrates, HMG-CoA reductase inhibitors (statins), emetine, theophylline (in overdose), zidovudine, snake venoms

Infection

- Viral myositis
- Bacterial myositis

Inflammatory

- Dermatomyositis/polymyositis
- Inclusion body myositis
- Sarcoidosis

Metabolic myopathies

- Muscle disease associated with endocrine disorder
 - Hypo- and hyperthyroidism
 - Hypo- and hyperadrenalism
 - Hyperparathyroidism and osteomalacia
 - Pituitary disorders, e.g. acromegaly
- Genetically determined
 - Disorders of carbohydrate metabolism: myophosphorylase deficiency, acid α -glucosidase deficiency
 - Disorders of fatty acid oxidation: acyl-CoA dehydrogenase deficiency, carnitine palmitoyltransferase deficiency
 - Abnormalities of the respiratory chain: defects of complexes I, III and IV
- Other metabolic myopathies
 - Alcohol myopathies
 - Myopathy with chronic kidney disease
 - Nutritional

Myopathy associated with malignant disease

suggesting a connective tissue disorder; anxiety, sweating and weight loss suggesting hyperthyroidism, or features compatible with high alcohol intake. The muscle pain described by patients with muscle disease may be important in suggesting whether there may be a metabolic cause. For instance, both defects of carbohydrate metabolism and fatty acid oxidation will cause muscle pain associated

with exercise. The pain associated with defects of carbohydrate metabolism occurs during high intensity exercise when glycolysis generates most of the energy required for muscle contraction, whereas defects of fatty acid oxidation cause muscle pain after prolonged exercise at a time when fatty acids are the predominant metabolic fuels.

The clinician must evaluate the clinical features and decide which investigations are appropriate. In many patients with suspected muscle disease, this will involve a combination of biochemical, molecular genetic, neurophysiological and morphological investigations. While many biochemical and genetic studies are performed on blood samples, morphological study and biochemical analyses such as measurement of muscle enzyme activity, require tissue. Muscle biopsy is a relatively simple procedure and there are two main methods: an open biopsy, in which relatively large amounts (0.5–3 g) of muscle can be removed, and a needle biopsy, in which smaller amounts (50–200 mg) are obtained. For most biochemical and histochemical studies, small amounts are sufficient. Morphological changes alone may be sufficient to suggest a diagnosis, for example of Duchenne muscular dystrophy. The diagnosis of metabolic myopathies has been greatly improved by the development of cytochemical techniques that can show, for example, the abnormal storage of glycogen or lipid, or demonstrate the presence or absence of specific enzyme activities in situ. A further development in this area is the use of specific antisera to enable the precise localization (and therefore the presence or absence) of proteins at the cellular level. This technique of immunocytochemistry provides valuable additional information in the investigation of muscle disease.

BIOCHEMICAL INVESTIGATION OF MUSCLE DISEASE

'Routine' biochemical studies

These include the measurement of plasma sodium, potassium, chloride, urea, bicarbonate, glucose, calcium and phosphate, together with simple tests of endocrine function. While not all these tests are necessary for each patient with muscle disease, disturbances of each parameter can result in muscle disease, as shown by the following examples. Severe hypokalaemia associated, for example, with diuretic use or liquorice ingestion, can result in muscle weakness. Renal failure may lead to muscle weakness for several reasons, including electrolyte disturbance and altered calcium metabolism. It must also be remembered that acute muscle necrosis from any cause (e.g. malignant hyperpyrexia, drugs, injury or metabolic myopathy) may itself cause acute kidney injury owing to the tubulotoxic effect of myoglobin. Muscle symptoms are common in endocrine disturbances: hypothyroidism, for example, may be associated with proximal weakness, often with discomfort in the affected muscles.

Plasma creatine kinase activity

The measurement of plasma enzyme activity is important in the diagnosis of muscle disease, and while the activities of several enzymes may be elevated, creatine

kinase (CK) is the most sensitive indicator of muscle damage. Skeletal muscle has the highest CK content of any tissue, more than three times as much as heart or brain, and consequently nearly all CK activity in normal plasma is derived from skeletal muscle. In addition, CK activity is more frequently abnormal than other enzymes in neuromuscular disease and the range of abnormal values is greater.

Human tissues contain three forms of creatine kinase, comprising dimers of the muscle and brain-type subunits, M and B. The combinations are CK-MM, CK-MB and CK-BB. Skeletal muscle contains mostly CK-MM with only a small amount of CK-MB, ranging from 0.2% to 15% of total enzyme activity (mean value of 5–6%). The proportion of CK-MB is higher in type I muscle fibres. Regenerating muscle fibres revert to an embryonic enzyme pattern and have about 40–50% CK-MB. Brain contains only CK-BB while heart muscle contains about 40% CK-MB, the rest being CK-MM. In normal adult plasma, CK activity is almost entirely due to the CK-MM isoform. Muscle damage will increase total CK activity and a proportion will be of the CK-MB type, but this is usually <6%. High plasma CK activity associated with a CK-MB fraction >6% may be associated with myocardial damage; however, there are several other situations in which the plasma CK-MB activity may be high:

- following acute muscle injury or surgical operations in healthy people, especially in those who regularly take vigorous exercise, the plasma CK-MB activity may rise above 6%. This has led to misleading results in marathon runners, acute myoglobinuria and a variety of surgical procedures
- in patients with chronic neuromuscular diseases, there tends to be a higher CK-MB activity owing to the increased percentage of regenerating fibres
- in children younger than early teenage, the percentage of CK-MB in plasma is higher than in adults, in the range of 14–26%. This could complicate the investigation of heart disease in this age group.

The activity of CK in plasma will vary even in healthy subjects and, as noted above, may be significantly elevated following exercise. While CK activity may be raised immediately after exercise, it reaches its peak after 1–2 days. Generally, the more severe the exercise, the higher the total activity and the more delayed the peak. Thus, a 24-fold increase in CK activity has been reported after a 53 mile walk and transient CK values of 10 000–20 000 U/L may be seen after intense training in young men, in whom subsequent investigation fails to detect any abnormality. The effect on CK activity is more pronounced in untrained subjects compared with trained, but generally does not result in greater than a four-fold increase, unless the exercise performed is severe, and returns to normal with resting.

Conditions other than exercise may cause significant increases in plasma creatine kinase activity (Box 33.2). The importance of obtaining a good clinical history and measuring CK activity under basal conditions is, therefore, of paramount importance if unnecessary invasive investigations are to be avoided. Creatine kinase activity in plasma is raised whenever there is necrosis

BOX 33.2 Causes of increased creatine kinase activity other than muscle disease

Muscle origin

- Exercise
- Trauma
- Large muscle mass
- African Caribbean and Indian Asian ethnicity
- Alcohol

Central nervous system disease

- Cerebral infarction or haemorrhage
- Bacterial meningitis
- Head injury

Cardiac disease

- Acute myocardial infarction
- Electrical cardioversion
- Mediastinal radiotherapy

Diseases of other organs

- Pneumonia, lung infarction
- Colonic infarction
- Metastatic carcinoma

Miscellaneous disorders

- Hypothyroidism
- Sepsis
- Shock
- Acute psychosis

Modified from Layzer 1985.

or regeneration of muscle and will, therefore, be elevated in most myopathies. Very high values are found in Duchenne muscular dystrophy and in conditions where severe muscle necrosis occurs, such as acute polymyositis and rhabdomyolysis associated with malignant hyperpyrexia or the metabolic myopathies. In myopathies where muscle destruction is not a major feature, for instance some endocrine myopathies, plasma CK activity may be normal or only mildly elevated. It must be remembered that plasma CK activity may also be elevated in severe neurogenic conditions that include active denervation, and thus it is not diagnostic of muscle conditions alone. Plasma CK activity may be used to follow the progress of myopathic disorders and their response to treatment. For example, the effective treatment of inflammatory muscle disease with steroids and/or other immunosuppressive treatments may be monitored by the fall in CK activity as well as by the improvement in muscle function.

Occasionally, a significantly elevated CK is found unexpectedly. Many of these patients will be found to have muscle disease when formally examined, but there are also individuals with elevated CK who show no signs of neuromuscular disease, so-called 'idiopathic hyperCK-aemia'. Some of these prove to have 'macro CK' – an entity consisting of CK bound to an immunoglobulin (usually IgG) – which is cleared more slowly from the plasma than the unbound enzyme. Endocrine dysfunction, such as hypothyroidism, can elevate CK without obvious muscular dysfunction and it is important to

remember that individuals with malignant hyperthermia can have elevated CK with no other features of neuromuscular disease.

Statin induced elevation of creatine kinase

Drug-induced elevation of CK occurs and, indeed, has become more common since the introduction of the HMG-CoA reductase inhibitors (statins). This class of drug frequently causes myalgia, often with no rise in plasma CK concentration, but only rarely causes muscle disease, although necrotising myopathy and rhabdomyolysis have been reported. Several risk factors that predispose to muscle disease in those taking statins are known, including genetic variants in drug transport molecules and hepatic drug metabolism. Factors that are associated with higher plasma concentrations of statins such as increasing age, female sex, liver or kidney disease, untreated hypothyroidism and drugs that inhibit the cytochrome P450 system, increase the risk of myalgia and rhabdomyolysis. Interfering drugs that are of particular concern include cyclosporin, fibrates, calcium channel blockers, protease inhibitors and warfarin; grapefruit juice also has a similar effect. Pravastatin is not metabolised by the cytochrome P450 system so may be a safer choice than other statins if combination treatment with these drugs is required. Low plasma concentrations of 25-hydroxycholecalciferol are associated with myalgia and may exacerbate statin associated muscle pain. There is some evidence that patients given vitamin D replacement before starting a statin are at lower risk of developing symptoms.

There is a strong association between statin induced myalgia and a common variant of the gene *SLCO1B1*, which codes for a transporter that mediates the hepatic uptake of statins apart from fluvastatin. In one study, >60% of cases could be attributable to the variant, which impairs statin uptake. Cyclosporin is thought to inhibit the transporter and can therefore increase plasma concentrations of most statins, even of those that are not metabolised by the cytochrome P450 system.

The underlying mechanism of statin toxicity is still debated, but theories include alterations in myocyte membrane cholesterol content, depletion of isoprenoids that control myofibre apoptosis and depletion of coenzyme Q₁₀ (ubiquinone). Hydrophilic statins such as pravastatin and rosuvastatin may be less myotoxic than other more lipophilic statins such as atorvastatin, simvastatin and lovastatin, possibly because of decreased penetration into muscle cells.

In most patients with statin-induced myalgia, the CK does not rise dramatically, if at all, and a minor rise may simply require monitoring and not cessation of treatment. Strategies for improving the tolerability of statin treatment include changing to a hydrophilic statin, reducing the frequency of doses to once or twice weekly, or supplementation with vitamin D and/or coenzyme Q₁₀. However, much of the evidence of benefit of dosage variations and supplements has been anecdotal and there are few data on the cardiovascular effects of such strategies.

Persisting elevation of CK following withdrawal of statin treatment should be investigated, as there is more likely to be an underlying muscle disorder. The use of

statins in patients with known muscle disease should be avoided if possible, although in individuals where there is a strong case for treatment, monitoring CK activity to detect progressive change is an alternative.

Other enzymes measurable in plasma

The activities of aldolase, lactate dehydrogenase and pyruvate kinase are also raised in destructive myopathies, but measurement of these enzymes provides no additional information to that given by CK measurement. Similarly, carbonic anhydrase III and a muscle-specific enolase, two enzymes that are specific to skeletal muscle, are also elevated in muscle disease, but the patterns of abnormality are similar to that of CK. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are also raised in the presence of muscle destruction and rise in parallel with CK. Measurement of plasma γ -glutamyl transferase activity may help to determine the tissue origin of high aminotransferases, as it is normal in muscle disease but usually raised with liver disease.

Myoglobinuria

In the presence of muscle damage, the muscle pigment myoglobin leaks into blood and urine. While myoglobin is a sensitive indicator of muscle destruction, it is neither significantly more sensitive nor more specific than CK. Myoglobin gives a positive reaction on urine dipstick testing for blood, which can be misinterpreted as being due to haematuria. In conditions in which there is severe muscle necrosis, rhabdomyolysis may occur. Causes include mechanical trauma, myotoxic agents (animal poisons, numerous drugs and alcohol), extremes of ambient temperature, infections and inherited muscle diseases such as malignant hyperpyrexia, some types of muscular dystrophy and defects of mitochondrial energy, carbohydrate and lipid metabolism. Myoglobin may be deposited in nephrons and cause acute kidney injury. The risk of injury appears to be associated with acute elevations of myoglobin.

INVESTIGATION OF MUSCLE DISEASE

Non-metabolic, genetically determined myopathies

The investigation of muscular dystrophies and other non-metabolic myopathies is largely dependent on morphological and/or genetic analyses. For example, the X-linked allelic disorders Duchenne and Becker muscular dystrophies may be diagnosed by identifying the defect at the genetic level; a deletion of the dystrophin gene is found in around 65% of Duchenne boys. The same is true for facioscapulohumeral muscular dystrophy, where a deletion of telomeric DNA on the long arm of chromosome 4 is seen in >95% of cases. In the limb girdle group of muscular dystrophies, the same phenotype is produced by defects in very different proteins (and their corresponding genes) such that muscle biopsy and immunocytochemical studies are usually required.

In membrane disorders, such as the myotonic dystrophies and congenital myotonias, genetic analysis is paramount. In contrast, the periodic paralyses, which are also caused by ion channel dysfunction, are associated with electrolyte changes that are important to define. In hypokalaemic periodic paralysis, the patient may experience episodes of weakness that last from hours to days and which can be provoked by carbohydrate ingestion. Serum potassium measured at the onset of weakness is low, but may normalize quickly despite persisting symptoms. In hyperkalaemic periodic paralysis, the potassium concentration is elevated and there is also a form in which potassium appears not to change. In certain populations, particularly in Asia, the combination of hypokalaemic paralysis and hyperthyroidism is found. Treatment of the underlying thyroid dysfunction cures the potassium disturbance and the muscle disease.

Malignant hyperpyrexia is a rare syndrome, in which there is a rapid rise of body temperature (up to 1 °C every 5 min), lactic acidosis, muscle rigidity, hyperkalaemia, very high plasma CK activity and myoglobinuria. The reaction may be triggered by several inhalational anaesthetics (e.g. halothane) and succinylcholine. The disorder has been linked to various different genetic defects including mutations in the ryanodine receptor gene. (Defects in this gene also give rise to the muscle disease, central core disease.) Plasma CK activity can also be increased in patients at risk. Diagnosis is dependent on *in vitro* testing of muscle strips for an abnormal contracture response to halothane, caffeine or a combination of both agents.

Metabolic, genetically determined myopathies

Whereas the biochemical investigations so far described are either general indicators of muscle damage or directed at systemic conditions in which muscle involvement occurs, the following section deals with specific investigations of genetically determined metabolic muscle disease. It is in this area that biochemical studies are of paramount importance. The three main areas to be described are disorders of carbohydrate metabolism, defects of the respiratory chain and defects of fatty acid oxidation. The discussion of each will be divided into sections dealing with the investigations performed in blood and/or urine, muscle tissue analyses (e.g. histochemical studies, when appropriate) and specific biochemical investigations.

Disorders of carbohydrate metabolism

Disorders of carbohydrate metabolism can be divided into two main groups:

- failure to metabolize glucose, either owing to impaired mobilization or breakdown of glycogen (e.g. myophosphorylase deficiency) or impaired glycolysis (e.g. phosphofructokinase deficiency)
- disorders resulting from lysosomal storage of glycogen (α -acid maltase deficiency) or from the deposition of abnormal polysaccharide (branching enzyme deficiency). For a detailed discussion of the

clinical and biochemical features, the reader is referred to the review by Chen (2001) (see Further reading, below).

Dynamic/functional tests. In diseases related to failure to metabolize glucose, the symptoms are related to the lack of energy (ATP) under conditions where muscle relies on glycolysis to meet this demand. The main clinical manifestations are cramp-like muscle pain and, occasionally, the appearance of contractures. The inability to derive energy from glycolysis is easily demonstrated by making the patient perform muscular work and measuring the rise of blood lactate. This is usually done under ischaemic conditions, but is equally effective without ischaemia (see [Appendix 33.1](#)).

Histochemistry. Histochemical methods are used to study both the amount of glycogen and several of the enzymes of glycogen mobilization and glycolysis. Glycogen is usually demonstrated by some variant of the periodic acid Schiff (PAS) technique. Myophosphorylase, phosphofructokinase, myoadenylate deaminase and lactate dehydrogenase activities are all detectable cytochemically, and absence of enzyme activity is diagnostic in clinical terms. The finding of glycogen storage with grossly elevated membrane-bound acid phosphatase activity is virtually diagnostic of acid α -glucosidase deficiency.

Biochemical investigations. The enzymes of glycogenolysis and glycolysis are all highly active, and homogenates prepared from needle-biopsy specimens are usually adequate for analysis. The measurement of these enzymes has been reviewed elsewhere (see Further reading, below) and only a brief summary is given here.

Acid α -glucosidase (acid maltase) is measured by monitoring glucose release from maltose or glycogen at acid pH or by using 4-methylumbelliferyl α -glucoside as substrate and measuring the fluorescence of 4-methylumbelliferone released. The process has been simplified by the availability of a sensitive immune capture technique and activity can now be measured in dried blood spots saved on filter paper. The simplest technique for the assay of **amylo-1, 6-glucosidase** activity is based on the fact that the hydrolytic activity of this enzyme is partly reversible; activity may be followed by measuring the incorporation of [14 C] glucose into glycogen in the presence of a muscle homogenate. **Branching enzyme** α -1: α -1,4-glucan:1,4-glucan-6-glucosyltransferase activity depends upon the stimulation of the rate of glycogen synthesis from glucose 1-phosphate catalysed by phosphorylase a (non-physiologically): activity is followed by the release of inorganic phosphate. The reaction catalysed by **phosphorylase a** is reversible, although, *in vivo*, the concentration of glucose 1-phosphate is at least two orders of magnitude too low to allow glycogen synthesis. The enzyme can therefore be measured in either direction. **Phosphorylase kinase** is measured by the rate of ATP-dependent conversion of phosphorylase a to phosphorylase b. **Phosphofructokinase** activity is measured in muscle homogenates by coupled enzyme assay in which the fructose 1,6-bisphosphate formed is converted to dihydroxyacetone phosphate, and this is converted to glycerol 3-phosphate with the oxidation of

NADH. **Phosphoglycerate kinase** and **phosphoglycerate mutase** are measured in muscle homogenates by coupled enzyme assays. **Lactate dehydrogenase** is measured by a standard spectrophotometric assay.

Defects of the respiratory chain

These disorders were first identified in muscle, but are now known to produce a wide range of clinical disorders often involving the central nervous system (see Further reading, below). The respiratory chain is composed of five complexes (Fig. 33.7) and defects have been identified in each of them as well as in many of the proteins required to assemble and maintain this pathway and the mitochondrial genome that encodes some of the components.

Dynamic/functional tests in blood. Elevated plasma lactate, often associated with high concentrations of pyruvate and alanine, is a common, but not universal feature of respiratory chain dysfunction. In some patients, resting lactate is normal, but increases to very high concentrations during aerobic exercise. Aerobic exercise tests can, however, be difficult to perform in children and patients with significant physical disability. Examination of the CSF lactate is of value in patients who have predominantly CNS symptoms since the lactate concentration may be inappropriately high in this compartment, but normal or near normal in blood. In patients with the Kearns–Sayre syndrome, elevated total protein concentrations are found in CSF, and this is one of the diagnostic criteria of the disorder. Recently, a fibroblast growth factor, FGF21, was found to be elevated in plasma in mitochondrial disease and appears to be a better biomarker for mitochondrial muscle disease than metabolites such as lactate.

Histochemistry. The activity of several mitochondrial enzymes can be demonstrated cytochemically. Cytochrome *c* oxidase (COX) and succinate dehydrogenase (SDH) are the most specific for the respiratory chain, but NADH oxidation and ATPase activity may also give non-specific clues to the presence of a disorder. The morphological hallmark of respiratory chain disease is the ragged red fibre originally described using the Gomori trichrome stain. The finding of COX positive and deficient muscle fibres (a mosaic) is highly suggestive of a defect in mitochondrial DNA (mtDNA), and this can easily be shown using COX and SDH stains in combination (Fig. 33.8). In this case, histochemical analysis is sufficient and the next step will be genetic analysis of mtDNA. Detailed biochemical analysis is still necessary, however, particularly for the investigation of complexes I and III. Newer techniques that combine gel electrophoresis, ‘in gel’ activity measurement and immunoblotting are also available and will certainly play a greater role in the diagnostic process in the future.

Biochemical investigations

Measurement of mitochondrial oxidations. The complete oxidation of metabolic fuels with concomitant synthesis of ATP can be studied in various ways, including overall flux from substrate to water, flux through various segments and the activities of individual components

A

B

C

FIGURE 33.8 ■ Histochemical demonstration of: (A) cytochrome *c* oxidase (complex IV) and (B) succinate dehydrogenase (complex II) activity. The reactions specifically identify respiratory chain complexes and the combination (C) permits the easy detection of muscle fibres lacking cytochrome *c* oxidase activity (light grey fibres). (Photographs courtesy of Dr B Krossnes.)

of the respiratory chain. These will be discussed below. In many instances, it is necessary to isolate mitochondria from tissue (usually muscle). This is a relatively straightforward, but critical, step, since the outcome of all further work will depend on the quality of the mitochondrial fraction prepared.

Flux through the whole respiratory chain can be studied either by measuring oxygen consumption or the production of ATP. Polarography measures the rate of change in oxygen concentration in solution, and since oxygen is the final electron acceptor of the respiratory chain, this provides direct measurement of activity. The working volume of the electrode determines how much mitochondrial protein is required and since human muscle biopsies are small, the smaller the volume the better. Several parameters may be assessed using polarography. First, the quality or state of the mitochondria may be inferred from the respiratory control ratio (RCR). This is the ratio of oxygen consumption in the presence of ADP to that when all ADP has been converted to ATP. The RCR in fact reflects the structural integrity of the mitochondria, since any damage to the inner membrane will dissipate the electrochemical gradient and thus the ability to synthesize ATP. The RCR in human skeletal muscle mitochondrial fractions is usually between 2 and 4. Flux through the respiratory chain is often expressed in terms of oxygen consumed per milligram of protein in the presence of ADP. It is also possible to measure ATP formed during respiration, either directly or by linking to a luminescent marker.

Flux through segments of the respiratory chain can be measured spectrophotometrically using artificial electron acceptors whose light absorption changes on reduction/oxidation. A commonly used acceptor is potassium ferricyanide. NADH produced by the oxidation of pyruvate, oxoglutarate or glutamate, yields electrons that enter the respiratory chain via complex I. Ferricyanide accepts electrons from cytochrome *c* with the result that it is possible to assess flux through the segment containing complex I, ubiquinone and complex III (see Fig. 33.7). Alternatively, using succinate as a substrate, electrons enter via succinate dehydrogenase that is part of the respiratory chain complex II. The ferricyanide-linked assay will then measure flux from complex II to cytochrome *c*.

Measurement of activity of individual respiratory chain complexes. The activity of these complexes is best measured in mitochondrial fractions. Where small amounts of tissue are available, partial purification is used.

Complex I activity is measured by determining rotenone-sensitive NADH-ubiquinone oxidoreductase activity. Low molecular weight, water-soluble ubiquinone or a ubiquinone analogue can be used as an electron acceptor. This assay requires that the mitochondria are made permeable to enable the NADH to reach its binding site on the inner aspect of the inner mitochondrial membrane. NADH oxidation is measured by the decrease in absorbance at 340 nm before and after the addition of rotenone. The use of rotenone, a specific complex I inhibitor, is essential since there are other enzymes capable of oxidizing NADH.

Complex II activity is measured by following the reduction of ubiquinone by succinate either directly or by

linking the reaction to an artificial electron acceptor such as dichlorophenol-indophenol. The succinate dehydrogenase component of complex II can be further studied by using phenazine ethosulphate rather than ubiquinone as the intermediate electron acceptor.

Complex III activity is measured by following the reduction of cytochrome *c* by ubiquinol. Ubiquinol is synthesized from ubiquinone by reduction with dithionite followed by organic extraction. Further studies of part of complex III can be made by measuring the transhydrogenase reaction, which gives information on the *b* cytochromes.

Complex IV activity is measured by following the oxidation of reduced cytochrome *c*. Reduced cytochrome *c* is prepared by addition of ascorbate, which is removed by gel filtration. Polarographic measurement of complex IV activity is also widely used. In this reaction, ascorbate and tetramethyl-*p*-phenylenediamine dihydrochloride (TMPD) are used as artificial electron donors to cytochrome *c*.

Complex V is rarely measured in patients with suspected mitochondrial disease, but several methods to measure oligomycin-sensitive ATPase activity have been used for mitochondria from other species.

Molecular biology techniques. Mitochondria are unique in that they contain their own DNA (mtDNA). This small genome encodes 13 polypeptides (seven that go into complex I, one in complex III, three into complex IV and two into complex V) and 24 RNA species that participate in intramitochondrial protein synthesis. Disorders caused by mtDNA mutations are highly variable, but there are some classic syndromes that are easily recognizable. For example, Kearns–Sayre syndrome and chronic progressive external ophthalmoplegia that can be caused by gene rearrangements (most often deletions); Leber hereditary optic neuropathy is due to a point mutation in complex I protein-coding genes, and myoclonus, epilepsy with ragged red fibres (MERRF) and myopathy, encephalopathy, lactic acidosis and stroke (MELAS) are due to point mutations in different mitochondrial genes. Since the mitochondrial genome is inherited exclusively from the mother, disorders in which maternal inheritance occurs gave the first clue to the possibility of mtDNA mutations.

Since the first mtDNA mutations were described in 1988, more than 150 different mutations have been found including both rearrangements (deletions or duplications) and point mutations. In the last few years, mutations in nuclear encoded genes affecting mitochondria have also been identified and this group is expanding. As stated earlier, the finding of a mosaic of COX positive and deficient fibres is highly suggestive of a defect involving mtDNA. This can, however, either be a primary mtDNA mutation, as, for example, in the syndrome of MELAS, or a secondary mtDNA defect caused by a nuclear genetic defect in a protein that has a role in mtDNA maintenance.

Defects of fatty acid oxidation

Muscle symptoms associated with a defect of fatty acid oxidation can occur alone or as part of a systemic abnormality. Symptoms may arise acutely or more chronically

and affected individuals are at risk of developing cardiomyopathy, hepatic dysfunction, sudden infant death and hypoglycaemic coma.

Dynamic/functional tests

Intermediary metabolites and metabolic fuels in blood. If a systemic defect is present, the inter-relationship between metabolic fuels is abnormal. In healthy subjects during stress or fasting, lipolysis is stimulated and free fatty acids are released into the circulation. Following uptake by tissues, fatty acids are converted to their acyl-CoA esters and oxidized by β -oxidation to generate acetyl-CoA. Acetyl-CoA may be further oxidized by the citrate cycle or converted to ketone bodies in the liver. Circulating ketone bodies are an important source of energy during stress or fasting and are readily oxidized by extrahepatic tissues, in particular muscle and brain. When fatty acid oxidation is impaired, the blood concentrations of free fatty acids increase, but there is no concomitant increase in the concentration of ketone bodies. Energy must, therefore, be derived from carbohydrate metabolism as long as glycogen stores last. Once these are depleted, hypoglycaemia can develop and may lead to permanent tissue damage or death. It is clear, therefore, that fasting is potentially dangerous for patients with fatty acid oxidation defects and should be avoided.

Measurement of plasma, tissue and urine carnitine concentrations. Patients with defects of fatty acid oxidation frequently have abnormalities of carnitine metabolism. Partial β -oxidation will continue to generate chain-shortened acyl-CoA ester intermediates that combine with carnitine in a reaction catalysed by carnitine acyltransferases. These carnitine esters are transported out of the mitochondrial matrix, resulting in a higher percentage of carnitine in the acylated form in blood and urine from patients compared with healthy subjects. In addition, in the presence of a defect in β -oxidation, there will be abnormal excretion of specific acylcarnitines, e.g. octanoylcarnitine in medium chain acyl-CoA dehydrogenase deficiency (MCAD). Secondary carnitine deficiency can occur in these individuals, although the mechanism remains uncertain, as total urinary excretion of acylcarnitines is not increased. Carnitine concentrations, free and acylated, are usually measured using tandem mass spectrometry. Since carnitine metabolism is perturbed by most defects of fatty acid oxidation, these measurements rarely help in making a specific diagnosis.

Mass spectroscopic measurement of specific acylcarnitines is a screening technique that is now widely used. This can be performed on dried blood spots (e.g. on a Guthrie card) and allows the detection of specific intermediates that are identified using tandem mass spectrometry. The metabolism of fatty acids proceeds by a chain shortening series of reactions that produce acetyl-CoA. In the presence of a block in this process, chain-shortened fatty acids will accumulate and these are esterified with carnitine, forming acylcarnitines that can be detected in blood. [Figure 33.9](#) shows typical profiles for three different defects that can be identified using this technique in dried blood samples. Owing to the frequency of MCAD

in certain populations and its association with sudden infant death, this technique is increasingly being used for screening of neonates.

Measurement of dicarboxylic acids and acylglycines in urine. When mitochondrial β -oxidation is impaired, dicarboxylic acids, e.g. adipic, suberic and sebacic, are generated by the partial oxidation of fatty acids in the endoplasmic reticulum (ω -oxidation) and by β -oxidation in peroxisomes. These dicarboxylic acids are excreted in the urine, and the pattern of the organic aciduria, detected by gas chromatography, may be helpful in the diagnosis of a defect of fatty acid oxidation. Acylglycines are formed in the liver by the combination of acyl-CoA esters and glycine, a reaction catalysed by glycine-N-acylase. Glycine conjugates are excreted in the urine and can be detected by gas chromatography. An isotope dilution analysis of urinary acylglycines has been introduced, which seems to be a very sensitive test for defects of medium chain acyl-CoA dehydrogenase deficiency.

Specific biochemical investigation

Measurement of flux through β -oxidation. Measurement of flux is an important investigation in defects of fatty acid oxidation. There are, however, many problems in accurately determining the flux in muscle preparations for diagnostic purposes. One of the most frequently used methods measures $^{14}\text{CO}_2$ formed by the oxidation of ^{14}C -labelled fatty acids. This method is inaccurate since $^{14}\text{CO}_2$ is only released by the further oxidation of acetyl-CoA by the citrate cycle, which is incomplete and not necessarily proportional to the flux through β -oxidation. Measurement of ^{14}C -labelled acid-soluble products is a much better indicator of flux, but this method is not suitable for ^{14}C -labelled medium and short chain fatty acids. An alternative approach is to determine $^3\text{H}_2\text{O}$ formed during the oxidation of ^3H -labelled fatty acids. Unfortunately, this technique is also limited because of the relatively few ^3H -labelled fatty acids available. Acylcarnitine profiles can be studied in fibroblasts using the same technique as for dried blood spots.

Measurement of carnitine transport and enzyme activity. Primary carnitine deficiency, due to a defect of carnitine transport, can be investigated by measuring the uptake of labelled carnitine into fibroblasts. Carnitine palmitoyltransferase activity is measured radiochemically. A number of different spectrophotometric and fluorometric techniques have been used to measure acyl-CoA dehydrogenase activities and the methods of choice are a dye reduction assay and the fluorometric ETF-reduction assay. Electron transfer flavoprotein activity can be measured by a dye reduction assay or by a catalytic assay using a physiological electron donor, reduced medium chain acyl-CoA dehydrogenase and the physiological electron acceptor ETF dehydrogenase. Electron transfer flavoprotein dehydrogenase activity can be measured by two different methods. One measures the NADH-ETF reductase activity anaerobically following the reduction of the ETF_{ox} flavin to the semiquinone. The other measures the co-proportionation of oxidized- and two-electron reduced to one-electron reduced ETF

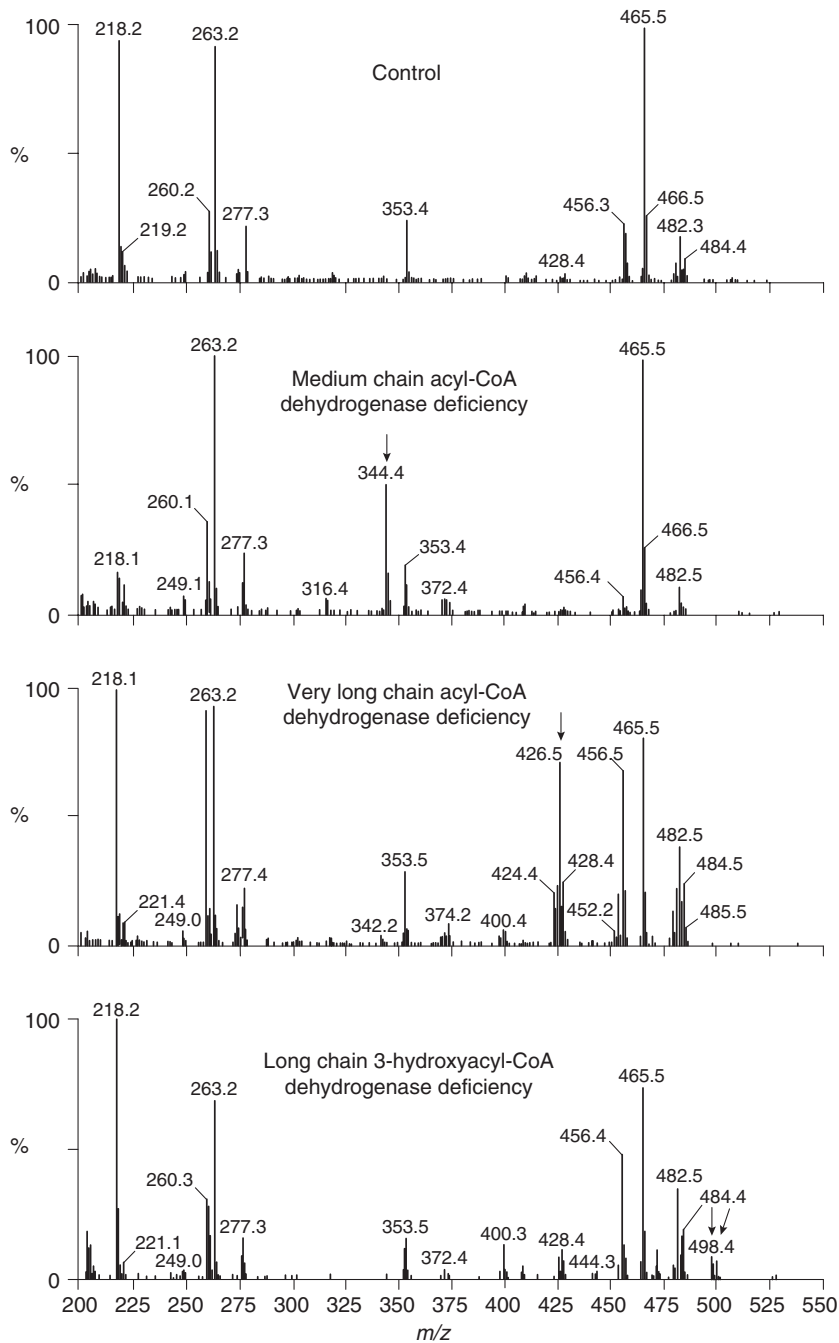

FIGURE 33.9 ■ Analysis of acylcarnitine intermediates using mass spectrometry. Acylcarnitine profile in dried blood spot from a healthy subject (upper panel) and patients with defects of fatty acid oxidation. The numbers above the peaks are m/z values that correspond to the molecular ions of butylated acylcarnitine species: free carnitine (m/z 218), free carnitine internal standard (m/z 221), C2-carnitine (m/z 260), C2-carnitine internal standard (m/z 263), C3-carnitine (m/z 274), C3-carnitine internal standard (m/z 277), C8-carnitine (m/z 344), C8-carnitine internal standard (m/z 353), C12-carnitine (m/z 400), C14:1-carnitine (m/z 426), C14-carnitine (m/z 428), C16-carnitine (m/z 456), C16-carnitine internal standard (m/z 465), C18:1-carnitine (m/z 482), C18-carnitine (m/z 484), 3-OH-C18:1-carnitine (m/z 498), 3-OH-C18-carnitine (m/z 500). Major diagnostic analytes are shown by arrows. For example, in medium chain acyl-CoA deficiency, medium chain (C8)-carnitine esters accumulate (m/z 344). In very long chain acyl-CoA dehydrogenase deficiency, C14 and longer chain fatty acids accumulate, while in long chain 3-hydroxyacyl-CoA dehydrogenase deficiency (bottom panel), long chain hydroxy forms of the carnitine esters accumulate.

semiquinone by following the disappearance of the ETF_{ox} flavin fluorescence. Enoyl-CoA hydratase activity is measured by following the hydration of the double bond of 2-enoyl-CoA esters. 3-Hydroxyacyl-CoA dehydrogenase activity is measured in the reverse direction following the oxidation of NADH or in the forward

direction by linking the reaction with 3-oxoacyl-CoA thiolase. 3-Oxoacyl-CoA thiolase activity is measured by following the decrease in absorbance resulting from the disappearance of a Mg^{2+} -enolate complex using a long chain 3-oxoacyl-CoA ester and acetoacetyl-CoA as substrates.

CONCLUSION

The investigation of muscle disease requires a combination of clinical investigation, morphological, biochemical and molecular genetic studies. Clinicians must recognize the characteristic patterns of weakness and important associated clinical features and then decide which investigations are appropriate. Biochemical studies will play an important part in the investigation, particularly in those patients with suspected metabolic myopathies. Many of the routine biochemical studies will be available at all hospitals, but the specialized tests to investigate metabolic myopathies are best performed in the few centres with a research interest in muscle disease.

ACKNOWLEDGEMENTS

I am grateful to my colleagues Mike Cullen, Margaret Johnson, Mori Pourfarzam and Bård Krossnes for giving me their illustrations and their experience and to Petter Sanaker for reading through the manuscript.

APPENDIX 33.1: THE FOREARM EXERCISE TEST

This consists of measuring lactate production following 1 min of exercise, which can be performed under ischaemic conditions or without. The use of ischaemia in patients with glycogen breakdown defects such as McArdle disease can be associated with rhabdomyolysis and should be avoided. The test is otherwise the same. If used, ischaemia is induced in the forearm by the use of a sphygmomanometer cuff placed around the upper arm and inflated to just above systolic pressure (*note*: a reliable cuff is essential since gradual loss of pressure will allow the entry of fresh blood).

The subject is asked to squeeze a (spare) sphygmomanometer bulb once every second for 1 min and then rest with the cuff still inflated for 1 min to allow lactate to leak out of the forearm muscles. The cuff is then released. Blood samples are taken prior to inflating the cuff and immediately following release, and at intervals (e.g. 2, 5, 7 and 12 min) after exercise. The pre-exercise blood sample must be withdrawn without stasis so a small, indwelling cannula (e.g. 21-G butterfly) is placed in an antecubital vein. Should stasis be required to place this, 10 min should be left before taking the pre-exercise sample. Samples taken into anticoagulants (e.g. fluoride oxalate) must be analysed within 30 min. Alternatively, samples can be mixed with ice-cold perchloric acid.

The normal response is for lactate to rise in the first sample after ischaemic exercise to between three and five times pre-exercise concentrations and then gradually decline. Healthy subjects perform this test easily, but patients with disorders of glycolysis often have to stop the exercise owing to pain and/or cramp. In disorders of glycogen mobilization or glycolysis, little or no rise in venous lactate will be seen. Since myoadenylate deaminase deficiency gives a similar clinical picture to myophosphorylase deficiency, ammonia concentration should be measured simultaneously with lactate. In myoadenylate deficiency, lactate rises normally, but there is no (normal) rise in ammonia. This provides, moreover, an internal control for the investigation in most instances, since failure of lactate to rise can also be due to poor effort during ischaemic exercise.

CONCLUSION 671

INTRODUCTION

Spinal paracentesis (lumbar puncture) was introduced at the end of the 19th century for the therapeutic relief of raised intracranial pressure secondary to tuberculous meningitis. Within a few years, however, it was being used to sample lumbar cerebrospinal fluid (CSF) to aid clinical diagnosis. Analyses that were undertaken in these early days included microscopy for cells and chemical tests to measure reducing substances, protein and chloride. Even today, counting cells and measuring total protein and glucose remain the mainstay analyses routinely carried out on CSF specimens. Yet, modern analytical techniques make possible the quantitative and qualitative detection of a vast range of biochemical substances. It is the purpose of this chapter to assess critically the role of laboratory studies of CSF in the investigation of central nervous system (CNS) disorders. The results of these analyses must be considered both in the clinical context and in conjunction with the findings of other investigations, including neuroimaging and neurophysiological measurements.

A few points should be kept in mind when handling CSF. Despite the fact that well-documented procedures exist that will minimize discomfort, including that of post-lumbar puncture headache, the anticipation of a lumbar puncture (LP) is something that causes distress

to many patients. This is not helped by the fact that, occasionally, even when carried out by an experienced practitioner, performing a satisfactory LP can prove difficult and uncomfortable and is not without the risk of epidural or subdural bleeding or infection. In many instances, only one spinal tap can be carried out. One reason is that the introduction of a needle into the lumbar sac to sample the CSF can lead to blood contamination of the remaining CSF. This can invalidate the taking of further samples for several days, the exact time being dependent upon the analyte being studied and the degree of blood contamination. There are also ethical reasons against repeating an invasive procedure for trivial reasons. Furthermore, in the very young, the volumes of CSF that can safely be taken are small. Collectively, this places a heavy burden of responsibility on laboratories to make sure that the maximum relevant information is achieved from the available fluid, and that none is wasted or prematurely discarded. Also, the analysis of CSF is multidisciplinary, and it behoves laboratories to ensure that there is the necessary cooperation among pathology specialties. It is strongly recommended that laboratories produce guidelines for doctors indicating sample requirements, and establish procedures to ensure that all CSF samples surplus to immediate analytical requirements are correctly stored. Like all body fluids, CSF is a potentially hazardous material and must be handled appropriately.

CEREBROSPINAL FLUID PHYSIOLOGY

Formation

In the normal adult, the total volume of CSF is about 150 mL. Cerebrospinal fluid is formed at a rate of approximately 500 mL/day, so the fluid is typically exchanged about four times daily (every 6 h). Infants and children have smaller CSF volumes that range from 30–60 mL in a neonate to 100 mL in a pre-teen.

While the choroid plexuses that line the ventricles are the major site of CSF production, as much as 30% of CSF is formed by fluid shifts across various vascular beds within the CNS, such as the cerebral capillaries and dorsal root ganglia. Unlike choroidal CSF, interstitial fluid forms throughout the brain and spine, and then diffuses into the CSF.

Cerebrospinal fluid formed in the lateral ventricles passes through the third and fourth ventricles into the cisterna magna, from where it circulates out into the cerebral and spinal subarachnoid spaces. The subarachnoid space lies between the two leptomeninges, the outer (arachnoid) mater and inner (pia) mater, which cover the whole brain and spinal canal down to the level of the second sacral vertebra. The flow of CSF from the cisterna magna is mainly upward and outward over the cerebral hemispheres to the main site of reabsorption through the arachnoid villi, which drain into the major dural sinuses. Flow down the cul-de-sac of the spinal cord is relatively sluggish. Thus, while the average turnover time of CSF is ~6 h, radiolabelled plasma albumin can continue to equilibrate with lumbar CSF for 1–2 days.

Composition

Solutes enter the CSF by a variety of processes, including active transport via specific transporter mechanisms present in choroidal epithelial cells, facilitated diffusion and passive diffusion.

Cerebrospinal fluid constituents may be derived from plasma, from the metabolic activities of cells normally present in the CNS or from cells and organisms present in the CSF as a result of pathological processes.

Analysis of cisternal or ventricular fluid

While the most common fluid obtained for analysis is lumbar CSF, there are occasions when CSF is taken from other regions, for example from one of the lateral ventricles (usually via a ventriculo-peritoneal or ventriculo-extracorporeal shunt), the 4th ventricle (by cisternal puncture) and even from around the cortex. It is extremely important that the anatomical site of the fluid is recorded, as the reference ranges for many constituents vary according to the anatomical source of the CSF.

INVESTIGATIONS RELEVANT TO PHYSIOLOGY AND PATHOPHYSIOLOGY

Sampling and pressure

Details of CSF sampling techniques are well described in standard textbooks of practical medical procedures. The

initial hydrostatic pressure is between 80 and 180 mmH₂O when the patient is in the lateral recumbent position. Ideally, four sequential fractions of CSF should be collected into sterile polypropylene containers. In an adult, a total of 10–12 mL of fluid should be withdrawn, but as little as 3 mL or less in the case of a neonate. The containers must be numbered in the order of collection. Typically, fraction 1, taken into a fluoride tube, is used for glucose (this fraction may also be suitable for protein measurement by some methods), fractions 2 and 3 are used for cell counts and microbiological examinations, i.e. Gram stain and culture, and fraction 4 is used for the assay of specific proteins and oligoclonal bands and, if required, spectrophotometry (in which case the tube must be protected from light from the moment of collection). Blood for glucose and, in the case of spectrophotometry, for total protein and bilirubin should be taken at the same time.

Appearance

Cerebrospinal fluid is normally crystal clear and colourless. The fluid appears turbid when there are more than 200×10^6 white cells/L ($200/\text{mm}^3$) or 400×10^6 red cells/L ($400/\text{mm}^3$). The presence of bacteria or contamination by epidural fat may also cause turbidity of the specimen. Clot formation may occur when protein concentrations are markedly elevated; where the source of the protein is blood then at least $1\,000\,000 \times 10^6$ red cells/L ($10^6/\text{mm}^3$) are required for clotting to occur. Cerebrospinal fluid may be coloured yellow by bilirubin or, rarely, by carotenoids, red (or more usually pink/orange) by oxyhaemoglobin or brown by methaemoglobin. Yellow discolouration of CSF is called *xanthochromia*, a term that has often been used to encompass the colours imparted by both bilirubin and oxyhaemoglobin. Because the presence of oxyhaemoglobin and bilirubin is most appropriately detected by spectrophotometry, where this technique is used, the term *xanthochromia* should be avoided to minimize confusion.

Cells

The total leukocyte count in normal adult CSF is rarely $>5 \times 10^6/\text{L}$ mononuclear cells (lymphocytes and monocytes). The presence of even one polymorphonuclear leukocyte (neutrophil, polymorph) in the CSF should be a cause for concern in an adult. In neonates, however, the normal cell count is $<30 \times 10^6/\text{L}$ (predominantly polymorphs), with $<10 \times 10^6/\text{L}$ lymphocytes. Changes that occur in the presence of CNS infections form an important part of the initial diagnosis and will be considered later.

Erythrocytes are not normally present in CSF. They appear either following trauma to blood vessels during LP or after an intracranial bleed. A traumatic LP occurs when the needle damages a blood vessel while passing through the vascular epidural space, thereby introducing blood directly into the lumbar sac, and is estimated to occur in 15–20% of all LPs. Traumatic contamination complicates interpretation in two ways.

- The first is in the investigation of suspected intracranial haemorrhage, especially subarachnoid haemorrhage. After haemorrhage, CSF will show equal staining of all samples, while a traumatic tap will

typically result in CSF that is stained initially, but clears in subsequent fractions; in the past this has been confirmed by performing red blood cell counts on the individual collection bottles. While the individual who performed the LP may often have an opinion on whether or not the puncture was traumatic, both clinical impression and sequential red blood cell counting have been demonstrated to be unreliable. The use of such evidence for substantiating an intracranial bleed should be avoided, and if spectrophotometry for detection of oxyhaemoglobin and bilirubin is unavailable or equivocal, the presence or absence of red cells is used to direct further investigations.

- The second is in the interpretation of the CSF white cell count (WCC). Usually an increase in the number of white cells is an indication of infection, but following a traumatic tap, white cells are more likely to be from the contaminating blood. When a CSF leukocytosis is suspected in spite of a traumatic tap, the predicted white cell count can be compared with that observed, as follows:

$$\text{predicted WCC} = \text{CSF red cell count} \times \left(\frac{\text{blood WCC} / \text{blood}}{\text{red cell count}} \right)$$

A ratio of observed (O) to predicted (P) WCC >1 implies CSF leukocytosis. There is a significant overlap of causes for O:P values between 0.75 and 1.0. However, an O:P ratio of <0.1 is highly predictive in terms of excluding infection.

Glucose

The brain has no significant glycogen store and is therefore wholly dependent upon the blood supply of glucose to satisfy its requirements. Although the brain is only about 5% of the total body mass, it uses 20% of the glucose available from the blood. Cerebrospinal fluid glucose concentrations can only meaningfully be interpreted in relation to the plasma concentration, measured on a sample ideally taken within 15 min of LP. Cerebrospinal fluid glucose is derived solely from plasma glucose and is normally 60–80% of the concentration in the latter, although, for the first six months of life, the CSF glucose concentration may equal that of plasma. The CSF:plasma glucose ratio falls below 0.6 in a number of conditions, and this finding can be used as a diagnostic aid. The most notable reductions are observed in bacterial, tuberculous and some fungal meningitides, and in hypoxia, whereas ratios are usually normal in viral meningitis. The exact cause of the lowered CSF:plasma glucose ratio is still unresolved and will be discussed below. Whatever the cause, a lowered ratio usually indicates a diffuse generalized meningeal disease. A false negative result may be obtained if the patient has been given prior treatment with antibiotics.

Glucose is transferred into the CSF by a specific membrane carrier transport system. In the adult, the usual ratio is maintained up to plasma glucose concentrations of 20 mmol/L. For plasma glucose concentrations higher

than this, the CSF glucose concentration does not rise further, probably due to saturation of the transport system. In severe hyperglycaemia, therefore, the CSF glucose may seem disproportionately low relative to that in the blood. It is important that this is not misinterpreted as evidence for infection. Furthermore, the CSF typically takes 2–4 h to equilibrate fully with a change in blood glucose. In a diabetic patient who has recently taken either insulin or an oral hypoglycaemic agent, it is therefore possible to have the paradoxical finding of a CSF glucose concentration that is higher than that in a paired blood sample.

Lactate

Cerebrospinal fluid lactate concentration is normally <2.5 mmol/L; concentrations are controlled independently of those in arterial blood, indicating that it is a product of metabolism within the CNS. An increased CSF lactate concentration is observed in cerebral hypoxia (for example, following a cerebral infarction) and, most notably, in bacterial meningitis, when it is often associated with a decreased CSF glucose concentration. Elevated CSF concentrations of lactate have been demonstrated in patients with inherited disorders of the mitochondrial electron transport chain involving the pyruvate dehydrogenase complex, which give rise to the mitochondrial myopathies. In those with predominantly neurological symptoms, lactate concentrations may be increased only in the CSF.

Proteins

Two-dimensional protein electrophoresis of CSF reveals 200–300 spots, of which about half correspond to 34 unambiguously identified proteins. Nearly all proteins give rise to multiple spots owing to heterogeneity arising from various combinations of glycosylation, phosphorylation and splice variants. Proteins in CSF can be grouped as follows:

- those arising from plasma proteins that have crossed the blood–CSF barriers
- those synthesized in the brain and secreted into the CSF
- those usually present inside CNS cells that have leaked into the CSF following cell damage. Proteins within this group are generally present in only trace amounts.

Table 34.1 lists the ten proteins with the highest concentrations in CSF and plasma.

Some 80% of the total CSF protein concentration is derived from plasma proteins that have diffused passively across the various blood–CSF barriers. The remainder comprises proteins that are synthesized within the CNS (Fig. 34.1). Some plasma proteins, such as transferrin, undergo receptor-mediated transfer. The cells of the choroid plexus also synthesize transferrin and prealbumin, so the CSF concentration is a function of several factors. In health, two factors influence the CSF concentrations of the individual plasma-derived CSF proteins. One is the degree of permeability of the combined blood–CSF barriers to the protein, which is inversely proportional to the Stokes radius of the protein. The other is the plasma concentration of the protein: in general, the CSF

TABLE 34.1 Comparison of the ten proteins with highest concentrations in CSF and plasma

CSF	Mean concentration (mg/L)	Plasma	Mean concentration (g/L)
Albumin	250	Albumin	45
β-Trace (prostaglandin D-synthase)	25	IgG	10
IgG	20	Fibrinogen	3
Transthyretin	17	Transferrin	3
Transferrin	14	α ₂ -Macroglobulin	2.5
α ₁ -Antitrypsin	8	Apolipoprotein A	2
Apolipoprotein A	6	IgA	2
γ-Trace (cystatin-C)	6	Haptoglobin	1.5
Orosomucoid	3.5	α ₁ -Antitrypsin	1.5
Haemopexin	3	Complement factor C3	1.5

FIGURE 34.1 ■ Protein composition of CSF showing those proteins that are plasma derived and those whose synthesis occurs within the CNS.

concentration is directly proportional to that in plasma, and inversely proportional to molecular size.

All the frequently measured plasma proteins are present in CSF, demonstrating the lack of an upper limit for molecular size exclusion by the blood–CSF barriers. In health, all CSF albumin and immunoglobulin come from the plasma. Albumin accounts for 50–60% of total lumbar CSF protein and is present at a concentration of about 1/250 of that

TABLE 34.2 Age-related values for lumbar CSF total protein, albumin and IgG

Age	CSF total protein (mg/L)	CSF albumin (mg/L)	CSF IgG (mg/L)
Pre-term			
27–32 weeks	1390 (770)	Reliable data not available	Reliable data not available
32–36	1200 (490)		
36–40	930 (290)		
Term			
0–1 weeks	770 (160)	Reliable data not available	Reliable data not available
1–4	660 (160)		
1–3 months	450 (130)		
3–6	290 (40)		
6–12	270 (70)	105 (29)	17 (4)
1–16 years	220 (50)		
17–30	367 (63)		
31–40	363 (61)		
41–50	433 (79)	204 (57)	24 (8)
51–60	479 (94)	242 (56)	27 (9)
61–77	526 (132)	238 (73)	26 (9)

Values are means and (standard deviations).

of the plasma. Permeability of the barrier alters with age; total CSF protein and albumin concentrations reflect this (Table 34.2). The albumin concentration (and thus that of total protein) also increases from ventricle to lumbar regions, reflecting both a change in the permeabilities of the blood–CSF barriers along the CNS axis and the longer time for equilibration of lumbar CSF with plasma.

Cerebrospinal fluid total protein concentrations may increase in two circumstances:

- when there is an increased permeability of the blood–CSF barriers, most commonly owing to infection (e.g. meningitis) or autoimmune inflammatory conditions (e.g. Guillain–Barré syndrome, which is particularly characterized by an acellular CSF and a protein concentration >1 g/L)
- when there is reduced flow of spinal CSF, such as occurs with a partial or complete blockage of CSF flow down the spine (e.g. owing to a prolapsed intervertebral disc, an abscess or a spinal tumour). In this circumstance there is increased equilibration of CSF with plasma, often accompanied by an inflammatory increase in permeability. In Froin syndrome, there is complete spinal block of CSF flow, usually

due to a spinal tumour; cerebrospinal fluid distal to the block stagnates, and this eventually allows complete equilibration of the CSF with plasma leading to protein concentrations that are similar in both fluids.

A comprehensive review of the role of CSF protein analysis in the investigation of CNS disorders is included in the Further reading list.

Assessment of blood–brain barrier permeability and reduced fluid flow

Measurements of total protein, albumin and α_2 -macroglobulin concentrations, and electrophoresis have all been advocated as investigations appropriate to the assessment of barrier permeability. Total protein has been the most widely used and must be interpreted against age-related reference intervals. Some authors have advocated a correction when blood is present due to a traumatic tap, recommending the subtraction of 10 mg/L for every 1000×10^6 erythrocytes/L. The cell count and protein determination must be performed on the same sample of CSF and there should not be any degree of cell lysis, which would otherwise render the correction void. The correction assumes a normal plasma total protein and haematocrit and, while it should be used with caution, provides an approximate measure of the degree to which the CSF protein concentration may be increased following addition of blood from whatever source.

Albumin is a better indicator of barrier dysfunction, for three reasons:

- it is not synthesized by the normal brain, unlike some of the proteins that contribute to CSF total protein
- it is a homogeneous protein, unlike total protein, which is a composite of variable proportions of multiple proteins
- its concentration has a lesser degree of age dependency than that of total protein.

Despite CSF protein concentrations reflecting plasma concentrations, there is generally no discriminatory advantage to be obtained by relating CSF values to those of plasma. The choice between total protein and albumin will depend both on which assay is available at an appropriate analytical standard and cost. Quality assurance programmes indicate similar overall analytical imprecision for total protein and albumin. Experience of using albumin as an alternative to total protein is, as yet, limited.

Intrathecal immunoglobulin synthesis

Intrathecal synthesis of immunoglobulins occurs where B lymphocytes are induced to migrate from the blood into the brain. Once these cells are sequestered in the brain, local cytokine production results in clonal expansion and differentiation into plasma cells, which then start secreting immunoglobulins intrathecally. Intrathecal synthesis of immunoglobulins occurs in a wide variety of neurological diseases, but is most commonly associated with multiple sclerosis and other autoimmune conditions, and infections of the CNS. The immunoglobulin most

widely studied is IgG, and this is associated mainly with subacute and chronic conditions.

Cerebrospinal fluid protein index. The general approach to detecting intrathecal synthesis relies upon the fact that it is possible to calculate the expected CSF concentration for any protein if the plasma concentration of that protein and the integrity of the blood–CSF barriers are known. The integrity of the blood–CSF barrier is given by the CSF/plasma quotient for albumin. If the blood–CSF barriers are intact, the albumin quotient is typically $<7 \times 10^{-3}$; as the barriers become progressively impaired, so the quotient rises, owing to passage of albumin from blood into CSF. Impairment of the barriers will also cause the protein in question to leak from plasma to CSF – but the CSF/plasma quotient for that protein remains roughly in proportion to that of albumin, assuming there is no local synthesis. If local synthesis of protein occurs, then the protein quotient will be increased relative to that of albumin. Thus the ratio of protein quotient to albumin quotient will be increased when local synthesis occurs.

The ratio of quotients is known as the protein index and is given by:

$$\text{protein index} = \frac{\text{CSF protein}}{\text{serum protein}} \times \frac{\text{serum albumin}}{\text{CSF albumin}}$$

This method has been widely used in the past to evaluate intrathecal IgG synthesis, but has now been superseded by examining CSF for IgG oligoclonal bands.

Oligoclonal bands

Locally synthesized IgG demonstrates qualitative differences from that which is normally present. Following serum electrophoresis, the normal gamma globulin region is revealed as a diffuse smear. As CSF gamma-globulins are normally derived from the plasma, they show a similar pattern on electrophoresis. When local synthesis is present, however, electrophoresis of CSF shows multiple discrete bands that are superimposed on the diffuse IgG background. These bands are not seen in the serum. The bands are thought to represent the products of the limited number of clones of plasma cells that are present in the CNS. The pattern is referred to as oligoclonal IgG banding. Due to its higher resolution, isoelectric focusing (IEF) is the method of choice for detecting oligoclonal bands (Fig. 34.2). Oligoclonal bands of IgM and free κ and λ light chains may be detected in a manner analogous to that of IgG.

Papers discussing the relative merits of these approaches (qualitative versus quantitative) are provided in the Further reading list. All the evidence indicates that detection of oligoclonal bands is significantly more sensitive than measuring the IgG index in detecting intrathecal synthesis. The reason is simple: owing to population variation and the compounded imprecision of the four immunoassays necessary to calculate the IgG index, the CSF IgG concentration needs to increase substantially before the index becomes abnormal. Oligoclonal bands, by contrast, can be detected when individual bands

FIGURE 34.2 ■ Isoelectric focusing (IEF) of serum and CSF showing the five basic patterns. (A) normal polyclonal pattern in both CSF and serum. (B) oligoclonal IgG in CSF, absent from serum, typical of local (intrathecal) IgG synthesis. (C) oligoclonal bands in both CSF and serum with an identical band distribution (spectrum), this is termed a 'mirror' pattern and is indicative of a systemic, but not intrathecal, limited clonal IgG synthesis. (D) here, there are oligoclonal bands in both CSF and serum, but there are additional bands in the CSF which are not present in the serum, indicative of both systemic and additional intrathecal limited clonal IgG synthesis. (E) there are identical bands in both CSF and serum. The pattern shows a striking ladder appearance with an identical spacing between adjacent bands. This is highly characteristic of a monoclonal gammopathy.

constitute only 1–2% of the total IgG concentration in CSF. A serum sample must be analysed concurrently with the CSF so that oligoclonal immunoglobulins present in the CSF may be shown to be unique to the CSF, as opposed to those that have originated in the plasma and diffused across the blood–CSF barriers (see Fig. 34.2).

Brain-specific proteins

Measurements of concentrations of proteins synthesized by cells within the CNS and released into the CSF during inflammation or cell destruction are now firmly established tools in the diagnosis of neurological disease. Often described as brain-specific proteins, they are more correctly referred to as brain-enriched proteins. They include proteins such as glial fibrillary acid protein (GFAP), a product of astrocytes; S100, a product of glial cells; 14-3-3, a neuronal cytoplasmic protein; tau and phosphorylated tau, products of the neuronal cytoskeleton; and the amyloid components A β 1-40 and A β 1-42.

Glial fibrillary acid protein is a component of the astrocyte cytoskeleton. When astrocytes are damaged or

undergo activation in response to a variety of cytokine messengers, GFAP may be released into the extracellular compartment from where it diffuses into the CSF. A raised CSF GFAP concentration generally indicates astrocyte damage and/or reactive astrocytosis.

All cells in the body differentially express the S100 family of proteins, of which 14 are currently known. They are found in the cytoplasm and all undergo conformational changes in response to binding calcium. They also interact with key enzymes in a variety of metabolic pathways. In this way, calcium fluxes within the cell can modulate metabolic activity. In the brain, the S100 β homodimer, produced by microglial cells, is the most important member. A high CSF concentration of S100 β is associated with gliosis. In addition, the monomer S100 β acts as a cytokine and is released by microglial cells in response to inflammatory mediators. It is of note that in high concentrations, S100 β can induce apoptosis in cells. As the CSF concentration represents a global average of the production throughout the brain, there may be regional high concentrations causing cell death, which may not always be detected by examining lumbar CSF.

14-3-3 Proteins derive their name from a classification scheme based upon separation by a combination of chromatography and the coordinates of the original protein spot on two-dimensional gel electrophoresis. Once again there is a family of at least ten members, of which 14-3-3 γ is the most important isoform in the CNS. 14-3-3 Proteins are cytosolic and they interact reversibly with a wide range of ligands. Their main physiological role is to connect the cytoplasmic region of cell-surface receptors with their intracellular effector molecules (usually enzyme precursors). 14-3-3 Proteins are ubiquitous in cells, and can make up as much as 1% of the total intracellular protein concentration. Thus 14-3-3 proteins are useful markers of cell disruption, and 14-3-3 γ is particularly helpful in neurology as it is associated primarily with neurons. 14-3-3 γ is a reliable marker of neuronal cell loss when such loss occurs rapidly and extensively, and high CSF values are found in paraneoplastic neurological syndromes, viral encephalitis and neurodegenerative conditions (such as sporadic Creutzfeldt–Jakob disease, CJD). It is not useful in conditions in which neuronal cell loss occurs slowly but progressively (e.g. in Alzheimer disease), because the rate at which it is released is no faster than that by which it is cleared from the CSF.

Tau protein and phosphorylated tau are components of the neuronal cytoskeleton. The phosphorylation of tau is enzymatic and controls the extent to which the protein is incorporated into the cytoskeleton. Tau can be phosphorylated at multiple sites, and in certain conditions, hyperphosphorylated tau is found. It is not yet clear whether the hyperphosphorylation is the cause or a consequence of the underlying conditions. Increased concentrations of total tau and hyperphosphorylated tau are associated with the formation of the neurofibrillary tangles that are seen in several neurodegenerative conditions, especially Alzheimer disease.

A β 1-40 and A β 1-42 are two proteolytic fragments of protein A β (which stands for amyloid protein β). A β is a

constitutive protein that is expressed by nearly all cells of the CNS. The normal metabolism of A β requires it to undergo highly specific proteolytic cleavage to form products that are highly soluble and readily removed. In some neurodegenerative conditions, however, the proteolysis is aberrant, giving rise to larger fragments that are insoluble, and which accumulate in the form of an extracellular amyloid. A β 1-40 and A β 1-42 are two of the normal fragments containing 40 and 42 amino acids, respectively. In some dementias, including Alzheimer disease, there is a *decrease* in the CSF concentration of both A β 1-40 and A β 1-42, which reflects the fact that these components, rather than being in the soluble form (and hence measurable in the CSF), are present as insoluble fragments that are deposited within the CNS.

Cerebrospinal fluid oto- and rhinorrhoea

The leakage of CSF from the intracranial cavity can potentially be serious and usually occurs following skull fractures, although it can be a complication of intracranial surgery, infection or neoplasia, and can also occur spontaneously. Cerebrospinal fluid is characterized by the presence of a β_2 -transferrin band. This is often termed *tautransferrin* but, as there is a risk of confusion with the other tau proteins (see above), the use of the name *asialotransferrin* is preferred. Asialotransferrin is a desialylated form of transferrin. In the blood, desialylated transferrin is rapidly removed (half-life 20 min) by the asialoglycoprotein receptor that is present on the cells of the liver and reticuloendothelial system. The asialoglycoprotein receptor is not expressed in the CNS, so asialotransferrin accumulates in CSF. In normal CSF, asialotransferrin constitutes about 25% of the total transferrin. Asialotransferrin is not present to any great extent in plasma, nasal secretions, tears, saliva or other potentially confounding fluids. Asialotransferrin is easily detected by immunofixation or immunoblotting following electrophoresis (Fig. 34.3). Other proteins that have been used include transthyretin (prealbumin), β -trace (prostaglandin D-synthase) and γ -trace (cystatin-C)

proteins. These are not CSF specific, detectable amounts of all occurring in normal plasma, so interpretation of fluid concentrations is difficult. Measurements of both glucose and chloride concentrations have been shown to lack the discriminatory power of asialotransferrin and should be discontinued.

Haem pigments and ferritin

Oxyhaemoglobin and bilirubin appear in the CSF in a time-dependent manner following an intracranial bleed. Oxyhaemoglobin is released during *in vivo* cell lysis, appearing within a few hours. Following a split into haem and globin, haem is then metabolized to biliverdin by an inducible haem oxygenase followed by reduction to bilirubin by biliverdin reductase; both enzymes are present in cells of the CNS. While animal studies indicate that enzyme induction is maximal by 12 h, this will not necessarily equate to the certainty that an increase in CSF bilirubin will be observable in all patients 12 h after a bleed, given the inevitable biological variation that occurs and possible interspecies differences. Evidence from one apparently definitive study, that CSF bilirubin concentrations were increased by 12 h in all of 111 patients after a proven intracranial bleed, has to be viewed with caution owing to the ambiguous definition of xanthochromia used in this study. Oxyhaemoglobin is also released as a result of *in vitro* lysis of red cells. While initial studies indicated that the degree of lysis is proportional to both red cell count and time delay before separation of supernatant from cells by centrifugation, more recent studies have indicated that the *in vitro* formation of oxyhaemoglobin cannot be reliably predicted. The very low concentration of bilirubin normally present in CSF arises from the passage of albumin-bound bilirubin from plasma into CSF and, hence, will be increased if either or both of the plasma albumin-bound bilirubin and CSF albumin is increased. Under certain circumstances, allowance can be made for this when determining if an intracranial bleed has occurred.

FIGURE 34.3 ■ Transferrin glycoforms in the detection of CSF rhinorrhoea. (A) lane 1, control serum; lane 2, control CSF; lanes 3 and 4, a sample of nasal fluid (NF) which does not contain CSF. The asialotransferrin band is indicated by the arrow. (B) lane 1, control serum; lane 2, control CSF; lanes 3 and 4, nasal fluid containing CSF. In each case, the nasal fluid samples were applied undiluted and diluted 1/10.

Release of iron from haem also stimulates CNS synthesis of ferritin, with subsequent passage of ferritin into the CSF.

Examination of CSF for haem and bilirubin

The currently recommended method for detecting haem and bilirubin in CSF is spectrophotometry, which should cover the range 350–600 nm. An accumulating body of evidence now indicates that visual inspection of CSF for xanthochromia is an unreliable method of confirming an intracranial bleed, because it is insensitive, subjective, non-quantitative, does not distinguish between oxyhaemoglobin and bilirubin and provides no objective record of detection. Direct chemical methods of measuring bilirubin concentration in CSF need to be evaluated rigorously, as does the measurement of CSF ferritin concentration in the investigation of intracranial bleeds.

Enzymes in CSF

Measuring enzyme activities in CSF used to be popular. For example, increased lactate dehydrogenase (LDH) activity has been reported to be a more sensitive and earlier marker than CSF glucose concentration in detecting bacterial meningitis. Unfortunately, however, there is significant overlap between cases diagnosed with bacterial and aseptic/viral meningitis. In addition, false elevations of LDH activity occur in erythrocyte-contaminated CSF. Lactate dehydrogenase activity is also increased in the presence of various primary CNS tumours and when there is meningeal metastatic spread, when the increase involves predominantly the LDH4 and LDH5 isoenzymes.

β -Glucuronidase, creatine kinase BB (CKBB), neuron-specific enolase (NSE), glucose 6-phosphate isomerase (G6PI) and alanine aminotransferase (ALT) are other intracellular enzymes known to be released into CSF by various primary and metastatic tumours. Creatine kinase BB and NSE are also increased during cerebral ischaemia and various meningoencephalitides, thereby limiting their specificities. Ischaemic brain damage can either be reversible or permanent. Although patients suffering major ischaemic events tend to have higher CSF activities of CKBB, LDH, NSE and ALT, the discrimination between recoverable and permanent damage usually requires serial sampling of CSF, and even then the predictive value is low.

Angiotensinogen-converting-enzyme (ACE) is a putative marker of neurological involvement in sarcoidosis. Care must be taken to correct for serum ACE activity, which may be increased in systemic sarcoidosis, and to correct for blood-CSF barrier leakage using either albumin or CSF total protein. The sensitivity of the test is low and the diagnosis of neurosarcoidosis, in the absence of positive CNS histology, remains a presumptive one based on the evidence of CNS inflammation, systemic sarcoidosis and exclusion of alternative diagnoses.

In recent times, measurement of enzyme activities in CSF has generally given way to quantitative immunoassays that measure the enzymes in terms of protein mass. The use of antibodies also means that isoform-specific

immunoassays, which offer significant advantages in terms of determining the tissue of origin over the more crude measurement of overall enzyme activity, can be developed.

Markers of inflammation

Neopterin is the oxidized form of D-7,8-dihydroneopterin, which is produced by macrophages when stimulated by γ -interferon released by activated T cells. Increased concentrations in body fluids are observed following viral, bacterial and fungal infections, as well as other cell-mediated immunopathologies, such as coeliac disease. Cerebrospinal fluid neopterin concentrations are normally very low, as pterins do not readily cross the blood-brain barrier. Increased neopterin concentrations in the CSF thus reflect the presence of activated microglia, the CNS equivalents of macrophages.

There is interest in the measurement of CSF concentrations of neopterin (and dihydroneopterin, which may be the dominant form in CSF, but is more difficult to measure) as a non-specific marker of CNS cellular immune activity. Particular applications have included monitoring the response of multiple sclerosis patients to treatment, detecting possible CNS infections in immunocompromised subjects, such as those with acquired immune deficiency syndrome (AIDS), and establishing evidence of infections when the aetiological agents are difficult to isolate.

β_2 -Microglobulin (β_2M) is an 11 800 Da protein that is non-covalently bound to the class I molecules of the major histocompatibility complex (MHC). While expressed on the surface of virtually all nucleated cells, it is present in highest concentrations on activated lymphocytes and macrophages. Cerebrospinal fluid concentrations of β_2M increase with age and appear not to be correlated with plasma concentrations in diseases affecting the CNS. Increased concentrations of CSF β_2M occur in conditions associated with the presence of activated lymphocytes within the CNS or with increased proliferation and turnover. Measurement of CSF β_2M concentration has been shown to be of value in the early detection of metastatic lymphomas and the spread of leukaemias to the CNS. While both neopterin and β_2M are potentially valuable markers of CNS inflammatory responses, their use as markers of specific pathologies is likely to be limited by the non-specific nature of the inflammatory response.

C-reactive protein (CRP) is a protein synthesized by hepatocytes. Synthesis is increased by several cytokines, but principally interleukin-6, which is released from macrophages that become activated during inflammatory events; this is most notable in bacterial infections, and occurs only to a much smaller degree in viral infections. The inflammatory cells themselves do not synthesize CRP. As with other plasma-derived proteins, the concentration of CRP in the CSF roughly parallels that in the plasma, and is normally $<50 \mu\text{g/L}$. Increased serum concentrations are observed in patients with bacterial meningitis. Measuring CSF CRP concentrations in bacterial meningitis is of limited value, however, as they are highly

variable and are often not as high as might be expected. This is most likely due to CRP binding by bacteria.

Non-biochemical investigations

The investigation of CNS disorders involves many disciplines (Box 34.1). While the naked eye examination of the CSF is a simple test to perform, it is vital to appreciate that it is subjective and unreliable, and that significant abnormalities may be present when the CSF appears to be clear and colourless. The diagnosis of bacterial meningitis is a

medical emergency and prompt treatment may mean the difference between complete recovery and severe morbidity or even death. Infections cause characteristic changes in the differential white cell count, and sometimes in a Gram stain of a spun deposit (Table 34.3). It is worth noting, however, that white blood cells do not appear in the CSF of patients with bacterial meningitis until ~12 h after the bacteria. These investigations, together with simple biochemical tests (glucose, protein and, if possible, serum CRP and CSF lactate concentrations) should be available as 'stat' tests offering results within 1 h of sampling. Most bacterial infections can be confirmed by standard culture techniques within 24 h. Antigen tests for a number of infective agents are also in use. A particular problem is the positive and rapid identification of viral and fungal infections. With most microbiological infections, polymerase chain reaction (PCR) is the analytical technique of choice in the acute stage of infection. In the subacute and chronic stages, however, PCR tests may be negative. In these instances, recourse to detection of specific antibody responses is necessary. Newer techniques include the detection of antigen-specific oligoclonal bands.

Modern imaging techniques, for example spiral computerized tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET), are important in the diagnosis of many CNS lesions, in conjunction with laboratory investigations of CSF. In some instances, for example intracranial tumours, imaging has largely replaced the need for CSF cytology. Nevertheless, CSF cytology still plays an important role in investigating raised white cell counts in inflammatory conditions and also in detecting and monitoring

TABLE 34.3 Characteristic CSF changes in meningitis and the differential diagnosis

Condition	Appearance	Cells $\times 10^6/L$ (per mm^3)	Gram stain or antigen tests or culture for pyogenic bacteria	Protein (g/L)	Glucose (mmol/L)	Differential diagnosis
Normal	Clear	0–5 lymphocytes ^a	Negative results	0.15–0.4 ^c	2.2–3.3 ^d	–
'Purulent' meningitis	Turbid	100–2000 polymorphs ^b	Positive results	0.5–3.0	0–2.2	Bacterial meningitis ^e Amoebic meningitis Cerebral abscess
'Aseptic' meningitis	Clear or slightly turbid	15–500 lymphocytes (polymorphs may predominate in the acute stage)	Negative results	0.5–1.0	Normal	Viral meningitis ^e Partially antibiotic-treated bacterial meningitis ^f Leptospirosis meningitis Encephalitis Brain abscess TB/fungal meningitis
Tuberculous meningitis	Clear or slightly turbid; fibrin web may develop	30–500 lymphocytes plus polymorphs	Negative results (scanty acid-fast bacilli may be seen in a Ziehl–Neelsen-stained smear)	1.0–6.0	0–2.2	TB meningitis ^e Brain abscess Cryptococcal meningitis

^aIn a neonate, up to 30×10^6 cells/L, mainly polymorphs. ^bA few cases of pyogenic meningitis may have $5–100 \times 10^6/L$ polymorphs. ^cIn neonates, protein concentration up to 1.5 g/L. ^dApproximately 60% of blood glucose concentration. ^eMost frequent cause. ^fGlucose concentration may be reduced.

CNS invasion by leukaemias. Background information on neuroradiological methods and clinical neurophysiological techniques may be obtained from the Further reading list.

BIOCHEMICAL INVESTIGATIONS IN CNS DISORDERS

Acute infections

Infections of the CNS that can present acutely include viral meningitis, bacterial meningitis, cerebral abscess, subdural empyema and viral encephalitis. Acute bacterial meningitis is a life-threatening infection that needs urgent treatment, whereas viral meningitis is generally a less severe disease that is usually followed by complete recovery.

The cellular and microbiological examination of CSF plays a central role in the investigation of suspected infection, and a full description can be found in the Further reading list. Nevertheless, there are occasions when this does not provide a definitive answer; biochemical tests are useful as adjuncts in the diagnosis of infection and need to be available on an urgent basis. Two tests widely employed have been measurement of CSF protein and glucose concentrations, and these have for many years been considered to be essential in the investigation of cases of suspected meningitis. Protein concentration is usually raised, more so in bacterial than in viral meningitis, but there is considerable overlap; rarely, it may be normal. The presence of protein is simply a marker of barrier impairment. Glucose concentrations are usually depressed in bacterial meningitis but often remain normal in viral meningitis. However, CSF glucose concentration may be reduced in some non-bacterial causes of meningitis. Concentrations <1.0 mmol/L are usually found only in severe bacterial meningitis. A CSF:plasma glucose concentration ratio of <0.4 is typical of bacterial meningitis, although a normal value does not exclude the diagnosis.

Cerebrospinal fluid lactate concentrations are raised in bacterial meningitis, but are usually normal (<2.5 mmol/L) in viral meningitis. Concentrations >3.5 mmol/L have been considered indicative of bacterial meningitis, with values <3 mmol/L being more consistent with a viral aetiology. Rapid measurement of CSF lactate has proved of particular value in cases of diagnostic difficulty, for example partially treated bacterial meningitis (when Gram stain and culture are negative and cell counts may be atypical), and early in some viral meningitides when there may be a predominance of polymorphs and variably depressed glucose concentrations. With a threshold of 3.5 mmol/L, the sensitivity and specificity of CSF lactate are greater than those of either CSF glucose or protein concentration, in terms of discriminating between bacterial and viral meningitis.

Measurement of serum CRP concentration may be of value in patients presenting with equivocal CSF findings, with concentrations >100 mg/L being consistent with a bacterial infection. Serum procalcitonin may provide even better discrimination between bacterial and viral

infections. Measurement of serum CRP concentration also enables a rational decision to be made on the duration of antibiotic therapy in patients with brain abscesses or subdural empyemata.

The most reliable indicator of acute infection remains the CSF cell count and differential, with measurement of CSF lactate concentration being used for diagnostically difficult cases. Measurement of cerebrospinal fluid protein appears to add nothing to the diagnosis. Chloride estimation, once widely advocated for the diagnosis of tuberculous meningitis, has been shown to be of no value.

Chronic infections

Chronic infection of the CNS may be caused by viruses, bacteria, spirochaetes, parasites and fungi. In patients who are immunocompromised, most commonly due to cytotoxic drug therapy for cancer, fungal infections and reactivation of latent viral infections are particularly troublesome. In all of these situations, the interpretation of standard PCR techniques can be difficult, as the mere presence of viral or bacterial nucleic acid alone does not always represent a causal relationship. Quantitative PCR, which measures the amount of nucleic acid and so gives an indication of the numbers of organisms present, is superior but still not definitive.

Serological tests for the presence of antibodies are based on the premise that the continued presence of the causative organisms will maintain production of specific antibodies. These tests can suffer from memory effects – the immune system generally maintains a vast memory bank of B cells that manufacture antibodies to individual target antigens. The immune system is frequently upregulated in many inflammatory conditions and this can lead to increased production of antibodies by some or many of these memory cells. If the upregulation occurs in response to a particular infectious agent, then the antibody production will be more specific towards that organism. Antibody production can be measured by enzyme-linked immunosorbent assay (ELISA) or similar technology. However, this approach can make it difficult to distinguish antibodies that vary in affinity from those that vary in quantity, for example a small amount of high-affinity antibody can give the same signal in an ELISA as a larger amount of low-affinity antibody. An alternative approach is to use immunoblotting after isoelectric focusing. This relies on coating a nitrocellulose or similar membrane with the target microorganism. This is then used to immunoblot the CSF and serum following isoelectric focusing. The membrane is subsequently tested for bound immunoglobulin. In this way, oligoclonal bands against the organism in question can be identified. The pattern can then be compared with that found in standard isoelectric focusing (which reveals total IgG oligoclonal bands). If the spectrum of bands seen on the antigen-specific blot resembles that on the total IgG blot, then the causative organism is identified. If, however, the antigen-specific pattern bears no resemblance to the total IgG pattern, then it is unlikely that the organism under study is causally related to the disease. Although the antigen-immunoblotting technique can be extremely

powerful, it is still under development and should be used as an adjunct to classic serological assays.

Haemorrhage and obstruction

Intracranial haemorrhage can occur due to spontaneous rupture of cerebral blood vessels, as a result of injury, malignancy-associated necrosis or as a consequence of bacterial meningitis leading to a diffuse vascular haemorrhage. All may result in the passage of blood into the CSF, with consequent formation of oxyhaemoglobin and bilirubin. By far the most important cause of an intracranial bleed is spontaneous rupture of a cerebral aneurysm into the subarachnoid space, termed a subarachnoid haemorrhage (SAH). In the majority of patients, diagnosis presents no problem. However, a number of studies have shown an initial misdiagnosis rate of up to 30%, often in patients presenting in a good clinical condition with no focal neurological signs, leading to a significantly poorer outcome than in those in whom the correct initial diagnosis has been made.

Following SAH, blood is usually visible on a computerized tomography (CT) scan, and this is the test of choice in the initial examination. This will be positive in over 95% of patients within the first 24h, but in only 50% one week after the bleed. It is in those patients in whom the CT scan is negative or not available that CSF should be examined for oxyhaemoglobin and bilirubin, preferably waiting for 12 h after the onset of symptoms prior to puncture to allow for the formation of bilirubin. Wherever possible, CSF should be examined by spectrophotometry with analysis and interpretation provided according to the guidelines cited in the Further reading list.

Hydrocephalus is a common complication of trauma and obstruction and is best investigated by CT scanning. Shunts inserted to drain CSF into the systemic circulation or peritoneal cavity may become obstructed with a subsequent increase in CSF protein concentration, which may provide an indication that obstruction has occurred.

Inherited metabolic diseases

Biochemical examination of CSF is of value in the diagnosis of certain inherited metabolic diseases.

Patients with primary defects of pyruvate metabolism, for example pyruvate dehydrogenase deficiency or mitochondrial disorders, present with a variety of clinical features. Some, when symptomatic, have a systemic metabolic acidosis with elevated blood lactate concentrations; some may have a near-normal hydrogen ion concentration, mild elevations only of blood lactate concentration but elevated CSF lactate concentration. Measurement of CSF lactate may thus be helpful when such defects are suspected, although normal concentrations do not exclude them. Cerebrospinal fluid lactate determination may also be helpful in certain organic acidemias.

Cerebrospinal fluid amino acid measurement is of established value in confirming the diagnosis of glycine encephalopathy (non-ketotic hyperglycinaemia) in neonates and infants. In this disorder, the CSF glycine concentration is high whereas the blood glycine concentration may

be only mildly elevated or within the reference range for age. The most sensitive discriminator is the CSF:plasma glycine molar ratio, which is increased from the normal 0.025–0.1.

In patients with defects in bipterin metabolism, measurement of CSF bipterin concentrations and the concentrations of the biogenic amine metabolites, homovanillic and 5-hydroxyindoleacetic acids, may be of value in confirming the diagnosis.

Malignancy

In space-occupying lesions of the brain that may be germ cell tumours, the initial approach is to measure serum human chorionic gonadotrophin (hCG) and α -fetoprotein (AFP) concentrations. Pointers to a possible germ cell tumour are a space-occupying lesion in the pineal or suprasellar regions in a male under 15 years of age. The nature of the tumour is usually defined from tissue obtained during surgery. Where operation is contraindicated and serum hCG and AFP concentrations provide no information as to tumour type, there may be a need to measure hCG and AFP concentrations in the CSF.

Rarely, there may be the requirement to examine CSF for monoclonal IgG, IgM, κ or λ when a CNS lymphoma is suspected.

Dementia

Dementia is defined as a global impairment or loss of intellectual function. There are over 50 identified causes of dementia, including various neurodegenerative diseases, such as Alzheimer disease and Parkinson disease; cerebrovascular diseases; infectious diseases; demyelinating disorders; metabolic disorders, such as Wilson disease and the leukodystrophies; malignancies; epilepsies; traumatic brain disease; systemic disorders, such as endocrine disease and vitamin deficiencies, and toxic disorders, including alcohol dependency and drug toxicity. Mental illnesses, such as depression and schizophrenia, may also present with features of dementia. With the increasing life expectancy in developed nations, neurodegenerative diseases, such as Alzheimer disease, are becoming major social burdens. As several types of dementia are treatable, it is important that a diagnosis can be made reliably. Many of these diagnoses are relatively straightforward and require laboratory blood tests that are covered elsewhere in this book. Few involve CSF analysis.

Unfortunately, there are no specific CSF tests for any of the dementias. The differential diagnosis is generally made using a combination of clinical features, CSF findings and the exclusion of other diagnoses. Recent developments in neurogenetics are particularly helpful where there is a familial predisposition, but may not be useful in the majority of cases, which are sporadic in nature.

Cerebrospinal fluid analysis in dementia is generally intended to exclude an infective or demyelinating disorder, as described elsewhere. In specific cases, CSF analysis is intended to detect evidence of neurodegeneration – the death of neurons. Examples include the neuronal

cytoplasmic proteins 14-3-3, neuron-specific enolase (NSE) and neurofilament proteins. Unfortunately, while the intracellular amounts of these proteins are quite high, for example 14-3-3 protein constitutes ~1% of the total cytoplasmic protein of neurons, CSF concentration is generally only raised when there is extensive neuronal loss occurring over a short time period. They can be useful markers in conditions such as sporadic Creutzfeldt-Jakob disease (CJD), paraneoplastic neurological disease and chronic viral infections such as subacute sclerosing panencephalitis (SSPE), but generally they are of little use in detecting slowly progressive neurodegeneration conditions, such as Alzheimer disease or Parkinson disease. In (new) variant CJD, 14-3-3 is a less sensitive marker than in sporadic CJD. The best markers currently available for Alzheimer disease are a combination of A β 1-40 and total tau (see above, Brain-specific proteins). Some dementias are associated with gliosis or astrocytosis, for example Pick disease, and this may lead to an increase in CSF concentrations of S100 β protein and/or glial fibrillary acidic protein (GFAP).

Cerebrovascular disease is second only to Alzheimer disease as a cause of dementia. The usual pathology is subcortical infarcts secondary to embolism or disease of small blood vessels (microangiopathy). Unfortunately, there are no reliable CSF diagnostic tests, although a comprehensive examination of blood haemostatic factors including platelet count, specific clotting factors and antiphospholipid antibodies may be helpful. A strong clinical clue is that cerebrovascular dementia, in contrast to other types, tends to be of acute onset and usually progresses in a stepwise manner.

Cerebrospinal fluid analysis in demyelinating diseases

There are many diseases that affect the myelin sheaths of neurons. One of the most significant is multiple sclerosis (MS), which affects ~125 per 100 000 young adults in the UK, with an annual incidence of ~5 per 100 000. The condition affects twice as many women as men, and usually first presents between the ages of 20 and 40. Autoimmunity is involved in the pathogenesis, but whether as a primary or secondary event is uncertain. Multiple sclerosis is a progressive disorder, typically presenting with a relapsing remitting clinical picture (relapsing remitting MS, RRMS). Some patients have a relentless progressive form of the disease, so-called primary progressive MS (PPMS), while the overwhelming majority of patients who start with RRMS eventually develop a progressive form of the condition, and these are classed as having secondary progressive MS (SPMS). This clinical stratification is important as a guide to choosing an appropriate therapeutic strategy.

The acute lesion of MS is the plaque, which is characteristically a demarcated area of demyelination associated with swelling of axonal cylinders and infiltration by inflammatory cells. This is followed by gliosis and disappearance of the inflammatory infiltrate leading to the formation of a chronic plaque, largely devoid of myelin. Some remyelination can occur during remissions, but this is generally incomplete. The cause of MS is unknown,

but epidemiological evidence suggests an environmental influence, possibly coupled to a genetic predisposition. There is a higher concordance of MS in monozygotic twins compared with dizygotic twins.

Clinical diagnosis of MS can be extremely difficult, particularly in the early stages of the disease when only an isolated focal region of the brain may be affected (this is sometimes termed clinically isolated syndrome). As more of the CNS becomes affected and the symptoms reflect this, then clinical diagnosis becomes easier. The diagnosis depends upon demonstrated clinical evidence for demyelination affecting different areas of the brain at different times. This spatial and temporal separation of lesions is the hallmark of RRMS, and clearly distinguishes MS from similar disorders of myelin, such as acute disseminated encephalomyelitis, in which the clinical presentation of symptoms is typically monophasic. Multiple sclerosis can also be distinguished on MRI by the characteristic individual lesions that are scattered throughout the CNS. Unfortunately, the brain accumulates small areas of damage as part of normal ageing, and it can be difficult to differentiate the lesions of MS from those of age.

While current guidelines, published in 2001 and reviewed in 2005, admit a more prominent role for MRI in the diagnosis of MS than previously, biochemically, the hallmark of MS remains the presence of oligoclonal IgG bands in the CSF that are absent from paired serum. These locally synthesized oligoclonal bands are found in at least 98% of patients with MS and are so indicative of MS that they are incorporated into the pathological definitions of the disease: a clinical diagnosis of MS, based in part on MRI findings has to be called into doubt if there are no oligoclonal bands in the CSF. Oligoclonal bands are not, however, specific for MS and can be found in many other inflammatory and autoimmune conditions affecting the brain. The presence of oligoclonal bands and a CSF protein of >1 g/L points to a diagnosis other than MS. The current gold standard method for detecting oligoclonal IgG is isoelectric focusing coupled to nitrocellulose immunoblotting. This approach is significantly more sensitive at detecting abnormalities of CSF IgG than any of the quantitative measurements (see p. 664).

Additional supportive evidence for MS may be provided by evoked potentials. These are electrical signals generated in response to sensory stimuli. Lesions affecting the optic nerve, the most common isolated site, may be detected by visual evoked potentials, which demonstrate attenuation of amplitude and prolonged latency.

CONCLUSION

Measurement of CSF lactate and glucose concentrations plays a limited but important role in the differential diagnosis of suspected acute CNS infection, particularly when the immediate microbiological examination of the CSF sediment does not provide a diagnosis.

Determination of CSF protein concentration is of limited value in the detection and differential diagnosis

of acute infection. Indeed, it may be misleading, as some have used a normal result as an indication not to proceed with a search for organisms. Protein analysis is of value in suspected Guillain-Barré syndrome and MS, when a value >1 g/L in the presence of oligoclonal bands points to an alternative diagnosis.

In most other disorders of the CNS, routine estimation of protein (and glucose) concentrations, although relatively cheap and apparently simple, does not appear justifiable unless it would truly influence patient management. This rarely appears to be the case where modern imaging techniques are available. The remainder of the tests described have a role appropriate to particular diagnostic problems.

The detection of locally synthesized oligoclonal IgG bands remains crucial in the investigation of suspected demyelinating disease, such as multiple sclerosis. Polymerase chain reaction (PCR) with an appropriate detection system is now the technique of choice in diagnosing acute viral infections, but antibody assays still have a role in chronic infections. At the same time, with increasing emphasis on ameliorating the harmful effects of inflammation, there may emerge a role for the measurement of concentrations of cytokines and other components of the inflammatory response. Continuing research into the various dementias has highlighted several useful biochemical markers that provide diagnostic information.

ACKNOWLEDGEMENT

We would like to acknowledge the contribution of Robert Beetham, who was a co-author of this chapter in previous editions of this book.

INTRODUCTION: PSYCHIATRY AS A CLINICAL DISCIPLINE

Psychiatry is the branch of medicine that deals with the disturbance, distress and disability arising from those disorders of the nervous system that affect mental functioning. ‘Mental’ functions are those that we regard as distinguishing human beings as persons, and are usually divided into the major domains of cognition (thinking, remembering, planning); perception (awareness of self and environment); mood (feelings, emotions, ‘affect’) and behaviour (objective manifestations of subjective states). Although it is clear that each of these mental functions must be *realized* in the human brain (and that they may be affected by overt damage to the brain, as in head injury), they have been regarded traditionally as *emergent* phenomena that are only tenuously dependent upon the biological structures and processes of the brain itself.

This ‘epiphenomenal’ view of mental functions has been reinforced by two separate sets of findings. First, the psychological and neurobiological study of normal mental functions is only beginning to link them to anatomically discrete structures or pathways. Instead, they have been found to rely on distributed systems of activity in many brain areas that appear to interact in a seemingly limitless pattern of complexity. Second, the delineation of abnormal states has been constrained by a failure to identify specific causes, biological markers or even reliable pathognomonic features, with the result that psychiatry has been slow to follow most other medical disciplines away from the description of clinical syndromes (clusters of clinical symptoms and signs) towards a classification of disorders based on aetiology.

Psychiatric diagnosis remains, therefore, near one extreme of a continuum from ‘organic’ (having often localized pathology, discrete (possibly pathognomonic) signs and objective laboratory findings) to

'non-organic' (unclear structural pathology, overlapping signs and no confirmatory tests). Psychiatrists' skills are largely clinical, and consist in eliciting a wide array of information directly from the patient by means of standardized interviewing and observation of behaviours and responses, supplemented by collateral information from informants such as carers, family members and others. Psychiatric decision-making begins with a comparison of this clinical information with what is known of the normal repertoire of mental states (taking into account age, sex and developmental and cultural factors), and proceeds with a systematization of the abnormal features to produce a set of recognized, but potentially overlapping, clusters. These form hypotheses to be tested by further enquiry, again usually direct questioning, so that the relative likelihood that the patient's presentation is due to one syndrome rather than another is evaluated. The end result of this iterative process is rarely a single clear-cut diagnosis but rather a shortlist of differential diagnoses stratified according to the balance of probabilities on the evidence available. Immediate management will proceed on the basis of the most likely (or most serious in the short term) diagnosis, and will be reassessed iteratively as above and modified as new information, such as response to initial treatment, emerges.

Investigations in psychiatry

The emphasis on clinical information, that is, information gained directly from the patient in the clinic or at the bedside, should not be taken to mean that there is no role for laboratory investigations in psychiatry. Also, a general physical examination should form part of every psychiatric assessment and this or particular features of the patient's history may lead to consideration of appropriate objective tests. What is true of psychiatry, as of all branches of medicine, is that no investigation should be regarded as 'routine': all investigations carry a finite risk of morbidity, and it is important to remember that this can be psychological as well as physical. Therefore, all investigations must be justified and the reasons for their selection or omission should be recorded (see below). It is also of great importance that the rationale for investigation, the intended procedures and potential unwanted effects be discussed with the patient and that his or her consent be sought before proceeding.

The reasons for selecting specific tests will be similar to other branches of medicine: screening (e.g. asymptomatic patients from high-risk population groups); baseline (to exclude or establish the extent of physical disorder, or as a preparation for certain treatments); monitoring (to monitor progression of primary physical disease or of disease secondary to the mental disorder or to monitor therapeutic drugs), and therapeutic (as part of the treatment plan, or to monitor compliance with treatment). A rational plan of investigation should be based on one or more specific purposes, as listed above, and be stratified into: primary (simpler, quicker, cheaper, more likely to gain information); secondary (more complex, expensive or specific) and tertiary (most complex, expensive or reliant on specialist operation).

This stratified approach clarifies the medicolegal status of investigations, at least in psychiatric practice: primary level tests should be considered for every patient, and if not performed, the reasons for omission should be recorded; secondary and tertiary level tests should be performed only if indicated by the presentation, by other findings or on specialist advice, and the reasons for their performance recorded.

THE CLASSIFICATION OF PSYCHIATRIC DISORDERS

Psychiatric illnesses are usually referred to as 'disorders' rather than 'diseases', in part because of the overlap in clinical features between individual conditions and, indeed, with what may be regarded as an extreme of normal behaviour.

There are two principal systems for classifying psychiatric disorders. One is provided by the *Diagnostic and Statistical Manual* (DSM) of the American Psychiatric Association. The current edition (DSM-5), published in 2013, includes 18 groups of disorders, including personality disorders, together with a group of conditions that are deemed to require further research before they can be accepted for clinical use.

The World Health Organization's (WHO) International Classification of Diseases (10th edition) (ICD-10) is more widely used outside the USA. The ICD-10 classification of mental and behavioural disorders is shown in [Table 35.1](#). The number of psychiatric disorders that are recognized is continuing to increase as new conditions are described and others are subdivided and reclassified. The number of psychiatric diagnoses listed in DSM-II in 1968 was 182, and this had slightly more than doubled to 365 in DSM-IV (1994). Although the number appears not to have been significantly increased in DSM-5, several conditions have been sub-divided and others unified and there is an effective overall increase.

Psychiatric disorders have traditionally been divided into neuroses (in which the symptoms, principally anxiety, vary only in severity from those of normal behaviour) and psychoses, with features such as delusions (an abnormal belief, e.g. of persecution) or hallucinations (perceptions lacking an objective stimulus) and typically with little insight. However, this is not to suggest that neuroses are less harmful in their effect. There are also conditions that have features that overlap these definitions (e.g. anorexia nervosa). The classification of some mental disorders as neuroses therefore has little practical value.

Psychiatric disorders are common: the overall prevalence in the general population is estimated to exceed 20%, comprising mainly depression, anxiety and adjustment disorders (e.g. grief reactions) and contribute to about 30% of consultations with family doctors; in hospitals, organic disorders (e.g. delirium, particularly in the elderly) are more common. The major psychoses (by any definition) (e.g. schizophrenia) are less common (<5% in total), but form a major part of the work of many psychiatrists.

TABLE 35.1 A classification of psychiatric disorders

Classification	Examples or notes
Organic disorders	Conditions with a structural (e.g. dementia) or functional (e.g. delirium in fever) basis
Mental and behavioural disorders due to psychoactive substance use	Includes alcohol and illicit or prescribed drug misuse
Schizophrenia and delusional disorders	Delusions are firmly held but abnormal beliefs; hallucinations are clear perceptions without an objective stimulus
Mood (affective) disorders	Depression, bipolar disorder (including mania) etc.
Neurotic, stress-related and somatoform disorders	Physical and/or psychological manifestations of anxiety are central. Includes conditions that suggest pathology in an organ or organs, but where none can be demonstrated
Behavioural syndromes	Having a psychological, physical or physiological cause
Disorders of personality and behaviour	Developmental disorders that do not have an obvious psychiatric or organic cause
Mental retardation	

There are several subspecialties within psychiatry. These include child psychiatry, old age psychiatry, substance misuse and forensic psychiatry.

This chapter primarily concerns the clinical biochemical aspects of psychiatric disorders and those general medical disorders that have psychiatric manifestations.

THE AETIOLOGY OF PSYCHIATRIC DISORDERS

The causation of most psychiatric disorders is multifactorial. Biological (e.g. genetic, organic), psychological and behavioural (e.g. abuse in childhood, emotional trauma), and social and environmental factors (e.g. social isolation) are all involved.

Alterations in neurotransmission are undoubtedly a key mechanism in schizophrenia and affective disorders, although the cause of this remains uncertain. In schizophrenia, for example, there is considerable evidence to implicate dopaminergic pathways, with increased activity in the subcortical and limbic regions of the brain and reduced activity in the prefrontal cortical regions. The drugs that are used in the treatment of schizophrenia all have effects on dopaminergic neurotransmission. Decreased monoamine activity has long been considered to be an important mechanism in depression, a notion that is supported by the efficacy of monoamine oxidase inhibitors in its management. Many addictive drugs have effects on neurotransmission: for example, cocaine blocks the reuptake of dopamine in the brain and benzodiazepines bind to receptors for γ -aminobutyric acid, an important inhibitory neurotransmitter.

Until recently, it has been difficult to study biochemical activity in the brain. Measurements of neurotransmitters and their metabolites made in peripheral blood, blood in veins draining the brain and in cerebrospinal fluid provide only indirect information about brain activity and none on localization. However, the techniques of positron emission tomography (PET) and single-proton emission tomography (SPET) are beginning to shed light on the molecular basis of psychiatric disorders. Functional MRI measures cerebral blood flow, which is

related to neuronal activity. And there can be little doubt that studies on the molecular genetics of receptors and enzymes involved in neurotransmission will contribute to a greater understanding of the biochemical disturbances that underlie psychiatric disorders.

BIOCHEMICAL INVESTIGATIONS IN PSYCHIATRIC DISORDERS

Although laboratory investigations do not have a specific role in the diagnosis of the majority of psychiatric disorders, they are important for several reasons. First, because many physical diseases can give rise to symptoms that occur in psychiatric disorders (e.g. psychosis and delirium in systemic lupus erythematosus), it is frequently important to exclude an organic cause in a patient presenting with an apparent psychiatric disorder (albeit the results of such investigations are usually negative). Features suggesting an organic cause for an apparent psychiatric disorder include late age of onset, with no previous history or family history of psychiatric disorder, and no psychological or social precipitating factor. Second, organic illnesses may be complicated by psychiatric disorders. For example, panic disorder, generalized anxiety, social phobia and depression, occur more frequently in patients with irritable bowel syndrome (IBS) than in the general population, and antidepressant and anxiolytic medication has been shown to benefit significant numbers of patients with refractory IBS. Another connection between organic illness and psychiatric disorders is that the latter may cause both metabolic and endocrine disturbances (e.g. amenorrhoea in anorexia nervosa).

Third, psychotropic medication can cause metabolic abnormalities, and particularly given the high prevalence of psychiatric disorders, and hence the use of psychotropic drugs, clinical biochemists must be cognizant of these, so that, for example, the finding of a high serum prolactin concentration in a patient being treated with an antipsychotic drug should not lead automatically to a search for a pituitary tumour. Fourth, substance abuse may involve the clinical biochemist both analytically and in relation to the metabolic disturbances that may ensue. While it is beyond the scope of this book to discuss the

TABLE 35.2 Laboratory investigations to exclude organic disease in patients with psychiatric symptoms

Investigation	Rationale
Full blood count	Anaemia can lead to cerebral hypoxia, causing confusion; macrocytosis may be due to vitamin B ₁₂ deficiency, a cause of dementia, and to a high alcohol intake; chronic anaemia may contribute to depression
Acute phase proteins	High erythrocyte sedimentation rate (ESR) suggests systemic illness, e.g. infection, malignancy, that may cause delirium; C-reactive protein (CRP) elevation may indicate abrupt onset of inflammation
Creatinine, 'electrolytes', estimated glomerular filtration rate (eGFR), calcium, liver function tests	Electrolyte disorders and renal and hepatic failure can cause delirium; they may result from behavioural disturbance secondary to psychiatric disorder
Blood gases	Hypocapnia can mimic anxiety (but note that, more frequently, hyperventilation secondary to anxiety or a panic attack can cause hypocapnia); hypercapnia in respiratory failure can cause delirium
Glucose	Hypoglycaemia can mimic anxiety (and, when chronic, may lead to behavioural disturbance and trigger referral to a psychiatrist); hyperglycaemia can cause delirium
Thyroid function tests	See text
Syphilis serology	General paresis (a late manifestation of neurosyphilis), presenting with dementia, tremor and upper motor neuron signs, can develop 5–15 years after primary infection, if this is not treated
Blood cultures	To detect occult sepsis
Blood alcohol	A frequent cause of and exacerbating feature in psychiatric presentations

Other laboratory investigations that may be valuable (though are less frequently required) include measurement of heavy metals, carboxyhaemoglobin (for carbon monoxide poisoning), antinuclear factor (for cerebral lupus erythematosus) etc.

role of the laboratory in the detection of substance abuse, the metabolic complications associated with some of the more frequently encountered substances are discussed in Chapter 40.

Table 35.2 summarizes the biochemical and other laboratory investigations that may be of value in excluding an organic cause for an apparent 'psychiatric presentation'; the ensuing sections of this chapter describe the major psychiatric manifestations of organic diseases and the metabolic changes that can occur in psychiatric disorders and as a result of their treatment.

PSYCHIATRIC MANIFESTATIONS OF ORGANIC DISEASE

Acute confusional state (delirium)

Delirium is a complex syndrome of altered consciousness, manifest by decreased awareness of the environment and inattention, together with cognitive impairment, with memory deficit, disorientation, decreased perception and language disturbance. There may, in addition, be emotional disturbances (e.g. anxiety, irritability) and psychomotor changes (e.g. agitation or retardation). Symptoms tend to fluctuate, confusion typically being greater at night or in unfamiliar surroundings (e.g. a hospital ward).

The causes include:

- metabolic and endocrine (see below)
- infection (systemic, particularly with high fever and meningeal/cerebral)
- vascular (e.g. cerebral haemorrhage and infarction)
- toxic (e.g. drugs, both intoxication and withdrawal, and toxins, e.g. carbon monoxide)
- neoplasia (primary cerebral tumours, cerebral metastases and paraneoplastic syndromes)

- trauma (e.g. subdural haematoma, cerebral contusion)
- miscellaneous (e.g. post-ictal, postoperative).

The metabolic and endocrine causes are summarized in Table 35.3. When one of these is the cause of acute confusion, there will often be other clinical features of, or clues to, the condition, but if this is not the case, the laboratory investigations performed beyond a standard 'biochemical profile' and full blood count (with differential) should reflect the relative frequency of the conditions. It should be noted that in the elderly, almost any acute illness can present with acute confusion, and that the elderly may be at increased risk of developing confusion in response to any causative condition as a result of poor nutrition, visual or auditory impairment, or incipient dementia. The tendency for elderly people to be taking multiple therapeutic drugs coupled with age-related changes in the rates of metabolism and excretion of drugs is another important factor.

Sepsis and drug intoxication or withdrawal are particularly common causes of delirium. Sepsis may increase the risk of drug-induced delirium by increasing the permeability of the blood–brain barrier. For drugs that are protein-bound, a low plasma albumin concentration may also increase toxicity by increasing the proportion of the drug present in the unbound form.

Anxiety

Anxiety is a normal response to a threat, but in the anxiety disorders, the response is out of proportion to any real danger and causes suffering and behavioural disturbance.

The anxiety disorders comprise three conditions: generalized anxiety disorder, in which symptoms are persistent, and two conditions in which they are episodic – panic disorder, in which there is no apparent stimulus,

TABLE 35.3 Metabolic and endocrine causes of delirium (acute confusional state)

Cause	Notes
Cerebral hypoxia	Secondary to, for example, cardiac failure, respiratory failure, hypotension, severe anaemia
Hypo-/hyperglycaemia	
Hyponatraemia	Dependent on the rate of fall as well as the absolute value of the sodium concentration
Hypo-/hypercalcaemia	
Renal failure	Depression is a far more frequent psychiatric manifestation of hypothyroidism
Liver failure	
Adrenal failure	
Hyper-/hypothyroidism	
Hyperpyrexia	
Acute porphyria	Causing rhabdomyolysis as in malignant hyperthermia or the 'neuroleptic malignant syndrome' due to central dopamine blockade
Vitamin deficiencies (thiamin, niacin and vitamin B ₁₂)	
Drugs	Including alcohol (ethanol), illicit agents and a wide range of therapeutic drugs, particularly in the elderly

and phobic anxiety disorders, in which anxiety stems from fear of situations, for example going out alone or being in crowded spaces (agoraphobia), or objects, for example spiders. All types can be associated with somatic symptoms, including chest pain, palpitation, dyspnoea (typically a feeling of not being able to take a full breath), paraesthesiae and sweating, but these are particularly associated with panic disorder. They may lead to the patient seeking urgent medical advice because they fear a serious illness, for example a heart attack. Patients with generalized anxiety disorder may seek medical advice because of bowel disturbance.

The somatic symptoms in the acute anxiety disorders are due to a combination of increased sympathetic activity, release of catecholamines and hyperventilation. The latter causes falls in arterial PCO_2 and hydrogen ion concentration (rise in pH) with normal bicarbonate and normal PO_2 , reducing the plasma concentration of ionized calcium and increasing neuromuscular excitability. Typically, symptoms can be provoked by over-breathing and abated by rebreathing into a paper (not plastic, which risks asphyxiation) bag. It is not usually difficult to distinguish hyperventilation in anxiety from hyperventilation in response to acidosis (e.g. ketoacidosis) or in pulmonary disease (e.g. asthma, pulmonary oedema) but, if necessary, arterial blood gases can be measured.

Hypocapnia can also cause anxiety. The symptoms produced (e.g. chest pain) may lead sufferers to believe that they have serious disease, inducing anxiety and setting up a vicious circle.

The differential diagnosis of anxiety disorders includes drug dependence and withdrawal, hyperthyroidism, hypoglycaemia, hypoparathyroidism and pheochromocytoma.

Thyroid function tests should always be performed in patients presenting with an apparent primary anxiety disorder. Anxiety, insomnia, emotional lability and difficulty concentrating are frequently present in patients with hyperthyroidism and the symptoms may occasionally be sufficiently severe to suggest hypomania. It may be difficult to distinguish between an anxiety state and mild hyperthyroidism: features suggesting the latter include eye

signs, the presence of a goitre and proximal myopathy. Tremor is often present in both conditions, but the hands tend to be warm and moist in hyperthyroidism as a result of the hyperdynamic circulation, but cold and clammy in anxiety disorder. Resting pulse rate is usually normal in anxiety disorders but increased in hyperthyroidism. The anxiety symptoms of hyperthyroidism usually respond to treatment with β -blockers.

The diagnosis of hypoglycaemia is discussed in detail in Chapter 17, and of pheochromocytoma in Chapter 38. Measurement of fasting blood glucose concentration during an attack is a simple matter; measuring plasma or urinary catecholamines or their metabolites is not, but pheochromocytoma, although rare, should be considered when there are predominant sympathetic symptoms (e.g. palpitation, sweating) and no obvious precipitating factor can be identified.

Dementia

Dementia – a condition characterized by a progressive decline in cognitive function (particularly loss of short-term memory) without confusion or loss of arousal – is common, particularly in the elderly, in whom Alzheimer disease and cerebrovascular disease (usually diffuse, small vessel disease) are the major causes. Metabolic and endocrine conditions are uncommon causes. A treatable cause should be sought through laboratory investigations and imaging, particularly in younger patients. The former should include a full blood count, erythrocyte sedimentation rate (ESR) and standard biochemical renal- liver- and bone-related tests, thyroid function tests, measurement of serum vitamin B₁₂ concentration and serology for systemic lupus erythematosus and syphilis (see Table 35.2). In individuals with a history of alcohol abuse, thiamin deficiency should be considered but is usually diagnosed on the basis of the therapeutic response to an intravenous bolus of thiamin. Heavy metal and carbon monoxide poisoning may need to be considered if there is possibility of exposure. A syndrome of 'pseudodementia' may arise in severe depression; this should be sought clinically as investigations are likely to be normal.

Considerable effort continues to be invested in research to determine the cause of Alzheimer disease and to identify early markers of the disease that could direct early intervention. To date, however, although various candidate markers have been investigated, none has been identified and the role of laboratory investigations is confined to eliminating treatable causes of dementia.

The pathological hallmarks of Alzheimer disease are senile plaques and neurofibrillary tangles throughout the cerebral cortex but particularly in the hippocampus. The first stage in the development of plaques is the deposition of β -amyloid protein, which is produced through the proteolysis of amyloid precursor protein (APP). This protein is coded for on chromosome 21, which may explain why individuals with Down syndrome (trisomy 21) are prone to the early development of Alzheimer-like changes in the CNS. Neurofibrillary tangles develop as a result of the aggregation of tau protein driven by its undergoing hyperphosphorylation, but the underlying cause of either of these processes remains unknown. As the disease develops, diffuse cerebral atrophy ensues. The most obvious functional abnormality in Alzheimer disease is a reduction in cerebral cholinergic activity. This has led to the development of treatments using cholinesterase inhibitors, but thus far, these are of limited benefit, and that only in early disease.

Most cases of Alzheimer disease are sporadic, but a small number show autosomal dominant inheritance, and are due to mutations in the genes coding for APP or presenilins 1 and 2. Genetic factors also impinge on sporadic Alzheimer disease: some 80% of patients possess at least one $\epsilon 4$ allele of the gene coding for apolipoprotein E (the usual allele being $\epsilon 3$). However, the basis of this association remains uncertain.

Depression

Introduction

Depression is one of the commonest psychiatric disorders. Its typical features are low mood, loss of interest and enjoyment (anhedonia), reduced energy and increased fatigue; other common features include psychomotor retardation, poverty of movement and disordered ideation (e.g. hypochondriasis, feelings of unworthiness). Somatic symptoms, particularly headache and fatigue, are common. In severe cases, auditory hallucinations, delusions and suicidal ideation may be present. Recurrent distinct episodes are common, although some patients experience a chronic, low-grade depression (dysthymia). Depression can occur on its own (unipolar disorder) or (less frequently) be a feature of bipolar affective disorder (manic depressive psychosis) with episodes of depression or hypomania interspersed with periods of normality.

Depression can develop as a natural response to physical illness (depressive adjustment disorder) but is typically not as severe as depression arising without precipitating factors. If the associated illness is self-limiting, it may only be transient. However, the boundary between depressive adjustment disorder and depressive illness is not clear-cut, and depressive symptoms arising in a patient with physical illness should not be assumed to be a

response to the illness. Indeed, because some depressive symptoms can be features of organic illness, the possibility of depression should be actively considered. Up to a third of patients with physical illness have depressive symptoms, and major depression is present in up to 15%, the prevalence correlating with the number of physical symptoms. Untreated comorbid depression worsens the outcome in physical illness (e.g. cardiovascular disease, diabetes, arthritis). Indicators of possible depressive disorder include: failure to adjust to the illness; reduced physical functioning; slower recovery than might be expected, and a reduction in social activity.

Depression and thyroid function

The differential diagnosis includes several other psychiatric disorders, and depression can coexist with other disorders, for example panic disorder. The most frequent organic disease that may be mistaken for depression is hypothyroidism, although apathy is more common than true depressive symptoms in the latter. Other features include inattentiveness and loss of short-term memory. Frank psychosis due to hypothyroidism ('myxoedema madness') is now rare. Hypothyroidism is a common condition, particularly in the elderly; its manifestations can be protean and it should be excluded by measuring thyroid stimulating hormone (TSH) and free thyroxine concentrations in any patient presenting with depression or a decline in cognitive function. The psychiatric manifestations improve with thyroxine replacement treatment, although sometimes the cognitive dysfunction persists, perhaps because of a deleterious effect of chronic thyroid hormone deficiency on the CNS. Depression that is refractory to treatment may show a pattern of 'sick euthyroidism' (low plasma TSH and free thyroxine concentrations, see Chapter 19), and the depression may respond to thyroxine treatment; thyroid function should be reassessed when the depression improves as there is unlikely to be primary hypothyroidism. In some patients, the initiation of thyroxine treatment can temporarily exacerbate the psychiatric symptoms or even, in susceptible individuals (e.g. those with a family history of affective disorder), precipitate a manic episode. It should be remembered that, particularly in elderly people, hyperthyroidism occasionally presents atypically (apathetic hyperthyroidism) and may be mistaken for depression. Thyroid disease is discussed in detail in Chapter 19.

Depression and adrenal function

Depression is a common feature of Cushing syndrome, whether pituitary dependent or independent or the result or administration of exogenous steroids (though this can also cause euphoria). That it is cortisol, rather than corticotrophin (adrenocorticotrophic hormone, ACTH) that is the cause of the depressive symptoms is suggested by the absence of any excess of depression in patients with Nelson syndrome (in which ACTH concentrations are high but cortisol is low). Furthermore, metyrapone, which inhibits the synthesis of cortisol and causes increased concentrations of ACTH, has a beneficial effect on depression in Cushing syndrome. Depression in

Cushing syndrome is more frequent in women and in older age groups, and its severity shows some correlation with the severity of other features of the condition. The acute administration of high doses of corticosteroids (e.g. prednisolone 30 mg/day) can lead to hyperphagia, insomnia and euphoria, and their sudden withdrawal can precipitate depression.

Patients with depression often fail to show suppression of plasma cortisol concentration in the overnight dexamethasone suppression test (see Chapter 18) and (though less frequently) in the formal low-dose test, in which dexamethasone 0.5 mg is administered 6-hourly for 48 h.

Depression can lead to accelerated loss of bone mineral density and increased risk of fracture: the hypercortisolaemia is likely, in part, to be responsible for this.

Depression can also be a feature of Addison disease. The symptoms may pre-date the classic physical signs of the condition but respond to cortisol replacement treatment.

Depression in the metabolic syndrome and diabetes

There is a well recognized association between diabetes mellitus and depression. Dr Thomas Willis, a 17th century British physician, considered that diabetes was caused by 'sadness or long sorrow'. One study has reported a prevalence of major depression in diabetes of 9.3%, compared with 6.1% in the general population. The presence of depression in diabetes is associated with poorer glycaemic control and poorer outcome but appropriate psychiatric intervention can reduce the morbidity associated with diabetes. Both diabetes and depression are risk factors for cardiovascular disease; the risk in patients with depression is approximately twice that in those without.

It seems more likely that diabetes predisposes to depression than vice versa. A nine-year prospective study of people with or without depression showed no excess risk of diabetes in those with depression. Further, treatment of depression in patients with diabetes has no effect on glycaemic control. How diabetes predisposes to depression is uncertain, but insulin resistance as part of the metabolic response to the psychosocial stress arising from having a chronic illness may, in part, be responsible.

The major underlying pathogenic factor in type 2 diabetes is resistance to the actions of insulin. Insulin resistance also underlies the metabolic syndrome (see Chapter 15). This syndrome comprises a range of abnormalities, including visceral obesity, dyslipidaemia, hyperglycaemia and hypertension that are risk factors for both type 2 diabetes and cardiovascular disease. The prevalence of the metabolic syndrome in patients with diabetes is high. Several other abnormalities have been described in both depression and the metabolic syndrome, including hypercortisolaemia, abnormal autonomic nervous system function (e.g. increased resting heart rate with reduced heart rate variability), endothelial dysfunction, increased platelet reactivity and evidence of persistent inflammation.

Plasma concentrations of nutritional factors such as 25-hydroxyvitamin D and ω -3 fatty acids have been found

to be consistently low in depressed patients, the former being linked to reduced activity and exposure to sunlight, the latter to modulation of cytokine activity leading to increased hypothalamo-pituitary-adrenal and inflammatory activity. There is no evidence of clinical benefit from dietary supplementation.

Post-traumatic stress disorder

This syndrome can arise as a result of exposure to any severe psychological trauma; physical trauma may also be involved. Examples of causes include experience of natural disasters, war, terrorism, witnessing violent death, torture and rape. Its features include:

- recurrent, intrusive recollections of the event ('flashbacks')
- feelings of detachment and isolation (avoidant symptoms)
- persistent symptoms of increased arousal (e.g. exaggerated startle reflex).

The severity of the condition in individuals is dependent both on factors related to the event itself (e.g. its severity, the proximity of the individual to it) and on the personality of the individual, any history of psychiatric illness and other factors.

Endocrine abnormalities associated with the post-traumatic stress disorder include decreased cortisol secretion secondary to decreased secretion of ACTH (despite increased secretion of corticotrophin releasing hormone, CRH). The ACTH response to CRH is reduced, and that to dexamethasone increased, suggesting enhanced negative feedback. This contrasts with the elevated cortisol and reduced sensitivity to dexamethasone that is characteristic of several other psychiatric disorders. The urinary excretion of catecholamines is increased and there is evidence of increased CNS noradrenaline (norepinephrine) and serotonin activity, these two neurotransmitters being known to have a role in storing and retrieval of memory. Some patients with post-traumatic stress disorder have increased plasma concentrations of thyroid hormones and an enhanced TSH response to TRH (thyrotrophin releasing hormone), yet are clinically euthyroid.

Functional magnetic resonance imaging (fMRI) of the brain suggests features in common between post-traumatic stress disorder and obsessive-compulsive disorder.

Schizophrenia

The history of schizophrenia research is littered with the discovery, and subsequent abandonment, of putative biomarkers of the disorder or its aetiology. Recent interest has focused on elevated plasma concentrations of inflammatory cytokines found in patients with both first episode psychosis and chronic schizophrenia. Acute inflammation has been reported to increase the relapse rate of schizophrenic symptoms, and the widespread direct and indirect influences of cytokines on brain neurotransmitter pathways and neural plasticity suggest a mechanism. Augmentation of antipsychotic treatment with the anti-inflammatory drugs acetylsalicylic acid (aspirin) and

celecoxib (a cyclooxygenase-2 inhibitor) has been advocated and may improve treatment response in some patients.

Despite the major functional abnormalities that may be present in patients with schizophrenia, significant metabolic disturbances are relatively uncommon. Basal concentrations of most hormones are normal in schizophrenia (elevations in vasopressin are an exception), although the TSH and gonadotrophin responses to their respective releasing hormones are typically blunted. However, significant metabolic abnormalities may develop as a consequence of treatment with psychotropic drugs, as described later in this chapter. Furthermore, substance abuse is frequent in patients with schizophrenia and this may cause metabolic abnormalities, e.g. hyponatraemia with amfetamines (particularly methylenedioxymethamphetamine, MDMA, 'ecstasy'), hypoglycaemia with ethanol (see Chapter 17) and decreased secretion of gonadotrophins with opioids.

ENDOCRINE AND METABOLIC MANIFESTATIONS OF PSYCHIATRIC DISEASE

The hypothalamus is central to the regulation of the endocrine system and the sympathetic nervous system, and is involved in behavioural responses, so it is not surprising that many psychiatric diseases affect endocrine function. Not all do, however: schizophrenia (see above) is a notable exception.

Abnormalities of the hypothalamo–pituitary–adrenal axis

Abnormalities of cortisol secretion are common in psychiatric disease. Approximately 50% of patients with depression have hypercortisolaemia (though with preservation of the normal circadian variation) secondary to increased secretion of CRH and hence ACTH, although the response of ACTH secretion to an intravenous bolus of CRH is reduced (in contrast to patients with Cushing disease, in whom it is typically exaggerated). Enhanced vasopressin secretion may also contribute to the increased secretion of ACTH in depression.

The reason for the increased CRH drive is unclear. It may be a result of impairment of the normal inhibitory feedback of cortisol on the hypothalamus, but this could be part of the underlying disorder or a response to it.

Individuals with alcohol dependence may develop features of Cushing syndrome (pseudo-Cushing) but these usually resolve rapidly on withdrawal of alcohol.

Similarity between the features of chronic fatigue syndrome and adrenal insufficiency have prompted research into endocrine function in the former condition. Plasma cortisol concentrations tend to be slightly lower than normal, although adrenal responsiveness to ACTH is not impaired, and the ACTH and cortisol responses to insulin-provoked hypoglycaemia are normal. Treatment with low doses (5–10 mg/day) of hydrocortisone has been shown to be of benefit in some patients.

Plasma cortisol concentrations are frequently decreased in patients with post-traumatic stress disorder; these patients often demonstrate increased sensitivity to the suppressive effects of dexamethasone on cortisol secretion. This contrasts with the findings in many other psychiatric disorders, in which hypercortisolaemia is accompanied by reduced sensitivity to dexamethasone.

The ACTH response to CRH is blunted in some patients with anxiety disorders but plasma cortisol concentrations are normal. Hypothalamo–pituitary–adrenal function has been reported to be normal in patients with schizophrenia.

Abnormalities of the hypothalamo–pituitary–thyroid axis

Patients with depression frequently demonstrate abnormalities of thyroid function. Up to 20% of patients with depression have been reported to have 'sick euthyroidism' (see above) or subclinical hypothyroidism, with normal thyroxine concentrations but slightly elevated concentrations of TSH secondary to increased secretion of TRH and with increased TSH responsiveness to TRH. This pattern is more common in patients with bipolar disorder. Other patients (more particularly those with unipolar depression) have a blunted TSH response to TRH. However, this is not specific to depression, having been reported in schizophrenia and alcoholism as well. Treatment with antidepressants leads to normalization of thyroid function tests, although it is of interest that treatment with tri-iodothyronine apparently enhances their efficacy in some patients, both increasing the rate at which they become effective and the overall response. This suggests that there may be a specific link between thyroid function and mood disorder rather than to the symptoms just being a consequence of reduced cerebral metabolism. Tri-iodothyronine is widely used by psychiatrists for this purpose.

Patients with other acute and chronic psychiatric illnesses may demonstrate the features of the sick euthyroid syndrome (see Chapter 19), and patients with anorexia nervosa typically demonstrate the abnormalities characteristic of starvation, with a low plasma thyroxine concentration, increased concentration of reverse tri-iodothyronine and a reduced TSH response to TRH.

Abnormalities of the hypothalamo–pituitary–gonadal axis

The secretion of gonadotrophin releasing hormone (GnRH) is impaired at low body weights (see Chapter 18), and oligo-/amenorrhoea is frequently reported by women with anorexia nervosa. Amenorrhoea is often a feature of moderate to severe depression, and may result from diminution of the release of follicle stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. Pulsatile release of both FSH and LH takes place during slow-wave (i.e. non-REM) sleep (SWS), but this phase of sleep is shortened or absent in moderate to severe depression. Testosterone has been reported to have an anti-depressant effect in depressed hypogonadal men.

Abnormalities of growth hormone secretion

Anorexia nervosa typically also causes increases in plasma growth hormone concentration with exaggerated responses to growth hormone releasing hormone (GHRH) but decreased concentrations of insulin-like growth factor 1 (IGF-1), probably due to a combination of weight loss and increased concentrations of glucocorticoids

Two major abnormalities of growth hormone secretion have been described in depression: hypersecretion during daytime and reduced secretion during sleep. As growth hormone is also secreted from the pituitary in bursts during SWS, the latter abnormality may arise from the reduction of SWS that is found in depression.

Abnormalities of prolactin secretion

Anxiety is a common cause of hyperprolactinaemia, and blood for prolactin measurement should always be drawn under conditions that minimize stress.

Nocturnal plasma prolactin concentrations are increased in some patients with schizophrenia, but elevated prolactin concentrations in this condition are usually a consequence of treatment with dopamine receptor antagonists (see below).

Prolactin secretion is usually normal in depressive illness, although responsiveness to stimuli such as L-tryptophan may be diminished.

Other metabolic abnormalities

Several psychiatric disorders can lead to abnormalities of fluid, electrolyte and acid–base balance. The respiratory alkalosis that can occur as a result of hyperventilation in anxiety states has been mentioned above. Abnormalities associated with drug abuse are discussed in relation to individual drugs in Chapter 40. Examples include hypophosphataemia in alcoholism and alcohol withdrawal, and potassium and magnesium depletion in patients abusing diuretics or laxatives. Severe hypokalaemia can develop in anorexia nervosa secondary to chronic starvation; this may be exacerbated by vomiting and laxative abuse. Patients with bulimia are particularly prone to developing potassium depletion with hypochloreaemic alkalosis as a result of self-induced vomiting. Hypophosphataemia may also occur but is particularly associated with refeeding (see p. 211). Multiple deficiencies of mineral nutrients can occur in both conditions, and in depression. Psychogenic polydipsia can cause profound hyponatraemia and may be difficult to distinguish from diabetes insipidus, as the chronically high urine output can lead to ‘medullary washout’ with a secondary decrease in the concentrating capacity of the kidneys (see Chapter 4).

METABOLIC COMPLICATIONS OF PSYCHOTROPIC DRUGS

Lithium

Lithium is a valuable mood stabilizing drug, widely used in the management of bipolar disorder, both for prophylaxis and in the treatment of acute episodes (particularly

of mania). However, it has the potential to cause severe adverse effects. These are directly related to its plasma concentration, and monitoring of plasma concentrations every three months is mandatory (see Chapter 39).

Lithium reduces the responsiveness of the distal parts of the nephron to vasopressin (antidiuretic hormone), resulting in a reduced capacity to concentrate the urine. This effect is demonstrable in most patients being treated with the drug but is rarely of clinical significance, although a few patients develop nephrogenic diabetes insipidus. This is partially reversible if lithium is withdrawn. Lithium is 95% excreted by the kidneys and dehydration decreases the glomerular filtration rate, so increasing the concentration of the drug and potentially exacerbating the toxic effect. However, provided that acute toxicity is avoided, lithium rarely causes long-term renal damage.

Lithium can also interfere with thyroid function and cause primary hypothyroidism, the risk of this being greater if thyroid autoantibodies are present. For these reasons, plasma creatinine (and hence estimated glomerular filtration rate (eGFR), thyroid stimulating hormone (TSH) concentrations should be measured before starting lithium treatment and at regular intervals (e.g. 4–6 monthly) thereafter.

Drugs causing hyperprolactinaemia

Prolactin secretion by the anterior pituitary is inhibited by dopamine, and given the fact that several antipsychotic drugs (e.g. phenothiazines, butyrophenones) are dopamine (D₂ receptor) antagonists, it is not surprising that these drugs are a frequent cause of hyperprolactinaemia. Metoclopramide and domperidone, two widely used antiemetic drugs, also have this effect. Prolactin concentration may be increased to as much as 2500 mU/L, well into the range seen in patients harbouring microprolactinomas. Clinical features of hyperprolactinaemia are, however, relatively uncommon, but amenorrhoea, galactorrhoea and breast enlargement may occur in women, and gynaecomastia and impotence in men. Hyperprolactinaemia is less frequent with the newer second generation antipsychotics, for example olanzapine and quetiapine (though it is seen with risperidone), whose actions are either non-dopaminergic or have higher affinity for 5-hydroxytryptamine (serotonin) receptors than dopamine receptors.

Drugs causing hyponatraemia

Several drugs used in the management of patients with psychiatric disease can interfere with water homeostasis (probably through stimulating vasopressin secretion) and lead to hyponatraemia. They include selective serotonin reuptake inhibitors (e.g. paroxetine) and carbamazepine, primarily an anticonvulsant but also used in the prophylaxis of bipolar disorder. In the majority of patients, any resultant hyponatraemia is only mild and is asymptomatic, but there is a risk of significant water retention leading to intoxication, and serum sodium concentration (and less frequently osmolality) should be monitored in patients being treated with these drugs.

Drugs causing hyperglycaemia and hyperlipidaemia

The prevalence of diabetes mellitus is higher in patients with schizophrenia in comparison with the general population, but the introduction of chlorpromazine in 1956 caused a significant further increase, and the term 'chlorpromazine diabetes' was used to describe this. The mechanism appears to be insulin resistance. Newer second generation antipsychotics can also cause hyperglycaemia and hypertriglyceridaemia, and sometimes hypercholesterolaemia, albeit less frequently. Clozapine is particularly implicated, followed by olanzapine; metabolic abnormalities are less common with risperidone and quetiapine, and least with aripiprazole. Weight gain is frequent with both clozapine and olanzapine. It is recommended that glycated haemoglobin (HbA_{1c}) and lipid concentrations should be measured at inception of treatment with any antipsychotic, and repeated twice yearly in patients on clozapine (they also require to be under surveillance for agranulocytosis, a potentially lethal adverse effect) and olanzapine, and annually for other antipsychotics.

Drugs interfering with hepatic function

Many drugs can cause mild hepatic abnormalities, usually manifest as an increase in plasma aminotransferase and/or alkaline phosphatase activity. Examples include chlorpromazine, haloperidol and some tricyclic antidepressants. Chlorpromazine can cause cholestasis, and this may persist after the drug has been discontinued. The hepatotoxicity of valproate is a particular problem. This drug, primarily used as an anticonvulsant, has become one of the most frequently used mood-stabilising drugs. Several cases of fatal hepatotoxicity have been reported. Patients present with lethargy, anorexia, nausea, and jaundice are found to have hyperammonaemia (although elevated ammonia concentrations have been reported in patients taking valproate in the absence of overt toxicity). Unfortunately, this reaction is an idiosyncratic one, being dependent neither on the dose nor the concentration of the drug, so that therapeutic monitoring of concentrations is of no value in preventing it.

Many drugs used in psychiatric practice affect plasma protein binding (notably carbamazepine) or the hepatic cytochrome enzyme system, causing changes in the availability of other drugs utilizing the same pathway. The result may be to reduce the therapeutic effects of a drug or increase its adverse effects.

FUTURE DEVELOPMENTS

Simple 'mono-neurotransmitter' models of psychiatric disorders are increasingly untenable and, along with them, simple distinctions between mental and physical illness. Evidence is accumulating of the interplay of neuroendocrine and inflammatory processes in many

psychiatric disorders, and that some disorders that cluster epidemiologically (depression and cardiovascular disease) might not be independent but manifestations of the same pathogenetic process. Although it seems unlikely that measurements of individual or even groups of simple analytes in peripheral blood will ever become of value in the diagnosis or management of the major psychiatric disorders, it is possible to envisage an increasing role for the clinical biochemist in psychiatry. Pharmacogenetics – the study of the genetic influence on responsiveness to drugs – has the potential to facilitate a more tailored approach to prescribing, in relation both to the selection and dosage of drugs. And, given that some psychiatric disorders are clearly at least in part of genetic origin, the identification of genes conferring susceptibility to these conditions will enable the development of microarray-based tests to identify individuals at high risk. These could then be targeted for intervention to manage other risk factors, or possibly prophylactic drug treatment.

CONCLUSION

At present, most psychiatric disorders are diagnosed clinically. The purpose of biochemical investigations in patients with psychiatric symptoms is to rule out an organic cause. However, many psychiatric disorders can give rise to metabolic and endocrine abnormalities, as can treatment with psychotropic drugs.

CONCLUSION 701

INTRODUCTION

Despite the significant advances seen in laboratory and imaging diagnostics, many of the conditions seen by neurologists are still diagnosed on purely clinical grounds. In neurology, there remains no substitute for a meticulous clinical history and careful examination.

Neurological investigations include all imaging modalities, neurophysiological tests of both the central and peripheral nervous system, and laboratory based investigations, including haematology, biochemistry,

immunology, histopathology and cytology. This chapter will focus on the neurological conditions for which biochemical abnormalities are pertinent. Separate chapters cover the biochemistry of cerebrospinal fluid and muscle disease and other conditions that overlap with general neurological practice.

ENCEPHALOPATHY

'Encephalopathy' is a term for any diffuse disease of the brain that alters brain function or structure. It is a common condition that encompasses coma, acute confusional

BOX 36.1 Some causes of metabolic encephalopathy

- Toxic
 - Alcohol
 - Drugs
 - Carbon monoxide
- Nutritional disorders
 - Thiamin deficiency (Wernicke–Korsakoff syndrome)
 - Vitamin B₁₂ deficiency
- Organ failure
 - Hepatic failure
 - Established renal failure
 - Cardiorespiratory failure (hypoxic/ischaemic and hypercapnic)
- Diabetic disorders
 - Hypoglycaemia
 - Hyperglycaemia (diabetic ketoacidosis and hyperosmolar hyperglycaemic state)
- Disturbances of sodium and water balance
 - Hyponatraemia
 - Hypernatraemia
- Hypercalcaemia
- Septic encephalopathy

state, delirium and dementia. The hallmark of encephalopathy is an altered mental state.

Encephalopathy is caused either by processes that directly affect the structure of the brain or by systemic and metabolic factors (see [Box 36.1](#)). Encephalopathy can occur acutely (over hours to days); subacutely (over weeks to months) or chronically (over years) ([Table 36.1](#)). Although the mechanism of many causes of encephalopathy is well understood, the pathophysiology of metabolic encephalopathy is less clear but is likely to involve changes in amino acids and neurotransmitter profile.

For patients presenting with altered consciousness, a detailed history often has to be taken from family, friends and other healthcare professionals, to determine pre-existing medical conditions and time of onset of altered mental state. For example, patients presenting with altered consciousness following apnoea or cardiac arrest are likely to be suffering from a hypoxic–ischaemic encephalopathy but alternative causes need to be excluded. Access to medication, previous psychiatric problems or use of illicit drugs may suggest intoxication. If the patient is known to have diabetes, hypo- or hyperglycaemia is likely. Patients on diuretics are at risk of hyponatraemia.

TABLE 36.1 Neurological causes of encephalopathy

Acute (hours to days)	Trauma Infection (e.g. meningitis/encephalitis) Vascular (e.g. stroke) Space occupying lesion
Subacute (weeks–months)	Infection (e.g. HIV, progressive multifocal leukoencephalopathy, Lyme disease) Neoplastic (primary or secondary) Inflammatory (e.g. cerebral vasculitis) Autoimmune encephalitis (immune-mediated, paraneoplastic, Hashimoto) Degenerative (e.g. Creutzfeldt–Jakob disease; mitochondrial disease)
Chronic (years)	Degenerative (Alzheimer disease, Parkinson disease)

Both a general systemic examination and detailed neurological examination are required to determine the cause of encephalopathy. Specific breath smells suggest certain causes, e.g. ammonia-like (uraemia); fruity-smelling (ketoacidosis); musty or fishy (acute hepatic failure); onion (paraldehyde), and garlic (organophosphates). Hypertension may indicate amphetamine or cocaine intoxication or a hypertensive encephalopathy. Examination of the skin may show signs of chronic liver disease, haemodialysis fistula, previous sternotomy scars from cardiac surgery or injection marks from intravenous drug use.

Neurological examination should be divided into focal (localizing) and global (non-localizing) signs. Global signs suggest a process affecting the whole brain and include altered consciousness (acute confusional state, delirium and coma). The level of coma can be quantified with the Glasgow Coma Score, for which the minimum score is 3/15 ([Table 36.2](#)).

Other global neurological signs include generalized seizures, tremor, asterixis (abnormal jerking tremor in hands seen in liver flap) and myoclonus (involuntary brief jerk-like twitching, often multifocal). Focal signs indicate a localized problem within one part of the brain, for example visual or language disturbance from cerebral cortex pathology or eye movement disturbance, slurred speech or swallowing problems from brainstem pathology. Focal neurological signs usually suggest a primary neurological cause of encephalopathy.

TABLE 36.2 Glasgow coma scale (GCS)

The total is obtained by adding together the scores for each column

Best eye response	Best verbal response	Best motor response
No eye opening	No verbal response	No motor response
Eyes open in response to pain	Incomprehensible sounds	Extension to pain
Eyes open to speech	Inappropriate words	Abnormal flexion to pain
Eyes open spontaneously	Confused	Withdrawal to pain
	Oriented	Localizes to pain
		Obeys commands

Two-thirds of encephalopathies are secondary to systemic metabolic factors. It is therefore important that these are excluded before assuming there is a neurological cause. Many metabolic encephalopathies are reversible if corrected promptly. Investigations for a patient with encephalopathy should include blood tests, urinalysis, imaging studies, and, when indicated, cerebrospinal fluid examination and an electroencephalogram. Increasingly, laboratory investigations can be used to make a definite diagnosis of neurological causes of encephalopathy owing to the improved recognition of antibodies for autoimmune encephalitis syndromes and biomarkers in neurodegenerative disease (Table 36.3).

Toxic and metabolic encephalopathy

Toxic encephalopathy is caused by exogenous substances including solvents, drugs, radiation, paints, industrial chemicals, and certain metals. Some of the more common causes are discussed below. More details can be found in Chapter 40.

Carbon monoxide

This colourless and odourless gas is the most common cause of accidental poisoning in Europe and North America, as well as being a major cause of suicidal deaths. When 20–30% of total haemoglobin is bound to carbon monoxide, it causes headache, nausea and shortness of breath; when 50–60% is bound, coma results. Carbon monoxide exposure is detected by measuring the carboxyhaemoglobin concentration in blood. Carbon monoxide poisoning is treated with oxygen, using hyperbaric facilities in severe cases, if available.

Alcohol

Alcohols, including ethanol, produce an altered mental state by central nervous system depression. Methanol and ethylene glycol similarly cause direct central nervous system depression but are also toxic via metabolism in the liver to formic acid (methanol) and glycolic and oxalic acids (ethylene glycol).

Methanol and ethylene glycol concentrations can be measured in the blood but usually the suspicion is raised by other biochemical abnormalities. Poisoning with either causes a high anion gap metabolic acidosis. Treatment is by blocking the action of alcohol dehydrogenase with ethanol or fomepizole to decrease the production of toxic metabolites.

Opioids

Overdose causes coma, pinpoint pupils and respiratory depression. This can be from iatrogenic, accidental or suicidal overdose (e.g. morphine) or from use of illicit drugs (e.g. heroin). Diagnosis is usually suspected from the clinical triad but a rapid urine screening test can confirm opioid exposure. Treatment is with naloxone, given as a bolus dose followed by an infusion if the patient responds, in addition to supportive care.

TABLE 36.3 Investigations for encephalopathy

Test	Cause of encephalopathy
First-line	
Blood/serum	
Full blood count	Elevated white cell count (infection), macrocytosis (alcohol, hypothyroidism)
Serum electrolytes (osmolality if required)	Hypo- and hypernatraemia, hypercalcaemia
Glucose	Hypo- and hyperglycaemia
Urea and creatinine	Uraemia
Liver function tests	Hepatic failure
Arterial [H ⁺] (pH)	Diabetic ketoacidosis and hypercapnic encephalopathy
Arterial PO ₂ and PCO ₂	Hypoxia/ischaemia and hypercapnia
C-reactive protein	Infectious
Erythrocyte sedimentation rate	Infectious and autoimmune
Thyroid function tests	Hashimoto thyroiditis
Vitamin B ₁₂ and folate	Nutritional deficiency
Urine	
Ketones	Diabetic ketoacidosis
Drug and alcohol screen	Toxic
Other	
CT brain	Structural
Second-line (as appropriate to the suspected clinical condition)	
Blood/serum	
Ammonia	Hepatic failure, inborn errors of metabolism, sodium valproate
Angiotensin-converting-enzyme	Sarcoidosis
Anti-nuclear, anti-neutrophil cytoplasmic, anticardiolipin antibodies, extractable nuclear antigens	Cerebral vasculitis
Thyroid peroxidase antibodies	Hashimoto thyroiditis/steroid responsive encephalopathy
Lactate dehydrogenase	Lymphoma
Syphilis, <i>Borrelia</i> and HIV serology	Infectious
Voltage gated potassium channel, N-methyl-autoimmune D-aspartate receptor, glutamate receptor and glutamic acid decarboxylase antibodies	Paraneoplastic
Antineuronal antibodies	Paraneoplastic
Cerebrospinal fluid	
Microbiology	Infectious, inflammatory, autoimmune and paraneoplastic
Protein, glucose	Infectious
Viral PCR	Inflammatory
Oligoclonal bands	Paraneoplastic
Antineuronal antibodies	Creutzfeldt–Jakob disease
14-3-3 protein	Carcinomatous meningitis
Cytology	
Other	
MRI brain	Structural, infectious, autoimmune
Electroencephalography	Seizures

Thiamin (vitamin B₁) deficiency

Wernicke–Korsakoff encephalopathy is a clinical triad of confusion, ataxia and ophthalmoplegia (eye movement disorder). It comprises two syndromes. First, Wernicke encephalopathy, an acute or subacute confusional state with ataxia and ophthalmoplegia and second, Korsakoff dementia, characterized by severe amnesia and confabulation. The former is often reversible but the latter is irreversible and persistent. Wernicke–Korsakoff encephalopathy is caused by thiamin deficiency and is most commonly seen in alcoholics but can also occur in patients with anorexia, hyperemesis gravidarum, those receiving total parenteral nutrition, or in the context of malabsorption and refeeding syndrome. The role of measurement of plasma thiamin concentrations in diagnosis and monitoring remains controversial and functional assessment by assay of red cell transketolase is no longer used by most laboratories for diagnosis. Therefore, laboratory tests are aimed at excluding other conditions and providing evidence of risk factors (e.g. macrocytosis and deranged liver function tests in alcoholism). Brain magnetic resonance imaging (MRI) can show signal change in the thalami, mammillary bodies, tectal plate and periaqueductal grey matter. Treatment is with parenteral thiamin. In the UK, normal practice is to give thiamin in a vitamin complex of riboflavin, nicotinamide, pyridoxine and ascorbic acid. Early treatment can reverse the symptoms rapidly and prevent dementia. Administration of intravenous glucose (including as part of parenteral nutrition) to patients who are severely malnourished, can exhaust their (already depleted) supply of thiamin and precipitate Wernicke–Korsakoff encephalopathy. Thiamin should therefore be administered before starting a glucose infusion in patients at high risk.

Vitamin B₁₂ deficiency

This causes a typical pattern of degeneration of the white matter producing encephalopathy, myelopathy (subacute combined degeneration of the spinal cord), peripheral neuropathy and optic neuropathy. Vitamin B₁₂ concentrations are easily measured and, if deficiency is corrected early, further damage can be prevented (See p. 688 and p. 693).

Liver failure

Hepatic encephalopathy occurs as a consequence of liver function disturbance and its severity is graded from 0 to 4 (Table 36.4).

Two situations can lead to severe hepatic encephalopathy – acute fulminant hepatic failure and decompensation of chronic liver disease. In the UK, acute liver failure is most commonly from paracetamol overdose or viral hepatitis, and chronic liver disease from alcohol abuse or chronic hepatitis B or C infection. Encephalopathy is thought to develop because hepatocellular dysfunction produces neurotoxins (e.g. ammonia), false neurotransmitters and benzodiazepine-like substances. In chronic liver disease, there can be the additional effect of porto–systemic shunting. This allows significant quantities of ammonia, formed in the bowel from protein, to reach the systemic circulation.

TABLE 36.4 Grading of hepatic encephalopathy (West Haven classification system)

Grading	Symptoms
0	Minimal hepatic encephalopathy. Lack of detectable changes in personality or behaviour. Minimal changes in memory, concentration, intellectual function, and coordination. Asterixis absent
1	Trivial lack of awareness. Shortened attention span. Impaired addition or subtraction. Hypersomnia, insomnia, or inversion of sleep pattern. Euphoria, depression, or irritability. Mild confusion. Slowing of ability to perform mental tasks. Asterixis can be detected
2	Lethargy or apathy. Slurred speech. Obvious asterixis. Drowsiness, lethargy, gross deficits in ability to perform mental tasks. Obvious personality changes, inappropriate behaviour and intermittent disorientation, usually regarding time
3	Somnolent but can be aroused. Unable to perform mental tasks. Disorientation about time and place, marked confusion, amnesia. Occasional fits of rage, present but incomprehensible speech
4	Coma with or without response to painful stimuli

The severity of the neurological disorder correlates poorly with ammonia concentrations so measurement rarely contributes to management. ‘Liver function tests’ will confirm that the concentration of bilirubin is high, often with abnormal liver enzyme activities and, more importantly, poor synthetic function with abnormal clotting. Plasma paracetamol concentration can be measured if overdose is a possibility. Patients with acute liver failure may require liver transplantation for survival but the encephalopathy of chronic disease may be reversed by conservative measures (see Chapter 14 for further details).

Chronic kidney disease and established renal failure

Uraemic encephalopathy presents with apathy, fatigue, inattentiveness and irritability, followed by confusion, hallucinations, slurred speech, tremor and asterixis. The mechanism is unclear but correction of uraemia reverses the encephalopathy. Suggested mechanisms include retention of organic acids, elevation of phosphate concentration in the cerebrospinal fluid (CSF), increased calcium content of the cerebral cortex owing to the action of PTH, and alteration of concentrations of neurotransmitters or proinflammatory cytokines. Although the degree of the rise in urea correlates with the severity of encephalopathy, it is not thought to be causative. The investigation, monitoring and treatment of uraemia are discussed in Chapter 7.

Respiratory failure

Hypercapnia occurs in respiratory failure either secondary to lung disease (e.g. chronic obstructive pulmonary disease) or to mechanical problems such as neurological

disease (e.g. myasthenia gravis). Clinically, hypercapnia presents with headache, papilloedema, mental slowing, drowsiness, confusion, coma and asterixis. The mechanism is unclear but thought to be due to a direct effect of carbon dioxide possibly on the hydrogen ion concentration (pH) of the CSF. Hypercapnia can be confirmed by measurement of PCO_2 on an arterial blood sample. Coma can occur with $PCO_2 > 9$ kPa. Treatment is of the underlying cause and, once corrected, there is no prolonged cerebral damage (see Chapter 5 for further details).

Cardiorespiratory failure

Hypoxic–ischaemic encephalopathy is caused by hypoxaemia and/or reduced blood flow to the brain from failure of the cardiac system, the respiratory system or both (e.g. myocardial infarction, drowning). When cerebral perfusion pressure falls, there is a failure of autoregulation leading to ischaemia and hypoxia and to cell death by both necrosis and apoptosis. The diagnosis is usually evident from the history. Myoclonus is common (Lance–Adams syndrome). There is a wide spectrum of clinical outcomes depending on the degree and duration of the insult from full recovery to severe prolonged disability and death.

Disorders of glucose metabolism

Hypoglycaemia causes confusion, seizures and coma and can cause permanent neurological damage if not reversed quickly. Up to 15% of patients with diabetes will have at least one episode of hypoglycaemic coma in their lifetime. Recurrent hypoglycaemia, such as that caused by an insulinoma, can be mistaken for epilepsy. The brain contains 1–2 g of glucose stored as glycogen, which is utilized within approximately 30 min if blood glucose concentration remains low. Ketones can also be used as an energy source but this is not sufficient in prolonged hypoglycaemia, nor are they available when hypoglycaemia is caused by high insulin concentrations. The most common causes of hypoglycaemia are accidental or deliberate overdose of insulin, insulinoma, and depletion of liver glycogen (e.g. acute liver failure, alcohol binge, severe starvation). Hypoglycaemia is easily detected by blood glucose measurement at the bedside (although it should be confirmed by laboratory measurements) (see Chapter 17 for further details).

Hyperglycaemic coma occurs in two forms – diabetic ketoacidosis and the hyperosmolar hyperglycaemic state. Coma is a late feature of diabetic ketoacidosis and develops when hyperglycaemia, dehydration, acidosis and shock are severe. Cerebral oedema is a rare but often fatal complication both of the condition and its treatment. The coma of the hyperosmolar hyperglycaemic state usually develops more insidiously and occurs in elderly patients, often with previously undiagnosed diabetes mellitus. Extreme hyperglycaemia with greatly increased plasma osmolality, electrolyte losses and dehydration exacerbated by impaired thirst awareness, are all thought to contribute to the development of the encephalopathy (see Chapter 16 for further details).

Hyponatremia

Hyponatremia has many causes, including liver and cardiac failure, syndrome of inappropriate antidiuresis (neurological causes of which include head trauma, bacterial meningitis, encephalitis, cerebral infarction, subdural and subarachnoid haemorrhage), vomiting and diuretic use. The severity of the symptoms is related to the rapidity of decline in plasma sodium. This is because hyponatremia causes extracellular hyposmolarity and a tendency for free water to shift from the vascular space to the intracellular space. When plasma sodium concentration falls slowly, over a period of several days or weeks, the brain is capable of compensating by extrusion of solutes to the extracellular space. This reduces the flow of free water into the intracellular space and symptoms are much milder for a given degree of hyponatraemia. When the plasma sodium concentration falls rapidly, this compensatory mechanism is overwhelmed and severe cerebral oedema may ensue. For example, a sodium concentration falling from normal to < 110 mmol/L over 24–48 h will often cause coma. It is necessary to correct the plasma sodium concentration in a controlled manner because of the risk of central pontine myelinolysis if the increase is too rapid (see Chapter 4).

Central pontine myelinolysis is characterized by quadriparesis, dysphagia, dysarthria, diplopia and altered consciousness. Areas of the brain other than the pons are also often involved. Magnetic resonance imaging reveals signal change within these areas but the appearances may be normal early in the course of the disease. Central pontine myelinolysis may prove fatal, and incomplete recovery is common in survivors.

Hypernatraemia

Common causes of hypernatraemia include diabetes insipidus, hyperglycaemia, diarrhoea and fluid deprivation. Again, it is the rate of change of sodium concentration that is important rather than the actual values. A sodium concentration of > 160 mmol/L can cause coma due to cerebral cellular dehydration if it develops rapidly. Treatment depends on the cause of the disorder and the total body fluid volume (see Chapter 4).

Hypercalcaemia

Severe hypercalcaemia (> 3.4 mmol/L) can lead to coma, preceded by fatigue, headache, muscle weakness, irritability and confusion. High concentrations of calcium ions decrease neuronal excitability, which together with dehydration is thought to cause the neurological problems (see Chapter 6).

Septic encephalopathy

Severe extracranial infection can be associated with an impaired mental state. The pathophysiological mechanism involves reduced cerebral blood flow and oxygen extraction by the brain, cerebral oedema, disruption of the blood–brain barrier owing to inflammatory mediators acting on the cerebrovascular endothelium, and

abnormal neurotransmitter compositions. Diagnosis of sepsis can be aided by the finding of a raised white blood cell count and raised inflammatory markers, and by blood cultures. Treatment is of the underlying infection with supportive care.

Autoimmune encephalopathy

The last decade has seen significant advances in our understanding of antibody-mediated encephalopathies. There are two types of antibodies detectable in blood in these conditions (Table 36.5): paraneoplastic antibodies to intracellular targets that are associated with cancer but are not pathogenetic, and antibodies to the extracellular domain of neuronal cell-surface proteins that directly cause encephalitis and are also often associated with cancer. Autoimmune encephalitis typically presents with subacute memory loss, psychiatric and behavioural disturbance and seizures. The detection of one of the specific antibodies supports a diagnosis of paraneoplastic encephalitis. Treatment is of the underlying cancer and with immunotherapy.

Hashimoto encephalopathy presents with seizures, behavioural and psychiatric manifestations, movement disorders and coma and is associated with the presence of high titres of anti-thyroglobulin or anti-thyroid peroxidase (TPO, antimicrosomal) antibodies. The condition can present without any features of thyroid disease. It is unclear whether the anti-thyroid antibodies are pathogenetic or simply represent an immune epiphenomenon but it is important not to miss this diagnosis as the condition responds to treatment with steroids.

Dementia

Dementia is a syndrome characterized by progressive deterioration of cognitive function without alteration of consciousness. Cognitive deficits most commonly affect memory, but other cognitive domains such as language,

praxis, visual perception and most notably executive function are also often affected. Diagnosis of dementia is generally by clinical criteria during life, although many of its causes are defined on the basis of histopathological criteria with the consequence that definitive diagnosis can only be made at post-mortem. However, over the last few years a number of laboratory CSF biomarkers have emerged and have an increasing role in diagnosis. Cerebrospinal fluid A β -40, A β -42, total tau and phosphorylated tau proteins are the most sensitive biomarkers for the diagnosis of Alzheimer disease and 14-3-3 protein for the diagnosis of Creutzfeldt-Jakob disease (see Chapter 34).

SPINAL CORD DISORDERS

Spinal cord disease usually presents with motor and/or sensory symptoms in either the upper and lower or just the lower limbs, depending on the site of the insult. Clinical signs include increased tone in the limbs, brisk reflexes and, typically, well-preserved muscle bulk. Bowel and bladder function can be compromised. The list of possible causes of spinal cord disease is extensive and includes vascular, degenerative, compressive, inflammatory, malignant, metabolic and infectious conditions. Metabolic causes include vitamin B₁₂ deficiency (Box 36.2) and adrenomyeloneuropathy. A normal MRI scan of the spinal axis will exclude a significant number of differential diagnoses.

Vitamin B₁₂ deficiency (subacute combined degeneration of the spinal cord)

Deficiency of vitamin B₁₂ can produce haematological and neurological abnormalities: features of gastrointestinal disease may also be apparent (see Chapter 12). From an early stage, it is the spinal cord that is predominantly affected. The onset of symptoms is insidious, with symmetrical, uncomfortable, tingling paraesthesiae, initially in the feet but later involving the hands. As the condition progresses, the gait becomes ataxic (sensory ataxia owing to loss of proprioception) and the limbs become weaker and increasingly spastic. Additional problems include peripheral polyneuropathy, optic neuropathy, psychiatric disturbance and dementia.

The exact pathophysiological process leading to neuronal damage in vitamin B₁₂ deficiency is unknown. Vitamin B₁₂ is involved as a cofactor in the conversion

TABLE 36.5 Antibody-mediated encephalopathy

Antibody	Associated tumour
Paraneoplastic antineuronal antibodies (intracellular)	
Anti-Hu	Bronchial small cell carcinoma (SCLC)
Anti-Ma2 (anti-Ta)	Testicular tumour
Anti-collapsin response mediator protein 5 (anti-CV2)	Lymphoma, SCLC
Antineuronal nuclear 3	SCLC
Autoimmune receptor antibodies (extracellular)	
Voltage-gated potassium channel	Uncommon
AMPA receptor (glutamate receptor 1,2 subunits)	SCLC, breast, thymoma (70%)
γ -Aminobutyric acid B-receptor	SCLC (47%)
Glutamic acid decarboxylase receptor	Rare
N-methyl-D-aspartate receptor	Ovarian teratoma (20–59%), rarely testicular teratoma or SCLC.

AMPA, amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid.

BOX 36.2 Causes of metabolic spinal cord disorders

- Vitamin B₁₂ deficiency
- Folate deficiency
- Copper deficiency (copper deficient myelopathy)
- Vitamin E deficiency
- Toxic myelopathy (e.g. lathyrism, fluorosis, drugs)
- Hepatic myelopathy
- Metabolic myelopathy of genetic origin
 - Hexosaminidase A deficiency
 - Adrenomyeloneuropathy

of homocysteine to methionine and of methylmalonyl-CoA to succinyl-CoA. It is possible that the impaired synthesis of methionine leads to a depletion of S-adenosylmethionine, which is required for myelin synthesis.

The diagnosis is confirmed by measuring vitamin B₁₂ concentration in the serum. In some patients, the concentration may be only 'low-normal'. In borderline cases, measurement of homocysteine and methylmalonate concentrations can be useful. It is important that the diagnosis is made as early as possible as this is a potentially reversible condition. Magnetic resonance imaging of the spine often shows the spinal cord to be atrophic and can show signal change in the dorsal columns.

Folate deficiency

Folate deficiency is usually associated with other nutritional deficiencies. Folate antagonists (e.g. methotrexate, trimethoprim and pyrimethamine) are also potential causes. Neurological manifestations are rare and the same as with vitamin B₁₂ deficiency. Treatment is by folate replacement, although any vitamin B₁₂ deficiency should be treated first to prevent exacerbation of spinal cord degeneration.

Copper deficiency

Copper deficiency is rare and causes both haematological and neurological disease. Neurological manifestations include myelopathy, peripheral neuropathy and optic neuropathy. Copper deficiency was recognized in ruminants (swayback disease) long before it was identified in humans. The presentation can be similar to that of subacute combined degeneration of the spinal cord. It is usually secondary to gastric surgery, gastrointestinal diseases or total parenteral nutrition, or to excess intake of zinc or iron, which reduce copper absorption in the gut. Copper deficiency myelopathy has been attributed to ingestion of zinc contained in denture cream in some patients. Treatment is with oral or intravenous copper replacement.

Vitamin E deficiency

Vitamin E deficiency is rare, and causes a spinocerebellar ataxia, retinopathy, myopathy and anaemia. Poor diet is not usually sufficient cause unless associated with malabsorption. Abetalipoproteinemia is a rare inherited disorder of fat metabolism that results in poor absorption of dietary fat and vitamin E. Vitamin E deficiency is discussed further below (see ataxia).

Hepatic myelopathy

Hepatic myelopathy is a rare complication of chronic liver disease. It has been suggested that it is caused by the neurotoxicity of ammonia or other metabolites bypassing normal liver metabolism. It is characterized by spastic paraparesis with minimal sensory and sphincteric involvement. Diagnosis is a process of exclusion requiring normal CSF analysis and brain imaging. Liver

transplantation may result in improvement, especially if performed early in the course of the disease.

Hexosaminidase A deficiency

This is a progressive neurodegenerative disease with variable age of onset and rate of progression and hence variable prognosis. The clinical presentation of the chronic form of hexosaminidase A deficiency may mimic spinocerebellar degeneration, Friedreich ataxia, or amyotrophic lateral sclerosis (see below).

Adrenomyeloneuropathy

This is the commonest clinical variant of adrenoleukodystrophy, a disorder of peroxisomal fatty acid oxidation causing the accumulation of very long chain fatty acids in myelin, adrenal cortex and Leydig cells of the testes. Patients with an adrenomyeloneuropathy presentation of this X-linked recessive disorder present in their third decade with a progressive spastic paraparesis and sphincter dysfunction. A sensorimotor peripheral neuropathy may be a feature and ataxia and dementia are seen occasionally. Adrenal insufficiency will often have been present since childhood and there may be hypogonadism. Around 50% of heterozygous females will show some symptoms later in life. The clinical findings and magnetic resonance imaging point to the diagnosis, which is confirmed by demonstrating hypoadrenalism and elevated concentrations of very long chain fatty acids (VLCFAs) in plasma and cultured skin fibroblasts. Genetic testing is available. The only gene in which mutations are known to cause adrenoleukodystrophy is *ABCD1*, which codes for a peroxisomal membrane transporter protein, although molecular genetic testing is rarely required to confirm the disease, especially in a male. Treatment is with steroid replacement, symptomatic management and supportive care.

PERIPHERAL NEUROPATHY

Peripheral nerve disorders are the most common neurological diseases and their prevalence has been estimated to be 2–8% of the adult population. There are many causes of peripheral neuropathy and the range of clinical presentation is wide. Peripheral neuropathy can be categorized by the clinical pattern: mononeuropathy (e.g. carpal tunnel syndrome); multiple mononeuropathy (e.g. mononeuritis multiplex in vasculitis), or distal symmetrical polyneuropathy (e.g. neuropathy in diabetes mellitus). With the help of electrodiagnostic testing (nerve conduction studies and electromyography), neuropathies can be further categorized as demyelinating, axonal or mixed type of neuropathy. Appropriate laboratory tests may help to identify a specific diagnosis. Neuropathies with a specific metabolic basis are listed in [Box 36.3](#). Peripheral neuropathies of toxic or metabolic aetiologies are usually symmetrical, distal, sensorimotor and axonal. The American Academy of Neurology has published practice parameters to guide laboratory and genetic testing in distal symmetric polyneuropathy (see [Further reading](#)).

BOX 36.3 Metabolic causes of peripheral neuropathy

- Diabetes
- Chronic kidney disease
- Liver disease
- Endocrine
- Immune mediated and paraproteinaemic
- Nutritional deficiency
- Vitamin deficiency
 - Vitamin B₁₂
 - Thiamin
 - Pyridoxine
 - Vitamin E
 - Niacin (vitamin B₃)
 - Pantothenic acid (vitamin B₅)
 - Folic acid
- Neuropathy associated with bariatric surgery
 - Hypophosphataemia
 - Copper deficiency
 - Strachan syndrome
- Metabolic
 - Refsum disease
 - Porphyria
 - Fabry disease
 - Cerebrotendinous xanthomatosis
 - Tangier disease
 - Amyloid
 - Mitochondrial disorders
- Paraneoplastic

Neuropathy can present with a variety of signs and symptoms. Symptoms can be classified as either positive or negative. Positive symptoms reflect inappropriate nerve activities, whereas negative symptoms reflect reduced nerve activity. Positive sensory symptoms are burning or lancinating pain and paraesthesiae, whilst negative sensory symptoms are numbness, lost of proprioception and difficulty differentiating cold and hot sensations. Weakness and fatigue can be considered as negative motor symptoms, while cramps, muscle twitching and myokymia are positive motor symptoms. The findings on clinical examination of the sensory systems include sensory loss, trophic skin changes, sensory ataxia and Charcot joints. Features of motor dysfunction are dominated by lower motor neuron wasting, normal tone, absent reflexes and flexor plantar responses. Peripheral nerves should also be palpated to check for thickening, which occurs in leprosy, amyloidosis and acromegaly. Gastrointestinal and cardiovascular symptoms can be prominent features in autonomic dysfunction, causing bloating, constipation, diarrhoea, light headedness, palpitations and excessive sweating. Blood pressure should be checked with the patient lying and standing to document a postural drop caused by autonomic dysfunction. Neuropathies with a metabolic cause tend to be symmetrical, other than for some types related to diabetes, and with variable onset.

The investigations should be guided by the clinical picture. Polyneuropathy can arise in the course of many illnesses, particularly diabetes (Table 36.6). Initial investigations would reasonably include the tests listed in Box 36.4 and should yield a diagnosis in 60–90% of patients. The majority of patients will have diabetes or alcohol exposure.

TABLE 36.6 Most common causes of a symmetrical neuropathy

Condition	Proportion of symmetrical neuropathies (%)
Diabetes	11–41
Chronic idiopathic axonal neuropathy	10–40
Paraproteinaemia	9–10
Alcohol misuse	7
Chronic kidney disease	4

BOX 36.4 Initial investigation of patients with peripheral neuropathy

- Full blood count and erythrocyte sedimentation rate (ESR)
- Fasting glucose
- Thyroid function tests
- Creatinine
- Liver function tests
- Vitamin B₁₂ with metabolites (methylmalonic acid with or without homocysteine) if low-normal
- Antinuclear antibodies (ANA)
- Serum protein electrophoresis with immunofixation if required
- Chest X-ray

There are no diagnostically useful antibody assays. More invasive tests (Box 36.5) are best undertaken after consultation with a physician or neurologist with an interest in peripheral neuropathy. The nerve conduction tests will reveal whether the neuropathy is axonal or demyelinating.

Despite all efforts, about one-third of patients with peripheral neuropathies remain without a diagnosis. About 40% of these will be found to have impaired glucose tolerance, although how much this contributes directly to the development of neuropathy is still debated. Treatment with diet and exercise reduces the rate of progression to diabetes and may also improve the neuropathy, at least in the short term.

BOX 36.5 Further investigation of patients with peripheral neuropathy

- Glucose tolerance test
- Nerve conduction studies, electromyography
- Bence–Jones protein in urine
- Immunological tests for antineuronal antibodies, anti-ganglioside antibodies, markers for vasculitis, anti myelin-associated glycoprotein antibodies, other connective tissue disorders
- Microbiology tests including for Lyme disease; HIV serology in at risk patients
- Cerebrospinal fluid for cells, protein, oligoclonal bands
- Tests for Sjögren syndrome, e.g. salivary flow rate, Schirmer test, Rose Bengal test
- Search for carcinoma, lymphoma or myeloma
- Molecular genetic tests
- Toxicology screening

Patients with non-painful chronic idiopathic neuropathies have been found to have higher blood triglyceride concentrations and more exposure to environmental toxins compared with controls. Currently, it is unclear whether these observations will translate into any therapeutic benefit.

Small fibre painful axonal neuropathy

There is a small subset of patients in whom small nerve fibres alone are affected and in whom pain and temperature sensation but not large fibre modalities (vibration and proprioception) are impaired. Conventional clinical neurophysiological tests are normal because they do not assess small nerve fibre function. Most patients with a small fibre neuropathy have diabetes mellitus or at least impaired glucose tolerance but a few have Sjögren syndrome and other rare causes.

Diabetic neuropathies

Peripheral neuropathy is rarely encountered in young patients with newly diagnosed diabetes mellitus but diabetes presenting in older patients is frequently associated with a neuropathy and this may be the presenting problem. Studies have suggested that after 25 years of diabetes, about 50% of patients will have evidence of a neuropathy, most commonly chronic diabetic peripheral neuropathy. Poor glycaemic control, duration of diabetes, hyperlipidaemia (particularly hypertriglyceridaemia), increased albumin excretion and obesity are risk factors for the development of neuropathy.

Although distal symmetrical peripheral neuropathy is the commonest presentation, the manifestations of diabetic neuropathy are varied and can be subdivided clinically into the symmetric polyneuropathies and the focal or multifocal neuropathies (Box 36.6).

Symmetrical polyneuropathies

The onset of distal sensory and sensorimotor polyneuropathy is insidious, with mild symptoms of numbness and paraesthesiae affecting the toes and feet. A burning pain, worse at night, may be a prominent symptom. The typical findings on examination are sensory loss to pinprick, light touch and vibration sensation in a stocking distribution, with absent ankle reflexes. Occasionally, there may be mild distal weakness. Foot ulceration and neuropathic arthropathy are potentially serious complications related to loss of pain sensation. Ulcers tend to be

situated at pressure points – over the toes, heels, malleoli and metatarsal heads. In some patients, neuropathy may be precipitated by the institution of therapy with either insulin or oral hypoglycaemics and even dietary control. The neuropathy then becomes evident 4–6 weeks after starting treatment, with painful paraesthesiae affecting the lower half of the legs.

Acute painful neuropathy is a distinct entity characterized by marked weight loss over a short period of time followed by severe burning pains in the feet with contact discomfort. By maintaining good glycaemic control, patients slowly improve.

Proximal symmetrical motor neuropathy and asymmetrical proximal neuropathy (see below) are now termed lumbosacral radiculoplexus neuropathy (diabetic amyotrophy). There is often diffuse lower back pain at the onset, followed by progressive proximal weakness and wasting of the muscles. The knee reflexes are absent but sensory loss is minimal. Good glycaemic control leads to slow recovery over 12–30 months.

Focal and multifocal neuropathies

An isolated third nerve lesion is the commonest of the cranial nerve palsies, usually with sparing of pupillary function; in about half of patients, there is aching retro-orbital pain. The lesion is thought to be an infarct in the nerve trunk (i.e. it has microvascular aetiology).

Diabetic patients are more prone to isolated peripheral nerve palsies (mononeuropathy), suggesting increased susceptibility to compressive injury as the nerves are damaged at sites of pressure (e.g. the ulnar nerve at the elbow, the median nerve at the wrist).

Lower limb asymmetrical proximal motor neuropathy, also called lumbosacral radiculoplexus neuropathy, is probably caused by an underlying microvasculitis. The onset is usually subacute, with thigh pain, followed by asymmetric weakness and wasting of the lower limb muscles, most often affecting hip and knee flexors. Sensory loss is minimal. The weakness can be very severe. Recovery is slow, occurring over 2–4 years and is often incomplete.

Pathophysiology of diabetic neuropathy

The pathophysiology of diabetic neuropathy is only partially understood. A combination of direct axonal injury from hyperglycaemia, insulin resistance, central adiposity (visceral fat produces toxic adipokines), endothelial injury and microvascular dysfunction is possibly responsible. Hyperglycaemia is known to increase flux through the polyol pathway, increase nonenzymatic glycation of proteins and enhance oxidative stress.

Polyol pathway. Aldose reductase converts glucose to sorbitol, which is then converted to fructose by sorbitol dehydrogenase. In nerves from diabetic patients, accumulation of sorbitol leads to a compensatory reduction in other osmolytes such as myoinositol and taurine. The loss of myoinositol may lead to a reduction in nerve Na^+, K^+ -ATPase, which then causes nerve conduction defects. Aldose reductase inhibitors showed early promise by reversing the biochemical changes in experimental

BOX 36.6 Presentations of diabetic neuropathy

- Symmetrical polyneuropathy sensory/sensorimotor and autonomic neuropathy
- Lumbo-sacral plexopathy
- Focal and multifocal neuropathies
- Cranial nerve palsies
- Trunk and limb mononeuropathy
- Asymmetric lower limb motor neuropathy
- Thoracoabdominal neuropathy

diabetic nerves but, in clinical trials, these compounds have had no significant impact on human diabetic neuropathy.

Non-enzymatic glycation. The formation of irreversible advanced glycation end products of various components in the nerves of patients with diabetes is believed to contribute to the structural changes that are seen in diabetic neuropathy. Myelin components and axonal cytoskeletal proteins are glycated, leading to impaired cytoskeletal assembly with consequently abnormal axonal transport and axonal atrophy. Aminoguanidine, developed as a potential inhibitor of glycation, causes improvement in Na^+, K^+ -ATPase activity and nerve conduction velocity when administered to experimental diabetic rats. It has not been tested in humans.

Oxidative stress. Diabetes is associated with the increased production of free radicals, which have the potential to cause damage to arteries. Endothelial cell function is altered and this may impair nerve blood flow and nerve oxygenation. Thioctic acid (α -lipoic acid) reduces oxidative stress, and is available in some countries for the treatment of diabetic patients with neuropathic pain.

Immune mediated neuropathies

Immune mediated neuropathies are heterogeneous disorders, with a wide range of presentations. The pathological process affects the nervous system either directly (e.g. demyelination) or indirectly (e.g. secondary to vasculitis).

Acute inflammatory neuropathies and variants

Guillain–Barré syndrome is an acute immune mediated polyradiculoneuropathy, usually with demyelination. In two thirds of patients it is preceded by an infection. The presentation is acute and evolves over a few weeks, typically with an ascending flaccid paralysis, early loss of deep tendon reflexes and minimal sensory signs. Sphincteric functions are usually spared. Significant autonomic features are common and neuropathic pain may be problematic. The salient feature of CSF analysis is elevated protein with a normal cell count. The finding of an increased cell count warrants further investigation for conditions such as human immunodeficiency virus (HIV) and Lyme disease. Antibodies associated with Guillain–Barré syndrome are shown in Table 36.7.

A variety of infections can precede the onset of Guillain–Barré syndrome and these can be associated

with various anti-ganglioside antibodies. *Campylobacter jejuni* is associated with GM1, GM1b, GD1a, GalNAc-GD1a, GD3, GT1a and GQ1b. *Haemophilus influenzae* is associated with GM1 and GT1a. *Mycoplasma pneumoniae* and cytomegalovirus are associated with galactocerebroside GM2 antibody.

The mainstay of treatment for Guillain–Barré syndrome is intravenous immunoglobulin or plasmapheresis, usually in an intensive care setting.

Chronic inflammatory demyelinating polyneuropathies and variants including paraproteinaemic neuropathies

Chronic inflammatory demyelinating polyneuropathy (CIDP) is a heterogeneous group of acquired immune-mediated neuropathies. It may present in isolation or as part of a systemic disease. The classic form of CIDP is symmetrical with motor involvement greater than sensory. Weakness is present in both proximal and distal muscles. It can be associated with various systemic diseases such as HIV infection, connective tissue disorders and paraproteinaemia (see Chapter 30). Serum protein electrophoresis is therefore one of the investigations that should be carried out routinely in all adult patients presenting with a peripheral neuropathy. Treatment of CIDP includes intravenous immunoglobulin, plasmapheresis and immunomodulating treatment including steroids.

Monoclonal gammopathy of unknown significance

This can cause a neuropathy that is slowly progressive over many years and has a symmetrical distribution, first affecting the feet with numbness and paraesthesiae but later involving the hands. Muscle weakness and wasting occurs months or years after the onset of sensory symptoms. The cause of the neuropathy is unknown. The commonest paraprotein to be detected is IgM, which can bind to peripheral nerves via the carbohydrate moiety in myelin-associated glycoprotein (MAG). Antibodies to MAG are found in 60% of patients. IgG and IgA neuropathies are less common, but are more responsive than IgM neuropathy to immunotherapy and plasmapheresis.

Multiple myeloma

This rarely causes an isolated neuropathy. When it does occur, it is sensorimotor in type and may be axonal and demyelinating. Treatment of the myeloma may stabilize the neuropathy.

TABLE 36.7 Antibodies associated with Guillain–Barré syndrome

Clinical syndrome	Anti-ganglioside antibody	Isotypes	Comment
Acute inflammatory demyelinating polyneuropathy	LM1	IgG	Present in 5–20% of patients. Not clinically useful
Acute motor (and sensory) axonal neuropathy	GM1, GM1b, GD1a	IgG	
Miller–Fisher variant of Guillain–Barré syndrome	GQ1b, GT1a	IgG	Highly specific and sensitive, found in 90% of patients

Adapted from Willison HJ, Yuki N. Peripheral neuropathies and anti-glycolipid antibodies. Brain 2002; 125: 2591–2625.

Waldenström macroglobulinaemia

This is commonly associated with a sensorimotor neuropathy in addition to the more generalized symptoms of fatigue, weakness and a bleeding diathesis.

POEMS syndrome

Polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and skin changes (POEMS syndrome) has a peak incidence at age 50–60 years. It is distinct from the neuropathy associated with myeloma and its pathogenesis remains unknown. The main clinical features are of a progressive sensorimotor neuropathy associated with a monoclonal plasma cell proliferative disorder and osteosclerotic bone lesions. The light chain is invariably λ rather than κ , and when present, the heavy chain is either A or G and only occasionally M. The endocrine disturbance can appear at any stage of the illness and can involve adrenal, thyroid, pituitary, parathyroid, gonadal or pancreatic function. There is no specific diagnostic test for POEMS syndrome.

Chronic kidney disease and established renal failure

Peripheral neuropathies are not uncommon in patients with chronic kidney disease (CKD). A variety of peripheral nerve disorders may occur: carpal tunnel syndrome, ulnar and femoral neuropathy and uraemic polyneuropathy. The pathogenesis probably involves anatomical vulnerability, ischaemia, deposition of β_2 -microglobulin-associated amyloid and tissue compression around nerves.

The neuropathy associated with non-diabetic renal disease is of insidious onset, progressing over months and is present in 60–100% of patients on dialysis. Neuropathy generally develops only at CKD stage 5 and is characterized by paraesthesiae, tingling and burning of the feet, cramps and restlessness of the legs. Weakness is uncommon and, when present, is relatively mild. Patients may also develop autonomic features, with postural hypotension, impaired sweating, diarrhoea, constipation or impotence. Although there is a correlation between the impairment of nerve conduction and decreased glomerular filtration rate, starting dialysis or increasing its rate does not seem to improve an established neuropathy. However, improvement is seen after renal transplantation. The neuropathy has been attributed to the inability of dialysis membranes to clear ‘middle molecules’ (see Chapter 7), which are thought to be neurotoxic. The evidence to support this hypothesis is conflicting.

Liver disease

The prevalence of peripheral neuropathy in chronic liver disease is variable. Alcohol is the commonest cause of neuropathy associated with liver disease owing both to the direct neurotoxic effect of alcohol and to liver failure. Peripheral neuropathy can occur as a direct result of a primary liver disease although the underlying mechanism of neuropathy is unclear. It can also be part of a systemic disease that affects both the liver and peripheral

nervous system for example, vasculitis. Most patients with chronic liver disease have evidence of an axonal neuropathy. There may be an additional autonomic neuropathy, which carries a poor prognosis, and carpal tunnel syndrome is common. Acute peripheral neuropathy, especially Guillain–Barré syndrome, can be associated with viral hepatitis. Primary biliary cirrhosis is associated with a painful sensory neuropathy with sensory ataxia.

Endocrine disturbances

Hypothyroidism

Hypothyroidism frequently causes carpal tunnel syndrome because of deposition of mucopolysaccharide complexes within the carpal tunnel. Adequate thyroxine replacement is often the only treatment necessary.

Hyperthyroidism

Hyperthyroidism can also cause carpal tunnel syndrome that typically resolves with treatment. The mechanism is thought to be the same as in hypothyroidism. Thyroid storm can be associated with acute neuropathy.

Acromegaly

Acromegaly causes swelling of the median nerve from oedema and/or hypertrophy, resulting in an increased incidence of carpal tunnel syndrome. Treatment of the acromegaly improves the symptoms. There can also be a polyneuropathy, which is often painful. The relationship between peripheral neuropathy and excess growth hormone is not clear and can be complicated by coexisting diabetes mellitus.

Nutritional peripheral neuropathies

Nutritional deficiencies and excess alcohol are associated with peripheral neuropathies as well as encephalopathy and spinal cord disorders (see previous sections).

Vitamin B₁₂ deficiency

This is commonly associated with peripheral neuropathy, which may be precipitated by nitrous oxide anaesthesia. Measurement of plasma vitamin B₁₂ concentration may give a low-normal value even though there is a true functional deficiency. It is therefore recommended that, for patients with a neuropathy and borderline B₁₂ value, plasma methylmalonate and homocysteine concentrations should also be checked. In one review, patients with abnormal methylmalonate and homocysteine concentrations accounted for 15% of those previously labelled as ‘cryptogenic neuropathy’ as the plasma vitamin B₁₂ concentrations were within reference limits. Interestingly, a megaloblastic anaemia is rarely seen in patients with a vitamin B₁₂ deficiency state and neurological complications.

Intramuscular injection of vitamin B₁₂ is the standard treatment for such deficiency, but the recovery of neuropathy is variable, and may not occur at all.

Thiamin (vitamin B₁) deficiency

Also known as beri-beri, this is now rarely encountered in developed countries; when it does occur, it is most often associated with alcoholism and severe anorexia. Thiamin and its coenzyme thiamin pyrophosphate are required for mitochondrial function and myelin formation. A deficiency state has to be more prolonged before the peripheral nerves become affected than is the case with encephalopathy. The symptoms are numbness and pain that start in the feet and may later involve the hands. Although direct measurements of thiamin concentration are available, their use in diagnosing thiamin deficiency is controversial. If deficiency is suspected clinically, treatment should be given immediately either orally or intravenously. Reversal of the neuropathy is unpredictable and it may take 12 months for any improvement to be seen.

Vitamin B₆ (pyridoxine) deficiency

This deficiency causes an axonal neuropathy that develops very slowly and typically results in distal numbness and mild weakness. In contrast, a severe ataxic painful neuropathy can result from vitamin B₆ toxicity at doses of more than 200 mg/day.

Vitamin E deficiency

Vitamin E deficiency only rarely causes an isolated neuropathy; measuring plasma vitamin E concentrations should not be part of the routine screen in neuropathy. Chronic vitamin E deficiency in developed countries is usually associated with disorders of lipid absorption. Vitamin E has a role in maintaining cell membrane structure and as a free radical scavenger. After long exposure to low concentrations of vitamin E, ataxia and axonal neuropathy may develop. The neurological features can improve with oral vitamin E treatment and it is also recommended that high doses of vitamin A should be given at the same time.

Niacin (vitamin B₃), pantothenic acid (vitamin B₅) and folic acid deficiencies

These are also associated with peripheral neuropathy.

Chronic hypophosphataemia

This is seen most commonly in patients on long-term parenteral nutrition and may result in a Guillain-Barré like syndrome.

Copper deficiency

Copper deficiency may be associated with gastric surgery and may mimic subacute combined degeneration of the cord (see p. 689).

Neuropathy associated with bariatric surgery

Untreated, up to 62% of patients who have had bariatric surgery develop a peripheral neuropathy. The neuropathy is predominantly sensory. Some 31% develop features

of encephalopathy, and 28% have Wernicke-Korsakoff syndrome. The onset varies from 3 to 20 months following surgery; outcomes are mixed. The most frequent associated deficiencies are iron, thiamin, folate, vitamin D and calcium. Delayed (>2 years after surgery) deficiency of copper has also been reported. Current guidelines recommend trace element and vitamin replacement and careful monitoring after surgery to minimize the development of neurological and other complications.

Strachan syndrome

Previously termed Jamaican neuritis, Strachan syndrome was first identified in the West Indies during periods of famine. It is characterized by a painful, predominantly sensory, ataxic neuropathy, and may also be associated with optic neuropathy, sensorineural hearing loss, dorsal lateral myelopathy, glossitis and stomatitis. It is thought to be caused by multiple deficiencies of thiamin, niacin, riboflavin, pyridoxine and cobalamin, and hence treatment is administration of multivitamins, although recovery may only be partial.

Metabolic neuropathies**Refsum disease (hereditary ataxia polyneuritis)**

This is an autosomal recessive metabolic disease, characterized by accumulation of phytanic acid in plasma and tissues. It is caused by deficiency of peroxisomal phytanoyl-CoA hydroxylase (phytanic acid oxidase), which converts phytanic acid to α -hydroxyphytanic acid; mutations in the gene for this enzyme (located on chromosome 10p13) have been identified in most patients, although other genes may also be involved. A progressive symmetrical demyelinating sensorimotor neuropathy, cerebellar ataxia, retinitis pigmentosa initially presenting with night blindness, and ichthyosis are hallmarks of the disease. The age of onset of the disease can vary from childhood to adulthood, and as the condition progresses, the patient develops an ataxic gait, distal limb weakness and numbness. Other important clinical features include a 'salt and pepper' type of retinal pigmentation (flecks of dark pigment with areas of whitish depigmentation), nerve deafness, cataracts and cardiomyopathy. Skeletal deformities, including kyphoscoliosis, pes cavus, and shortened metacarpals and metatarsals, are also encountered. Optic atrophy, cataract and vitreous abnormalities cause further deterioration of vision.

The neuropathy starts distally with marked wasting and weakness. Symptoms of pain and paraesthesiae occur in some but not all patients. The tendon reflexes are lost as the condition progresses and there is loss of sensation (especially vibration sensation and joint position sense) in a glove and stocking distribution. The peripheral nerves may be enlarged. Without treatment, there is gradual deterioration, but about half of those affected may enter a phase of remission that can last for several years.

The diagnosis of Refsum disease is made on the basis of clinical findings and a plasma phytanic acid concentration >200 μ mol/L. However, plasma accumulation of phytanic acid is not specific for the condition as raised

concentrations may occur in other peroxisomal disorders. In addition, patients have been recorded with defective α -oxidation but normal phytanic acid concentrations. Therefore, to be certain of the diagnosis of Refsum disease, it has to be shown that there is a defect in α -oxidation. This can be done by measuring the production of $^{14}\text{CO}_2$ from a cultured skin fibroblast monolayer using (1- ^{14}C) phytanic acid as substrate. Cerebrospinal fluid protein concentration is often raised. Molecular genetic testing is available.

Phytanic acid is derived exclusively from the diet, therefore dietary control is the treatment of choice. This requires the elimination, as far as possible, of all dairy products and any fatty meat or oily fish. However, such a diet is protein and energy poor so liquid nutritional supplements are often required. In those who respond with a fall in plasma phytanic acid concentrations, progression of the neurological damage is halted, and in those with neuropathy, there is improvement in nerve conduction velocities. As dietary manipulation takes time to correct plasma phytanic acid concentrations, weekly plasma exchange can be used to attain normal concentrations quickly for patients with more rapid clinical progression.

Porphyric neuropathy

Porphyria is a rare but important cause of peripheral neuropathy. Its diagnosis depends on demonstrating an abnormality in haem metabolism (see Chapter 28). Only the hepatic porphyrias (acute intermittent porphyria, AIP, hereditary coproporphyria and variegate porphyria) are associated with neuropathy, the most severe attacks being associated with AIP. Within 2–3 days of the onset of an acute attack, the neuropathy begins with back and limb pains and the early development of marked symmetrical limb weakness, which may spread to involve the cranial nerves and respiratory muscles. The patient may have paraesthesiae and the sensory loss may be either in a symmetrical glove and stocking distribution or patchy. Autonomic features can also be present – hypertension, tachycardia, constipation and bladder disturbance. Other clinical problems such as seizures or psychiatric disturbance and a normal CSF protein may help to distinguish porphyric neuropathy from the Guillain-Barré syndrome. The exact pathogenetic mechanism is not clear but evidence suggests that both direct toxic effects of 5-aminolaevulinic acid and intracellular metabolic derangements, including reduced activity of Na^+, K^+ -ATPase, contribute to the neurological disorders.

Treatment of an acute episode includes avoiding any drugs that may exacerbate the condition, and appropriate sedation and pain relief. A glucose infusion should be commenced. The use of specific measures, for example haematin, is discussed in Chapter 28. Recovery is usually good but may be incomplete in some patients.

Fabry disease (*angiokeratoma corporis diffusum*; α -galactosidase deficiency)

This is an inherited X-linked recessive disorder of glycosphingolipid metabolism resulting from a deficiency of the enzyme ceramide trihexosidase (α -galactosidase).

The gene for this enzyme (GLA) lies on the long arm of the X chromosome between Xq21.33 and Xq22. However, females heterozygous for the condition have low enzyme activity and can be mildly affected clinically. The accumulating ceramide trihexoside consists of sphingosine (a long chain amino alcohol) linked to a long chain fatty acid. The trihexose (glucose–galactose–galactose) is linked to the primary alcohol group on C1 of ceramide. Because of the low ceramide trihexosidase activity, cleavage of the terminal galactose from the ceramide trihexoside does not occur.

The clinical effects are produced by the deposition of ceramide trihexoside (globotriaosylceramide) in the vascular endothelium. The characteristic manifestations are renal impairment, neuropathic pain and cutaneous angiokeratomas in a bathing trunk distribution. The onset of symptoms is in late childhood or early adolescence, with episodes of severe shooting and burning pains and paraesthesiae in the feet and hands (Fabry crisis), which may be severe enough to confine the patient to a wheelchair. Exercise, fatigue and emotional stress are recognized precipitants of acute painful episodes. The symptoms subside as the patient gets older. In contrast, the characteristic purple skin lesions, corneal dystrophy and renal involvement causing hypertension and CKD become more evident with age. Involvement of the myocardium and mitral valve disease (incompetence and prolapse) are very common, but established renal failure is the usual cause of death. Clinical examination reveals only minimal abnormalities suggesting a peripheral neuropathy. Anhidrosis may suggest autonomic involvement and nerve conduction studies show a mild axonal neuropathy with a selective loss of small myelinated fibres and unmyelinated axons.

Diagnosis in males is reliably made by measuring ceramide trihexosidase activity in plasma, leukocytes or cultured skin fibroblasts. Blood spots can be used for screening at-risk populations. Enzyme activity can also be measured in duodenal or jejunal biopsy material. Glycolipid can be measured in urine sediment. Molecular genetic testing is the most reliable method for the diagnosis of carrier females. Predictive testing is available for at-risk asymptomatic adults and for high risk pregnancies. Standard treatment is enzyme replacement therapy. There have been no human trials of gene replacement to date.

Cerebrotendinous xanthomatosis (*cholestanolosis*)

Cerebrotendinous xanthomatosis is a rare, autosomal recessive lipid storage disease with multiorgan involvement. The clinical manifestations usually start at infancy and develop during the first and second decades of life. Peripheral neuropathy, especially the subtype of axonal sensorimotor neuropathy, is common. Patients may also develop a progressive cerebellar ataxia, juvenile cataracts, chronic diarrhoea and tendon xanthomas. A deficiency of hepatic mitochondrial 27-hydroxylase has been identified. Biochemical findings include high plasma and tissue cholestanol concentration, normal to low plasma cholesterol concentration, decreased chenodeoxycholic acid, increased concentration of bile alcohols

and their glycoconjugates and increased concentrations of cholestanol and apolipoprotein B in cerebrospinal fluid. Molecular genetic testing for *CYP27A1*, the only gene in which mutations are known to cause cerebrotendinous xanthomatosis, is available.

Treatment with chenodeoxycholic acid inhibits abnormal bile acid synthesis and is most effective in reducing elevated plasma cholestanol concentrations and reducing bile alcohols. The use of hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitors (statins) may offer some help in slowing the neurological progression.

Tangier disease

This is a rare autosomal recessive disorder of lipid transport, characterized by a deficiency of plasma high density lipoprotein (HDL) and tissue storage of cholesteryl esters, especially in the tonsils, giving them a distinct orange–grey colour (see also Chapter 37). The cause of the neuropathy is not clear, but it seems unlikely that low HDL alone is responsible. Neuropathy occurs in about two-thirds of patients and may be the initial symptom in one half of cases, although in others it is evident only on clinical examination. The low plasma concentrations of HDL are thought to be from increased breakdown. There is hypocholesterolaemia with normal or increased concentrations of triglycerides. There is no specific treatment.

Amyloidosis

There are several types of amyloidosis, including primary, secondary, familial and dialysis-related. The associated constitutional symptoms of weight loss and other organ involvement (e.g. heart or kidneys) should provide the clue to consider amyloid as a cause of neuropathy.

Amyloid neuropathy occurs in approximately 15% of patients with primary amyloidosis, and the median duration of symptoms before diagnosis is 29 months. It can be symmetrical or focal, and can have variable degrees of sensory and/or motor involvement. The neuropathy is chronic, debilitating and relentlessly progressive. Autonomic disturbances also occur. Associated biochemical abnormalities are summarized in [Box 36.7](#).

Secondary amyloidosis occurs in conditions such as chronic infection and rheumatoid arthritis and will not be discussed in detail here.

Familial amyloid polyneuropathy (FAP) is usually dominantly inherited and caused by a mutation in the gene coding for transthyretin (TTR, prealbumin), a protein that is produced in the liver and normally functions as a carrier molecule for thyroxine and retinol. As the same mutation is found in Swedish, Portuguese and

Japanese patients, it is likely that the original mutation was in the Viking population that travelled to Europe and the Far East.

The diagnoses of primary and familial amyloidosis can only be made by demonstrating amyloid deposits in appropriately selected tissue. Initial samples are obtained from low-risk sites such as abdominal wall subcutaneous fat, bone marrow or rectum, and only if these are normal should an affected organ be biopsied. If TTR amyloid is detected, the gene should be sequenced to confirm the mutation, which will allow appropriate genetic counselling.

In FAP, younger patients with aggressive disease may be considered for liver transplantation, which seems to have a favourable effect on the course of neuropathy but not on cardiac or ocular lesions. Oral administration of tafamidis meglumine, which prevents misfolding and deposition of mutated TTR, is under evaluation in patients with FAP. High dose melphalan and stem cell transplantation can be effective. Supportive treatment such as management of neuropathic pain and gastroparesis is also very important. Treatment with melphalan and prednisone gives a survival benefit for patients with primary amyloidosis.

Mitochondrial disorders

The term ‘mitochondrial encephalomyopathy’ reflects the major neurological features – central nervous system and muscle – associated with mitochondrial disorders. Muscle disorders and the relevant mitochondrial enzyme defects are discussed in Chapter 33. It is not uncommon to find some minor peripheral nerve involvement in mitochondrial diseases (approximately 30% of patients), but it is rare for it to be the presenting or dominant clinical feature. [Table 36.8](#) summarizes the main associations.

Paraneoplastic neuropathies

The paraneoplastic neurological syndromes occur in <1% of malignancies and can present months or years before a cancer diagnosis. More than 25% of paraneoplastic neurological syndromes present as diseases of the peripheral nervous system, including sensory and autonomic neuropathies and Lambert–Eaton myasthenic syndrome.

BOX 36.7 Biochemical abnormalities associated with primary amyloidosis

- Proteinuria (80%) with elevated plasma creatinine concentration
- Bence–Jones protein (20%)
- Serum paraprotein (60–70%): IgG > IgA > IgM

TABLE 36.8 Neuropathy in mitochondrial disease

Type	Mitochondrial disease
Axonal	MELAS (A3243G mutation). Sensorimotor neuropathy can be acute or subacute
Demyelinating	MNGIE. Symmetrical sensorimotor neuropathy (occasionally axonal change predominates) MELAS

MELAS, mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes; MNGIE, mitochondrial neurogastrointestinal encephalopathy.

TABLE 36.9 Autoantibodies in paraneoplastic syndromes with peripheral neuropathy

Antibody	Malignancy	Neuropathy
Anti-Hu	Small cell carcinoma of bronchus (SCLC)	Sensory Sensorimotor Motor Autonomic
Anti-Ri Anti-Yo	SCLC, breast Breast, ovary	Sensorimotor Sensorimotor Motor
Anti-CV2	SCLC, breast, colon, prostate, thymus, non-Hodgkin lymphoma	Sensorimotor Autonomic
Voltage-gated potassium channel	Thymoma, SCLC, Hodgkin lymphoma	Neuromyotonia

The most common underlying malignancy in paraneoplastic neuropathies is a small cell carcinoma of bronchus, occurring in 50–75% of patients, presenting classically with a subacute sensory neuropathy and associated with anti-Hu antibodies (also known as antineuronal nuclear antigen antibodies or ANNA-1) in the plasma or CSF. In the majority of patients, the neurological involvement extends beyond the peripheral nervous system, and includes brain stem or limbic encephalitis and cerebellar degeneration.

The other nervous system-specific antibodies are outlined in Table 36.9. Although useful to confirm a clinical diagnosis of paraneoplastic syndrome, most of these markers are not specific enough to determine the origin of the cancer. Examination of CSF often shows an elevated protein with oligoclonal bands and an increased lymphocyte count. The tumour remains undetectable in 15% of patients.

The response to immunomodulatory therapies (steroids, immunosuppressants, intravenous immunoglobulin and plasma exchange) is variable.

MOVEMENT DISORDERS

The term ‘movement disorders’ refers to the neurological conditions that have as their predominant feature an excess or a paucity of movement, which may be voluntary or automatic. Disorders in which there is a predominant excess of movement are often referred to as hyperkinesias. Dyskinesia is also often used as a term referring to hyperkinetic involuntary movements. The five major categories of dyskinesias, in alphabetical order, are chorea, dystonia, myoclonus, tics and tremor.

Disorders with a paucity of movement are referred to as the hypokinesias. The characteristic hypokinetic disorder is Parkinson disease, in which there is bradykinesia (a slowness of movement), reduced amplitude of movements, rigidity and loss of postural reflexes. Tremor (a dyskinesia) is also a common feature of Parkinson disease.

Many of the movement disorders are associated with alterations in the basal ganglia or their connections. They

can also arise as a consequence of cerebellar disease, which typically results in impairment of coordination (asynergy, ataxia), problems with judgement of distance (dysmetria) and a kinetic limb tremor.

Myoclonus and many forms of tremors do not appear to be related primarily to basal ganglia pathology, and often arise as a consequence of abnormal neural activity elsewhere in the central nervous system. Myoclonus can also be present in diseases that involve the cerebellum, such as mitochondrial diseases and storage disorders (e.g. sialidosis and ceroid lipofuscinosis).

In the late onset sporadic movement disorders, protein misfolding and aggregation, with neuronal dysfunction and cell death, is the likely underlying pathological process. In diseases with a younger age of onset, genetic abnormalities leading to cell damage (often owing to deficiencies of proteins involved in mitochondrial function) or biochemical abnormalities (such as deficiencies in enzymes involved in dopamine synthesis) as well as metabolic or storage disorders are more likely.

Parkinsonism

Parkinsonism may be caused by many conditions other than Parkinson disease (PD). However, by far the commonest cause of parkinsonism is idiopathic PD, which is the commonest condition seen in adult movement disorder clinics. Whilst a large number of other movement disorders are genetic in aetiology, patients with a monogenic form of PD are rare. Abnormalities in ten genetic loci have so far been identified in PD. Mutations of the *PARK2* gene, which encodes the protein parkin (a component of a ligase complex that has a role in protein degradation) are the commonest autosomal recessive mutations in young onset patients. Mutations of *PARK8*, which result in abnormalities of LRRK2 (leucine-rich repeat kinase 2, a protein kinase) are the commonest dominant mutations identified. There are likely to be a large number of susceptibility genes for the development of PD, the most recently recognized significant one being a glucocerebrosidase gene mutation, which in homozygous individuals causes Gaucher disease.

The clinical syndrome of PD arises predominantly as a consequence of loss of nigrostriatal dopaminergic neurons but other neuronal populations including serotonergic, noradrenergic and cholinergic neuronal transmission are also important and are increasingly recognized as having a likely role in the development of the non-motor features of PD, such as autonomic dysfunction (postural hypotension, abnormal sweating, bladder, bowel and sexual dysfunction), mood disorders, sleep disorders and dementia.

The phenotype of monogenic PD is almost identical to that of sporadic disease; individuals are very responsive to medication but dystonia in the limbs may be present at onset and patients often develop early motor complications. The so-called ‘atypical parkinsonian syndromes’ are much less common than idiopathic PD and are generally not responsive to the usual first line treatment, levodopa, progress more rapidly and lead to a greater loss of independence with a mean survival of 3–9 years.

There are other rarer causes of parkinsonism, including mitochondrial disorders and neurometabolic disorders. Drug-induced parkinsonism from dopamine blocking drugs is an important differential diagnosis in anyone presenting with a relatively acute disorder.

Tremor

Tremor is a rhythmic oscillation of one or more body parts and is probably the commonest type of movement disorder presenting to neurologists. Tremor can be classified according to its phenomenology (rest, action, kinetic, task specific and body part involved), frequency and amplitude or, more specifically, by aetiology (e.g. Parkinson disease, essential tremor or secondary tremor as in thyrotoxicosis). The parkinsonian syndromes and other degenerative disorders are the commonest causes of rest tremor, along with secondary causes, such as toxins and drug therapies. The commonest causes of action or kinetic tremors are enhanced physiological tremor (stress, anxiety and exercise), essential tremor and cerebellar disease.

Dystonia

Dystonic contractions of muscles have a longer duration than myoclonus or chorea, involve simultaneous contractions of agonist and antagonist muscles, result in twisting (torsion) postures of the body parts involved, and consistently involve the same pattern of muscle movements.

Dystonia can be classified based upon the age of onset (important as the younger the age of onset, the more likely it is that it will spread to involve other body parts) the body part involved (focal, multifocal, hemidystonia, segmental or generalized) and additionally whether it is:

- primary (usually genetic or undetermined)
- a 'dystonia plus' syndrome with associated parkinsonism or myoclonus
- a secondary dystonia (as a consequence of brain injury or drug therapy)
- heredodegenerative dystonia (associated with diseases such as Huntington chorea)
- dystonia as a feature of other neurological diseases, such as Parkinson disease.

Adult-onset primary focal dystonia is the commonest form and typically affects the neck muscles (cervical dystonia or spasmodic torticollis). Task-specific action dystonias include writer's cramp and musician's dystonia. A comprehensive description of all of the dystonic disorders is beyond the scope of this chapter but important and treatable causes based on the aetiological classification are briefly described below.

DYT1 dystonia (Oppenheim dystonia). This is an autosomal dominant condition with a penetrance of between 30% and 40%. There is a deletion of one of a pair of CAG triplets in the *TOR1A* gene (also known as *DYT1*) on chromosome 9q. This gene codes for torsin A, a heat shock protein. The mutation is commoner in the Ashkenazi Jewish population (1 in 2000). The onset of dystonia is typically before the age of 40 and

it usually involves the upper or lower limbs first. It is a pure dystonic syndrome and conventional imaging (MRI) is normal. Patients with severe generalized dystonia as a consequence of this condition may respond well to deep brain stimulation.

Dopa-responsive dystonia (DRD). Some forms of dystonia respond to levodopa therapy (e.g. dystonia associated with Parkinson disease) but the term 'dopa-responsive dystonia' is specifically reserved for the syndrome arising as a consequence of an autosomal dominant mutation in the GTP-cyclohydrolase 1 gene. It is a disorder of tetrahydrobiopterin synthesis leading to inhibition of phenylalanine, tyrosine and tryptophan hydroxylases and failure of production of catecholamines and indoleamines. Dopa-responsive dystonia should be considered in anyone with early onset dystonia because treatment with L-dopa can lead to dramatic resolution of symptoms. It is an important differential to consider in any patient with presumed dystonic cerebral palsy or young onset spastic paraparesis. The most important diagnostic test is a trial of L-dopa. Other helpful tests include:

- sequence analysis of the GTP-cyclohydrolase 1 gene (positive in approximately 60% of patients with DRD)
- CSF analysis to detect reduced total biopterin and neopterin concentrations
- an oral phenylalanine loading test: a positive result is an elevated plasma phenylalanine:tyrosine ratio following oral phenylalanine.

The gene causing DRD has been mapped to chromosome 14q, although approximately 40–50% of patients with DRD have no identified mutation. If a patient is diagnosed with DRD, there should be an assiduous search for other possibly affected family members (misdiagnosed in some cases to have multiple sclerosis or cerebral palsy), who may benefit from L-dopa therapy.

Tetrahydrobiopterin (TH) deficiency is usually a more serious form of DRD and is transmitted as an autosomal recessive disorder, presenting with dystonia and parkinsonism in infancy. Biochemical analysis of CSF will provide some evidence, but ultimately testing for the gene mutation is required to establish the diagnosis. Decreased CSF concentrations of homovanillic acid and 3-methoxy-4-hydroxyphenylethylene glycol, with normal 5-hydroxyindoleacetic acid concentrations, are the biochemical hallmarks of TH deficiency.

Wilson disease

Wilson disease arises as a consequence of an inborn error of copper metabolism manifesting as hepatic cirrhosis and basal ganglia damage (hepatolenticular degeneration). It can present in a number of different ways and so any patient with a movement disorder under the age of 50 years should be tested. Nearly all patients with neuropsychiatric Wilson disease have Kayser–Fleischer rings (copper deposition at the edge of the corneas), hence slit-lamp examination is an effective screening tool. The average delay from symptom onset to diagnosis is close to 24 months. The initial manifestations of the illness are neurological in ~40% of patients (usually after the age of

12 years). The remainder present with features of liver disease (~40%) or a psychiatric illness.

Wilson disease is inherited as an autosomal recessive trait. The gene responsible lies on chromosome 13q14.3 encoding for a copper-transporting P-type ATPase (ATP7B). The enzyme binds copper in its large N-terminal domain and aids in intracellular processing in the hepatocyte. Intestinal absorption of copper is normal in Wilson disease. There are two pathways for copper excretion from the hepatocyte aided by ATP7B. One is by attachment to caeruloplasmin in the Golgi apparatus, and subsequent delivery of the copper-caeruloplasmin complex into the plasma. A second is promotion of copper excretion into the bile. Mutations of ATP7B lead to failure to excrete copper by both routes, with accumulation of free copper in the circulation and in the tissues, including liver, brain, eyes, kidneys and bones.

The diagnosis and treatment of Wilson disease are discussed in Chapter 14.

Chorea

The term *chorea* is derived from a Greek word meaning 'dance'. Historically, it was first used to describe St Vitus dance, which may have simply described chaotic but voluntary movements occurring in the context of religious fervour. Sydenham chorea describes a childhood chorea occurring as a parainfectious component of acute rheumatic fever but the best known 'choreic' disorder is probably Huntington disease.

Chorea consists of involuntary, continual, abrupt, rapid, brief, unsustained, irregular movements. Its causes can be divided into inherited and acquired. Huntington disease is the commonest inherited disorder: the rest are all rare. Inherited neurometabolic disorders such as the lysosomal storage disorders, amino acid disorders and glucose transporter deficiency syndromes can also have chorea as a predominant phenotypic feature. Of the acquired causes, focal striatal pathology (strokes and space occupying lesions), drug-induced disorders (such as the chorea seen as a complication of long-term dopaminergic therapy in Parkinson disease), chorea gravidarum and thyrotoxicosis are important causes, as are systemic lupus erythematosus, primary antiphospholipid syndrome and central nervous system (CNS) infection.

Myoclonus

The literal meaning of myoclonus is a 'quick movement of a muscle'. Myoclonus can be positive (an active muscle contraction) or negative (sudden and brief loss of muscle tone). The commonest pathological form is probably cortical myoclonus caused by metabolic or toxic encephalopathies. Brief muscle jerks as a consequence of cortical motor discharges, sometimes in response to action or sensory stimuli, are seen.

Asterixis is a form of negative myoclonus in which there is a brief loss of muscle tone, most commonly affecting gait and sustained upper limb posture. 'Liver flap', with an irregular loss of wrist extensor tone seen in hepatic failure and carbon dioxide retention, is a form of metabolic upper limb myoclonus.

Tics

Tics are brief and intermittent movements of muscles and groups of muscles resulting in sudden, abrupt and repetitive movements that may mimic gestures or be fragments of normal behaviour. Tics may therefore be simple or complex movements. Gilles de la Tourette syndrome is the commonest tic disorder and is characterized by motor and vocal or phonic tics beginning in childhood, often accompanied by obsessive-compulsive disorders, poor impulse control and other behavioural problems.

ATAXIA

Ataxia, meaning a 'lack of order', is a term which refers to the type of clumsiness produced by dysfunction of the cerebellum or cerebellar pathways. Impaired balance, gait disorder and clumsiness of the hands, together with dysarthria and jerky tremor of the eyes (nystagmus) are the typical clinical signs. The commonest causes of acquired cerebellar ataxia are acute and chronic alcohol consumption, prescribed drug intoxication (often anti-epileptic drugs), cerebrovascular disease, metastatic cancer and multiple sclerosis. The differential diagnosis in patients where these are excluded is very long and includes all types of neurological pathological processes. The most important feature in the history is the age at onset of ataxia. Ataxia presenting in childhood is more likely to be due to an inherited disorder and onset in adulthood is more likely to be a sporadic ataxia.

The autosomal dominantly inherited cerebellar ataxias (or spinocerebellar ataxias) may be caused by a daunting list of genetic abnormalities, many of which are trinucleotide repeat disorders. No single clinical feature is specific for a particular mutation and even within families there is considerable variability in the phenotype. There are a large number of recessive ataxias but the commonest by far is Friedreich ataxia, which has a prevalence of about 1 in 50 000.

Friedreich ataxia

In this condition, in addition to the ataxia and dysarthria, there may be sensory loss and corticospinal tract signs with absent reflexes. Neurophysiological testing reveals an axonal peripheral neuropathy and skeletal abnormalities (e.g. kyphoscoliosis), hypertrophic cardiomyopathy, and diabetes are common. The genetic abnormality is an expanded trinucleotide repeat of GAA in a gene on chromosome 9q coding for the protein called frataxin. Point mutations are less common. Frataxin is a mitochondrial protein encoded by nuclear DNA and is probably involved in iron transport. Excessive iron accumulation in mitochondria is a feature of the condition.

Ataxia with isolated vitamin E deficiency

This is a rare, but important, disorder that has a phenotype similar to Friedreich ataxia but with additional ophthalmoplegia and retinitis pigmentosa. It arises as

a consequence of defects in the *TTP1* gene coding for α -tocopherol transfer protein that incorporates α -tocopherol into lipoproteins secreted by the liver. The reason for its importance is that it can be treated with vitamin E.

Abetalipoproteinemia

This is a rare autosomal recessive deficiency of apolipoprotein B-containing lipoproteins. The abnormality arises as a consequence of microsomal triglyceride transfer protein (MTP) deficiency. The age of onset is typically in teenage years or early adulthood and the syndrome itself arises as a result of vitamin E deficiency. The main features are a cerebellar ataxia with polyneuropathy, acanthocytosis (characteristically shaped abnormal red blood cells), a coeliac syndrome, and retinal degeneration. It can be treated with high doses of vitamin E.

Ataxia telangiectasia

Ataxia telangiectasia arises as a consequence of a mutation in the 'ataxia telangiectasia mutated' (*ATM*) gene, which codes for a protein kinase that plays an important role in cell cycle control, apoptosis and DNA double-strand break repair. As well as an ataxic neurodegenerative disorder, the abnormality leads to an increased incidence of malignancy. The disorder begins early in childhood, typically at the age of 1–2 years, with truncal ataxia and dysarthria. Oculocutaneous telangiectasias, recurrent sinopulmonary infections and malignancies, particularly leukemia or lymphoma are characteristic features. Plasma α -fetoprotein concentration is elevated, there is evidence of both B cell and T cell immune deficiency and chromosome breaks can be identified.

Early onset ataxia with oculomotor apraxia and hypoalbuminemia

This is caused by a mutation in the aprataxin gene. Cerebellar ataxia and peripheral neuropathy are the commonest features along with oculomotor apraxia. Choreiform movements of the limbs and mental deterioration are also seen. Hypoalbuminemia and hypercholesterolemia are typical and brain MRI or computed tomography show marked cerebellar atrophy. Ataxia with oculomotor apraxia type 2 has also been identified with a similar clinical picture but with mutations in the senataxin gene.

Fragile X-associated tremor/ataxia syndrome

This condition is associated with a tremor that appears very similar to that of essential tremor. Other clinical features include a cerebellar ataxia and mild to moderate executive dysfunction. Both sexes can be affected. The disease is rare and is characterized pathologically

by intranuclear inclusions. An increased T2 signal in the middle cerebellar peduncle is a relatively specific MRI appearance.

Hexosaminidase deficiency (GM2 gangliosidosis)

This group of conditions is characterized by accumulation of GM2 ganglioside and glycosphingolipids within neuronal cells (and other cell types) owing to a genetically determined deficiency of the enzyme hexosaminidase. Depending on subunit composition, there are three possible isoenzymes: hexosaminidase A ($\alpha\beta$), hexosaminidase B ($\beta 2$) and hexosaminidase S ($\alpha 2$). The two classic subtypes are Tay–Sachs disease and Sandhoff disease.

In Tay–Sachs disease, there is absence of hexosaminidase A ($\alpha\beta$) and hexosaminidase S ($\alpha 2$). Hexosaminidase B ($\beta 2$) activities are normal or slightly elevated. The abnormality lies in the α -subunit, possibly owing to a mutation at the locus on chromosome 15. In Sandhoff disease, there are low activities of both hexosaminidase A and B. Hexosaminidase S activity is increased. There is a deficiency of the β -subunit owing to a mutation at the locus on chromosome 5.

There is a spectrum of clinical presentations of these conditions:

- *infantile onset* is the best known and presents at the age of six months with myoclonic seizures and progressive visual loss. A macular cherry-red spot is seen. There is progressive dementia and death within 4–6 years. This group includes both Tay–Sachs and Sandhoff disease
- *juvenile onset* is at 1–4 years, with dementia, seizures and ataxia. A cherry-red spot at the macula may or may not be present
- *an ataxic form* of GM2 gangliosidosis is characterized by a slowly progressive cerebellar or spinocerebellar ataxia with onset in late childhood or the adolescent period, which can be the manifestation of either hexosaminidase A or hexosaminidase A and B deficiencies
- *a spinal muscular atrophy form* is recognized with slowly progressive generalized muscle wasting and weakness. Only a deficiency of hexosaminidase A has been identified in this form, which can present in childhood or early adulthood
- *an adult onset* type is characterized by early onset of dementia, seizures and normal pressure hydrocephalus.

In addition to measuring hexosaminidase activities in plasma, leukocytes or cultured skin fibroblasts, a rectal biopsy should be done in adult onset cases to look for the characteristic changes in autonomic nerve fibres that are apparent on electron microscopy.

Cerebrotendinous xanthomatosis (cholestanolosis)

This is a leukodystrophy characterized by severe progressive ataxia and limb spasticity by the age of 30.

Characteristic appearances include tendon xanthomas and zonular cataracts. Dementia may occur at a young age before the other physical signs are evident and it can be difficult to make a clinical diagnosis at this early stage. Pathologically, there is widespread CNS demyelination with degeneration of the spinal cord. See page 695 for further details about the underlying biochemical abnormalities and potential treatment.

Neuronal ceroid lipofuscinosis

This is another condition in which the age of presentation determines the subtype. Early development is usually normal, with the age of onset from six months to 30 years. Patients present with myoclonus, ataxia and visual loss (except in the late onset variety). If seizures are a feature, they tend to be refractory to treatment. Most cases are autosomal recessive but the adult onset can be autosomal dominant. The incidence varies throughout the world with a particular predilection for the infantile subgroup in Finland of 1:13 000 live births.

Histological examination reveals an accumulation of autofluorescent lipopigment inclusions in body tissues and the diagnosis is made from biopsy of skin, conjunctival or rectal tissue. Abnormal accumulation of S-methylated methionine has been found in the brains of affected infants and of ϵ -N-trimethyl lysine in those from patients with the juvenile onset form. There is a profound deficiency of endo- β -N-acetylglucosaminidase, which is required for the cleaving of chilibiosyl residues. All forms of this condition lead to learning disability, seizures, ataxia and, in the early onset types, visual loss. Life expectancy is severely limited.

Coeliac disease

This is an immunologically mediated disease (see also Chapter 12) strongly associated with certain human leukocyte antigens. It is common and in large case series, neurological complications have been reported in up to 6% of patients. Cerebellar ataxia is one of the commonest neurological associations. The occurrence of anti gliadin antibodies in otherwise idiopathic ataxia requires further dedicated research studies and it remains possible that adult onset sporadic ataxia with no clear cause and associated coeliac disease is no more than a chance occurrence.

INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

Inflammation is a common pathological process within the CNS, by far the commonest form being multiple sclerosis (MS). Diagnosis is made on clinical grounds together with MRI evidence. Oligoclonal bands are present in the CNS in up to 95% of patients with clinically definite MS (see Chapter 34). Other inflammatory conditions affecting the CNS include systemic lupus erythematosus, Sjögren disease, Behçet disease, polyarteritis nodosa, paraneoplastic disorders, acute disseminated encephalomyelitis and vasculitis. Mimics of MS also

include granulomatous disorders (sarcoidosis, Wegener granulomatosis), diseases of myelin (metachromatic leukodystrophy, adrenomyeloleukodystrophy), vitamin B₁₂ deficiency, and certain infectious diseases (Lyme disease, neuroborreliosis, human T-lymphotropic virus type 1, HIV, progressive multifocal leukoencephalopathy and neurosyphilis).

CONCLUSION

The conditions discussed above represent a very small fraction of all neurological disorders. There are many more for which clinical biochemistry, at our current level of understanding, has little to offer in everyday clinical practice. These include headache, epilepsy, sleep disorders, cerebrovascular disease (beyond glucose and lipid chemistry), neurological malignancies, dementia and neurological trauma. There are also many conditions, for which biochemical perturbations are an important part of diagnoses, however a full discussion is beyond the scope of this chapter. These include many other inherited metabolic diseases, a multitude of which have neurological manifestations.

ACKNOWLEDGEMENT

We would like to acknowledge the contribution of J. Gareth Llewelyn, Mark Cossburn, Alistair Church and Huw R. Morris, who wrote the chapter for the previous edition of the book.

Lipids and disorders of lipoprotein metabolism

Graham R. Bayly

CHAPTER OUTLINE

INTRODUCTION 703

LIPIDS 703

- Sterols 703
- Fatty acids 704
- Triglycerides 704
- Phospholipids 704
- Eicosanoids 705
- Sphingolipids 705
- Nuclear lipids 706

LIPOPROTEINS 706

- Chylomicrons 707
- Very low density lipoproteins 708
- Intermediate density lipoproteins 708
- Low density lipoproteins 708
- High density lipoproteins 708
- Lipoprotein(a) 708
- Lipoprotein X 708

APOLIPOPROTEINS 708

- Apolipoprotein A 709
- Apolipoprotein B 709
- Apolipoprotein C 709
- Apolipoprotein D 710
- Apolipoprotein E 710
- Apolipoprotein M 710
- Apolipoprotein(a) 710

CHOLESTEROL ABSORPTION 710

TRIGLYCERIDE DIGESTION 711

BILE ACID METABOLISM 711

LIPOPROTEIN METABOLISM 711

CONCLUSION 736

INTRODUCTION

'Lipid' is the term used to describe a number of substances of diverse chemical structure that bear little functional relationship to each other but which have in common the property of being soluble in organic solvents and virtually insoluble in water. Lipoproteins are macromolecular protein complexes that allow hydrophobic lipids to be transported within the hydrophilic environment of the circulation. Lipids are essential for health, but excessive concentrations of cholesterol and triglycerides in the circulation, whether due to lifestyle factors or to inherited disorders of lipoprotein metabolism, are major factors in the development of atherosclerosis and cardiovascular disease. These conditions are the focus of this chapter, although other lipids and their functions are discussed briefly.

LIPIDS

Lipids can be broadly divided into sterols, including cholesterol; fatty acids or substances containing fatty acids such as triglycerides and phospholipids; eicosanoids; the fat-soluble vitamins (A, D, E and K), and sphingolipids. The major classes of lipids and their principal functions are summarized in Table 37.1.

TABLE 37.1 Major classes of lipids and their function

Lipid	Function
Cholesterol	Structural component of membranes; precursor for bile acid and steroid synthesis
Fatty acids	Energy source
Triglycerides	Energy store
Phospholipids	Structural component of membranes
Eicosanoids	Multiple, including effects on blood coagulation, bronchial and vascular contractility, reproduction
Sphingolipids	Central nervous system; blood group substances
Fat-soluble vitamins	
Vitamin A	Vision
Vitamin D	Calcium homeostasis and maintenance of bone integrity; various other functions, e.g. in immunomaturation
Vitamin E	Neural function; antioxidant
Vitamin K	Activation of clotting factors

Sterols

Cholesterol

Cholesterol (Fig. 37.1) is the major sterol in humans, being present in all body cells and most body fluids. The majority of the cholesterol in the body is in the free, unesterified form; it is this form that is the structural component of cell membranes. Cholesteryl esters in normal cells represent a store for future use and appear microscopically as intracellular droplets. Cholesterol is present in the diet but most cholesterol in the body is made by de novo synthesis from acetate. The rate-limiting step in the synthetic pathway is the conversion of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) to mevalonate, catalysed by the enzyme HMG-CoA reductase. The liver is responsible for most cholesterol synthesis. Cholesterol is a precursor for the synthesis of gonadal and adrenal steroid hormones, vitamin D and bile acids.

Although only a small amount of the body's cholesterol pool comes from dietary cholesterol, this has an important role in regulating the rate of cholesterol synthesis. The liver is the key organ in maintaining cholesterol balance; any excess cholesterol is excreted by the liver into the bile, either directly, or after conversion into bile acids.

Cholesterol and membranes. Cholesterol is a major component of cell membranes. Cholesterol and sphingomyelin form plasma membrane 'lipid rafts' or caveolae. Caveolae are cell surface invaginations found in differentiated cells and characterized by the presence of a protein, caveolin-1; they are sites where signalling molecules are concentrated. In order for these signalling molecules to function, the cholesterol concentration of the plasma membrane must remain constant. This is achieved by a regulatory system that senses the cholesterol content of

FIGURE 37.1 ■ Structure of cholesterol.

the membrane and modulates the transcription of genes encoding proteins involved in cholesterol synthesis (e.g. HMG-CoA synthase and HMG-CoA reductase) and cholesterol uptake (e.g. the LDL receptor). The system that does this is a family of membrane-bound transcription factors called sterol regulatory element-binding proteins (see p. 721).

Phytosterols

Phytosterols are sterols derived by plants; they differ slightly from cholesterol. There are two general types: δ^3 -phytosterols (e.g. β -sitosterol) and 5α -reduced phytosterols, otherwise referred to as 'stanols'. In natural foods, the sterols predominate. Both sterols and stanols are incorporated into commercially available foods promoted as cholesterol-lowering agents: they act by competing with cholesterol for absorption from the gut, and may lower plasma cholesterol concentration by 10–15%.

Fatty acids

Fatty acids (Fig. 37.2) have the general chemical formula RCOOH. Those relevant to human nutrition are the long chain (C_{12} – C_{20}) fatty acids containing even numbers of carbon atoms. They are further defined as saturated, for example stearic (C18:0); monounsaturated, for example oleic (C18:1), and polyunsaturated, for example linoleic (C18:2) and linolenic (C18:3), the second figures indicating the number of double bonds. In general, dietary saturated fatty acids originate from animals and the unsaturated fatty acids from plants. There are, however, exceptions, for example palmitic acid (C16:0) is saturated but derived from palm oil, and the ω -3 series, which are unsaturated but found in fish. The position of the carbon of the first double bond in the polyunsaturated fatty acids differentiates the ω -6 series (where the first double bond starts beyond the 6th carbon atom from

Saturated

Monounsaturated

Trans

Cis

FIGURE 37.2 ■ Structure of fatty acids.

the methyl end of the molecule), from the ω -3 series, where it starts beyond the 3rd carbon atom.

The long chain fatty acids are oxidized for energy production by a process known as β -oxidation; this results in the sequential shortening of the chain by two carbon atoms and the production of acetyl-CoA. Small amounts of long chain fatty acids are elongated to very long chain fatty acids (VLCFAs), which have a structural function in certain specialized cells.

Triglycerides

Triglycerides (see Fig. 37.3) comprise three fatty acids esterified with a glycerol backbone. 'Triacylglycerols' is the correct chemical name but they are more commonly known as 'triglycerides' and this term will be used throughout this chapter. Triglycerides are the major dietary fat. They are hydrolysed in the gut by lipases to fatty acids and monoglycerides. The monoglycerides undergo re-esterification in enterocytes and subsequent incorporation into chylomicrons. The major sites of endogenous triglyceride synthesis are the liver and adipose tissue. In normal circumstances, hepatic triglyceride is secreted in very low density lipoproteins (VLDL). In certain pathological states, triglyceride accumulates in hepatocytes, leading to hepatic steatosis. Adipose tissue triglyceride represents the major energy store of the body. Fatty acids are mobilized from adipose tissue triglycerides by the action of hormone-sensitive lipase (HSL), which is activated by glucagon and adrenaline (epinephrine) and inhibited by insulin.

Phospholipids

Phospholipids, like triglycerides, have a glycerol backbone; in phospholipids, this is esterified with two fatty acids and the third hydroxyl group is linked via a phosphodiester bond to an amino alcohol such as choline, serine or ethanolamine (Fig. 37.4). Phospholipids are therefore amphipathic molecules, with both hydrophilic (phosphate group) and hydrophobic (fatty acid) domains. This property is responsible for the capacity of phospholipids to solubilize other lipids and accounts for their location on the surfaces of lipoprotein molecules and in the cell membrane lipid bilayer.

FIGURE 37.3 ■ Structure of triglycerides.

FIGURE 37.4 ■ Structure of phospholipids.

Eicosanoids

This group of compounds takes its name from the systematic name of C_{20} (eicosa-) fatty acids from which they are derived. It includes prostaglandins, thromboxanes and leukotrienes. These were originally named because they were found in prostate, platelets (thrombocytes) and white cells (leukocytes), respectively. They have major effects on the immune response, reproductive function (including the induction of labour), cholesterol metabolism, smooth muscle function (causing vasoconstriction or dilatation), platelet aggregation and thrombosis.

Prostaglandins contain a substituted cyclopentane ring. Thromboxanes are oxygenated eicosanoids closely related to the prostaglandins. The rate-limiting step in the synthesis of both (see Fig. 37.5) is the phospholipase A_2 -mediated release of fatty acids from phospholipids. The principal precursor of prostaglandins is arachidonic acid ($\text{C}_{20:4}$, eicosatetraenoic acid). The first two steps in their synthesis are catalysed by prostaglandin endoperoxide synthase, which has both cyclooxygenase and peroxidase activity. The major products of this enzyme's activity are prostaglandin G_2 (PGG_2) and prostaglandin H_2 (PGH_2). These are both prostaglandins of the 2 series, having 2 carbon-carbon double bonds. Prostaglandin H_2 is converted to thromboxane A_2 (TXA_2) in platelets and prostacyclin (PGL_2) in the arterial wall. Arachidonic acid also serves as a substrate for various lipoxygenases, which generate the leukotrienes, inflammatory mediators and potent stimulators of muscle contraction. Eicosatrienoic acid ($20:3$) and eicosapentenoic acid ($20:5$), are alternative precursors for prostaglandin synthesis. The latter generates prostaglandins of the 3 series and leukotrienes of the 5 series.

Eicosanoid imbalance is of interest in atherosclerosis because several recognized risk factors for atherosclerosis, such as smoking, hypertension and diabetes mellitus, are associated with changes in eicosanoid production.

Aspirin inhibits cyclooxygenase, thereby reducing prostaglandin, especially platelet TXA_2 , synthesis. This is the rationale for the use of aspirin in the prophylaxis of atherosclerotic vascular disease. Steroids directly inhibit the release of arachidonic acid from membrane phospholipids.

Sphingolipids

The backbone of sphingolipids is sphingosine or a similar long chain base. The sphingolipids vary in chain length from C_{14} to C_{20} . Sphingosine itself has 18 carbon atoms and is formed from the condensation of palmitoyl CoA ($\text{C}_{16:0}$) with serine. Another fatty acid chain is joined to sphingosine through an amide link to form a ceramide. Ceramides have a free hydroxyl group that allows reaction with another component. If this contains a phosphate group, then the resultant products are a type of phospholipid called sphingophospholipids, also termed sphingomyelins (Fig. 37.6), which are essential components of nerve cells. If a carbohydrate group is attached to ceramide then glycosphingolipids, or simply glycolipids, are formed. These include cerebrosides, sulfatides, globosides and gangliosides. Glycosides of ceramide are referred to as cerebrosides: they are present in relatively high concentrations in brain. Many glycosphingolipids contain oligosaccharides; those that contain more than one molecule of sialic acid are referred to as gangliosides.

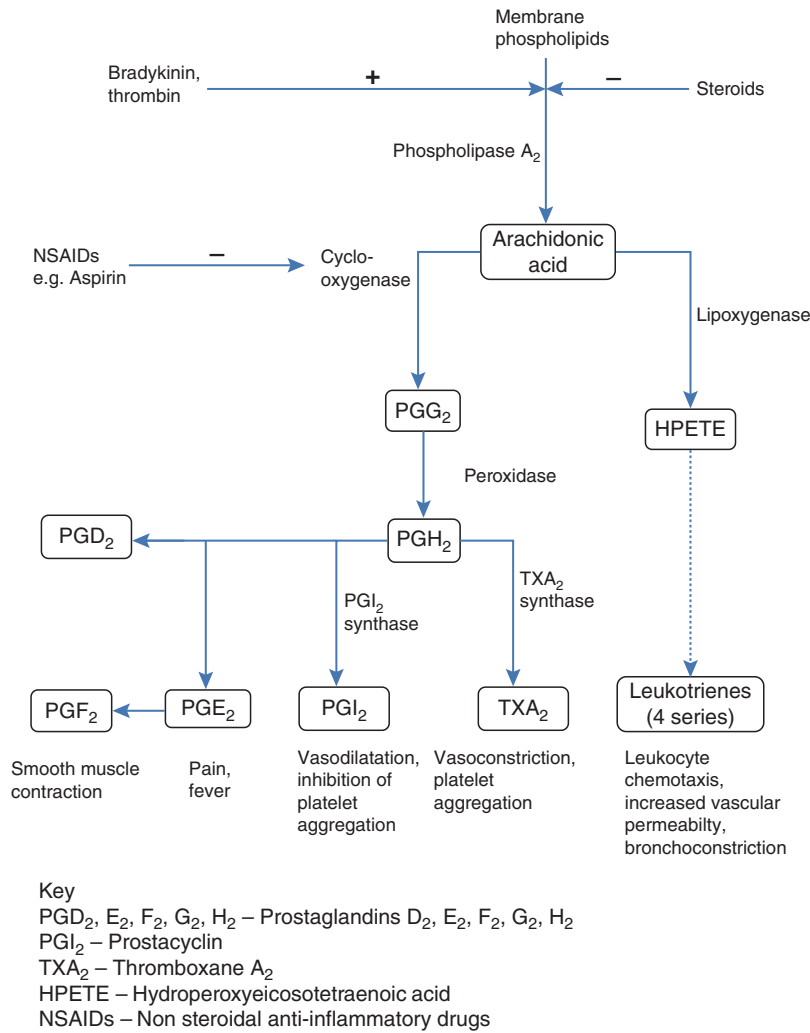

FIGURE 37.5 ■ An outline of eicosanoid synthesis.

Nuclear lipids

The nucleus is a highly structured organelle. For a long time, it was thought that lipids, which quantitatively are a minor component of the nucleus, only served a structural role and originated in the cytoplasm. It is now recognized that lipids serve other functions including signalling and modulating. Lipid-metabolizing enzymes have been demonstrated to be present within the nucleus. Phospholipids are the predominant class of lipid in the nucleus, with lesser amounts of cholesterol, free fatty acids, diglycerides and sphingolipids. The nucleus is surrounded by the nuclear envelope, which comprises an outer nuclear membrane and an inner nuclear membrane. Cholesterol has a structural role in the outer nuclear membrane, which is continuous with the endoplasmic reticulum; the inner nuclear membrane is associated with the nuclear lamina and chromatin and is deficient in cholesterol. The inner and outer nuclear membranes are joined by the pore membranes at the nuclear pores, which are associated with the nuclear pore complexes that allow passive transfer of molecules <50 kDa between the cytoplasm and nucleoplasm. The passage of larger molecules is energy dependent and requires a nuclear localization signal.

Lipids with very long chain fatty acids are associated with the pore membrane–nuclear pore complexes and appear to be essential for maintaining their function.

LIPOPROTEINS

The lipoproteins are submicroscopic, macromolecular complexes of lipids (cholesterol, triglycerides, phospholipids) and proteins (apolipoproteins, enzymes), held by non-covalent forces. The basic structure of lipoproteins is a hydrophobic core of triglycerides and/or cholesteryl esters surrounded by a layer of amphipathic phospholipids, unesterified cholesterol and proteins (see Fig. 37.7). The hydrophilic surface protects the hydrophobic core from the aqueous environment. Lipoproteins differ in their relative concentrations of protein to lipid and in their constituent lipids and proteins (Table 37.2). The densities of lipoproteins are inversely related to their size. The lipoproteins can be classified on the basis of their size, density or protein composition. The nomenclature of the lipoproteins is based on their density: chylomicrons (<0.95 g/mL); VLDL (0.95–1.006 g/mL); intermediate density lipoproteins (IDL) (1.006–1.019 g/mL); low density

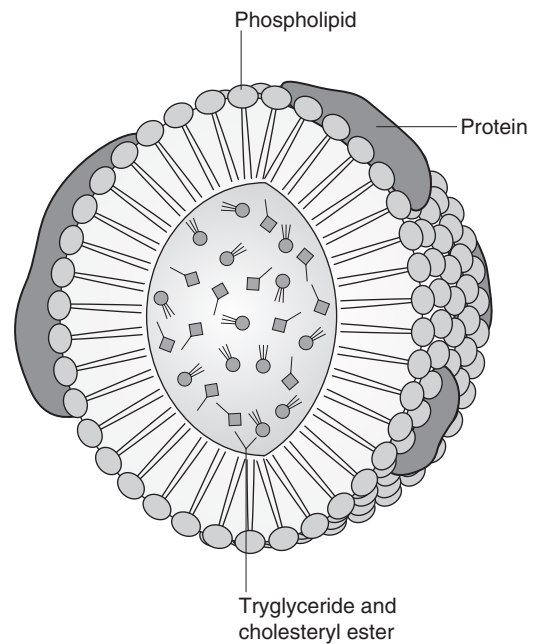

FIGURE 37.7 ■ Generic lipoprotein structure.

TABLE 37.2 Characteristics and major functions of apolipoproteins

Name	Chromosome	Amino acids	Mol wt (kDa)	Structural role	Function
A-I	11	243	29	HDL	LCAT activator
A-II	1	77	17 (dimer)	HDL	LPL regulator, LCAT and CETP cofactor
A-IV	11	396	44	Chylomicrons, HDL	LCAT activator
A-V	11	366	41	Chylomicrons, VLDL, HDL	LPL activator, chylomicron assembly
C-I	19	57	7	Chylomicrons, VLDL, HDL	LCAT activator
C-II	19	79	9	Chylomicrons, VLDL, HDL	LPL activator
C-III	11	79	9	VLDL, chylomicrons, HDL	LPL inhibitor, VLDL assembly
B-100	2	4536	500	VLDL/IDL/LDL	LDL-R ligand
B-48	2	2152	240	Chylomicrons and remnant particles	Structural component of chylomicrons
D	3	169	33		Transport of small lipophilic molecules
E	19	299	34	Chylomicrons, VLDL, remnants	LDL-R ligand for chylomicron remnants; LRP ligand
M	6	188	26		Transport of small lipophilic molecules
(a)	6	Variable	200–800	Lp(a)	

lipoproteins (LDL) (1.019–1.063 g/mL) and high density lipoproteins (HDL) (1.063–1.210 g/mL). The classes are not homogeneous; each represents a continuum of particles of differing size, density and fate and, in the case of VLDL, also of origin. The physicochemical characteristics of the principal lipoproteins are summarized in Table 37.3.

The apolipoprotein (apo) B-containing lipoproteins contain only one molecule of apo B per lipoprotein particle whereas multiple molecules of the other apolipoproteins are present in other lipoprotein particles.

Chylomicrons

Chylomicrons are the largest and most buoyant class of lipoprotein. The major protein component is apo B-48 but they also contain apo A-I, apo A-II and apo A-IV. After secretion, they acquire apo E and apo C from HDL. Chylomicrons are formed in the intestine and are the transport vehicle for dietary fat. The largest chylomicron particles have a diameter of over 1000 nm, whereas the smallest (75–200 nm) overlap with the apo B-100-containing lipoproteins. Some of the smaller particles within the chylomicron range are this size when they are

TABLE 37.3 Characteristics of the major lipoprotein classes

Lipoprotein	Hydrated density (g/mL)	Diameter (nm)	Molecular weight (kDa)	Electrophoretic mobility	Major apolipoprotein
Chylomicron	<0.95	75–1200	50 000–1 000 000	Origin	B-48
VLDL	0.95–1.006	30–200	10 000–80 000	Pre- β	B-100
IDL	1.006–1.019	25–35	5000–10 000	Slow pre- β	B-100
LDL	1.019–1.063	18–25	2300	β	B-100
HDL ₂	1.063–1.12	9–13	400	α	A-I (and A-II)
HDL ₃	1.12–1.21	7–9	200	α	A-I
Pre- β ₁ HDL	1.21	5–7	70	Pre- β	A-I

secreted by enterocytes, while others represent partially delipidated 'remnant' particles. The core of chylomicrons is composed predominantly of triglycerides derived from the diet.

Very low density lipoproteins

These are the largest of the lipoproteins containing endogenously produced lipids. The major protein component of VLDL is apo B-100 but they also contain apo C-I, apo C-II, apo C-III, apo E and small amounts of apo A. Like chylomicrons, VLDLs acquire the majority of their component apo E and apo C from HDL in the circulation; the core of VLDLs is composed predominantly of triglycerides. In contrast to chylomicrons, the triglycerides in VLDL are endogenous in origin.

Intermediate density lipoproteins

These particles are produced during the conversion of VLDL to LDL; their densities lie between those of these lipoproteins. The core of IDLs contains cholesteryl esters and triglycerides.

Low density lipoproteins

These are the major cholesterol-containing lipoproteins and represent the end-product of VLDL catabolism. The core of LDLs comprises mainly cholesteryl esters; the protein component is apo B-100.

High density lipoproteins

These are the smallest and densest of the lipoproteins. They may be sub-classified on the basis of size, density, shape, surface charge and electrophoretic mobility, as well as apolipoprotein composition (Table 37.3). High density lipoprotein is usually divided into three major subclasses. Nascent, discoidal or pre- β ₁ HDL comprises predominantly apo A-I and phospholipid. It is the preferred substrate for the ATP binding cassette transporter A1 (ABCA1), which actively exports free cholesterol from peripheral cells and macrophages. HDL₃ is formed from pre- β ₁ HDL by the acquisition of free cholesterol. It is the preferred substrate for lecithin cholesterol acyl transferase (LCAT), which esterifies free cholesterol, increasing the size of the particle and allowing the uptake of more free cholesterol, producing the larger and more cholesterol-rich HDL₂.

High density lipoprotein particles may contain apo A-I alone (LpA-I), both apo A-I and apo A-II (LpA-I/A-II) or apo A-II alone (LpA-II). LpA-I predominates in HDL₂, whereas LpA-I/A-II predominate in HDL₃. LpA-II represents a very small proportion of both HDL₂ and HDL₃.

Lipoprotein(a)

Lipoprotein(a) (Lp(a)) consists of LDL with its apo B-100 bound by a disulfide bond to apolipoprotein(a) (apo(a)). It is thought to be assembled extracellularly, either in the circulation or on the surfaces of hepatocytes.

The plasma concentration of Lp(a) is genetically determined and is inversely related to the length of the apo(a), so that the greater the chain length, the lower the concentration. Epidemiological studies suggest that a high Lp(a) concentration is an independent risk factor for cardiovascular disease (CVD), particularly in subjects with familial hypercholesterolaemia.

Lipoprotein X

Lipoprotein X is a lipoprotein that is found only in the plasma of subjects with cholestasis or who have familial lecithin cholesterol acyltransferase deficiency. It is composed of phospholipids, free cholesterol and proteins; the major protein is albumin but small amounts of apo C and apo D are also present. It contains no apo B. Unlike all other lipoproteins, it migrates towards the cathode on agarose gel electrophoresis.

APOLIPOPROTEINS

The apolipoproteins are amphipathic; their hydrophobic regions interact with the lipids in the lipoprotein particle while their hydrophilic regions allow interaction with the aqueous environment. They have three functions: they provide the structural element to the lipoprotein particles, they act as ligands for specific receptors and they also act as activators or inhibitors of specific enzymes involved in lipoprotein metabolism.

On the basis of electrophoretic mobility, HDL and LDL were originally referred to as α - and β -lipoproteins. The nomenclature of the corresponding apolipoproteins has arisen from this, apo A being the apolipoprotein derived from HDL (α -lipoprotein) and apo B being derived from LDL (β -lipoprotein).

Apolipoprotein A

Apolipoprotein A-I

Apolipoprotein A-I (apo A-I) (molecular weight 29 kDa) is the major protein of HDL, constituting 70–80% of HDL protein. It is synthesized primarily in the liver and small intestine. In addition to its structural role in HDL, it is also an activator of lecithin cholesterol acyltransferase (LCAT). Reverse cholesterol transport is dependent on the ability of apo A-I to promote cellular cholesterol efflux, to bind to lipids, to activate LCAT and, within mature HDL, to interact with lipid transfer proteins and specific receptors. The gene for apo A-I (*APOA1*) is part of a gene cluster on the long arm of chromosome 11 that includes *APOC3*, *APOA4* and *APOA5*.

Epidemiological studies have shown that plasma apo A-I concentrations, like those of HDL-cholesterol (HDL-C), are inversely related to cardiovascular risk.

Apolipoprotein A-II

Apolipoprotein A-II (apo A-II) (molecular weight 17 kDa, as homodimer) is also synthesized in the liver and, to a lesser extent, the small intestine. It accounts for about 20% of HDL protein. Some HDL contains apo A-I and apo A-II while some HDL contains apo A-I alone. A small amount of plasma apo A-II is associated with chylomicrons and VLDL. Apo A-II regulates lipoprotein lipase (LPL) activity, and is a cofactor for LCAT and for cholesteryl ester transfer protein (CETP). Like apo A-I, it appears to be inversely related to the risk of coronary disease. It may play a role in the remodelling of HDL, possibly by an effect on the reactivity of HDL towards lipid transfer proteins, enzymes and receptors, including the scavenger receptor B1 (SRB1) (see p. 719).

Apolipoprotein A-IV

Apolipoprotein A-IV (apo A-IV) (molecular weight 44 kDa) is synthesized only in the small intestine. It has been suggested that it may have a role in intestinal lipid transport, increasing the residence time of nascent chylomicron particles, allowing for greater expansion of their cores and thus capacity to transport triglycerides. The majority of apo A-IV in plasma exists in the free form. A small amount is associated with HDL and chylomicrons. In vitro, apo A-IV activates LCAT, although not as effectively as does apo A-I. It may also be necessary for the maximal activation of LPL by apo C-II. Over-expression of *APOA4* in mice results in increased plasma concentrations of total- and HDL-cholesterol, and triglycerides; despite this, it protects against diet-induced atherosclerosis. In humans, apo A-IV deficiency has been reported in patients with apo A-I and apo C-III deficiency, and this may account for the fat malabsorption seen in affected individuals.

Apolipoprotein A-V

The *APOA5* gene is expressed in liver, and apolipoprotein A-V (apo A-V), in contrast to other apolipoproteins, is present at very low concentrations in the plasma (approximately 5 nmol/L). It is found primarily in HDL.

Apo A-V affects plasma triglycerides through an effect on the lipolysis of the triglyceride-rich lipoproteins, possibly by binding to the lipoprotein, endothelial proteoglycans and LPL and thus stabilizing the lipolytic machinery. Although plasma concentrations of apo A-V show little correlation with plasma triglyceride concentration or with prevalence of cardiovascular disease, genetic studies have shown polymorphisms in *APOA5* to be strong determinants of both. Genetic variants in humans have been identified, in association with both high and low triglyceride concentrations. Deficiency leads to reduced LPL activity and a type V dyslipidaemia (p. 726).

Apolipoprotein B

This lipoprotein exists in two forms; apolipoprotein B-100 (apo B-100), which is made in the liver and is the structural protein of VLDL, IDL and LDL, and apo B-48, which is synthesized in the intestine and is incorporated into chylomicrons. Both apo B molecules remain with the lipoprotein particle in which they are secreted throughout the lifespan of that particle, unlike the other apolipoproteins, which readily transfer between different classes of lipoproteins. Increased plasma concentrations of apo B-containing lipoproteins confer an increased risk for the development of atheroma. Both forms of apo B are produced from the *APOB* gene; post-transcriptional editing of the mRNA in the intestine leads to the production of apo B-48.

Apolipoprotein B-100

Apolipoprotein B-100 (apo B-100) (molecular weight 500 kDa) is necessary for the assembly and secretion of VLDL. It contains several very hydrophobic areas that serve as strong lipid-binding domains. It also has several domains that could serve as binding sites for heparin-like molecules and form the basis for some of the cell surface interactions of the apo B-containing lipoproteins. In addition, apo B-100 contains an LDL receptor binding domain (amino acids 3100–3400), which allows the specific uptake of LDL by the LDL receptor.

Apolipoprotein B-48

The amino terminal 48% of apo B-100 forms apolipoprotein B-48 (apo B-48) (molecular weight 240 kDa). This apolipoprotein is produced from the *APOB* gene in the intestine by an mRNA editing process; a cytidine deaminase, *APOB* mRNA editing enzyme complex 1 (apoBec-1), binds to and acts on the cytosine molecule at base 6666 of the mRNA to form a uracil. The editing enzyme complex is only found in intestinal epithelial cells. Its action results in the glutamine 2153 triplet of CAA being converted into the stop codon, UAA. Thus protein synthesis is prematurely terminated at amino acid 2152 and, as a result, apo B-48 does not contain the LDL receptor binding domain present in apo B-100.

Apolipoprotein C

There are three apolipoprotein Cs, all of which are synthesized in the liver. In plasma, they transfer between the

triglyceride-rich lipoproteins (chylomicrons, VLDL and their remnants) and HDL.

Apolipoprotein C-I

Apolipoprotein C-I (apo C-I) (molecular weight 7kDa) forms a minor component of VLDL, IDL and HDL; it acts as an activator of LCAT.

Apolipoprotein C-II

Apolipoprotein C-II (apo C-II) (molecular weight 9kDa) is a component of chylomicrons and VLDL, in which it functions as an activator of LPL. Apo C-II is also found in IDL and HDL.

Apolipoprotein C-III

Apolipoprotein C-III (apo C-III) (molecular weight 9kDa) is synthesized mainly in the liver and, to a lesser extent, the intestine. It forms a major structural component of VLDL but is also present in chylomicrons and HDL. It acts as an inhibitor of LPL, and has more recently been shown to promote hepatic assembly and secretion of VLDL. Apo C-III also inhibits hepatic uptake of chylomicron and VLDL remnant particles, possibly by preventing interaction of apo E on these remnant particles with the hepatic receptor. High plasma apo C-III concentrations are associated with high plasma triglyceride concentrations.

Null mutations have been reported which are associated with low plasma triglyceride and LDL, and high HDL concentrations. However, the *APOC3* gene is close to the *APOA1* gene, and both are deficient in some forms of apo A1 deficiency, which cause low plasma HDL and triglyceride concentrations.

Apolipoprotein D

Apolipoprotein D (apo D) (molecular weight 33 kDa) is a lipoprotein-associated glycoprotein, forming a minor component of HDL, VLDL, IDL and LDL. It transports small hydrophobic ligands, including sterols and cholesterol. Apo D is associated with increased activity of lipoprotein lipase, and missense mutations cause elevated triglycerides. The apo D concentrations in the hippocampus and cerebrospinal fluid (CSF) of patients with Alzheimer disease are increased.

Apolipoprotein E

Apolipoprotein E (apo E) is a 299 amino acid glycoprotein (molecular weight 34kDa) synthesized by the liver and found in all classes of lipoproteins except LDL. It is involved in the control of chylomicron and VLDL remnant removal from the circulation. It also has antioxidant properties, and controls the efflux of cholesterol from cells, together with apo A-I. Apo E is a polymorphic protein: three common isoforms occur, which can be separated by isoelectric focusing and are designated apo E2, apo E3 and apo E4. Apo E2 differs from apo E3 by only a single amino acid, Cys being substituted for Arg

at residue 158. Apo E4 also differs from apo E3 by only a single amino acid, Arg being substituted for Cys at residue 112. The apo E3/E3 phenotype is the most common, comprising 50–70% of the population, whereas the apo E2/E2 phenotype is the least common, occurring in about 1% of the population.

The apo E3 isoform is associated with normal chylomicron and VLDL metabolism. The E2 isoform does not function as an effective ligand for the receptor-mediated uptake of remnant particles, having less than 2% of normal apo E3 binding to the LDL receptor. As a result, remnant lipoproteins tend to accumulate in the plasma of individuals homozygous for apo E2/E2. The E4 isoform is associated with higher concentrations of LDL-cholesterol than E3. Apo E4 homozygotes are also at increased risk of Alzheimer disease. Apo E synthesis is upregulated to aid cell repair in response to cellular stress or injury. Apo E4 is more susceptible to proteolytic cleavage than E2 or E3. This results in accumulation of intracellular fragments that cause changes in the cytoskeleton and the formation of neurofibrillary tangles.

Apolipoprotein M

Apolipoprotein M (apo M) (molecular weight 26kDa) fulfills the criteria for being an apolipoprotein as it is not found free in plasma but is predominantly associated with HDL. Like apo D, it is a member of the lipocalin family of proteins, which contain a binding domain for small lipophilic ligands, and may therefore have a role in transport of small lipid molecules. Although apo M is found in association with only 5% of HDL particles, where it may potentiate the antioxidant effect of HDL, its concentration is positively correlated with cholesterol concentration, suggesting that it may also have a role in cholesterol metabolism.

Apolipoprotein(a)

This apolipoprotein (apo(a)) is a large glycosylated protein of variable size (molecular weight 200–800 kDa). It contains multiple kinks in the polypeptide chain that are termed 'kringles'. Apo(a) is a homologue of plasminogen; it contains a single copy of plasminogen kringle 5, multiple copies of plasminogen kringle 4 and an inactive protease domain. Kringle 4 shows wide variation in the number of repeats within the apo(a) molecule. In a subpopulation of LDL particles, apo(a) forms disulphide bridges with apo B-100 to form a distinct lipoprotein class termed lipoprotein(a) (Lp(a)) (see p. 708). The function of apo(a) is unknown. It has a strong homology with plasminogen and may interfere with fibrinolysis.

CHOLESTEROL ABSORPTION

Cholesterol of both dietary and biliary origin is absorbed in the upper jejunum facilitated by a specific transporter protein, the Niemann–Pick C1-like 1 (NPC1L1) protein. This has 50% homology with the product of the *NPC1* gene, the Niemann–Pick C1 disease protein, which is involved in intracellular cholesterol trafficking. Niemann–Pick C1-like 1 protein transports plant sterols as well as cholesterol.

In small intestinal enterocytes, dietary cholesterol is released by the action of lysosomes and selectively esterified by acyl-CoA cholesterol acyltransferase 2 (ACAT2) prior to incorporation into chylomicrons. Any excess free cholesterol in enterocytes, together with any absorbed plant sterol, is excreted back into the intestinal lumen. The apical excretion of cholesterol and other sterols back into the gut lumen is a function of two hemitransporters of the ATP binding cassette transporter family, *ABCG5* and *ABCG8*. These are also responsible for the excretion of cholesterol and other sterols into the bile by hepatocytes. Expression of *ABCG5* and *ABCG8* in hepatocytes and enterocytes is under the control of the liver X receptor (LXR) and is induced by cholesterol feeding.

Cholesterol absorption reflects the imbalance between the movement of cholesterol across the brush border into enterocytes and its excretion by enterocytes back into the intestinal lumen. In normal individuals, the rate of cholesterol absorption correlates with the plasma sterol concentrations. The rate of cholesterol absorption is a predictor of benefit of statin treatment and response to ezetimibe (a selective inhibitor of NPC1L1). Those with higher rates of cholesterol absorption show reduced CVD benefit from statins, and increased cholesterol lowering with ezetimibe.

β -Sitosterolaemia, also referred to as phytosterolaemia, is an autosomal recessive disorder caused by mutations in *ABCG5* or *ABCG8*, in which there is increased absorption of dietary non-cholesterol sterols, and consequently an increased concentration (30–100-fold) of these sterols in blood. A ‘normal’ Western diet contains similar amounts (200–500 mg/day) of cholesterol and of non-cholesterol sterols (mainly plant but also some fish sterols). Approximately 55% of the cholesterol is usually absorbed, but normally less than 1% of the non-cholesterol sterols. In the absence of a functional *ABCG5/8* heterodimer, subjects overabsorb cholesterol and non-cholesterol sterols from enterocytes, because these transporters usually excrete some cholesterol and almost all non-cholesterol sterols back into the gut lumen. They also fail to excrete cholesterol and non-cholesterol sterols into the bile. These sterols become deposited at various sites in the body causing tendon xanthomas and premature atherosclerosis. Clinical features also include arthritis and haemolytic episodes. Treatment comprises a diet low in dietary sterols. Ezetimibe is also effective by inhibiting sterol absorption via NPC1L1.

TRIGLYCERIDE DIGESTION

Fat (triglyceride) digestion starts in the stomach, where lingual and gastric lipases hydrolyse 25–30% of ingested triglycerides into diglycerides and free fatty acids. In the duodenum, partially digested lipids mix with bile and pancreatic secretions. The latter contains a mixture of enzymes, including carboxyl ester lipase and pancreatic triglyceride lipase, which are capable of further hydrolysing dietary lipids to monoglycerides, free fatty acids, glycerol and cholesterol. The bile acids serve to solubilize the lipids and result in the formation of micelles, the contents

of which are absorbed by enterocytes. The absorption of monoglycerides is by passive diffusion. Within the enterocytes, triglycerides are resynthesized from free fatty acids and either monoglycerides or glycerol.

BILE ACID METABOLISM

Approximately 500 mg of cholesterol is converted, in the liver, to bile acids each day. This replaces the bile acids lost in the stools and represents approximately 5% of the bile acid pool, as the enterohepatic circulation is 95% efficient. The synthesis and secretion of bile acids, together with hepatic cholesterol secretion into bile, represents the major pathway for the elimination of cholesterol from the body. The synthesis of the full complement of bile acids from cholesterol requires 17 enzymatic steps. It is under negative feedback control: accumulation of bile acids leads to reduced activity of the key enzymes 7 α -hydroxylase and sterol 12 α -hydroxylase. The products of the bile acid synthetic pathway are the primary bile acids, cholic and chenodeoxycholic acids. In the gut, these primary bile acids are converted into secondary and tertiary bile acids by the action of anaerobic bacteria. The bile acids present in bile are a mixture of primary, secondary and tertiary, the latter being a consequence of enterohepatic circulation.

A number of enzymatic defects in the synthetic pathway of bile acids have been described; in general, the earlier in the pathway, the earlier in life clinical problems become manifest and the greater their severity. One of these disorders, due to defective sterol 27-hydroxylase activity, is cerebrotendinous xanthomatosis (CTX). In this condition, cholesterol and its 5 α -reduced derivative, cholestanol, accumulate in the blood and tissues. As a result of this accumulation, affected individuals develop tendon xanthomas like those found in familial hypercholesterolaemia. In CTX, however, these sterols also accumulate in myelin sheaths, leading to progressive neurological dysfunction.

The bile acids act to solubilize fats during absorption from the gut, but they also have a solubilizing action in the bile. If the proportions of bile acids, cholesterol and phospholipid in the bile are disturbed, there is an increased risk of gallstones being formed.

LIPOPROTEIN METABOLISM

Lipoprotein metabolism is summarized in [Figure 37.8](#).

Assembly of apolipoprotein B-containing lipoproteins

The assembly of the apo B-containing lipoproteins requires the coordinated synthesis of apo B and lipids. First, apo B has lipid added to it by microsomal triglyceride transfer protein (MTP) as it is being synthesized in the endoplasmic reticulum, to form a nascent lipoprotein particle. Further triglyceride may be added, forming VLDL2. In the next step, VLDL2 is exported from the endoplasmic reticulum by a membrane associated protein

FIGURE 37.8 ■ Outline of the metabolism of the apo B-containing lipoproteins.

complex comprising a coatome protein (COPII) and a GTPase (sar1b). The resulting sar1/COPII vesicles then fuse with the Golgi apparatus. Apo A-IV, apo C-III and apo A-I are added to the surface of the lipoprotein. In the presence of large amounts of free fatty acids and triglycerides, phospholipase D1 and extracellular signal-regulated kinase 2 (ERK2) increase the formation of lipid droplets that deliver lipids to the Golgi apparatus and promote the further addition of lipid to VLDL2, which is thereby converted to VLDL1.

In healthy individuals, most VLDL particles are small and relatively triglyceride-poor VLDL2. In conditions such as insulin resistance and type 2 diabetes there is increased production of larger, triglyceride-rich VLDL1, which in turn generate atherogenic remnants, small dense LDL particles and triglyceride rich HDL particles that are more readily catabolized, leading to low concentrations of circulating HDL.

Apolipoprotein B is constitutively synthesized, but the rate of production of apo B-containing lipoproteins is related to the availability of fatty acids for triglyceride synthesis. When there is a plentiful supply of fatty acids, the majority of the apo B that is synthesized is incorporated into lipoproteins; however, when fatty acids are in short supply, the apo B is degraded intracellularly.

Once lipoprotein particles are fully formed, they are transferred to the cell surface for secretion. Very low density lipoprotein particles (200nm) and chylomicrons (1000nm) are large in the context of classic transport vesicles (range 50–80nm). The intracellular transport of chylomicrons and some VLDL particles relies on sar1/COPII vesicles. Defects in the *SARA2* gene that codes for sar1b result in chylomicron retention disease, in which there is an inability to secrete chylomicron particles. Apo B-48 is absent from the circulation, but apo B-100 containing lipoproteins are still present, although in reduced amounts,

as sar1b is also involved in later stages of the VLDL pathway. Newly synthesized VLDL is not necessarily secreted from the cell, and may undergo immediate degradation. Sortilins (see p. 721) are now recognized to be involved in routing newly synthesized lipoproteins either to intracellular degradation or for export into the circulation.

Exogenous pathway

Enterocytes absorb dietary cholesterol and triglyceride from the gut in the form of free cholesterol, fatty acids and monoglycerides. After re-esterification, cholesteryl esters and triglycerides (containing fatty acids of chain length C_{14} and greater) are incorporated into the cores of chylomicron particles. Enterocytes synthesize apo B-48 (the major protein of chylomicrons), apo A-I, apo A-II and apo A-IV that, together with phospholipids, form the surface layer of chylomicrons. Apolipoprotein B-48 is essential for chylomicron secretion. Secretory vesicles bud off from the Golgi apparatus and migrate to the basolateral regions of enterocytes. Here, they fuse with the plasma membrane and release chylomicrons into the intestinal lymphatics. The chylomicrons pass in the lymphatics to the thoracic duct and enter the circulation via the left subclavian vein.

There is only one apo B-48 molecule per chylomicron particle and it remains with the particle throughout its life until, as a chylomicron remnant, it is taken up by the liver. In contrast, multiple copies of the other apolipoproteins are present in a single chylomicron particle. These other apolipoproteins do not remain with a given chylomicron particle throughout its life but are exchanged with other lipoproteins. From the time of secretion, chylomicrons undergo constant modification, gaining apo C-II, apo C-III, apo E, phospholipids and cholesterol from HDL. The acquisition of apo C-II allows chylomicrons to interact with LPL, which is sited on the vascular endothelium, especially in adipose tissue and muscle. Lipoprotein lipase acts extracellularly to hydrolyse triglycerides within the chylomicron cores; the fatty acids thus released can be either utilized as an energy source or re-esterified and stored in adipose tissue as triglycerides. As hydrolysis proceeds, the cores of the chylomicrons reduce in size and excess surface components – phospholipids, free cholesterol, apo C-II and apo C-III – are transferred back to HDL. Apolipoprotein C-III may exert a modulating effect on LPL-catalysed chylomicron hydrolysis. Both apo C-II and LPL are necessary for normal chylomicron catabolism. Continuing loss of apo C-II as the mass of individual chylomicron particles is reduced eventually prevents further interaction with LPL, and chylomicron remnant particles are generated. These remnants have a relatively high content of cholesteryl esters and apo E.

Chylomicron remnants are normally cleared quickly from the plasma by the liver. They enter the space of Disse through the fenestrated sinusoidal endothelium, together with lipoprotein lipase. The space of Disse is rich in heparan sulfate proteoglycans (HSPRG) as well as hepatic lipase (HL) and apo E, which are secreted by hepatocytes. The proteoglycans and apo E bind the remnants that are further catabolized by HL and LPL, becoming enriched in apo E and further depleted in

triglycerides. The remnants may then be taken up in a process directly mediated by HSPRG or via apo E binding to the LDL receptor related protein (LRP). This LRP mediated uptake may be of remnant particles alone, or of remnants bound to HSPRG. The LDL receptor is also able to uptake chylomicron remnants via apo E binding in a process independent of HSPRG.

The cholesteryl esters delivered to the liver by chylomicron remnant particles may be utilized for the synthesis of bile acids or membranes or be secreted in VLDL, while the apo B-48 undergoes degradation.

In summary, chylomicron metabolism essentially comprises two steps. In the first step, most of the fatty acids derived by peripheral lipolysis of chylomicrons enter adipocytes for storage as triglycerides or other cells for oxidation for energy production. A small fraction of the released fatty acids is bound to plasma albumin and transported in the blood to the liver and other tissues. The second step involves remnant particles delivering the remaining triglycerides and almost all the cholesterol to the liver.

Lipolysis in adipose tissue

Triglycerides in white adipose tissue, far from being an inert store, are continuously undergoing lipolysis and re-esterification. In the fasting state, and at times of increased energy demand, free fatty acids are released into the circulation and transported to other tissues. The lipolysis of triglycerides in white adipose tissue is initiated by adipose triglyceride lipase (ATGL). Its action results in the production of diglycerides and free fatty acids, but it has very little hydrolytic activity towards diglycerides. Hormone sensitive lipase, which until recently was thought to be the rate-limiting enzyme involved in the release of free fatty acids from adipose tissue, is actually rate limiting for the hydrolysis of diglycerides rather than triglycerides. The monoglycerides resulting from the action of HSL are acted on by a third enzyme, monoglyceride lipase (MGL).

Adipocyte lipolysis is controlled by a number of lipolytic and antilipolytic hormones, including catecholamines and insulin.

Endogenous pathway

Hepatocytes are the originators and often also the acceptors of particles involved in the endogenous pathway, which shows many points of similarity with the exogenous pathway.

The liver secretes VLDL, a triglyceride-rich lipoprotein. The triglycerides are produced either de novo by hepatocytes or taken up from the plasma. These triglycerides, together with cholesterol derived from chylomicron remnants or from de novo synthesis, are secreted with phospholipids and apo B-100 as nascent VLDL. Some apo C-I, apo C-II, apo C-III and apo E are also present in the nascent VLDL particle, but the majority of these apolipoproteins are probably acquired from HDL within the circulation in the same way as in the exogenous pathway. In situations where there is an excess of hepatic triglyceride, large VLDL particles are secreted. Large VLDL particles are also secreted in familial hypertriglyceridaemia, whereas

in familial combined hyperlipidaemia (see p. 724), the rate of VLDL secretion is increased but a relative scarcity of triglycerides ensures that the individual VLDL particles are smaller and relatively poor in triglycerides.

The initial metabolic transformation of VLDL is a progressive LPL-mediated lipolysis analogous to the process involving chylomicrons. This requires apo C-II and produces cholesteryl esters and apo E-rich remnant particles. As in chylomicron metabolism, the surface components of VLDL are transferred back to HDL as the cores shrink. VLDL remnants comprise small VLDL particles and IDL. About half are cleared by the liver in a process that involves uptake by LRP, which recognizes apo E. The remainder undergoes further hydrolysis by HL to form LDL.

Low density lipoprotein is the major cholesterol-carrying lipoprotein in the plasma and usually accounts for 70% or more of the total plasma cholesterol. Virtually the only protein contained in the LDL particle is a single molecule of apo B-100, which acts as the ligand for the LDL receptor. LDL receptors are present on hepatocytes as well as the cells of peripheral tissues. Approximately 50% of plasma LDL uptake by the LDL receptor-mediated mechanism is hepatic. The major determinant of plasma LDL-C concentration is the number of functional LDL receptors.

Low density lipoprotein receptors recognize both apo B-100 on LDL and apo E on remnant particles and HDL. Once a lipoprotein has been bound to the receptor, the receptor-lipoprotein complex localizes in the coated pit region from where it is internalized by endocytosis. The LDL receptor is recycled while the lipoprotein undergoes lysosomal degradation to unesterified cholesterol

and amino acids. The cholesterol thereby released is available for further metabolic transformations as well as to regulate the transcription and/or translation of the HMG-CoA reductase and the LDL receptor genes. The cholesterol may be re-esterified by the action of ACAT and stored, or may be utilized for bile acid, steroid or membrane synthesis.

Hepatic cholesterol trafficking

The liver is the key organ for the regulation of cholesterol; not only is it responsible for the majority of cholesterol synthesis but it also acquires cholesterol from all lipoprotein classes. The cholesterol secreted into bile is mostly derived from lipoproteins with only a small contribution coming from de novo hepatic synthesis or hepatic cholesteryl ester stores. This involves preferential trafficking of lipoprotein-derived cholesterol, which involves multiple cholesterol transport-related gene products, the expression of which is regulated by the concerted activity of sterol-activated transcription factors.

High density lipoprotein metabolism (see Fig. 37.9)

Assembly of lipoproteins

Apo A-I is exported into the circulation by liver and intestinal cells. Here it may combine with phospholipids to form nascent (discoidal or pre- β_1) HDL.

Pre- β_1 HDL may also be formed from spare surface components of triglyceride rich lipoproteins (VLDL, chylomicrons, and their remnants) following the action of lipases.

FIGURE 37.9 ■ Outline of HDL metabolism and its role in reverse cholesterol transport.

Cholesterol efflux

Except in steroidogenic tissues (adrenals and gonads), the catabolism of cholesterol in peripheral cells is limited to its partial degradation by 27 α -hydroxylase. Excess free cholesterol has to be removed. This occurs by an active process, or by diffusion. Free cholesterol is actively exported by ATP binding cassette transporter A1 (ABCA1), which preferentially binds pre- β_1 HDL. Expression of ABCA1 is regulated by the liver X receptor/retinoid X receptor (LXR/RXR) system; the physiological ligand of LXR is oxysterol, the cellular concentration of which increases in parallel with that of cholesterol.

Diffusion is non-specific efflux of cholesterol from cell surface membranes to an extracellular 'acceptor'. All HDL particles can act as acceptors of free cholesterol. This is a bidirectional process. Net efflux is increased by the activity of LCAT, which esterifies free cholesterol in lipoproteins, thereby increasing the concentration gradient between HDL and the cell membrane. Cholesterol efflux by diffusion is not as dependent on the activity of LCAT as previously thought, as it may also be facilitated by the SRB1 and the ATP binding cassette transporter G1 (ABCG1). The SRB1 binds preferentially to larger (HDL2) particles. In peripheral cells, SRB1 forms a hydrophobic channel through which free cholesterol can readily diffuse, enhancing the rate of efflux. The ABCG1 increases the concentration of free cholesterol within the plasma membrane and makes it more readily desorbed. This promotes the step which is normally rate limiting in cholesterol efflux by diffusion. Cholesterol efflux capacity correlates inversely with atherosclerosis, after adjustment for plasma HDL concentration. However, although both plasma apo A-I and HDL predict efflux capacity, they account for <50% of the variation seen. This emphasizes the importance of overall flux through the pathway of reverse cholesterol transport rather than simply plasma HDL concentration in the development of atheroma.

Reverse cholesterol transport

Free cholesterol exported from peripheral cells or macrophages combines with apo A-I to form 'nascent' pre- β_1 HDL. Esterification of free cholesterol on the surface of the HDL particle by LCAT produces hydrophobic cholesteryl esters that migrate to the centre of the particle, releasing capacity to accept more free cholesterol, and transforming it into a larger, more spherical particle (HDL3). HDL3 accepts more cholesterol by active export or facilitated diffusion, and LCAT further increases particle size. More free cholesterol, phospholipids and apolipoproteins (C-II, C-III, E) are also transferred from triglyceride-rich lipoproteins (TGRLs) and their remnants as triglycerides are removed from these particles by the action of LPL. The HDL particle increases in size to become HDL2, which contains a greater proportion of apo A-II and is the preferred ligand for the hepatic SRB1 receptor. When HDL2 is bound, cholesteryl esters are taken up into the cell, converted to free cholesterol and

may then be excreted in bile. Scavenger receptor B1 is present on the basolateral membrane of hepatocytes where it promotes influx of cholesterol, and on the canalicular membrane where it promotes efflux to bile. Cholesterol taken up into the hepatocyte by SRB1 may also be trafficked across the cell and pumped into bile by ABCG5/G8 at the canalicular membrane.

High density lipoprotein 2 may also transfer cholesterol to TGRLs in exchange for triglycerides, catalysed by CETP. This potentially 'diverts' cholesterol from the 'normal' reverse cholesterol transport pathway into potentially atherogenic lipoproteins, and may therefore be proatherogenic. However, in transferring cholesterol to the VLDL/LDL pathway, it allows for cholesterol clearance via hepatic LDL receptors, and may theoretically be antiatherogenic in situations where clearance of cholesterol from HDL via SRB1 is saturated. The triglycerides that enrich HDL as a result of this exchange are hydrolysed by lipases and this results in small dense HDL, which is more readily catabolized by the kidney, depleting plasma HDL. This CETP-mediated exchange is increased in the presence of increased circulating amounts of TGRLs and this accounts for the inverse relationship between plasma triglycerides and HDL. HDL2 is a substrate for hepatic and endothelial lipases (ELs) and secretory phospholipase A2 (sPLA2). These may regenerate pre- β_1 HDL or HDL3, but if HDL is triglyceride-enriched by excessive CETP activity then the HDL particle may disintegrate, promoting catabolism in the kidneys.

High density lipoprotein therefore exists as a complex interchange of lipoproteins. ABCA1, ABCG1, LCAT and LPL all increase particle size, while CETP, SRB1, HL, EL and sPLA2 tend to reduce size, with net transport of free cholesterol from peripheral cells to the liver. These interactions also have the potential to 'divert' cholesterol to atherogenic TGRLs, with loss of apo A-I, especially in conditions where TGRLs are increased.

High density lipoprotein cholesterol (HDL-C) shows an inverse relationship with atherosclerosis in epidemiological studies, although this is not a straightforward as previously thought. Very high concentrations of HDL-C are associated with increased risk of atherosclerosis, which could be due to HDL being 'trapped' as a 'dysfunctional' pool in plasma rather than reflecting an increased flux through the reverse cholesterol transport pathway. This highlights the importance of qualitative changes in HDL that may affect its function, and the overall net flux through the reverse cholesterol transport pathway (see p. 714) as well as total plasma concentration.

High density lipoprotein has direct anti-atherogenic properties including:

- downregulation of the expression of adhesion molecules on the surface of the vascular endothelium
- inhibition of platelet aggregation
- prevention of the inhibition of nitric oxide synthase by oxidized LDL
- upregulation of ATP binding cassette transporter A1 (ABCA1) and activation of intracellular signalling leading to stimulation of cholesterol efflux.

In addition, paraoxonase, an ester hydrolase that is transported bound to HDL, has antioxidant properties.

ENZYMES INVOLVED IN LIPOPROTEIN METABOLISM

Lecithin cholesterol acyltransferase

Lecithin cholesterol acyltransferase (LCAT) is a glycoprotein that has both a phospholipase A2 and an acyltransferase action. It is essential for the normal maturation, interconversion and rearrangements of all lipoprotein classes and is involved in reverse cholesterol transport. It is synthesized by the liver and circulates in the plasma reversibly bound to HDL and LDL. Lecithin cholesterol acyltransferase catalyses the esterification of free cholesterol on the surfaces of lipoproteins. The preferred substrate for LCAT is HDL, which contains apo A-I, its most potent activator. The ability of apo A-I to activate LCAT depends on the lipid composition of HDL, being most effective in small HDL particles, which have a low ratio of phospholipid to apo A-I. The cholesteryl esters formed by the action of LCAT expand the cores of the HDL particles. Lecithin cholesterol acyltransferase activity may be a rate limiting step in reverse cholesterol transport, making it a potential therapeutic target in the prevention of atherosclerosis, although evidence as to the effect of LCAT on the development of atherosclerosis is conflicting. Both recombinant LCAT and small molecule activators of LCAT activity are being explored as possible therapies.

Mutations in the *LCAT* gene cause either familial LCAT deficiency, when there is no LCAT activity or fish eye disease, with partial LCAT deficiency (see p. 729).

Lipases

Lipoprotein lipase

Lipoprotein lipase (LPL) is an extracellular enzyme that is bound by the glycosaminoglycan heparan sulphate to capillary endothelial cells. It is present in large amounts in the capillaries of adipose tissue and muscle, both skeletal and cardiac. Lipoprotein lipase belongs to the triglyceride lipase gene family, which also includes HL, EL, and pancreatic triglyceride lipase (PTL). It is the major lipolytic enzyme involved in the intravascular metabolism of the triglyceride-rich lipoproteins. Myocytes and adipocytes secrete LPL in a catalytically inactive form, which is then transported to the capillary endothelial surface.

Along with HL and EL, LPL is a homodimer. Interaction of the dimer with heparan sulphate on the endothelial surface serves to anchor and stabilize the LPL. LPL monomers that are catalytically inactive are found in the circulation in association with remnant particles and may play a role in enhancing their clearance. Presence of apo C-II is required for full activity.

Lipoprotein lipase catalyses the partial hydrolysis of the core triglycerides of chylomicrons and VLDL to monoglycerides and fatty acids. The fatty acids are taken up by the tissue and either re-esterified and stored (in adipose tissue), utilized as an energy source (in muscle) or secreted (in lactating breast tissue). The monoglycerides are further hydrolysed to glycerol and fatty acids.

Lipoprotein lipase binds to heparin, which results in its release into the circulation. This is used in the assay

of LPL activity (post-heparin lipolytic activity, PHLA). Lipoprotein lipase regulates the plasma concentrations of triglycerides and HDL. Individuals with low PHLA, such as those who are heterozygous for LPL deficiency, have high triglyceride and low HDL concentrations in plasma, and an increased risk of atherosclerosis.

A large number of mutations in the *LPL* gene have been described. Some are a cause of the familial chylomicronaemia syndrome (see p. 725), while others have less severe effects. It is estimated that 20% of patients with hypertriglyceridaemia are carriers of *LPL* gene mutations. The Asn291Ser mutation is present in 2–5% of Caucasians and is associated with a 31% increase in plasma triglyceride concentrations and an increased risk of coronary heart disease and type 2 diabetes. Asn291 is located in part of the molecule involved in homodimer formation, so it is likely that this mutation causes an increase in the relative amount of LPL present as inactive monomer. The risk of Alzheimer disease is also increased in Asn291Ser carriers.

Small amounts of LPL have been demonstrated to be present on arterial endothelium and also within the intima of arteries. LDL binds to LPL with an affinity similar to chylomicrons and VLDL. Although LDL is not the physiological substrate for LPL, the LPL present in the arterial wall may, by binding to LDL, increase the residence time of LDL in the arterial wall, thus promoting atherogenesis.

Hepatic lipase

This enzyme is a product of the same gene family as LPL. It is synthesized in the liver, where 95% remains, bound to the exterior of the hepatocyte membrane in the spaces of Disse; the remainder is found in the adrenals, ovaries and macrophages. HL has a role in the remodelling of chylomicron remnants, IDL, LDL and HDL and is involved in reverse cholesterol transport. Its concentration is inversely related to that of HDL. Its predominant activity on HDL is as a phospholipase, whereas in other lipoproteins it acts as a triglyceride lipase. In addition, HL may influence lipoprotein metabolism by means of its capacity to form a 'bridge' between lipoproteins and lipoprotein receptors.

Enzyme activity is lower in females than males and is modulated by insulin resistance, dietary fat intake, visceral obesity, physical activity, smoking and certain drugs. The size and buoyancy of LDL are inversely related to HL activity; when its activity is high, small, dense LDL particles are produced.

Like LPL, HL can bind to heparin, which results in its release into the circulation. This activity is utilized in HL assays.

Endothelial lipase

Endothelial lipase is the third member of the triglyceride lipase gene family and like the others it exists as a homodimer. It is produced by hepatic endothelial cells, and unlike HL and LPL it functions at the site of synthesis. It is also found in macrophages. Its predominant activity is as a phospholipase A1. Transcription is induced by

cytokines and physical forces, which has led to the suggestion that it may play a role in the development of atheroma. Overexpression is associated with reduced plasma concentrations of HDL.

Lipase maturation factor 1

This membrane bound protein located in the endoplasmic reticulum is essential to the folding and assembly of the dimeric lipases (LPL, HL, EL). Loss of function mutations in *LMF1* cause failure in the assembly of homodimers, thus preventing these lipases from attaining normal catalytic activity. This produces combined lipase deficiency with marked hypertriglyceridaemia.

Pancreatic triglyceride lipase

This enzyme, synthesized by pancreatic acinar cells, is essential for the digestion of dietary triglycerides. Enzyme activity requires formation of a complex with its protein cofactor, colipase. Following emulsification, the second step in the digestion of dietary triglycerides involves their hydrolysis to fatty acids and monoglycerides, which are incorporated into micelles with bile salts. Pancreatic triglyceride lipase (PTL) accounts for the majority of triglyceride lipase activity in the upper small intestine of adults.

The pancreatic acinar cells also synthesize two pancreatic lipase-related proteins (PLRP1, PLRP2) that have a high degree of structural and sequence homology to PTL. PLRP2 may play a role in dietary fat digestion in the newborn but no catalytic activity has, as yet, been demonstrated for PLRP1.

Hormone sensitive lipase

This enzyme is not related to any of the above lipases. It is a neutral intracellular lipase that has catalytic activity against diglycerides, monoglycerides and cholesteryl esters. It is predominantly located in adipose tissue. It is also expressed in the adrenals, testes and ovaries and, to a lesser extent, in skeletal muscle, cardiac muscle, macrophages and pancreatic islets. The activity of HSL is rate limiting in the release of fatty acids from adipose tissue. It is subject to a complex control mechanism, which involves both prolipolytic (ACTH and catecholamines) and antilipolytic (insulin) hormones, via cyclic AMP-dependent protein kinase phosphorylation. HSL interacts with adipocyte lipid binding protein (ALBP), which is a member of a family of lipid binding proteins that bind fatty acids and other hydrophobic ligands. In vitro, monoglycerides and fatty acids exert feedback inhibition on HSL; the interaction with ALBP, which sequesters these products, may prevent this happening in vivo. HSL is also responsible for most cholesteryl ester hydrolase activity in the adrenals.

Carboxyl ester lipase

This enzyme is a non-specific lipase capable of hydrolysing cholesteryl esters, triglycerides, diglycerides, monoglycerides, phospholipids, lysophospholipids and

ceramide. It is the only enzyme in the gut with cholesteryl esterase action; all its other actions can also be effected by other enzymes, for example the triglyceride lipase action of pancreatic triglyceride lipase. Most carboxyl ester lipase (CEL) is synthesized by pancreatic acinar cells but it is also synthesized by the liver, macrophages and lactating breast tissue. In the intestine, CEL is attached to the brush borders of enterocytes by means of its heparin binding domain. It is taken up by enterocytes, possibly by endocytosis and may be involved in the intracellular processing of lipids during the assembly of chylomicrons. The fact that CEL acts on ceramide is important because ceramide can disrupt intracellular lipid and protein trafficking, resulting in a block in the assembly of large lipoproteins and their secretion by enterocytes; CEL prevents ceramide disrupting this process.

Vitamin A is ingested in the form of retinyl palmitate or retinyl acetate, which need to be hydrolysed prior to absorption. It is likely that this hydrolysis is a function of CEL in the neonatal period, although in the adult, other enzymes may be involved.

Lysosomal acid lipase

Lysosomal acid lipase (LAL) is secreted as a 399-amino acid precursor, which includes a 27-amino acid signal peptide for transport across the membrane of the endoplasmic reticulum. Further processing, including N-glycosylation in the endoplasmic reticulum and the attachment of mannose 6-phosphate residues in the Golgi, leads to lysosomal targeting. LAL is responsible for the breakdown of cholesteryl esters and triglycerides that are delivered to lysosomes as a result of receptor-mediated uptake of lipoproteins.

Wolman disease is an autosomal recessive disease that presents in the neonate and is characterized by hepatosplenomegaly, steatorrhoea and abdominal distention, results from complete lack of LAL activity, causing massive accumulation of both cholesteryl esters and triglycerides in macrophages throughout the body. Affected children usually die before their first birthday. Enzyme replacement therapy has now been developed but its efficacy remains to be fully established.

Cholesteryl ester storage disease is caused by partial deficiency of LAL. It is a rare autosomal recessive disorder, characterized by hepatomegaly, abnormal liver function tests, hypercholesterolaemia and premature atherosclerosis. The hepatomegaly is a consequence of accumulation of cholesteryl esters and triglycerides in both hepatocytes and Kupffer cells.

Phospholipase A2

Phospholipase A2 (PLA2) is one of a family of phospholipases, enzymes that hydrolyse phospholipids. It exists in five forms. Three are found within cells. Two are secreted, one of which, lipoprotein-associated PLA2 (LpPLA2) is also known as platelet activating factor acetyl hydrolase (PAF-AH). Lipoprotein-associated PLA2 promotes the hydrolysis of oxidized phospholipids in lipoproteins,

generating lysophospholipids and proinflammatory oxidized fatty acids.

There is a correlation between plasma LpPLA₂ concentration and atherosclerosis. It is unclear whether this association is causal, but inhibition of LpPLA₂ is of potential therapeutic value, and clinical trials are underway.

Acyl-CoA:cholesterol acyltransferase

Acyl-CoA:cholesterol acyltransferase (ACAT) catalyses the esterification of cholesterol. Two forms have been identified: ACAT1 is found ubiquitously in the endoplasmic reticulum of cells; ACAT2 is predominantly found in the endoplasmic reticulum of the liver and intestine. ACAT1 is sensitive to the degree of membrane cholesterol enrichment, and it is thought that its function is to maintain the cholesterol content of cell membranes at an optimal level by catalysing the esterification of excess free cholesterol. ACAT2 is responsible for the secretion of cholesteryl esters into the apo B-containing lipoproteins.

TRANSFER PROTEINS INVOLVED IN LIPOPROTEIN METABOLISM

Cholesteryl ester transfer protein (CETP)

This is a hydrophobic glycoprotein that is secreted mostly by the liver. In the blood, it is mainly bound to HDL. It facilitates the transfer of cholesteryl esters from HDL to the triglyceride-rich lipoproteins and LDL, and of triglyceride from triglyceride-rich lipoproteins to HDL. The extent of this exchange depends on the plasma concentration of triglycerides; the more triglyceride is transferred into HDL, the more is available as a substrate for HDL, and the greater the capacity for HDL to become more delipidated (and so more rapidly degraded). This is the explanation for the well-recognized inverse relationship between plasma triglyceride and HDL-cholesterol concentrations.

Cholesteryl ester transfer protein has been viewed as both anti- and pro-atherogenic. Its anti-atherogenic action is related to its role in reverse cholesterol transport: its pro-atherogenic action is related to its capacity to transfer cholesteryl esters from HDL to the atherogenic lipoproteins (VLDL, IDL and LDL). Under normal conditions, CETP-mediated cholesteryl ester transfer from HDL is predominantly to LDL. When the plasma concentration of VLDL is increased, as in type 2 diabetes, CETP-mediated cholesteryl ester transfer is preferentially directed towards the large VLDL particles, which consequently become cholesterol enriched and more atherogenic.

Although there is uncertainty about the potential effects of CETP activity on atheroma formation, it is a target for lipid-modifying drug therapy. Drugs that inhibit CETP may raise plasma HDL concentrations by over 100%. The results of clinical trials to see if this translates into effective reduction of clinical cardiovascular endpoints are awaited.

Phospholipid transfer protein (PTP)

This glycoprotein is a member of the same gene family as CETP. Along with other genes involved in lipid metabolism

the *PLTP* gene is under control of the liver X receptor (LXR). Phospholipid transfer protein is important in the remodelling of HDL, the generation of pre- β_1 HDL, the transfer of surface lipids from the triglyceride-rich lipoproteins to HDL during intravascular lipolysis and the facilitation of HDL-mediated efflux of phospholipids and cholesterol from cells. PTP activity is higher in hypertriglyceridaemic than normotriglyceridaemic individuals, and is correlated with the degree of insulin resistance. Its activity has also been found to be increased in subjects with familial combined hyperlipidaemia.

Fatty acid transport proteins

Fatty acid transfer proteins (FATPs) are membrane proteins that facilitate the uptake of fatty acids by cells. They also have acyl-CoA synthase activity. They form a family of six proteins that differ in tissue expression, intracellular localization and responsiveness to insulin. FATP1 and FATP4 have been implicated in insulin resistance. The former is highly expressed in adipose tissue and skeletal muscle whereas the latter is principally expressed in the small intestine. FATP2 is located in peroxisomes of the kidney and liver. It is important for the formation and oxidation of very long chain fatty acyl-CoA and is involved in the activation of bile acids in the liver; it is therefore sometimes referred to as very long chain acyl-CoA synthase. FATP3 is located in mitochondrial membranes. FATP5 is located in the membrane of the endoplasmic reticulum and is also involved in the activation of bile acids. FATP6 is located in the plasma membrane of cardiac myocytes, where it probably plays an important role in the supply of fatty acids as an energy source.

RECEPTORS INVOLVED IN LIPOPROTEIN METABOLISM

The LDL receptor

This receptor is a transmembrane protein that can be expressed by most cell types under certain conditions. The LDL receptor (LDLR) binds two apolipoprotein ligands, apo B-100 and apo E and, for this reason, is sometimes referred to as the B-100/E receptor. Uptake of LDL via the LDLR is mediated through its interaction with apo B-100. Although VLDL and IDL also possess apo B-100, it is not accessible for binding: IDL binds to LDLR via apo E. Subclasses of HDL containing apo E can also bind to the LDLR. Indeed, lipoproteins that contain multiple copies of apo E bind to the LDLR with much greater affinity than does LDL.

The *LDLR* gene is located on chromosome 19. The LDLR protein contains 843 amino acids and comprises five domains (see Fig. 37.10). At the amino terminal end is the ligand binding domain (exons 2–6), which mediates binding to apo B-100 or apo E. Next, there is a domain (exons 7–14) homologous to the epidermal growth factor (EGF) precursor. This contains three EGF repeats separated by a region of beta sheet folded in a specific orientation called a 'beta propeller'. At the acid pH found in

FIGURE 37.10 ■ The LDL receptor. EGF, epidermal growth factor.

endosomes, this domain undergoes a conformational change bringing the beta propeller adjacent to repeats 4 and 5 in the ligand binding domain and releasing bound LDL. It also serves to maintain the correct orientation of the ligand binding domain on cell surfaces. The specific orientation determined by this EGF domain is required for the binding of LDL to the receptor but not for the binding of apo E-containing lipoproteins. The third domain (exon 15) consists of a peptide chain enriched in serine and threonine to which sugar chains are attached. The fourth domain (exon 16) comprises hydrophobic amino acids that span the membrane and thus function as an anchor. The carboxy terminal portion constitutes the intracellular cytoplasmic domain (exons 17–18) and appears to be important in targeting the receptor to the coated pit region.

Expression of *LDLR* is under feedback control: in the steady state, the number of LDL receptors is controlled to allow uptake of sufficient cholesterol for cell growth and to balance losses. This feedback is by membrane bound transcription factors known as sterol regulatory element binding proteins (SREBPs) (see p. 721) and their associated insulin signalling (Insig) and SREBP cleavage activating proteins (SCAPs). The function of LDLRs is dependent not only on their binding to lipoprotein particles but also on their clustering in clathrin-coated pits for the subsequent internalization of the bound lipoproteins by endocytosis.

Low density lipoprotein receptor-associated protein 1 (LDLRAP1) binds the LDLR, clathrin and the clathrin-associated adaptin protein complex 2 (AP-2), and is essential for the endocytosis of LDLRs into hepatocytes. Mutations in the *LDLRAP1* gene cause the rare clinical phenotype of autosomal recessive familial hypercholesterolaemia.

LDL receptor-related protein

LDL receptor-related protein (LRP) is expressed by hepatocytes and has multiple ligands including apo E, HL and lipoprotein lipase. Following synthesis, LRP becomes associated with another protein, LDL receptor-related protein associated protein (LRPAP1), which acts as a chaperone to facilitate the passage of LRP to the cell surface. LRP is involved in the apo E-mediated uptake of remnant particles by the liver, and is sometimes referred to as the 'apo E receptor'.

The apo E4 polymorphism has an impact on the uptake of cholesterol to neuronal tissue by LRP. This may partially explain the increased risk of Alzheimer disease in those with the apo $\epsilon 4/\epsilon 4$ genotype.

Scavenger receptor class B type 1

This is a 509-amino acid protein comprising short N- and C-terminal cytoplasmic and transmembrane domains and a large extracellular loop. Its amino acid sequence is 30% homologous with that of CD36 (see below). Like CD36, scavenger receptor class B type 1 (SRB1) can bind to a number of lipoproteins and modified lipoproteins (HDL, LDL, VLDL, oxidized LDL). It is present in a number of tissues but is most highly expressed in tissues that process HDL cholesterol and cholesteryl esters for excretion or as metabolic substrates, i.e. the liver and steroidogenic tissues. SRB1 binds HDL and mediates the selective uptake of cholesteryl esters from the cores of HDL particles to the plasma membrane without entailing the uptake and degradation of the whole HDL particle. This process is dependent on apo A-I. These cholesteryl esters are then hydrolysed extralysosomally by tissue-specific neutral cholesteryl hydrolases; in the adrenals this may be by HSL.

Scavenger receptor class B type 1 is also able to mediate the efflux of unesterified cholesterol from cells to lipoproteins. Thus, SRB1 is involved at both ends of reverse cholesterol transport; initially with the efflux of free cholesterol from peripheral cells to HDL and at the end in the delivery of cholesteryl esters and unesterified cholesterol to the liver for secretion into bile. The membrane-containing protein PDZK1 (the PDZ group of proteins are named from the initial letters of the first three proteins found to share this structural domain), controls the basal hepatocyte and enterocyte SRB1 content, whilst in the adrenals, ACTH binding to the melanocortin 2 receptor stimulates the expression of SRB1. This in turn promotes the uptake of cholesteryl esters from HDL, which provides a pool of free cholesterol within the adrenals for synthesis of glucocorticoids. In the liver, SRB1 is downregulated by fibric acid derivatives. Scavenger receptor class B type 1 has been shown to mediate the binding and endocytosis of lipopolysaccharides, suggesting that it may have a role in their cellular uptake and clearance in sepsis.

There is evidence that loss of function mutations in the *SCARB1* gene that codes for SRB1 are associated with increased concentrations of HDL but a paradoxical increase in cardiovascular disease.

Other scavenger receptors

CD36 (which stands for Cluster of Differentiation 36) is a receptor found in caveolae in the cell surface plasma

membrane. Like SRB1 it is a Class B scavenger receptor. CD36 can bind native and oxidized LDL. Together with the scavenger receptors A1 and A2 (SR-AI, SR-AII) it mediates the avid uptake of oxidized LDL by endothelial macrophages.

Peroxisome proliferator-activated receptor family

Nuclear receptors play a key role in glucose and lipid homeostasis and in the inflammatory response. They are activated by a variety of ligands, including fatty acids. Among these receptors is the peroxisome proliferator activated receptor (PPAR) family. When they bind to a ligand, PPARs form heterodimers with the nuclear retinoid X receptor (RXR), which bind to response elements in the promoter regions of target genes, thus promoting their transcription. By this means, PPARs control the expression of genes that maintain lipid and glucose homeostasis. This makes them a potential therapeutic target.

The PPAR family includes PPAR α , PPAR γ and PPAR β/δ . The fibrate family of lipid-lowering drugs are activators of PPAR α and the thiazolidinediones, which are insulin sensitizing agents, are ligands for PPAR γ . The intravascular lipolysis of lipoproteins is promoted by fibrates through increased LPL activity and reduced expression of the LPL inhibitor, apo C-III. Fibrates also induce the expression of apo A-V, which impacts on plasma triglyceride concentrations and of apo A-I and apo A-II, leading to increased production of HDL. Activation of PPAR γ induces the expression of genes for proteins that control adipocyte fatty acid metabolism, including LPL and fatty acid transport proteins, thus facilitating the hydrolysis of lipoprotein triglycerides and promoting the storage of the released fatty acids as adipocyte triglycerides.

Other nuclear receptors

As well as PPARs, other nuclear receptors such as the liver X receptors (LXRs) and farnesoid X-activated receptor (FXR) have been demonstrated to exert control over lipid metabolism. The LXR is a sterol responsive nuclear receptor that is activated in response to excess of cholesterol within the cell. When activated, it triggers transcription of the inducible degrader of LDLR (IDOL); this causes ubiquitination of the cytoplasmic domain of LDLR, which promotes its destruction within the cell. Activated LXR also activates ABCA1 and ABCG1, which promotes cholesterol efflux from the cell. The net effect is to reduce cellular cholesterol uptake and increase efflux from the cell, this restoring sterol homeostasis.

OTHER PROTEINS INVOLVED IN LIPOPROTEIN SYNTHESIS, TRANSPORT AND METABOLISM

Microsomal triglyceride transfer protein

Microsomal triglyceride transfer protein (MTP) is a member of a group of proteins that are able to transfer of lipids between membranes. MTP is an 894 amino acid (97 kDa)

protein that forms a heterodimer with protein disulfide isomerase (PDI); the two subunits are held together by non-covalent interactions. This protein is present in high concentrations in the lumen of the endoplasmic reticulum and plays an important role in the maturation of the endoplasmic reticulum and its secreted proteins. Protein disulfide isomerase does not demonstrate isomerase activity when combined with MTP, but is required for retention of MTP in the endoplasmic reticulum at the site of apo B translocation. The promoter region of MTP is upregulated by cholesterol and downregulated by insulin. Microsomal triglyceride transfer protein binds and shuttles individual lipids between membranes.

Microsomal triglyceride transfer protein activity is essential for the synthesis of chylomicrons and VLDL. After the assembly of chylomicrons and VLDL within the lumen of the endoplasmic reticulum of enterocytes and hepatocytes respectively, they are transported to the Golgi apparatus and then secreted. Loss of function mutations in MTP cause abetalipoproteinaemia (see p. 724)

Microsomal transfer protein also transfers lipid to antigen presenting molecules on the surface of natural killer T cells. These mediate a number of autoimmune disorders, making MTP a pharmacological target, with inhibition having the potential to achieve both lipid lowering and anti-inflammatory effects. Inhibitors of MTP, which effectively lower plasma LDL-cholesterol concentrations, are in clinical trials, although it remains to be seen whether their use will be limited because of their tendency to cause an increase in hepatic steatosis.

ATP binding cassette transporter family

The ATP binding cassette (ABC) transporter family comprises more than 50 different proteins. Within this family, ABCG1, ABCG5, ABCG8 and ABCA1 are all sterol induced. ABCG5 and ABCG8 form a heterodimer, which mediates the excretion of absorbed plant sterols and cholesterol from enterocytes into the lumen of the gut and from hepatocytes into the bile. ATP binding cassette transporters A1 and G1 facilitate the export of cholesterol from peripheral cells, where its combination with apo A-I and phospholipids to produce HDL is the first step in reverse cholesterol transport.

Proprotein convertase subtilisin kexin 9

Proprotein convertase subtilisin kexin 9 (PCSK9) is one of nine members of the subtilisin protease family. The *PCSK9* gene is mainly expressed in liver and is regulated by sterol regulatory element binding proteins (see p. 721). The PCSK9 protein is synthesized as a 72 kDa protein that undergoes self-cleavage to a 63 kDa protein, which is found in the Golgi. Proprotein convertase subtilisin kexin 9 regulates LDLR activity by accelerating the degradation of mature receptors. It is expressed on the cell surface but also circulates free in plasma.

Gain of function mutations in the *PCSK9* gene are a rare cause of autosomal dominant hypercholesterolaemia (familial hypercholesterolaemia). Loss of function

mutations are associated with reduced plasma LDL-cholesterol concentration and lower than average risk of CVD. This makes both gene inactivation and immunological blockade of PCSK9 action attractive targets for lipid lowering therapy. Therapeutic agents are in clinical trials, and have been shown to reduce plasma LDL-cholesterol concentrations by >50%.

Sterol regulatory element binding proteins

Sterol regulatory element binding proteins (SREBPs) are membrane-bound transcription factors that activate genes involved in cholesterol synthesis. They provide the means by which cellular cholesterol exerts negative feedback on cholesterol synthesis. There are three SREBPs: SREBP-2 activates genes involved in cholesterol synthesis, the other two (SREBP-1a and SREBP-1c) have more effect on the genes involved in fatty acid synthesis. When cholesterol is abundant in a cell, the SREBPs remain in the endoplasmic reticulum associated with an escort protein, SREBP cleavage activating protein (SCAP), and the endoplasmic reticulum retention protein, insulin signalling protein (Insig). When a cell is relatively cholesterol-depleted, SCAP dissociates from Insig and results in the release of SREBP-SCAP from the endoplasmic reticulum. To exert their action, SREBPs must undergo two-step proteolytic cleavage in the Golgi to release their N-terminal fragment. These fragments travel to the nucleus where they bind to the steroid response elements (SREs) in the promoter regions of a number of the genes encoding enzymes involved in cholesterol synthesis, including squalene synthase and HMG-CoA reductase, and the *LDLR* gene.

When intracellular cholesterol content is again adequate, the proteolytic release of the N-terminal fragment is blocked and the N-terminal fragments in the nucleus are degraded.

Both *SREBP* genes contain intronic sequences that code for a micro-RNA (miR-33). Micro-RNAs (miRNAs) are small non-coding RNAs approximately 22 nucleotides in length that bind to the three prime untranslated region (3'UTR) of mRNAs, causing their reduced translation or destruction. Micro-RNA-33 reduces translation of mRNA for *ABCA1*, *ABCG1* and genes involved in fatty acid oxidation. This effect is complementary to the primary effect of SREBP on cholesterol and fatty acid synthesis and serves to further increase the accumulation of cholesterol and triglycerides within cells.

In the liver, insulin stimulates SREBP-1c production, and in states of hyperinsulinaemia with insulin resistance this may contribute to the accumulation of fat in hepatocytes, and drive increased VLDL synthesis. It is also possible that reduced *ABCA1* expression caused by miR-33 may account in part for the low HDL seen in insulin resistant states.

These recent insights into control of lipid metabolism by miRNAs makes them potential therapeutic targets, and initial studies have shown that HDL can be increased by antisense oligonucleotides designed to block miR-33.

Sortilins

Sortilins are receptors that regulate intracellular transport by shunting proteins through secretory or endocytic pathways. They share in common a 700 amino acid extracellular domain which forms a ten bladed beta propeller and acts as a ligand binding site. This is designated the vacuolar protein sorting ten protein domain (VPS10P).

Genome wide association studies suggest that two of these receptors, sortilin and sorting protein-related receptor with type A repeats (SORLA), have a role in lipid metabolism and atherosclerosis, and may account for variability in cardiovascular risk. Reduced quantities of SORLA are associated with increased smooth muscle cell migration and lipid loading of macrophages in atheromatous plaques. This effect may be mediated by SORLA binding of LPL and apo A-V on the cell surface. Overexpression of the sortilin gene, *SORT1* is associated with lower plasma LDL-cholesterol concentrations, either indirectly by reducing VLDL output from the liver, or directly by acting as an alternative hepatic receptor for LDL.

Glycosylphosphatidylinositol-anchored HDL-binding protein 1

Glycosylphosphatidylinositol-anchored HDL-binding protein1 (GPIHBP1) is a 184 amino acid protein that is a member of the GPI anchored Ly6 (lymphocyte antigen 6) group of proteins. It was originally identified as a protein capable of binding HDL. It is now recognized to be essential to the function of lipoprotein lipase. This protein binds LPL in the subendothelial space and transports it to the luminal surface of endothelial cells, where it anchors the LPL protein by means of the GPI domain. Genetic studies have shown that mutations in GPIHBP1, and mutations in LPL that make it unable to bind GPIHBP1, are both associated with increased plasma triglyceride concentrations.

Angiopoietin-like protein 3

Angiopoietin-like protein 3 (ANGPTL3) acts in the liver to promote the production and secretion of apo B containing lipoproteins. In the circulation, it inhibits the activities of LPL. It may also affect the activity of EL and thereby modulate HDL cholesterol concentrations. Loss of function mutations in the *ANGPTL3* gene have been associated with a combined hypolipidaemia phenotype, with low plasma concentrations of cholesterol, HDL-cholesterol and triglycerides.

CLASSIFICATION OF LIPOPROTEIN DISORDERS

Fredrickson originally suggested dividing the hyperlipidaemias into five types (I–V) based on which of the apo B-containing lipoprotein classes were shown to be increased on paper electrophoresis of a fasting sample.

TABLE 37.4 World Health Organization classification of hyperlipidaemia

Type	Major lipid abnormality	Minor lipid abnormality	Electrophoretic mobility	Lipoprotein abnormality
I	↑ Triglycerides	↑ Cholesterol	Staining at origin	Chylomicrons present
IIa	↑ Cholesterol		↑ β band	↑ LDL
IIb	↑ Cholesterol ↑ Triglycerides		↑ β and pre-β band	↑ LDL and ↑ VLDL
III	↑ Cholesterol ↑ Triglycerides		Broad β band	IDL present in detectable amounts
IV	↑ Triglycerides	↑ Cholesterol	↑ Pre-β band	↑ VLDL
V	↑ Triglycerides	↑ Cholesterol	↑ Pre-β band and staining at origin	↑ VLDL and chylomicrons present

This was subsequently modified by the World Health Organization, which introduced a subdivision of type II into two (types IIa and IIb) (Table 37.4).

The Fredrickson classification is limited in being only a description of the lipoprotein phenotype manifested in an individual, and only covers abnormal elevations of the apo B containing lipoproteins. It does not differentiate primary from secondary causes of any particular phenotype, and does not include deficiencies of the apo B containing lipoproteins or disorders of HDL metabolism. It soon became clear that the type I phenotype can be caused by any one of three inherited abnormalities, all of which result in a functional deficiency of lipoprotein lipase. Type III is caused by an inherited defect in apo E causing reduced binding to the LRP (apo E) receptor in the liver. The other types (IIa, IIb, IV and V) can each be a consequence of

one or more inherited defects or may reflect secondary causes. Thus classifying an individual into one of these Fredrickson classes gives no indication as to the genetic basis of the manifested lipoprotein disorder, its mechanism, the need for family screening or the management required. It is now recognized that even the type I and type III phenotypes can have multiple other genetic causes due either to single gene disorders or the cumulative effect of multiple small genetic variants together with secondary environmental influences. For all these reasons, this classification has largely been superseded by a clinical and genetic classification, which relates to the molecular mechanism underlying the clinical phenotype. The genetic basis of the primary dyslipidaemias and the relationship, where known, to the corresponding clinical and Fredrickson phenotypes is given in Table 37.5.

TABLE 37.5 Clinical/genetic classification of dyslipidaemias

Clinical disorder	Lipid changes			WHO phenotype	Lipoprotein	Protein	Gene
	LDL	TG	HDL				
Dysbetalipoproteinaemias							
Decreased beta lipoproteins							
Abetalipoproteinaemia	↓↓	↓↓	↓	N/A	Absent Apo B	MTP	<i>MTP</i>
Chylomicron retention disease	↓	→	↓	N/A	Absent B-48, decreased B-100	Srb1	<i>SARA2</i>

^aDenotes gain of function mutation.

Lipids may be deposited in certain extravascular sites in the presence of significant hyperlipidaemia. In certain instances, the site and form of this lipid deposition may be characteristic of the underlying lipid abnormality (Table 37.6).

THE PRIMARY DYSLIPOPROTEINAEMIAS

A primary dyslipoproteinaemia is an inherited disorder of lipoprotein metabolism that may manifest as hyperlipidaemia, hypolipidaemia or normolipidaemia associated with lipoproteins of abnormal composition

or an abnormal distribution of the normal lipoprotein classes.

Hypobetalipoproteinaemia

The term 'hypobetalipoproteinaemia' describes the situation when the total plasma cholesterol, LDL-cholesterol or apo B concentrations are less than the 5th centile. This may be secondary to an underlying disorder, for example fat malabsorption, or a consequence of an inherited defect in lipoprotein metabolism (primary hypobetalipoproteinaemia). Primary hypobetalipoproteinaemia encompasses three disorders: abetalipoproteinaemia, chylomicron retention disease and familial hypobetalipoproteinaemia.

TABLE 37.6 Extravascular manifestations of hyperlipidaemia

Extravascular site of lipid deposition	Type of hyperlipidaemia
Xanthelasma (periorbital)	Any form of hypercholesterolaemia; may occur with normal lipid concentrations; common in hyperlipidaemias due to cholestasis
Corneal arcus (around the iris of the eye)	Arcus senilis can occur with increasing age in subjects with normal lipid concentrations; if present in a subject <45 years, probably denotes presence of significant underlying hyperlipidaemia (usually ↑ LDL)
Tendon xanthomas (occur in extensor tendons of hands, feet, Achilles tendon and patellar tendon)	Virtually pathognomonic of familial hypercholesterolaemia; also found in the very rare conditions, β-sitosterolaemia and cerebrotendinous xanthomatosis
Tuberous and tuberoeruptive xanthomas (occur over extensor surfaces of limbs, i.e. elbows/knees)	Remnant hyperlipoproteinaemia and familial hypercholesterolaemia
Palmar crease xanthomas	Remnant hyperlipidaemia
Eruptive xanthomas (occur in crops, particularly over the extensor surface of the elbows and over the buttocks)	Chylomicronaemia

Abetalipoproteinaemia

This is a very rare autosomal recessive condition, first described in 1950 by Bassen and Kornzweig. It typically presents in infancy with failure to thrive and chronic diarrhoea owing to fat malabsorption. Other features include acanthocytosis (caused by abnormal erythrocyte membrane lipid composition) and an atypical retinitis pigmentosa (as a result of vitamin A deficiency). Later manifestations are night blindness and neurological disability, particularly ataxia, caused by vitamin A and vitamin E deficiencies, respectively. The primary aim of treatment in these subjects is to ensure that fat-soluble vitamin intake is sufficient, which may require their parenteral administration.

There is a complete absence of all apo B-containing lipoproteins in the plasma, and no circulating apo B, whereas HDL and apo A-I concentrations are approximately 50% of normal. Plasma cholesterol concentration is low (typically 0.5–1.5 mmol/L) and plasma triglyceride concentration is very low (<0.2 mmol/L). On microscopy, lipid droplets can be seen to accumulate intracellularly in hepatocytes and enterocytes, suggesting a defect in the assembly of the apo B containing lipoproteins. The cause is now known to be loss of function mutations in the *MTP* gene (see p. 720). In the presence of defective MTP, no apo B-containing lipoproteins are formed. The malabsorption of fat and the fat-soluble vitamins is a result of the failure of chylomicron formation.

Chylomicron retention disease

The inheritance of chylomicron retention disease is probably autosomal recessive. It is characterized by an absence of apo B-48 in plasma and lack of a postprandial lipaemic response. Affected individuals also have low LDL, HDL and fat-soluble vitamin concentrations and their LDLs are enriched in triglycerides. They have fat malabsorption and steatorrhoea and, without supplementation of fat-soluble vitamins, develop neurological dysfunction. Enterocytes of affected individuals contain fat droplets, and apo B-48 is demonstrable immunochemically within the enterocytes. Chylomicron retention disease is caused by mutations in the *SARA2* gene. The protein product of the *SARA2* gene is sar1b, which is involved in the transport of chylomicrons through the enterocyte secretory pathway (see p. 712).

Familial hypobetalipoproteinaemia

Familial hypobetalipoproteinaemia (FHBL) is an autosomal co-dominant disorder resulting from mutations in *APOB* generating premature stop codons and therefore truncation of apo B. These truncated forms have a reduced capacity for lipid binding and thus result in the secretion of smaller, denser, relatively lipid-poor lipoprotein particles. Lipoprotein particles containing the larger truncated forms (e.g. apo B-89 and apo B-75) fall into the VLDL fraction when secreted, whereas those containing the smaller forms (e.g. apo B-29) fall into the HDL fraction. There is a threshold in apo B size under which the apo B cannot form a lipoprotein; this threshold is between apo B-28 and apo B-29. Mutations producing truncated forms of apo B greater than apo B-48 are associated with

the production of normal chylomicrons. Apolipoprotein B forms smaller than B-67 are incorporated into VLDL in the normal way but are not able to interact with LDL receptors.

Individuals heterozygous for FHBL associated with truncated apo Bs are often asymptomatic, but a small proportion have loose stools. The plasma LDL-cholesterol concentration in heterozygotes would be expected to be about 50% of that in unaffected family members, but concentrations of about a third of normal are actually observed, possibly because of reduced hepatic secretion or upregulation of LDL receptors that results in increased clearance. A high incidence of non-alcoholic fatty liver disease is reported in FHBL heterozygotes. Homozygous FHBL clinically resembles abetalipoproteinaemia.

Familial combined hyperlipidaemia

This condition is the most common lipid disorder in subjects presenting with ischaemic heart disease. It is inherited as an autosomal dominant trait, but usually does not become manifest until adulthood. The typical findings are a raised plasma apo B-100 concentration and an increase in plasma concentrations of LDL (high total cholesterol), VLDL (high triglycerides) or both. Different individuals within a kindred may have any of these phenotypes, and in a single individual, the phenotypic pattern may change over time. Plasma HDL-cholesterol concentration is usually low; this probably results from increased transfer of cholesteryl esters from HDL to the triglyceride-rich lipoproteins. The LDL particles in familial combined hyperlipidaemia (FCH) tend to be smaller and denser than usual; thus individuals with FCH display the 'atherogenic lipid profile' comprising high plasma triglyceride and low HDL-cholesterol concentrations and small, dense LDL particles.

Overproduction of apo B-100 occurs in FCH, so that affected individuals have raised plasma apo B concentrations even though their lipid concentrations may be normal. The development of hyperlipidaemia is dependent on an increase in the availability of hepatic triglycerides; this explains the observation that affected subjects are frequently obese, and may have other features of the metabolic syndrome. The phenotype expressed is thought to reflect the efficiency with which the VLDL is processed in affected individuals. Thus individuals who have one abnormal LPL gene (parents of children with LPL deficiency) may appear to have FCH because of the resultant slowed clearance of VLDL.

Genetic studies have suggested a link between FCH and the upstream transcription factor 1 (USF1) gene. This is a transcription factor responsible for upregulating the transcription of a number of genes involved in glucose and lipid metabolism, including those coding for apo A-V.

Familial hypertriglyceridaemia

Some families show Mendelian inheritance of hypertriglyceridaemia. In most cases this reflects an increase in VLDL, with moderately elevated triglyceride concentrations (4–10 mmol/L). In some cases, there is a more severe hyperlipidaemia (>10 mmol/L) and fasting

chylomicronaemia. The latter causes a Fredrickson type I phenotype, while less severe hypertriglyceridaemia generally causes a type IIb, IV or V pattern. Severe hypertriglyceridaemia is typically autosomal recessive and in addition to defects in LPL and apo C-II, which have long been recognized as causes of type I hyperlipidaemia (chylomicronaemia syndrome), it is now recognized that loss of function mutations in genes including *APOA5*, *LMF1* and *GPIHBP1* may produce a similar phenotype, often inherited in an autosomal recessive manner. By contrast, the cumulative effect of multiple small effect polymorphisms in genes including *LPL*, *APOA5*, *GCKR* and *APOB*, interact with environmental factors to produce more moderate hypertriglyceridaemia, and a variety of lipoprotein phenotypes. These include IIb, IV, V and, sometimes, type III. The environmental factors interacting with these genetic variants to produce moderate or severe fasting hypertriglyceridaemia are the same as those causing secondary hyperlipidaemia, e.g. diabetes, insulin resistance or excessive alcohol consumption. VLDL particles are larger than usual, and relatively deficient in apo B in familial hypertriglyceridaemia, which suggests that an important factor is overproduction of triglycerides by the liver. Chylomicronaemia syndrome, caused by autosomal recessive major loss of function mutations in single genes, often manifests in childhood, whilst other causes of familial hypertriglyceridaemia rarely manifest before adulthood.

In patients with a fasting plasma triglyceride concentration >10 mmol/L, there is a risk of acute pancreatitis, and reducing this risk is usually the first priority of treatment, before addressing residual cardiovascular risk. Fibrates or ω 3-fatty acids, in combination with a low fat diet and avoidance of excessive alcohol consumption, are usually effective. Plasma exchange, and intravenous insulin infusion (to increase lipoprotein lipase activity), have both been used in severe cases although the evidence for their long-term effectiveness is limited.

Chylomicronaemia syndrome

Chylomicronaemia syndrome manifests as eruptive xanthomata (see Fig. 37.11), lipaemia retinalis, hepatosplenomegaly and recurrent bouts of abdominal pain that may be symptoms of acute pancreatitis. Plasma triglyceride concentrations are markedly increased (>10 mmol/L), HDL-cholesterol concentrations are very low and chylomicrons are present in the fasting state. Three inherited causes of this condition have been described: lipoprotein lipase deficiency, apo C-II deficiency and familial lipoprotein lipase inhibitor. Secondary causes, including excessive alcohol consumption and newly diagnosed type 1 diabetes, may produce a very similar phenotype in genetically predisposed individuals.

Lipoprotein lipase deficiency. This is a rare autosomal recessive condition with an incidence of approximately 1 in 1 000 000. Presentation is usually in childhood with recurrent abdominal pain. Affected individuals may have low, normal or increased concentrations of immunoreactive LPL in post-heparin plasma but catalytic activity is undetectable. Gene replacement therapies for

FIGURE 37.11 ■ Eruptive xanthomata over the elbow.

the most severe forms of this condition are undergoing clinical trials.

Obligate heterozygotes for LPL deficiency have been shown to have low plasma LPL activity: some may develop severe hypertriglyceridaemia, and a small number, pancreatitis.

Apo C-II deficiency. Homozygous apo C-II deficiency tends to present later and be somewhat milder than LPL deficiency. Apo C-II is detectable in about 50% of individuals with apo C-II deficiency, but the protein produced is unable to activate LPL. It is possible that the concentrations of the triglyceride-rich lipoproteins may reach a level at which LPL can hydrolyse them even in the absence of apo C-II: this could account for the milder form of the disease as compared with that seen with primary deficiency of the enzyme.

Relatives who are obligate heterozygotes for the abnormal gene usually have normal lipid and lipoprotein concentrations. This implies that up to a 50% reduction in the apo C-II concentration does not compromise the rate of chylomicron and VLDL clearance.

Familial lipoprotein lipase inhibitor. Families have been described whose affected members have chylomicronaemia apparently caused by an inhibitor of LPL. The defect appears to be inherited in an autosomal dominant fashion. The inhibitor has not been identified.

Remnant hyperlipoproteinaemia

The characteristic feature of remnant hyperlipoproteinaemia (RH) is cholesterol enrichment of the VLDL fraction, reflecting an accumulation of remnant particles, both chylomicron remnants and intermediate density lipoprotein. These remnants are responsible for the abnormal electrophoretic pattern, which gave the condition its former name of broad β disease (type III in the Fredrickson classification), since a broad β band is seen on electrophoresis instead of the usual two distinct pre- β (VLDL) and β (LDL) bands. Remnant hyperlipidaemia is also sometimes referred to as dysbetalipoproteinaemia. Subjects with this disorder show a mixed hyperlipidaemia, often with approximately equal plasma concentrations of cholesterol and triglycerides.

The predominant defect found in most subjects with the condition is the presence of apo E2, which displays a recessive mode of inheritance. While apo E2 homozygosity is essential for the accumulation of remnant particles, it is not sufficient for the manifestation of the condition. A super-imposed genetic or environmental factor is necessary before remnant hyperlipidaemia becomes manifest, such as the concomitant inheritance of another primary hyperlipidaemia or, more frequently, a secondary cause such as obesity, excessive alcohol consumption, diabetes or hypothyroidism. The 10% of individuals with RH who do not show homozygosity for apo E2/2 have a variety of molecular defects, including point mutations resulting in amino acid substitutions at residues 142, 145 or 146, or the insertional variant, apo E-Leiden; a few lack apo E entirely.

Remnant hyperlipoproteinaemia rarely presents before adulthood. It is associated with characteristic xanthomata occurring in the palmar creases (Fig. 37.12) which are virtually pathognomonic, and tuberous or tuberoeruptive xanthomata over the extensor surfaces of the elbows and knees (Fig. 37.13). There is an

increased risk of premature atherosclerosis involving the peripheral vascular system as well as the coronary arteries.

Familial hypercholesterolaemia

This term encompasses a group of disorders due to mutations causing reduced clearance of LDL by the LDL receptor resulting in marked hypercholesterolaemia and premature atherosclerosis. 'Classic' familial hypercholesterolaemia (FH) is due to mutations in the *LDLR* gene. Autosomal dominant mutations are now recognized in three genes causing conditions collectively referred to as autosomal dominant hypercholesterolaemia (ADH), which includes classic FH. A further gene locus has recently been associated with this clinical phenotype, but the causative gene has not yet been identified. A rare autosomal recessive condition has also been described with a similar clinical and biochemical phenotype. The four clearly defined disorders that result in FH are as follows:

- classic FH – ADH 1
- familial defective apolipoprotein B-100 – ADH 2
- gain of function mutation in PCSK9 – ADH 3
- loss of function mutation in LDLRAP1 – autosomal recessive hypercholesterolaemia.

Classic familial hypercholesterolaemia (FH). This is the most severe of the hyperlipidaemias with respect to the propensity of affected, untreated individuals to develop atherosclerosis. It manifests in the heterozygous state as marked hypercholesterolaemia, owing to high LDL-cholesterol concentration, and premature cardiovascular disease. Heterozygous FH is one of the commonest inherited metabolic diseases, with a frequency of about 1 in 500 in most populations. Tendon xanthomata in the extensor tendons of the digits (Fig. 37.14) and in the Achilles tendons (Fig. 37.15) occur in approximately 70% of untreated heterozygotes and their presence in affected individuals or first-degree relatives aids the clinical diagnosis, which is based on criteria defined by the Simon Broome Trust (Box 37.1).

Based on the frequency of the heterozygous state, homozygous FH would be expected to have an incidence of one in 1 000 000. Most apparently homozygous FH

FIGURE 37.15 ■ Xanthomata in the Achilles tendon.

BOX 37.1 Diagnostic criteria for familial hypercholesterolaemia (FH)

A diagnosis of definite FH using the Simon Broome^a criteria requires:

- serum cholesterol >7.5 mmol/L (>6.7 mmol/L in children <16 years) *or* LDL cholesterol >4.9 mmol/L (>4.0 mmol/L in children <16 years) *plus*
 - tendon xanthomas in the patient or first- or second-degree relative
- or*
- DNA-based evidence of a pathogenic mutation in *LDLR*, *APOB* or *PCSK9*

A diagnosis of possible FH requires:

- serum cholesterol concentration >7.5 mmol/L (>6.7 mmol/L in children <16 years) *or* LDL cholesterol >4.9 mmol/L (>4.0 mmol/L in children <16 years) *plus*
 - a family history of myocardial infarction before age 60 years in a first-degree relative or before age 50 years in a second-degree relative
- or*
- serum cholesterol concentration >7.5 mmol/L (6.7 mmol/L in children <16 years) in a first- or second-degree relative.

^aThe Simon Broome Trust maintains a register of FH patients in the UK. It is named after a patient with the condition.

subjects are actually compound heterozygotes. The hypercholesterolaemia is far more severe in subjects with two mutant genes; cutaneous xanthomata often occur in childhood and coronary artery disease may present during the first decade of life. LDL apheresis has now become standard treatment in these patients in addition to lipid lowering drugs and diet. This can significantly increase life expectancy, particularly if the condition is diagnosed at a young age.

Classic FH, which accounts for the defect in 80–90% of patients with familial hypercholesterolaemia, is due to mutations of the LDL receptor gene. Around 20 common

mutations account for 50% of cases, but over 1200 mutations have now been described, including a number of pathogenic intron mutations.

In vitro, it has been demonstrated that cells from FH heterozygotes have about half the number of functional LDL receptors than do cells from normal individuals. The effect of this deficiency of functional LDL receptors in vivo is that plasma LDL-cholesterol concentrations are increased to approximately twice the usual level, owing to a combination of reduced LDL uptake and LDL overproduction. The overproduction of LDL results from defective hepatic IDL uptake by the LDL receptor so that extracellular IDL to LDL conversion is increased. Hepatic cholesterol synthesis is also upregulated because of reduced LDLR-mediated cholesterol uptake.

Familial defective apolipoprotein B-100 (FDB). This is an autosomal co-dominant disorder that results from an abnormality in the LDLR-binding domain of apo B-100. Most cases are due to mutations in the *APOB* gene at the codon for amino acid 3500 where Arg to Gln and Arg to Trp substitutions have been described. The arginine to glutamine substitution has been shown to change the conformation of the C-terminal tail, which results in reduced binding to the LDLR. Other mutations have been described that have a less severe effect on the ability of apo B to bind to LDL receptors. FDB is phenotypically very similar to classic FH; affected subjects have elevated plasma total and LDL cholesterol concentrations but the hypercholesterolaemia is usually less severe and tendon xanthomas are less common.

Gain of function mutation in PCSK9. This variant of FH was characterized by studying families that phenotypically were similar to classic FH and FDB. It was shown to be caused by gain of function mutations in the gene coding for proprotein convertase subtilisin kexin 9 (PCSK9). These mutations increase the rate at which PCSK9 degrades LDL receptors, resulting in reduced receptor expression on the cell surface. These mutations tend to be associated with a more severe clinical phenotype, with affected individuals showing higher plasma LDL-cholesterol concentrations and more aggressive vascular disease than seen in classic FH.

Autosomal recessive hypercholesterolaemia. Patients with autosomal recessive hypercholesterolaemia (ARH) phenotypically resemble classic FH homozygotes. They have large xanthomas (tendon, tuberous, planar) that present in childhood, and develop premature atherosclerosis, particularly of the coronary and carotid arteries. They also develop aortic stenosis. Plasma LDL-cholesterol concentrations in patients with ARH are generally higher than those found in classic FH but not as high as those seen in homozygous FH.

Autosomal recessive hypercholesterolaemia results from a mutation in the *LDLRAP1* gene. LDLRAP1 mediates normal LDL receptor-mediated endocytosis after LDL is bound to the receptor, and this process is defective in ARH. Obligate heterozygotes for ARH

who carry a single pathogenic *LDLRAP1* mutation have normal plasma LDL-cholesterol concentrations.

Polygenic hypercholesterolaemia

Hypercholesterolaemia is more common in Western societies than would be expected, given the frequency of the individual monogenic disorders discussed above. The remainder of individuals with primary hypercholesterolaemia are therefore referred to as having polygenic hypercholesterolaemia. The term 'polygenic' is used because the individuals' genetic background affects the extent to which lipoprotein metabolism will be influenced by environmental factors.

The monogenic disorders are associated with the same increased risk for atherosclerosis in different populations. However, the frequency with which polygenic hypercholesterolaemia occurs in different populations varies widely, as does the incidence of coronary artery disease. Populations with a high mean plasma cholesterol concentration have a high rate of coronary artery disease. It is believed that the difference between populations in the frequency of hypercholesterolaemia reflects one or more environmental factors, the most obvious being diet and, in particular, the saturated fat content of the diet.

The frequency with which polygenic hypercholesterolaemia is diagnosed in a population depends on the value taken as the upper cut-off for a 'normal' cholesterol. If 5 mmol/L is used, about 50% of most adult populations will be classified as hypercholesterolaemic, as the population mean cholesterol concentration is typically 5.5–6.0 mmol/L in many Western countries. At this level, CVD risk is already twice that of a population with a mean cholesterol <4.0 mmol/L, so a statistical definition of 'normal' based on population values is unhelpful. Laboratories will generally refer to 'ideal' cholesterol targets. In the UK, these are currently total cholesterol <4.0 mmol/L and LDL-cholesterol <2.0 mmol/L.

Dysalphalipoproteinaemias

The dysalphalipoproteinaemias are disorders of the synthesis and secretion of apo A-containing lipoproteins. With the exception of apo A-I Milano (see below), all other genetic causes of familial hypoalphalipoproteinaemia are associated with some degree of increased cardiovascular risk.

Abnormal apolipoprotein A structure

Population screening for apo A-I structural variation has revealed at least 11 variants. The best described is apo A-I Milano, which is associated with a low HDL (HDL2) concentration but no increased incidence of atherosclerosis. Apolipoprotein A-I Milano results from substitution of cysteine for arginine at position 173, which has the effect of changing the physical property of one of the amphipathic helical regions involved in lipid binding and also allows disulphide bonding to other proteins. Dimers with apo A-II and apo E have been observed. In addition, LCAT activity is reduced.

Apo A-I deficiency

At least three types of apo A-I deficiency have been described, all associated with corneal clouding and premature coronary heart disease. Heterozygotes have 50% of normal HDL concentrations. HDL is virtually undetectable in homozygotes. In one type there is deficiency only of apo A-I, another also has deficiency of apo C-III and has low plasma triglyceride concentrations. The *APOC3* gene is 3' to the *APOA1* gene but in the opposite orientation. These two genes are normally convergently transcribed from opposite DNA strands. In patients with combined deficiency of apo A-I and apo C-III, an inversion of approximately 5.5 kb containing portions of the *APOA1* and *APOC3* genes has been identified. In a third form, there is deficiency of apo A-I, apo C-II and also apo A-IV. These may show fat malabsorption due to the deficiency of apo A-IV.

Disorders of HDL metabolism (Box 37.2)

Tangier disease

Tangier disease is a rare autosomal recessive condition characterized by storage of cholesteryl esters in macrophages. This is responsible for the characteristic orange appearance of the tonsils. Splenomegaly also occurs, and is often accompanied by mild thrombocytopenia and reticulocytosis, but hepatomegaly and lymphadenopathy are less constant features. Corneal clouding may occur and most affected individuals have some neurological dysfunction.

Total plasma cholesterol concentrations are low (typically <3 mmol/L) but, unlike the apo B deficiency states, plasma triglyceride concentrations are normal or increased. Virtually no HDL-cholesterol is present (<0.1 mmol/L) and only pre- β_1 HDL particles are detectable in plasma. The concentrations of apo A-I and apo A-II are approximately 1–3% and 5%, respectively, of values found in normal individuals. An increase in pro-apo A-I can be demonstrated by isoelectric focusing but rapid catabolism of pro-apo A-I results in reduced conversion of pro-apo A-I to the mature form and consequently low plasma concentrations of apo A-I. Although it appears that Tangier patients are at increased cardiac risk, the level of risk varies between affected families and

is not as high as predicted from epidemiological studies based on their plasma HDL-cholesterol concentrations. This may be related to their low LDL-cholesterol concentrations, but thrombocytopenia and relative platelet hyporeactivity may also be important factors.

Tangier disease is caused by the loss of function of the cholesterol-efflux regulatory protein, ABCA1, resulting from mutations in the *ABCA1* gene. Individuals homozygous for *ABCA1* mutations are at increased risk of coronary artery disease compared with unaffected individuals and heterozygous individuals are at intermediate risk.

Familial lecithin-cholesterol acyltransferase deficiency

Familial LCAT deficiency is an autosomal recessive condition. The gene for LCAT is located on chromosome 16; mutations in this gene that are associated with no LCAT activity result in familial LCAT deficiency. The clinical features of this condition include corneal opacities, haemolytic anaemia, proteinuria, high plasma triglyceride and low HDL-cholesterol concentrations. Despite the low HDL-cholesterol concentrations, premature atherosclerosis is rarely seen. Heterozygous carriers lack clinical features but have HDL-cholesterol concentrations about 50% of normal.

Lecithin-cholesterol acyltransferase deficiency results in an inability to esterify free cholesterol in plasma and hence the accumulation of free cholesterol in all lipoprotein fractions. Lipoprotein particles may also be of abnormal size or shape as well as composition; thus the HDL particles are either disc shaped or unusually small spherical particles similar to newly secreted HDL. Lipoprotein X is detectable on electrophoresis.

Fish eye disease

Fish eye disease is an autosomal recessive disorder resulting from mutations in the *LCAT* gene. In contrast to familial LCAT deficiency, there is detectable LCAT activity. Corneal opacities that give the eyes the appearance of those of dead fish have been described in association with low HDL-cholesterol concentrations (approximately 10% of normal). LDL is enriched in triglyceride; the concentration of VLDL is increased but the composition is normal.

Hepatic triglyceride lipase deficiency

Several familial cases of HL deficiency have been reported and inheritance appears to be autosomal recessive, with heterozygotes showing an intermediate phenotype. Homozygotes have severe hypertriglyceridaemia, hypercholesterolaemia, and increased IDL concentrations, producing a phenotype similar to type III or remnant hyperlipidaemia. HL deficiency is distinguished by an absence of post heparin HL activity. Apolipoprotein A-I and HDL-cholesterol concentrations are slightly raised, with HDL particles being abnormally triglyceride-rich HDL2. Premature vascular disease has been reported in HL deficiency, although the exact role of HL in the development of atherosclerosis remains uncertain, as increased HL activity (e.g. secondary to anabolic steroid use) may also result in increased vascular disease.

Cholesterol ester transfer protein deficiency

Several mutations of the *CETP* gene that cause CETP deficiency have been described. Homozygous CETP-deficient subjects have high plasma concentrations of HDL-cholesterol, apo A-I, apo A-II and apo E. Plasma HDL-cholesterol concentrations are usually >3 mmol/L in homozygous subjects who have a complete absence of CETP activity, values of 2–2.5 mmol/L are typically seen in heterozygotes. These subjects also have an approximately 40% reduction in LDL-cholesterol and apo B. Cholesterol ester transfer protein deficiency is relatively common in Japan, where it accounts for about half of all cases of hyperalphalipoproteinaemia, but it is rare in Caucasians. There is evidence that, when associated with a high plasma HDL concentration, CETP deficiency protects against the development of atheroma. On this basis, drugs that inhibit CETP have been developed: these produce an increase in plasma HDL-cholesterol concentration of over 100% and fall in LDL-cholesterol concentration of around 40%. Because of the complex relationship between CETP activity, HDL concentrations and atherosclerosis, the effect of these agents on cardiovascular outcomes will need to be tested in clinical trials before it is clear whether or not CETP inhibition has therapeutic value.

ACQUIRED HYPERLIPIDAEMIAS

Acquired, or secondary, hyperlipidaemia is caused by alterations in lipoprotein metabolism resulting from another disease state or from drug therapy. Treatment of the underlying condition or discontinuation of the precipitating drug may correct the hyperlipidaemia. However, in some cases, such as chronic kidney disease or diabetes, where metabolism remains disturbed despite treatment, hyperlipidaemia may persist. In these conditions the increased vascular risk is a function of qualitative as well as quantitative changes in plasma lipoproteins. In particular, LDL exists in a small, dense form which is more readily oxidized and consequently more atherogenic. Cardiovascular risk therefore remains higher than is predicted from cholesterol and triglyceride measurements alone. The secondary hyperlipidaemias are summarized in [Box 37.3](#).

Xanthomata may occur in acquired hyperlipidaemia just as in the primary lipid disorders with the same pattern of lipid abnormalities: thus eruptive xanthomata occur in the chylomicronaemia syndrome, whatever its aetiology. Florid cutaneous lipid deposition may occur in the presence of abnormal lipoproteins such as lipoprotein X in cholestasis (see below) or where monoclonal immunoglobulins bind lipoproteins or their receptors and interfere with lipid metabolism, as may occur in monoclonal gammopathy of uncertain significance (MGUS) and multiple myeloma.

Diabetes mellitus

Poorly controlled diabetes gives rise to hypertriglyceridaemia. In both types of diabetes, there is insulin deficiency,

^aExcept cholestasis in which there is an increase in the abnormal lipoprotein, lipoprotein X.

^bThe presence of abnormal immunoglobulins, as occurs in multiple myeloma, benign monoclonal gammopathies and systemic lupus erythematosus can give rise to any abnormality of the lipoprotein pattern due to binding to lipoproteins, enzymes or receptors and thereby preventing normal lipoprotein metabolism.

^cOften accompanied by a low HDL.

either absolute in type 1 diabetes or relative in type 2 diabetes. Insulin activates lipoprotein lipase and thereby enhances clearance of triglyceride-rich lipoproteins, but has the opposite effect on the HSL of adipose tissue. Thus, in insulin deficiency there is, in addition to reduced clearance, an increased influx of free fatty acids to the liver, leading to increased hepatic triglyceride synthesis.

In well-controlled diabetes, although plasma total cholesterol and triglyceride concentrations may be normal, there often remains a significant dyslipidaemia, sometimes referred to as an 'atherogenic lipoprotein phenotype'. Plasma HDL-cholesterol concentration is usually low (<1.1 mmol/L) and triglyceride concentration elevated (>1.7 mmol/L). This pattern is indicative of the presence of small, dense LDL particles, which are more susceptible to oxidation and more atherogenic. It has been demonstrated that apolipoproteins A-I, A-II, B, C-I and E become glycosylated in patients with diabetes: it is possible that this glycation affects the normal uptake of remnant particles, resulting in their persistence in the circulation with atherogenic consequences.

The genetic background on which a secondary hyperlipidaemia is superimposed will affect its severity; for example, diabetic patients who manifest fasting chylomicronaemia are likely to have an underlying primary hypertriglyceridaemia.

Hypothyroidism

Various lipid abnormalities may occur in patients with untreated hypothyroidism, but the commonest is an increase in plasma LDL-cholesterol concentration. This is a consequence of a reduction in LDL receptors, resulting in reduced clearance of LDL. Lipoprotein lipase activity may also be impaired in hypothyroidism, which explains the hypertriglyceridaemia that sometimes occurs.

Since both overt and subclinical hypothyroidism are relatively common, it is imperative that all subjects found to have hyperlipidaemia are screened for hypothyroidism. If they are found to be hypothyroid, treatment with thyroxine should be instituted. If the subject does not have cardiovascular disease, the lipid profile should be rechecked once the euthyroid state is regained before a decision on lipid-lowering treatment is made. If the subject already has cardiovascular disease when hypothyroidism is diagnosed, it may be unwise to delay lipid lowering therapy, but it should be instituted with care since hypothyroidism increases the risk of statin-induced adverse muscle effects.

Nephrotic syndrome

Longstanding nephrotic syndrome is associated with accelerated atherosclerosis; thus lipid-lowering treatment will usually be required. There is evidence that, in the nephrotic syndrome, the hyperlipidaemia may worsen renal function: oxidized LDL has been shown in vitro to affect mesangial cells and accelerate glomerulosclerosis. The hyperlipidaemia occurring in the nephrotic syndrome is most commonly hypercholesterolaemia, but mixed hyperlipidaemia also occurs. The hypercholesterolaemia is a result of hepatic overproduction of apo B-100 as part of the generally increased hepatic protein synthesis typical of the condition. Hydroxymethylglutaryl-CoA (HMG-CoA) reductase activity is also increased. The increase in triglyceride results from reduced removal of chylomicrons and VLDL due to impaired lipoprotein lipase activity. HDL may be lost in the urine and, dependent on whether or not increased synthesis matches the rate of loss, the plasma HDL-cholesterol concentration may be low, normal or occasionally high.

Chronic kidney disease

Patients with chronic kidney disease (CKD) are at very high risk of cardiovascular disease. The lipid abnormality most commonly seen is hypertriglyceridaemia; the lipoprotein profile is characterized by a high concentration of intestinally derived apo B-48-containing lipoproteins and their remnants. The composition of the lipoproteins is also changed. The apo C-III concentration of the triglyceride-rich lipoproteins is increased and, since apo C-III inhibits both lipoprotein lipase and the hepatic uptake of chylomicron and VLDL remnants, this results in

increased plasma triglyceride concentrations. Although total cholesterol may be relatively 'normal', much of the LDL is small and dense and therefore is particularly atherogenic. Although hypertriglyceridaemia is usually present, the most extensive evidence for reduction in cardiovascular disease risk by lipid modification is through use of HMGCoA reductase inhibitors (statins), which reduce LDL, even though they have comparatively little effect on plasma triglycerides.

Renal transplantation

After transplantation, the hyperlipidaemia that accompanies impaired renal function may be corrected, but this is not always the case. In addition, immunosuppressant therapy, including corticosteroids, may itself cause hyperlipidaemia. The degree of hypercholesterolaemia is often greater with sirolimus and ciclosporin than with tacrolimus. Thus, subjects post-transplant remain at high risk of cardiovascular disease, and since they will have been hyperlipidaemic prior to transplantation, therapy to improve their lipids is warranted. Caution needs to be taken, however, because of the well-documented interactions between ciclosporin and both statins and fibrates.

Liver disease

The liver plays a central role in lipoprotein metabolism. In addition, the only physiological means the body has of excreting cholesterol is by its hepatic secretion into the bile.

Cholestasis is frequently accompanied by a mixed hyperlipidaemia due to the accumulation of remnant lipoproteins. Lipoprotein X is found uniquely in cholestasis. This lipoprotein contains bile acids, apo C, apo D, albumin and cholesterol, and while it falls within the LDL density range, unlike all the other lipoproteins, it migrates towards the cathode on lipoprotein electrophoresis. The atherogenic potential of lipoprotein X is undefined; when present in massive amounts (cholesterol >50mmol/L), lipoprotein X has been associated with hyperviscosity. Plasma Lp(a) concentration is low and HDL-cholesterol is high in cholestasis; these abnormalities may, in part, explain the fact that cholestasis is not generally associated with a high cardiovascular risk.

Non-alcoholic fatty liver disease (NAFLD) is a manifestation of the metabolic syndrome and, as such, is associated with an increased cardiovascular risk. The dyslipidaemia associated with NAFLD is either hypertriglyceridaemia or mixed hyperlipidaemia; it is frequently associated with small, dense LDL particles. Where the condition runs in families, it is difficult to distinguish from familial combined hyperlipidaemia. Subjects with NAFLD may have abnormal plasma liver enzyme activities (particularly increased aminotransferases) and caution therefore needs to be exercised when starting lipid-lowering agents. However, owing to the increased cardiovascular risk, treatment is warranted. Statins are generally the drug of first choice unless severe hypertriglyceridaemia is present creating a risk of pancreatitis. Although liver enzymes should be monitored, treatment is usually safe, and in some individuals, normalization of the lipid profile results in a reduction in the aminotransferase activities.

Alcohol

Alcohol causes hypertriglyceridaemia in susceptible individuals. This results from a combination of increased production and impaired removal of VLDL. In severe cases, this may result in chylomicronaemia, which may result in acute pancreatitis.

Epidemiological studies have suggested that moderate alcohol intake (no more than 1–2 units per day) is associated with a lower mortality than either higher alcohol intakes or abstinence from alcohol. Such moderate intake is associated with an increase in plasma HDL-cholesterol concentration, which may be responsible for the apparent cardiovascular protection.

Drug-related hyperlipidaemia

Various drugs, including antihypertensive agents (β -blockers, thiazides), corticosteroids, sex steroids, immunosuppressants, second generation antipsychotics and antiretroviral drugs, can affect lipoprotein concentrations.

The effect of antihypertensives on the lipid profile has been extensively studied since early hypertension trials demonstrated that effective lowering of blood pressure reduced the incidence of strokes but not that of coronary heart disease. The effect of β -blockers depends on their selectivity: non-selective (e.g. propranolol) and β_1 -selective (e.g. atenolol) β -blockers raise plasma triglycerides and lower HDL, whereas β -blockers with intrinsic sympathomimetic activity (e.g. pindolol) are lipid neutral. The hyperlipidaemia associated with diuretic therapy appears to be caused by the unopposed α -adrenergic activity elicited by these drugs; the low dosages (e.g. 2.5 mg of bendroflumethiazide) now used for treatment of hypertension have a negligible effect on the lipid profile.

Glucocorticoid treatment results in an increase in plasma LDL, HDL and triglyceride concentrations. Oestrogens increase hepatic VLDL secretion and increase HDL (HDL₂). In postmenopausal women, they also tend to reduce LDL. Progestogens, on the other hand, tend to reduce HDL (especially HDL₂) and raise LDL. With both oral contraceptives and hormone replacement therapy, the magnitude of the changes in the lipoproteins depends on the dose, the route of administration, the particular oestrogen and progestogen involved and whether or not there is an underlying primary hyperlipoproteinaemia. The use of oral oestrogen results in exposure of the liver to supra-physiological doses of oestrogen, with stimulation of hepatic lipoprotein synthesis. Severe hypertriglyceridaemia may be precipitated by the use of oral oestrogen in susceptible individuals, who may have a normal plasma triglyceride concentration or only mild hypertriglyceridaemia when not taking oestrogen or using topical (patch) oestrogen hormone replacement therapy. Of the progestogens, the 19-nortestosterone derivatives (e.g. norethisterone, levonorgestrel) are considerably more androgenic than the C21 progestogens (e.g. medroxyprogesterone acetate, dydrogesterone) and result in greater reductions in plasma HDL concentrations.

Tamoxifen, a selective oestrogen receptor modulator that has agonist and antagonist oestrogen effects, has a predominantly agonistic effect on the liver and thus can cause severe hypertriglyceridaemia.

Among immunosuppressant drugs, both the calcineurin inhibitors (ciclosporin, tacrolimus) and the non-calcineurin inhibitor, sirolimus, can cause hyperlipidaemia, which, in most individuals, is an isolated increase in plasma LDL concentration.

Hypertriglyceridaemia is a common side-effect of second generation antipsychotic drugs including clozapine, olanzapine and quetiapine. This may be severe, and cases of pancreatitis, thought to result from the hypertriglyceridaemia, have been reported.

Antiretroviral drug treatment is frequently associated with dyslipidaemia. The combination of fat redistribution, insulin resistance and dyslipidaemia seen in subjects on antiretroviral treatment is referred to as 'the lipodystrophy syndrome'. The fat redistribution is characterized by loss of subcutaneous fat and accumulation of intra-abdominal fat. This is associated with regimens containing protease inhibitors and nucleoside reverse transcriptase inhibitors, whereas the dyslipidaemia and insulin resistance are associated particularly with protease inhibitors. Care is required in treating dyslipidaemia in these individuals as a number of antiretroviral therapies interact with lipid lowering treatments.

ACQUIRED HYPOLIPIDAEMIA

Acquired or secondary hypolipidaemia is much less common than its hyperlipidaemic equivalent. It occurs with cachexia, malabsorption, hyperthyroidism, malnutrition, liver failure and some forms of malignancy. It is of no direct clinical consequence, being only a manifestation of the underlying condition.

Drug therapy can also cause hypolipidaemia. Excessive thyroxine will cause a reduction in total cholesterol, mimicking that seen with thyrotoxicosis. Drugs including fibrates and thiazolidinediones have been reported occasionally to cause an unpredictable and profound paradoxical fall in plasma HDL-cholesterol concentration in susceptible individuals.

INVESTIGATION OF LIPID DISORDERS

The simple appearance of a serum or plasma sample may indicate a lipid disorder. Chylomicrons and VLDL are large enough to scatter light. Chylomicrons are less dense than plasma and will form a layer on the surface of a sample left standing at 4°C overnight. If present in very large amounts, VLDL will make the sample appear opalescent.

Total cholesterol

This is the most commonly used single measure of lipid status. It has been used extensively in epidemiological studies, and may have some use in monitoring treatment. However, it is inadequate on its own for the diagnosis of lipid disorders, or as the only measure prior to starting

treatment. A full fasting lipid profile including triglyceride and HDL-cholesterol should be measured at least once to avoid missing significant dyslipidaemias with normal total cholesterol. LDL-cholesterol, non-HDL-cholesterol and apo B measurements may have benefits in assessing cardiovascular risk and the adequacy of treatment.

Cholesterol is generally measured by enzymatic methods using cholesterol oxidase. Although analytical CV is low (typically <3%), intraindividual biological variation is around 5% so it is important to appreciate that the critical difference between consecutive measurements in monitoring therapy may be around 0.8 mmol/L. Fasting or non-fasting makes little difference ($\pm 3\%$) to measurements.

Triglycerides

Triglyceride increases up to 2–3-fold after a meal, and so samples should be taken after an overnight (>12 h) fast in order to obviate difficulties of interpretation resulting from the presence of chylomicrons or chylomicron remnants. Most triglyceride methods involve hydrolysis of triglycerides and measurement of the free glycerol released. Glycerol blanking is not routinely performed. In certain circumstances, such as patients with uncontrolled diabetes mellitus, on haemodialysis, or with the rare X-linked recessive disorder glycerol kinase deficiency, the glycerol content of the sample may be significantly raised. In these situations, high concentrations of glycerol in the plasma will produce falsely high triglyceride results, and glycerol blanking is essential to obtain a valid result.

Plasma triglyceride concentration has a much greater biological variation than does that of cholesterol, at ~20% even in fasting samples.

High density lipoprotein cholesterol

Plasma HDL concentration is generally measured by direct (homogeneous) methods that rely on antigen/antibody complex formation, or polyethylene glycol (PEG) modified enzymes that react selectively with cholesterol in HDL. These assays can provide reliable results in the presence of triglyceride concentrations up to 10 mmol/L.

Low density lipoprotein cholesterol

LDL-cholesterol (LDL-C) can be derived by substituting the results of the analysis of total cholesterol (TC), HDL-cholesterol (HDL-C) and triglyceride (TG) (fasting) into the Friedewald formula:

$$\text{LDL-C} = \text{TC} - \left(\text{HDL-C} + \frac{\text{TG}}{2.2} \right)$$

(all measurements being in mmol/L).

The Friedewald formula assumes that most of the triglyceride in the plasma is in VLDL and that there is a molar ratio of 5:1 of triglyceride to cholesterol in the VLDL fraction. For this reason, the Friedewald formula is not applicable in subjects with remnant hyperlipidaemia in whom the remnant lipoprotein fraction is cholesterol-enriched. In addition, it is not applicable to subjects with plasma

triglyceride concentrations >4.5 mmol/L since, at these levels, VLDL contains a greater proportion of triglyceride, and so the formula overestimates VLDL-cholesterol and underestimates LDL-cholesterol. Although most laboratories report derived plasma LDL-cholesterol concentrations on samples with triglycerides up to 4.5 mmol/L this tendency for VLDL to contain a greater proportion of triglyceride is sometimes present at lower concentrations of triglycerides, to a degree which may be clinically significant. The error in calculated LDL-cholesterol is $>10\%$ in more than 30% of subjects with a plasma triglyceride concentration of 2.3–3.4 mmol/L and in $>40\%$ of subjects with triglycerides of 3.4–4.5 mmol/L.

Directly LDL-cholesterol assays are being used increasingly. In general, they compare well with LDL-cholesterol as measured using ultracentrifugation. They have the advantage of being able to measure LDL-cholesterol in non-fasting samples, but because they are immunoseparation methods, have the disadvantage of higher cost compared with the simpler enzymatic measurement of total and HDL-cholesterol, and triglyceride.

Plasma LDL-cholesterol concentration is increasingly used in epidemiological and therapeutic studies and treatment goals based on LDL-cholesterol have been incorporated into most national guidelines.

Non-HDL-cholesterol

Non-HDL-cholesterol is derived simply using the formula (total cholesterol – HDL-cholesterol). The major difference from LDL-cholesterol is that it includes cholesterol in VLDL. In some epidemiological studies it has been shown to predict vascular risk almost as well as apo B and better than LDL-cholesterol. This may simply be because VLDL is atherogenic in its own right, but also because non-HDL-cholesterol may reflect LDL particle number better than measurement of LDL-cholesterol concentration alone.

Other advantages of non-HDL-cholesterol are that it can be measured in non-fasting samples, and that its measurement has better precision and accuracy than Friedewald derived LDL-cholesterol. It is also cheaper than measurement of apo B. It has been adopted in a number of current guidelines alongside LDL-cholesterol.

Apolipoproteins

Apolipoprotein A-I

Apolipoprotein A-I measurement has been advocated as an alternative to HDL-cholesterol, but it is generally more expensive, and clear advantage over measurement of HDL-cholesterol with modern homogeneous assays has not been demonstrated.

Apolipoprotein B

Apolipoprotein B measurement does serve a useful purpose in the investigation of lipid disorders. As there is only one apo B molecule in each apo B containing lipoprotein particle, measurement of apo B provides a measure of particle number. There is epidemiological evidence that

this may provide a better predictor of cardiovascular risk and response to treatment than measurement of LDL-cholesterol (directly measured or derived). This is because small dense LDL particles will tend to result in lower concentrations of LDL-cholesterol, but are relatively more atherogenic than less dense, cholesterol-enriched LDL.

Apolipoprotein B measurement may be helpful in diagnosis, particularly in patients with mixed hyperlipidaemia. Apo B is often elevated in familial combined hyperlipidaemia, and low in proportion to total cholesterol in remnant hyperlipidaemia.

Apolipoprotein B and non-HDL-cholesterol show similar ability to predict cardiac risk in population studies. Apolipoprotein B may, however, be superior in patients with a large proportion of small dense LDL including those with type 2 diabetes and the metabolic syndrome.

Apolipoprotein E

Although it is not essential for managing patients, knowledge of the apolipoprotein E phenotype (based on electrophoresis) or confirmation of an $\epsilon 2/\epsilon 2$ genotype is sometimes helpful in confirming a diagnosis of remnant hyperlipoproteinaemia. It should also be remembered that the finding of an $\epsilon 2/\epsilon 2$ genotype on its own does not establish the diagnosis as other factors need to be present before the typical clinical phenotype becomes manifest.

Lipoprotein(a)

Standardization has only become available for Lp(a) over the last few years. Very wide variation between methods made the assay of limited utility in the past. It is important that assays are independent of the number of kringle 4 repeats in the highly variable region of the molecule. Plasma Lp(a) concentration is normally <30 mg/dL but shows a highly positively skewed distribution. High concentrations are associated with an increased risk of cardiovascular disease, and the greatest utility of measurement is in assessing risk in those with high plasma LDL-cholesterol concentration.

In patients with familial hypercholesterolaemia who have very high Lp(a) concentrations (>60 mg/dL), LDL apheresis, which selectively removes apo B containing lipoprotein particles, is occasionally used, as statins have very little impact on Lp(a).

Post-heparin lipolytic activity

The intravenous injection of heparin leads to the release into the circulation of both LPL and HL. Measurement of LPL activity is useful in the differential diagnosis of severe hypertriglyceridaemia where chylomicronaemia is present (type I hyperlipidaemia). This may be due to a deficiency of lipoprotein lipase.

Lipoprotein separation techniques

Ultracentrifugation

Preparative ultracentrifugation is the reference procedure for isolating lipoproteins; it involves sequential isolation of lipoprotein classes from plasma after adjustment

of the density with sodium chloride, potassium bromide, sodium bromide or mixtures of these salts. This is a time-consuming procedure and may take up to five days for isolation of all subclasses to be completed. Losses may occur at all stages and artefacts may also be introduced. It is generally reserved for research studies.

Lipoprotein electrophoresis

Electrophoresis on cellulose acetate, paper, agarose and polyacrylamide has been used as a means of separating the lipoprotein classes and, indeed, the separation pattern on paper electrophoresis was the basis of the Fredrickson classification of lipid disorders. For therapeutic purposes, the Fredrickson classification has been replaced by defining the genetic basis of the hyperlipidaemia. It may still be of use in the diagnosis of remnant hyperlipidaemia with its broad β band, and may be helpful in deficiency states; for example, in demonstrating the lack of pre- β and β bands in abetalipoproteinaemia.

Genotyping

Genetic testing is particularly used for the diagnosis of remnant hyperlipidaemia, and familial hypercholesterolaemia (FH). Homozygosity for the $\epsilon 2$ allele of the apolipoprotein E gene is seen in remnant hyperlipidaemia. FH is due to mutations in *LDLR*, *APOB*, *PCSK9* or *LDLRAP1* genes.

Genotyping will also be used increasingly to confirm the diagnosis of rare monogenic lipid disorders. In addition, genome-wide association studies are starting to identify single nucleotide polymorphisms (SNPs) in multiple genes that may have minor effects individually but clinically significant effects cumulatively. This is starting to provide insight into the genetic basis of many common lipid and lipoprotein phenotypes, but has not yet found application in routine practice.

A further application of genetic testing is in tailoring therapy. A SNP in *SLCO1B1* has been described which is associated with a four-fold increased risk increased risk of statin toxicity in heterozygotes and 16-fold increased risk in homozygotes. This gene codes for an organic anion transporter protein (OATP1B1) that is responsible for the uptake of statins to their site of action in the liver. Deficiency results in reduced efficacy and increased plasma levels with consequent increased risk of myositis. Fluvastatin is not taken up via this mechanism, and may be more effective and better tolerated in individuals with this polymorphism.

TREATMENT OF HYPERLIPIDAEMIA

Management of patients with hyperlipidaemia requires a full history, including a personal history of cardiovascular disease and conditions that can cause dyslipidaemias, family history of cardiovascular disease (with age of onset), lifestyle factors and drugs that may produce lipid abnormalities. Clinical examination and a detailed family history may suggest a specific genetic diagnosis, which may be confirmed by lipid, lipoprotein or genetic testing.

Genetic lipid disorders may require more aggressive treatment, particularly if they suggest (e.g. in FH) that cholesterol levels have been elevated since soon after birth. They may also indicate the need for family screening.

All patients should receive lifestyle advice (including advice concerning smoking cessation where relevant). The aim of dietary advice is both to achieve weight loss (where needed) and an appropriate balance of nutrients including control of the amount of fat, and especially saturated fat, in the diet. Causes of secondary dyslipidaemia should be treated: correction of untreated hypothyroidism or newly diagnosed diabetes may produce a marked fall in plasma lipid concentrations.

In patients with fasting serum triglyceride concentrations of >10 mmol/L, there is a risk of acute pancreatitis, and treatment to lower the triglycerides should normally be the initial priority. Fibric acid derivatives (fibrates) and high doses of fish oils (e.g. Omacor®) are generally the first-line treatments. Some patients with type 2 diabetes may benefit from the introduction of insulin.

In other cases, treatment is based on serum lipid concentrations and an assessment of a patient's overall cardiovascular risk. Reduction in cardiovascular risk is the main aim, and statins are generally the first-line treatment. They have the most extensive evidence base and are generally used even if triglyceride concentrations are slightly or moderately raised, so long as this is not high enough to cause pancreatitis.

The highest priority is to treat those with clinical evidence of vascular disease (including cerebrovascular and peripheral vascular as well as coronary disease, i.e. secondary prevention). Primary prevention (i.e. in the absence of vascular disease) is targeted to those at the highest risk. This includes those with genetic hyperlipidaemias (e.g. FH), those with conditions known to cause qualitative lipoprotein changes that increase risk (e.g. diabetes, when treatment is generally recommended above the age of 40), and those estimated to be at high risk of cardiovascular disease based on lipid results and cardiovascular risk factors. Various risk calculation tools are available for calculation of ten-year or lifetime risk, based on epidemiological data (see Chapter 38 for a more detailed discussion).

The aim of treatment is ideally to reduce serum total cholesterol concentration to <4 mmol/L and LDL-cholesterol concentration to <2 mmol/L. Targets for non-HDL-cholesterol of <2.5 mmol/L and apo B of <0.8 g/L are also recommended. These targets recognize that residual risk of cardiovascular event after LDL-cholesterol reduction with statins depends on LDL particle number, which may better be reflected by measuring plasma apo B concentration.

If targets are not achieved, then fibrates, ezetimibe or bile acid sequestrants are all options, usually in addition to a statin, although none have such a robust evidence base as statins for reducing cardiovascular events. Use of lipid lowering drugs in combination is usually safe although care must be taken to identify patients who are at increased risk of skeletal myopathy.

In patients with FH, drug treatment is generally considered by the age of ten, with the aim of reducing serum LDL-cholesterol concentration by $>50\%$. In those with a more severe phenotype or with homozygous FH, LDL

TABLE 37.7 Drugs used in the treatment of dyslipoproteinaemias

Drug group	Mode of action	Indications/advantages	Adverse effects
Bile acid sequestrants (e.g. cholestyramine, colestipol, colesevelam)	Interrupt the enterohepatic circulation by binding bile salts. This results in increased hepatic LDL uptake but also increased cholesterol synthesis	Raised LDL-C. Safe in pregnancy. Used in LRCCT ^a and shown to reduce morbidity and mortality from coronary artery disease	Increase triglyceride concentration. Constipation, diarrhoea, nausea, abdominal bloating or discomfort. May interfere with absorption of other drugs
Fibric acid derivatives (e.g. fenofibrate, bezafibrate, gemfibrozil)	PPAR α agonist activity has multiple effects including increased LPL activity, increased <i>ABCA1</i> transcription, reduced hepatic VLDL production, increased LDLR mediated uptake and increased biliary cholesterol secretion	Hypertriglyceridaemia (\uparrow VLDL) Mixed hyperlipidaemia (\uparrow VLDL and \uparrow LDL) and remnant hyperlipoproteinaemia. Tendency for HDL-C to increase	Increased creatine kinase and myopathy – care necessary if using in combination with a statin (avoid gemfibrozil). Indigestion. Cholelithiasis. Potentiation of oral anticoagulants. Abnormal liver enzymes
Hydroxymethoxyglutaryl-coenzyme A reductase inhibitors (e.g. simvastatin, pravastatin, fluvastatin, atorvastatin and rosuvastatin)	Inhibit the rate-limiting enzyme of cholesterol synthesis thus increasing LDL receptor-mediated uptake from plasma	Raised LDL-C. Well tolerated. Clinical endpoint studies showing benefits in reducing cardiovascular events and total mortality (CTT ^b). ASTEROID ^c (rosuvastatin) showed regression of coronary atherosclerosis	Occasional patients develop myopathy and rhabdomyolysis, especially with concomitant use of drugs including ciclosporin, gemfibrozil and erythromycin. Abnormal liver enzymes
ω -3 Fish oil rich in the polyunsaturated fatty acids: eicosapentaenoic and docosahexanoic acids, e.g. Omacor [®] , Maxepa [®]	Reduces VLDL triglyceride synthesis	High triglyceride concentrations due to increased VLDL, whether alone or in combination with chylomicronaemia. At pharmacological dosage also possesses antithrombotic and anti-inflammatory properties	Nausea, flatulence
Ezetimibe	Specific inhibitor of intestinal cholesterol absorption. Blocks enterohepatic recirculation of biliary cholesterol, as well as reducing absorption of dietary cholesterol	As an adjunct to a statin for the treatment of elevated LDL-C or alone if a statin is not tolerated or inappropriate. Can also be used to treat β -sitosterolaemia (phytosterolaemia)	Gastrointestinal disturbance. Raised creatine kinase or myalgia
Drugs in clinical trials			
CETP inhibitors (anacetrapib; evacetrapib)	Inhibit cholesterol ester transfer protein	As adjunct to statins to raise HDL-C and reduce cardiovascular risk	Effect of increasing HDL-C on cardiovascular outcome still uncertain.
MTP inhibitors (lomitapide)	Inhibit microsomal triglyceride transfer protein	Clinical trials ongoing in homozygous FH and in familial hypertriglyceridaemia	Hepatic steatosis
LDL antisense oligonucleotides, e.g. mipomersen (KYNAMRO [®])	Reduce LDL synthesis by inhibiting <i>APOB</i> transcription	Hypercholesterolaemia	
PCSK9 inhibitors	Increase LDL receptor activity by genetic inhibition or immunological blockade of PCSK9	Hypercholesterolaemia	Reduce HDL-C as well as LDL-C cholesterol. Injectable. Effect on outcome unclear
Drugs under development			
Apo A-I based therapies	Apo A-I mimetics and synthetic HDL particle infusion		
LPL gene replacement ABCA1 agonists LCAT activators Lp-PLA ₂ inhibitors		LPL deficiency	

^aLRCCT, Lipid Research Clinics Coronary Primary Prevention Trial^bCTT, Cholesterol Treatment Trialists collaboration (a meta-analysis of the major statin trials)^cASTEROID, A study to evaluate the effect of rosuvastatin on intravascular ultrasound derived coronary atherosclerosis burden.

apheresis is a treatment option. New agents such as MTP and PCSK9 inhibitors, and apo B mRNA antisense oligonucleotides are in development or clinical trials.

A summary of drugs used to treat hyperlipidaemia, and of those currently in development or clinical trials, is given in [Table 37.7](#).

Side-effects of statins and other lipid lowering treatments include elevation of transaminases and muscle effects ranging from an asymptomatic slight rise in creatine kinase (CK), through myalgia or myositis, with or without a rise in CK, to, rarely, rhabdomyolysis. Patients should be warned of possible effects and liver enzymes should be monitored. Drug interactions (e.g. with immunosuppressant drugs) increase the risk of myositis. Genetic variants may also increase the risk of muscle side-effects (see p. 734).

While targeting those at highest risk, and treating them aggressively with lipid lowering drug treatment, is highly effective in individuals, it is important to recognize that the greatest impact on population rates of CVD would still to be made by changing the diet and lifestyle habits of the population as a whole.

CONCLUSION

The principal lipids present in the blood are cholesterol, triglycerides and phospholipids. They are transported, in association with various apolipoproteins, in lipoprotein particles. Lipids have essential functions in cellular structure and metabolism but, at present, the major clinical interest in them derives from the relationship between the plasma cholesterol concentration (specifically LDL-cholesterol) and the risk of developing atherosclerosis.

Lipid metabolism is complex; there is a continuous flux of lipoprotein particles between the blood and tissues, and of the lipid and protein components between lipoprotein particles. Abnormalities of plasma lipids and of

lipoprotein composition occur frequently. They can arise as a result of a disease that secondarily affects lipid metabolism (e.g. diabetes, hypothyroidism) or be primary, that is, genetically determined.

In the genetic hyperlipidaemias, appropriate investigation will define the nature and severity of the disorder and provide a rational basis for treatment. Greater understanding of the details of lipoprotein metabolism will continue to identify new therapeutic targets and bring the potential for effective new therapies. In the majority of cases, the aim is to reduce the risk of cardiovascular disease, and therefore specific therapy for the hyperlipidaemia needs to be accompanied by action against all the other pertinent risk factors.

APPENDIX 765

INTRODUCTION

The cardiovascular or circulatory system consists of the heart and blood vessels (arteries, arterioles, capillaries, venules and veins). When it functions normally, effective circulation of blood maintains perfusion of the tissues, so that substrates for cellular metabolism are provided and excretory products removed. Among other vital functions, it also allows hormones to be transported from their organs of origin to their target tissues, defends against infection through facilitation of the movement of white cells and cytokines, and promotes haemostasis through delivery of platelets and clotting factors to traumatized tissue.

Circulation of blood is maintained by the pumping action of the heart, a muscular organ consisting of two atria and two ventricles. The atria receive blood (the left atrium from the lungs and the right atrium from the rest of the body) and pass it to the ventricles. The right ventricle pumps deoxygenated venous blood to the lungs for oxygenation while the left ventricle supplies oxygenated blood to the rest of the body (including itself) via the aorta, arteries, arterioles and capillaries.

Cardiovascular disease

Cardiovascular disease (CVD) collectively comprises disease of the heart and of blood vessels (almost invariably arteries) supplying any organ. The organs most commonly affected by arterial disease are the heart (coronary artery disease), the brain (cerebrovascular disease) and the limbs (peripheral arterial disease). Renovascular disease is an important cause of chronic kidney disease and of hypertension.

Cardiovascular disease is the leading cause of death in England and Wales, currently responsible for one in three deaths. For every death due to CVD, there are at least two major non-fatal CVD events. It is also the leading cause of death globally: the World Health Organization (WHO) estimated that 17.3 million people died from CVD in 2008, representing 30% of all deaths. Of these, an estimated 7.3 million deaths were due to coronary heart disease and 6.2 million were due to stroke (cerebrovascular disease). Although approximately 80% of CVD is due to modifiable factors and is potentially preventable, CVD deaths continue to rise, largely because preventative measures are insufficient or ineffective. Low- and middle-income countries are disproportionately affected,

with less than 20% of global deaths from CVD occurring in high-income countries (Fig. 38.1). Mortality due to all main communicable diseases, including HIV/AIDS, tuberculosis and malaria, is expected to decline globally between now and 2030. By 2030, it is anticipated that CVD alone will be responsible for more deaths in low-income countries than infectious diseases, maternal and perinatal conditions, and nutritional disorders combined, driven in particular by the increased global prevalence of obesity. Worldwide, it is estimated that in 2030, non-communicable diseases will account for more than three-quarters of all deaths, and almost 23.6 million people will die from CVD. Thus, CVD is today the largest single contributor to global mortality and is set to continue to dominate mortality trends on the world stage well into the future.

Atherosclerosis is by far the most common cause of cardiovascular disease in developed countries: thus the term ‘cardiovascular disease’ is generally used and perceived to mean ‘atherosclerotic disease’, the term ‘coronary artery disease’ or ‘coronary heart disease’ to mean atherosclerosis

of the coronary arteries, and ‘cerebrovascular disease’ to mean atherosclerosis of the cerebral vasculature. Coronary artery atherosclerosis leads to diminished blood supply to, or ischaemia of, the myocardium. When this becomes critical the heart muscles die, leading to a ‘myocardial infarction’ (MI), often, but not invariably, accompanied by diagnostic changes on the electrocardiogram (ECG). Acute coronary syndrome (ACS) is a blanket term for patients presenting acutely with clinical features of myocardial ischaemia, and encompasses ST elevation MI (STEMI), non-ST elevation MI (NSTEMI) and unstable angina (UA) (Fig. 38.2). Death from ischaemic heart disease leading to failure of the heart to maintain circulation may occur acutely in the setting of a myocardial infarction (either due to a large area of infarction or to cardiac dysrhythmia, which interferes with effective ventricular contraction) or in the setting of chronic heart failure. Treatment of MI with thrombolytic drugs or percutaneous coronary intervention (PCI) with or without stenting can be life-saving but depends on prompt and accurate diagnosis.

FIGURE 38.1 ■ Projected deaths by cause in 2004, 2015 and 2030, in low-, middle- and high-income countries. Countries are categorized by the World Bank according to 2004 gross national income per person: low income < US\$826; middle income US\$826–\$10 065; high income > US\$10 066. FIGURE 38.2 ■ Categories of acute coronary syndromes, and the investigations used to discriminate between them. NSTEMACS, non-ST elevation ACS; STEMI, ST elevation myocardial infarction; UA, unstable angina.

Role of the laboratory

The clinical biochemistry laboratory plays a critical role in the management of acute myocardial ischaemia, where delay in diagnosis and treatment directly increases morbidity and mortality. For many years, the diagnosis of acute MI relied on criteria that had been established by the World Health Organization (WHO) in 1979: rise in a biomarker of cardiac myocyte injury was one of the criteria but was not a prerequisite. The development of more specific and sensitive cardiac biomarkers has facilitated earlier and more accurate diagnosis, which permits more timely and appropriate intervention. In 2000, recognition of the fact that the newer cardiac biomarkers could identify myocardial micronecrosis, even when conventional diagnostic criteria excluded MI, led to a new joint European Society of Cardiology and American College of Cardiology (ESC/ACC) committee universal definition of 'myocardial infarction', in which biomarker measurement played a fundamental role. The definition was further revised in 2007 and again in 2012 by the Joint Task Force of the European Society of Cardiology, American College of Cardiology Foundation, the American Heart Association and the World Health Federation (ESC/ACCF/AHA/WHF). The current universal definition of acute MI has a rise and/or fall in cardiac biomarkers (preferably troponin) as the central feature of the definition (Box 38.1).

Identification of those at high risk of developing coronary atherosclerosis allows earlier intervention to prevent related clinical events, and there has also been sustained focus on developing biomarkers to aid prediction of cardiovascular risk. The laboratory also plays important roles in the diagnosis of heart failure and in the investigation of hypertension.

After sections describing the structure of heart muscle and arteries, and the pathogenesis of atherosclerosis, these roles will be explored in turn.

BOX 38.1 Definition of myocardial infarction

Criteria for acute myocardial infarction

The term acute myocardial infarction (MI) should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischaemia.

Under these conditions any one of the following criteria meets the diagnosis for MI.

- Detection of a rise and/or fall of cardiac biomarker values (preferably cardiac troponin, cTn) with at least one value above the 99th percentile upper reference limit (URL) and with at least one of the following:
 - symptoms of ischaemia
 - new or presumed new significant ST-segment-T wave (ST-T) changes or new left bundle branch block (LBBB)
 - development of pathological Q waves in the ECG
 - imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
 - identification of an intracoronary thrombus by angiography or autopsy.
- Cardiac death with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes or new LBBB, but death occurred before cardiac biomarkers were obtained or before cardiac biomarker values would be increased.
- Percutaneous coronary intervention (PCI) related MI is arbitrarily defined by elevation of cTn values ($>5 \times 99$ th centile URL) in patients with normal baseline values (≤ 99 th centile URL) or a rise of cTn values $>20\%$ if the baseline values are elevated and are stable or falling. In addition, either: (i) symptoms suggestive of myocardial ischaemia or (ii) new ischaemic ECG changes or (iii) angiographic findings consistent with a procedural complication or (iv) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality are required.
- Stent thrombosis associated with MI when detected by coronary angiography or autopsy in the setting of myocardial ischaemia and with a rise and/or fall of cardiac biomarker values with at least one value above the 99th percentile URL.
- Coronary artery bypass grafting (CABG)-related MI is arbitrarily defined by elevation of cardiac biomarker values ($>10 \times 99$ th centile URL) in patients with normal baseline cTn values (≤ 99 th centile URL). In addition, either (i) new pathological Q waves or new LBBB or (ii) angiographic documented new graft or new native coronary artery occlusion or (iii) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Criteria for prior myocardial infarction

Any one of the following criteria meets the diagnosis for prior MI.

- Pathological Q waves with or without symptoms in the absence of non-ischaemic causes.
- Imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract, in the absence of a non-ischaemic cause.
- Pathological findings of a prior MI.

CARDIAC MUSCLE STRUCTURE AND BIOCHEMISTRY

Cardiac muscle is found only in the heart; it has much in common with skeletal muscle but is anatomically distinguishable from both skeletal muscle and smooth muscle. Like skeletal muscle, cardiac muscle consists of densely packed bundles of cylindrical muscle cells, multinucleated fibres (~50 µm in diameter and up to several cm in length) which microscopically show characteristic cross-banding or striations. Unlike skeletal muscle cells, cardiac muscle cells are branched and interconnected; they do not have a nerve end plate but are myogenic, initiating contraction without neural control.

All striated muscle (i.e. both skeletal and cardiac, but not smooth muscle) fibres contain many myofibrils, cylindrical bundles composed of two types of contractile protein filaments: thick filaments of myosin (~15 nm in diameter) and thin filaments of actin (~7 nm in diameter). Muscle contraction involves the ATPase-dependent sliding of the thick myosin filaments across thin actin filaments. Each myofibril consists of a chain of contractile units called sarcomeres, each approximately 2.3 µm in length. Electron microscopy reveals that each sarcomere consists of several distinct regions consisting of dark bands alternating with light bands, giving rise to the striated appearance of skeletal and cardiac muscle. The light bands contain only thin actin filaments, whereas the dark bands contain thick myosin filaments overlapping with the actin filaments.

The cyclical interactions between actin and myosin that result in striated muscle contraction are regulated by intracellular calcium concentration, and are initiated by the release of calcium ions from the sarcoplasmic reticulum. The principal proteins which regulate these interactions, tropomyosin and troponin, are located on the actin filament (Fig. 38.3). Tropomyosin is an actin-binding protein which forms a continuous strand lying along the length of the actin filament. Troponin is a tadpole-shaped flexible complex of proteins that lies against the tropomyosin strand. It comprises three subunits:

- troponin T (TnT, 37 kDa), responsible for binding of the complex to the Tropomyosin strand of the thin filament, to form the troponin-tropomyosin (T-TM) complex
- troponin I (TnI, 22.5 kDa), holds T-TM complex in place by Inhibiting the activity of actin-myosin ATPase in the presence of low calcium, thus inhibiting contraction
- troponin C (TnC, 18 kDa), which senses and binds to Calcium and regulates contraction.

The structure of the ternary troponin complex implies that calcium binding to TnC removes the carboxy terminal of TnI from the actin filament. This alters the flexibility and mobility of the troponin complex, forcing tropomyosin away from the actin filaments and exposing the myosin binding site. Myosin cross-bridges then attach on to the actin filament resulting in muscle contraction.

FIGURE 38.3 ■ The thin filament of the cardiomyocyte, consisting of actin with the tropomyosin strand lying along its length and the troponin complex lying against the tropomyosin strand. The three proteins, which constitute the troponin complex (troponin T (TnT), troponin I (TnI) and troponin C (TnC)) are mostly bound to the myofibril, with small amounts of free TnT and TnI in the cytoplasm. From: Gaze D C, Collinson P O 2008 Multiple molecular forms of circulating cardiac troponin: analytical and clinical significance. *Annals of Clinical Biochemistry* 45(4): 349–355, with permission.

Troponin C has only one form, which is distributed throughout all muscles, whereas TnT and TnI each have skeletal muscle and cardiac isoforms, the latter denoted by cTnT and cTnI respectively. Although most intracellular troponin is bound to the thin filament of the myofibril, a small amount of cTnT (6–8%) and cTnI (2–4%) exists free in the cytoplasm.

Effective ventricular pumping depends on effective contraction of the myocardium, the thick muscle that comprises most of the ventricular wall. Immediate energy for muscle contraction is supplied by the hydrolysis of ATP by actin-myosin ATPase, largely generated by the β-oxidation of fatty acids, with oxidative metabolism of ketone bodies and pyruvate generating a lesser amount of ATP. The ATP hydrolysis sites are on the cross-bridges formed between the interacting myosin and actin filaments, and the ATPase is highly active only when they interact in muscle contraction. Depleted ATP concentrations are maintained by the donation of phosphate groups to ADP by phosphocreatine in a rapid transphosphorylation reaction catalyzed by creatine kinase (see Chapter 33). The

myocardium has a rich blood supply and normally extracts approximately 75% of the oxygen from blood passing through the left ventricle. This is facilitated by myoglobin, a cytoplasmic haem-containing protein, which is found in striated muscle and has a high affinity for oxygen. Cardiac muscle cells generate most ATP from the β -oxidation of fatty acids. They are highly dependent on aerobic respiration and do not function well when oxygen supply from coronary arteries is critical.

ARTERIAL STRUCTURE AND FUNCTION

The walls of medium-sized arteries, such as the coronary vessels consist of three cellular compartments separated by two layers of condensed elastic connective tissue (Fig. 38.4). The innermost tunica intima is separated from the media by a thin layer of elastic tissue called the internal elastic lamina. The media is composed of spirally arranged smooth muscle cells which maintain arterial tone and determine the luminal diameter. The tunica media is separated from the tunica adventitia by the external elastic lamina, which is a loose assembly of connective tissue and fibroblasts surrounding the artery. The intima is lined by a single-celled layer of endothelium, which separates the constituents of blood from the arterial wall. The endothelium appears to play a critical role in the regulation of vascular tone, as well as inhibition of leukocyte adhesion and platelet aggregation, through the release of mediators such as nitric oxide (NO) and prostacyclin. Endothelial cells also express tissue plasminogen activator (tPA) and plasminogen activation inhibitor-1 (PAI-1), thus controlling the relative balance between prothrombotic and fibrinolytic activity.

ATHEROSCLEROSIS

Atherosclerosis is a chronic, degenerative, inflammatory condition affecting medium-sized and large arteries. (Atherosclerosis does not normally affect veins, although, when they are used as arterial conduits, e.g. as coronary artery bypass grafts, atherosclerosis may develop very rapidly.) It involves the slowly progressive deposition of lipid and matrix proteins in the arterial wall, which eventually causes narrowing of the lumen. Clinical features

of atherosclerosis are absent until an advanced stage (after several decades) when there is a critical reduction in blood supply to the affected tissues, causing ischaemia or infarction. The acute clinical events associated with atherosclerosis are in most cases due to lesions that are unstable and liable to rupture, leading to haemorrhage into the atherosclerotic plaque. The resultant thrombosis, the formation of an occluding clot within an artery, is the usual cause of myocardial infarction.

Theories of early atherogenesis

Athere is the Greek word for 'gruel', and describes the appearance of the contents of the advanced plaque. Understanding of the cellular events that lead to coronary atherosclerosis has grown substantially over the last 2–3 decades due to: (1) application of cell-specific monoclonal antibodies for immunocytochemical analysis of human lesions; (2) the cloning and characterization of the genes of several cytokines, growth factors and cell surface receptors that may be involved in atherogenesis and that have allowed studies of gene expression, and (3) the use of experimental models including the development of gene knock-out animals.

The response-to-injury hypothesis

Ross first proposed his response-to-injury hypothesis in the early 1970s, focusing on the role of platelets as a possible source of growth factors, and their interaction with the damaged artery wall. With the subsequent realization that the endothelial layer remains intact until the stage of a very advanced ulcerated plaque, the theory was refined to emphasize the importance of more subtle forms of injury to the endothelium, without gross anatomical defects. It was proposed that a number of different agents could contribute to endothelial injury, including smoking, hypertension, hyperlipidaemia and viral infection (Box 38.2). This view has been supported by studies using measures of endothelial dysfunction.

The lipid oxidation hypothesis

The lipid oxidation hypothesis of Steinberg and colleagues provided a further mechanism of endothelial injury, as well as an explanation for the formation of macrophage-derived foam cells that are characteristic of the early lesions of atherosclerosis (Fig. 38.5).

BOX 38.2

Potential causes of endothelial dysfunction

- Elevated/modified LDL
- Cigarette smoking
- Hypertension
- Diabetes mellitus
- Genetic
- Infectious microorganisms
- Elevated plasma homocysteine

FIGURE 38.5 ■ Steps in the lipid oxidation hypothesis of atherogenesis proposed by Steinberg and colleagues. Adapted from Steinberg, D, Parthasarathy S, Carew T E, Khoo J C, Witztum J L 1989 Beyond cholesterol. Modification of low density lipoprotein that increases its atherogenicity. *N Engl J Med* 1989; 320: 915–924.

Monocytes adhere to the endothelium and accumulate within the subendothelial space at an early stage of the process. Together with smooth muscle cells in the arterial wall, they take up cholesterol in an unregulated manner and are converted to lipid-laden foam cells within the arterial wall, giving rise to the first macroscopically evident lesion, the fatty streak. However, such excessive cellular uptake of cholesterol cannot occur via the low density lipoprotein (LDL) receptor pathway because of the tight regulation of LDL receptor expression by intracellular cholesterol. Goldstein and Brown proposed the existence of the 'scavenger receptor', which allows the unregulated uptake of cholesterol in the form of modified LDL. Several scavenger receptors have now been identified by molecular cloning, the most important of which appears to be CD36 (also called scavenger receptor B). Uptake by these receptors requires chemical modification of the LDL particle by enzymatic, non-oxidative alteration; oxidation, which accelerates the accumulation of cholesterol; glycosylation, or glycoxidation. The oxidation process modifies a lysine amino acid on the apolipoprotein B. Oxidation of LDL can occur in any of the cells within the artery, including the endothelial cells, macrophages, smooth muscle cells and T lymphocytes.

The oxidation of LDL results in the formation of isoprostanes which are chemically stable, free radical-catalysed products of arachidonic acid that are structural isomers of conventional prostaglandins. They reflect

lipid peroxidation and are markers of oxidant stress in hypercholesterolemia and atherosclerosis. Levels of isoprostanes are increased in atherosclerotic lesions and localize to foam cells and the extracellular matrix.

Oxidized LDL particles promote atherosclerosis via one or more of the following effects:

- chemoattractant for monocytes
- promotion of inflammatory and immune changes via cytokine release from macrophages and antibody production
- unregulated uptake via the scavenger pathway leading to foam cell formation (foam cells can rupture, releasing oxidized LDL, intracellular enzymes, and oxygen free radicals that can further damage the vessel wall)
- induction of apoptosis of vascular smooth muscle and human endothelial cells, which suggests a mechanism for the response to injury hypothesis of atherosclerosis
- disruption of the endothelial cell surface which impairs endothelial function, reducing the release of nitric oxide (NO), which is a major mediator of endothelium-dependent vasodilation; damage to the endothelium also promotes platelet adherence and the release of cytokines that stimulate smooth muscle proliferation
- causes an increase in platelet aggregation and thromboxane release, which contributes to vasoconstriction and intravascular thrombus.

There is persuasive evidence supporting the notion that LDL oxidation occurs *in vivo*. Lines of argument include: (a) epitopes of oxidized LDL have been demonstrated in atherosclerotic lesions; (b) LDL isolated from lesions has similar properties to oxidized LDL, cross-reacts with antisera raised against malondialdehyde- and 4-hydroxynon-enal-modified LDL, and is recognized by the scavenger receptor; (c) LDL modification also appears to lead to the expression of neo-antigens that elicit an autoimmune response – autoantibodies to oxidized LDL have been found in human plasma, and within human atherosclerotic lesions.

Inhibiting LDL oxidation *in vivo* by treatment with antioxidants such as vitamin E inhibits experimentally induced atherogenesis; vitamin E can also reduce the uptake of oxidized LDL *in vivo* by reducing expression of the CD36 receptor. Severity of atherosclerosis in several different animal models (rabbit, monkey, hamster, mouse) can be significantly ameliorated by treatment with a variety of antioxidant compounds. Large clinical trials of antioxidants (vitamin E or β -carotene) in the general population have, however, been singularly disappointing, with no effect on cardiovascular outcomes demonstrated by meta-analyses. Rather than the lipid oxidation theory not being relevant to human atherogenesis, this finding may be due to the wrong antioxidant being chosen, the wrong dose, the wrong subjects or the wrong stage of atherogenesis being targeted: foam cell formation is the earliest stage of the atheromatous plaque, and cardiovascular outcomes are noted with advanced plaque formation, generally several decades later.

The fibrofatty lesion

The mature plaque is characterized by a fibrous cap, composed of smooth muscle cells and extracellular matrix, overlying a pool of lipid, cholesterol crystals and inflammatory cells. The conversion of the fatty streak (Fig. 38.6A) into a fibrofatty plaque (Fig. 38.6B) necessitates the recruitment and proliferation of vascular smooth muscle cells. This process is driven by the synergistic interplay of several growth factors, such as platelet-derived growth factor, insulin-like growth factor and basic fibroblast growth factor. These factors are smooth muscle cell mitogens and/or chemotactic factors and are likely to be important contributors to the process.

The complicated plaque/plaque rupture

Unstable plaques, prone to fissuring and rupture, are characterized by a large lipid pool, thin fibrous cap, fewer smooth muscle cells and larger numbers of inflammatory cells (Fig. 38.6C). Activated macrophages within the plaque are a rich source of matrix metalloproteinases (MMPs). These are a family of proteases which, together with other proteases such as cathepsins and elastases, play a key role in tissue remodelling. Under normal physiological circumstances, there is a balance between MMPs, which degrade cardiac extracellular matrix, and tissue inhibitors of metalloproteinases (TIMPs). However, increased MMP activation has been implicated in a wide variety of cardiovascular pathologies, including atherosclerosis. This has the potential to cause localized regions of de-endothelialization that

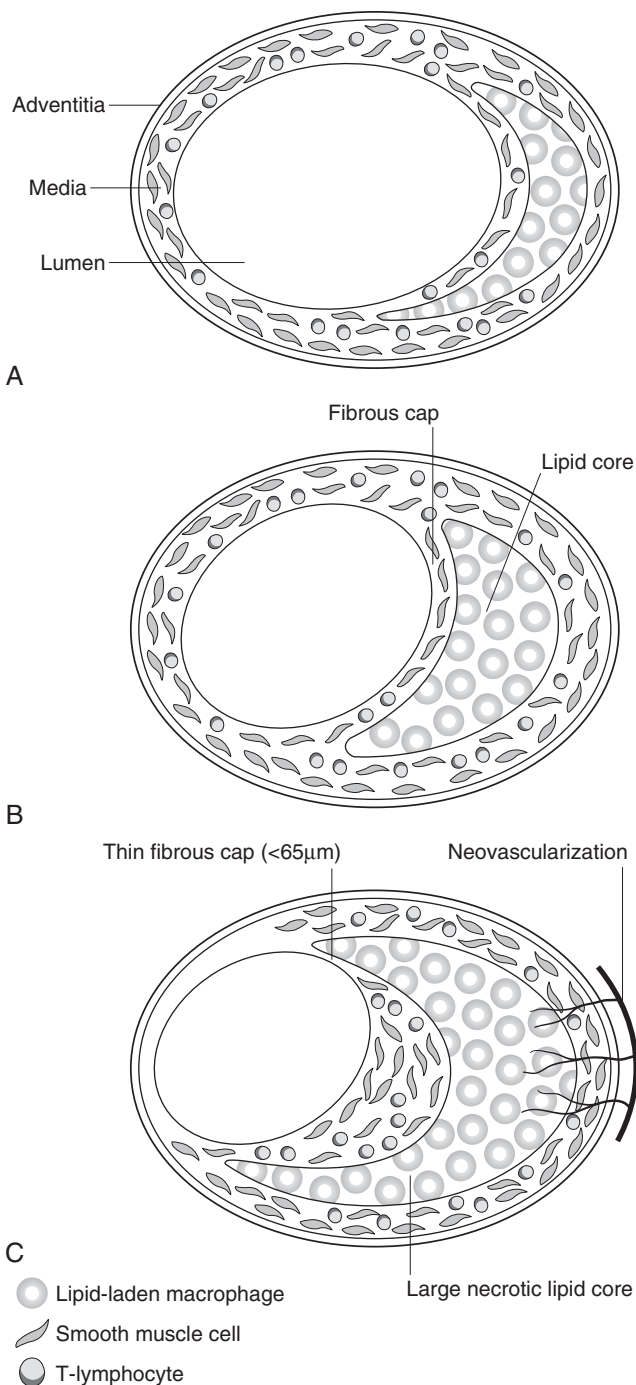

FIGURE 38.6 ■ Features of an atherosclerotic plaque. (A) Fatty streak. Subendothelial collection of lipid-laden macrophages. Plaque grows in an outward direction so that the lumen is conserved. (B) Mature plaque/fibrofatty plaque, characterized by a fibrous cap consisting of smooth muscle cells and extracellular matrix, e.g. collagen. (C) Unstable plaque, characterized by more inflammatory cells and fewer muscle cells, particularly in the shoulder region. Large necrotic lipid core, thin fibrous cap and proliferation of adventitial vasa vasorum.

may destabilize the plaque and lead to focal thrombosis and plaque rupture. The shoulder region of the plaque appears to be particularly vulnerable. In most cases of fatal myocardial infarction, at least one major coronary artery is narrowed by more than 75%, and this is usually associated with plaque fissuring and thrombosis.

ACUTE MYOCARDIAL DAMAGE

Chest pain is responsible for a large proportion of attendances at Accident and Emergency Departments; the spectrum of differential diagnoses is broad and, in addition to ACS, includes muscular pain, which is of little consequence, as well as other potentially fatal diagnoses such as pulmonary embolism. These diagnoses can often be distinguished clinically at the bedside on the basis of the history, examination and ECG findings.

Myocardial ischaemia due to obstructive but stable coronary artery atherosclerosis classically causes pain, discomfort or a feeling of tightness or heaviness in the central chest, left arm or jaw, usually precipitated by exertion and relieved by rest or anti-anginal drugs (e.g. sublingual glyceryl trinitrate). Stable angina results from ischaemia which is of insufficient severity to cause myocardial necrosis; transient ischaemic changes may be apparent on the ECG. Acute coronary syndrome results from erosion or rupture of atherosclerotic plaques in the coronary arteries, with release of the prothrombotic contents of the plaque and superimposed platelet aggregation and thrombosis. The pain is more severe, lasts longer than that of stable angina and does not improve with rest. Ischaemic changes on the ECG may be seen. Complete occlusion of a coronary vessel results in MI with classical ST elevation, i.e. STEMI.

However, history and ECG are not always helpful in differentiating causes of chest pain. A significant proportion of ACS patients do not describe classical pain, and many patients with non-cardiac pain describe features which may suggest cardiac pain. Typically ischaemic ECG abnormalities may not be present in ACS. Most patients with ACS have a partial or transient coronary artery occlusion causing myocardial ischaemia without persistent ST elevation, i.e. unstable angina (UA) or NSTEMI. The term 'non-ST elevation ACS' (NSTEMACS) encompasses both UA and NSTEMI; it reflects the fact that both conditions are considered to be on the same spectrum of myocardial injury, sharing a common pathogenesis but differing in severity and prognosis. The principal feature distinguishing NSTEMI from UA is biochemical evidence of myocyte necrosis.

The importance of accurately and rapidly distinguishing ACS from non-cardiac chest pain is that early treatment of ACS significantly influences mortality and morbidity. Early exclusion of ACS will also help reduce costs of unnecessary hospital admission and investigations, as well as reducing the patient burden.

The relative frequency of the diagnoses in patients admitted with an ACS is approximately: STEMI 30–33%, NSTEMI 25% and UA 38–42%. In STEMI patients, immediate thrombolysis (either with drugs or PCI) is indicated as soon as possible after diagnostic ECG is performed, without waiting for confirmatory elevated serum biomarkers. Patients with NSTEMACS benefit from potent antithrombotic treatment (e.g. low molecular weight heparin/platelet inhibition). The TACTICS-TIMI 18 trial (Fig. 38.7) has indicated that the NSTEMI subgroup may benefit from early coronary angiography and revascularization, whereas those with UA do not, although other studies have not confirmed this benefit and more work needs to be done.

FIGURE 38.7 ■ TACTICS-TIMI 18 trial, indicating improved outcome when patients with NSTEMI and elevated troponin (cTnI Pos) were treated with early invasive intervention (INV) compared to conservative management. The same benefit was not observed in NSTEMI patients without a raised troponin (cTnI Neg). Data from Morrow D A et al. 2007 National Academy of Clinical Biochemistry Laboratory Medicine Practice Guidelines, Clinical Characteristics and Utilization of Biochemical Markers in Acute Coronary Syndromes. Clinical Chemistry 53: 552–574, with permission.

Nonetheless, it is clear that rapid and accurate diagnosis of ACS is key to improved outcomes. In both STEMI and NSTEMI, damaged myocytes release structural proteins into the circulation, which can be measured and used as biomarkers of acute myocardial injury. The precise definition of myocardial infarction, developed by the 2007 ECC/ACC/AHA/WHF Global Task Force, bases its first criterion on elevations of cardiac biomarkers (see Box 38.1). The current definition gives a preference for use of cardiac troponin, although there is an acknowledgement that the definition is likely to evolve with further scientific advances.

Biomarkers of acute myocardial damage

Within seconds of the onset of myocardial ischaemia, aerobic metabolism ceases within the myocyte, anaerobic glycolysis is initiated and potassium begins to leak out of the cell. This is followed within minutes by leakage of metabolites, a fall in pH and increase in intracellular calcium. Within hours, with sustained depletion of ATP, myocyte necrosis results in irreversible ultrastructural changes. These changes include disruption of the sarcolemma and leakage of macromolecules such as cTnT and TnI, CK-MB and myoglobin.

Since the development of thrombolytic therapies for acute myocardial injury, which must be administered early to be effective, it has become critical to be able to detect myocyte necrosis promptly and accurately. Throughout the 1980s and 1990s, the gold standard for diagnosis of MI was the cardiac-specific isoform of creatine kinase (CK-MB). However, it became apparent that serum CK-MB was not elevated in all cases of myocardial injury: biopsy of myocardium taken during coronary artery bypass surgery for unstable angina showed areas of myocardial micronecrosis, which had not been accompanied by a CK-MB rise. Thus, there has been a drive to develop more specific and sensitive biomarkers of cardiac necrosis, and there is a range of markers currently available, with varying tissue specificity, sensitivity and pattern of release into the circulation (Fig. 38.8).

FIGURE 38.8 ■ Pattern of release of some biomarkers into the circulation after acute myocardial infarction.

The pattern of release of biomarkers is influenced by:

- subcellular location: soluble cytosolic molecules are released more rapidly than molecules bound to the myofibrils
- molecular mass: smaller molecules can enter the circulation directly via the microvascular endothelium but are also cleared through the glomerulus
- cytosolic enzymes: increased intracellular calcium activates cytosolic enzymes, including caspase, which promotes dissociation of structurally bound proteins such as cTnT and cTnI.

The ideal biomarker of myocardial injury has a detectable increase in the circulation early, is specific for myocyte necrosis and is not elevated in non-cardiac conditions. None of the currently available cardiac biomarkers meet these criteria, but awareness of their limitations considerably improves clinical utility. The current marker of choice is cTn, with little to choose between cTnI and cTnT.

Troponins

Over the past 20 years, cardiac troponin (cTn) measurement has revolutionized diagnosis of patients with suspected acute coronary syndromes. Monoclonal antibody-based assays specific for the cardiac isoforms of TnT and TnI have been developed that reliably identify myocardial micronecrosis even when CK-MB is not elevated. Recognition of their superior clinical value led in 2000 to the new universal definition of MI based on the elevation of cardiac troponins, updated in 2007 and 2012 to include evidence-based clinical and analytical guidance on use of biomarkers in management of ACS. Cardiac troponins now play a pivotal role in the diagnosis of AMI as well as an important role in the risk stratification of ACS. The current definition of AMI requires detection of a rise and/or fall of cTn (ideally), with at least one measurement >99th centile of a reference population, together with clinical or ECG evidence of ischaemia.

Although most usually found in the myofibril, a small proportion of total cTn also exists in a cytosolic pool (approximately 6% of cTnT and 3% of cTnI) (see Fig. 38.3). The biphasic release of cTnT from damaged heart muscle probably reflects this distribution: the initial release into the circulation following membrane damage during severe ischaemia becomes detectable at 3 h with a peak at 14 h. This is followed by slow dissociation from and degradation of myofilaments, leading to continuous release over 3–5 days. Elevations persist for up to ten days, permitting late diagnosis of MI. There is some debate over whether cTn is released before cell death occurs, i.e. at a reversible stage of injury. In support of this is the finding of transient minor elevations in circulating cTn in some triathletes following extreme exercise. However, in practical terms this is not a critical issue, since, in the majority of situations apart from extreme exercise, increased cTn is associated with a poorer outcome regardless of whether the injury is perceived to be reversible. As well as being the basis for diagnosis of MI, cTn is also helpful for risk assessment and management of suspected ACS patients. Patients previously classified as UA on the basis of normal CK-MB, may be reclassified as NSTEMI, with increased serum concentrations of troponins associated with higher risk of recurrent cardiac events.

In some cases, cardiac TnT antibodies also cross-react 0.5–2.0% with skeletal muscle TnT, thus skeletal muscle may be a source of raised plasma levels. TnI is thought not to be expressed at all in skeletal muscle and may therefore be more specific for myocyte necrosis. However, in the majority of clinical situations, the specificity of cTnT is comparable to cTnI.

There is only one commercially available cTnT assay, but a range of immunoassays for cTnI, which exhibit different analytical sensitivities and specificities. Potential causative factors include a lack of standardization, the occurrence of post-translational modifications of both cTnI and cTnT, and variation in cross-reactivities of the antibody to the various detectable forms of cTnI resulting from its degradation.

The ESC/ACC consensus document on the definition of myocardial infarction recommends that individual laboratories use a cut-off value equal to the 99th percentile of the reference population. At present, cTnT and cTnI are normally undetectable in healthy subjects using conventional assays; therefore, the 99th centile is very low and most assays do not have good precision at this low concentration. This limits the capacity to detect change with serial samples but does not significantly increase the number of false positive results. Thus, in an appropriate clinical scenario, any elevation of cardiac troponin T or I concentration above the 99th centile for a reference population indicates myocardial infarction. The absolute cut-off varies with the assay used, although for cTnT (for which assay there is currently only one manufacturer), this value is often taken to be 0.1 µg/L. It is important that clinicians are familiar with the 99th centile value of the assay used in their own laboratory and are aware that decision limits will vary with different assays. A regularly updated table showing the characteristics of commercially available cTn assays is maintained by the International Federation of Clinical Chemistry and Laboratory Medicine and can be found at: <http://www.ifcc.org/ifcc-scientific-division/documents-of-the-sd/>.

As data have accumulated, it has become evident that even small elevations of troponin are associated with poorer outcomes. In patients with ACS whose troponin concentration is less than the 99th centile, there is still an association between troponin value and clinical outcome. It is thus also useful to define the lower limit of detection. This may be taken to be the lowest concentration at which a between-batch CV of 10% is achievable, and for cTnT this is around 0.03 µg/L. However, most cTn assays in current routine clinical use have poor precision below the 99th centile. The recognition that the assay has clinical utility in this range has led to a continued drive to develop tests which reliably detect lower concentrations, resulting in several generations of troponin assays.

Although terminology for naming generations of cTn assays has been inconsistent, contemporary assays are generally referred to as 'sensitive' assays. The next generation of assays should be able to measure cardiac troponin with a total CV of <10% at concentrations significantly lower than the 99th centile of the normal reference population. Thus they are likely to be termed 'high sensitivity' cTn (hs-cTn) assays. They should reliably measure troponin in most normal individuals and be able to detect changes in serial measurements in the range below the 99th centile, potentially resulting in earlier diagnosis and better management of ACS.

High-sensitivity troponins

The newest generation of Tn assays have a limit of detection that is of the order of 10–100-fold lower than the 'sensitive' assays currently available. By definition, these hs-cTn assays measure cTn in the majority of normal healthy subjects with acceptable precision. They have the potential to increase the promptness and accuracy of diagnosis of ACS. There are a number of different hs-cTn assays in various stages of development; in the case of hs-cTn, a value >14 ng/L is considered abnormal. Separate

decision limits are required for different hs-cTnI assays in the absence of standardization.

Because small differences can be very significant when dealing with such low values, hs-cTn assays are more subject to analytical factors than sensitive assays. Even mild haemolysis reduces hs-cTn values, and sample type (heparin vs EDTA vs serum) can also influence the result. There is greater potential for increase originating from skeletal muscle with hs-cTn compared with the sensitive assay. Some assays show gender-based differences in the 99th centile value.

Since hs-cTn assays can detect cTn in individuals without apparent myocardial damage, it is possible to establish a reference interval for healthy subjects. Values above the 99th centile (a considerably reduced diagnostic threshold compared to 99th centile of the sensitive assays) are associated with a poorer prognosis, and emphasis on detection of a rise and/or fall is likely to be important. Early studies indicate that hs-cTn is likely to facilitate the early diagnosis of AMI as it is presently defined. However, the trade-off for increased diagnostic sensitivity is a reduction in diagnostic specificity. The proportion of patients falsely diagnosed with an MI increases if the diagnosis is based on hs-cTn, particularly if clinical symptoms or ECG changes are uncertain. Even within the reference interval, it is apparent that the higher the value, the greater the risk to the individual, and hs-cTn thus appears to be a better marker for stratifying long-term risk in ACS compared with sensitive assays.

There remain many unanswered questions relating to the use of hs-cTn assays in ACS, including what degree of change can be called an increase, exactly what an increase means, what are its prognostic implications and whether it can be used to influence management to improve outcomes. Until these questions can be answered, the role of hs-cTn in the acute setting will continue to evolve, and must be interpreted in conjunction with the clinical picture. There may be particular problems if the assay is used unselectively in patients with low likelihood of ACS.

Utilization of hs-cTn measurements may be more useful for risk stratifying patients in settings other than acute coronary syndromes including renal insufficiency, heart failure, cardiac amyloid and the elderly.

Other causes of elevated cTn

cTnT and TnI are sensitive and specific markers of myocardial injury when used as recommended by the current universal definition of myocardial infarction, with a cut-off point of the 99th centile. However, lowering the cut-off point may lead to interpretation of an elevated cTn as due to ischaemia, when the elevation is due to myocardial damage due to other causes. To avoid misdiagnosis, it is important to recognize the wide spectrum of disease states other than ACS that can cause raised cTn. These include disorders that would be in the differential diagnosis of MI such as pulmonary embolism, heart failure and myocarditis. The differential diagnosis is given in [Box 38.3](#). Although increased cTn that is not due to ACS may be perceived to be a confounder of clinical interpretation, careful consideration of the source of

the elevation will help the clinician determine its clinical significance. There have been occasional descriptions of falsely elevated cTn as a result of analytical interference, but this is a rare occurrence and most frequently elevated cTn in the absence of ischaemia reflects myocardial damage from another cause. Abnormal results may also occur as a result of microparticle interference in anticoagulated samples.

Creatine kinase-MB (CK-MB)

Creatine kinase (CK) is present in large amounts in both skeletal muscle as well as heart muscle, and is also found in brain. Its lack of specificity limits its effectiveness as a cardiac marker, false positives in trauma or post-surgery patients being a particular problem. The enzyme is formed from two dimers, M and B (each with a molecular weight of 40 kDa), and thus three different isoenzymes are possible: CK-MM, CK-BB and CK-MB. The MB isoenzyme is predominantly found in the heart, comprising about 40% of the CK activity in cardiac muscle, and 2% or less of the activity in most skeletal muscle groups and other tissues.

CK-MB isoenzyme is quickly and easily measured and is widely available; it was the gold standard cardiac biomarker until the discovery of the more specific and sensitive cardiac troponin. Measurement of MB isoenzyme can be undertaken by either measurement of the catalytic activity of the MB fraction after antibody inactivation of MM ('activity' measurement) or by direct measurement of CK-MB by immunological detection using antibodies ('mass' measurement). Most current assays measure CK-MB mass, which is more sensitive than activity. Mass assays also largely avoid detection of macro-CKs (CK linked to IgG and dimers of mitochondrial CK), which can confound diagnosis using assays of CK activity. The presence of macro-CK should be considered when CK-MB is a very high percentage (>20%) of total CK.

Even though CK-MB is largely confined to the heart, there are measurable amounts in skeletal muscle, accounting for up to 20% in some muscle groups, although the overall figure is about 1%. Thus, coexisting skeletal muscle injury (including exercise and rhabdomyolysis) can reduce the specificity of CK-MB. Following MI, plasma CK-MB achieves a peak slightly before total CK and also returns to normal more quickly. CK-MB

rises at about 3–4 h after myocardial necrosis, peaks in 10–24 h, and returns to normal within 72 h. Although potentially helpful in the diagnosis of MI at an early stage, it is less useful for the confirmation of diagnosis of late-presenting MI, since the concentration of enzyme generally returns to within the reference limit by three days. The same property makes CK-MB useful for detection of reinfarction, as cTn does not normalize so quickly; however, further increase of cTn from a high baseline also indicates re-infarction.

CK-MB is outperformed in specificity by contemporary cTn assays, and the newer more sensitive cTn assays are likely to take over any remaining clinical utility for CK-MB.

Myoglobin

Myoglobin is a relatively small (17.8 kDa) haem-containing protein found in abundance in the cytoplasm of striated muscle cells, where its main function is oxygen transport. Myoglobin accounts for about 2% of total muscle protein. Its high tissue:plasma ratio, in combination with its small size, means that it rapidly increases in the circulation after myocyte necrosis. Indeed, it is the earliest indicator routinely available for the detection of both skeletal and cardiac muscle damage, appearing in the circulation within 1–3 h of myocardial necrosis, peaking at 6–9 h, before returning to normal by 24–36 h. Its small molecular size also results in a relatively short time frame for its detection as it is also cleared rapidly by the kidneys.

Myoglobin has long been used as an indicator of muscle damage and has received much attention as a cardiac biomarker because of the rapidity of its release. However, its generalized distribution in all striated muscle limits its specificity as a marker of myocardial damage and its usefulness has declined with the increasing availability of cardiac-specific biomarkers. Its relatively high negative predictive value implies that it may be most useful in the early ruling out of acute MI.

Myoglobin can be measured by radioimmunoassay in serum. However, biomarkers of ACS require a short analytical turnaround time if measurements are to be clinically useful. More rapid measurement is provided by latex agglutination immunoassay or fluoroimmunoassay. Clinical utility of point-of-care measurement of myoglobin in combination with cTn with or without CK-MB mass in excluding ACS is currently being evaluated.

Heart-type fatty acid binding protein (H-FABP)

These are also relatively small (15 kDa) proteins found in large amounts in organs associated with significant fatty acid metabolism, which includes the liver and intestine as well as the heart. There are nine distinct types. The H-FABP isoform is present at high concentration within cardiac myocytes, although it is also found at lower concentration in other tissues such as skeletal muscle, distant tubules of the kidneys, the brain, lactating mammary glands and placenta. Under aerobic conditions, long-chain free fatty acid (FFA) metabolism represents the major source of ATP generated in the myocardium. Free fatty acids are poorly soluble in the aqueous phase

and circulate in plasma mainly bound to albumin. In the myocyte cytoplasm, long-chain FFAs are reversibly bound to H-FABP, which is thought to facilitate their transport to the mitochondrial outer membrane where the process of beta-oxidation is initiated.

The potential of H-FABP as a biochemical marker of myocardial injury has been recognized since it was demonstrated to be released from injured myocardium in 1988. Several studies reported its clinical usefulness as an early marker of acute MI (using the World Health Organization criteria as was standard clinical practice at that time). In general it has been shown to perform at least as well or better than myoglobin: this is probably due to its higher relative concentration in cardiac muscle, myoglobin being found in similar amounts in cardiac and skeletal muscle. After acute MI a rise is detectable in plasma as early as 1.5 h after symptom onset, a peak concentration is reached after 4–6 h and, due to rapid renal clearance, the concentration returns to baseline within 20 h.

The normal basal concentration of H-FABP detectable in plasma is likely to be due to continuous release from damaged skeletal muscle. Although its small size makes it useful as an early marker, it also means that it is normally cleared rapidly by the kidney. In renal impairment the plasma level of H-FABP is markedly raised, rendering interpretation difficult. With normal renal function, sustained high concentrations might be indicative of reinfarction, which may be missed by markers such as cTn, which returns to baseline more slowly.

Modern H-FABP assays rely on monoclonal antibodies that have no cross-reactivity (unlike the earlier assays). Point-of-care testing has recently become available. As a standalone test, current H-FABP assays have not been yet shown to have the requisite specificity or sensitivity to safely diagnose early MI. Further work needs to be done to examine its potential role, which may be as part of a panel with a marker which has a complementary timeframe.

Other

Copeptin, a peptide of 39 amino acids, is the C-terminal part of pro-arginine vasopressin (AVP) and is released together with AVP during processing of the precursor peptide. It is thus a surrogate marker for vasopressin, which is significantly involved in the regulation of the endogenous stress response and is present at elevated concentrations in MI, heart failure and different states of shock. Copeptin concentrations are elevated 0–4 h after the onset of symptoms of acute MI, and may be of value in combination with troponin.

Other potential biomarkers of acute myocardial injury that have been evaluated but where insufficient evidence exists to support routine use include ischaemia-modified albumin (IMA), glycogen phosphorylase isoenzyme (GP-BB) and soluble CD40 ligand, among others.

Tests for other causes of chest pain

Measurement of D-dimer may be of some use in the diagnosis of pulmonary embolism. D-dimer is a degradation product released into the circulation when fibrin

(involved in thrombus formation) undergoes endogenous fibrinolysis. A low plasma concentration in the setting of a low clinical risk of pulmonary embolism excludes the diagnosis of pulmonary embolism. However, if the clinical risk is high then the patient needs further investigation (e.g. ventilation-perfusion scanning, CT pulmonary angiography) even if the D-dimer concentration is low. Elevated concentrations of D-dimer occur non-specifically in other conditions, for example MI, pneumonia and other forms of sepsis.

HEART FAILURE

Heart failure (HF) is a failure of the heart to fill with (diastolic HF) or to eject (systolic HF) blood, or both. The term 'congestive heart failure' implies congestion in the lungs due to back pressure caused by failure of the left ventricle to pump blood around the body. By far, the commonest cause is ischaemic heart disease, but it may also result from any structural or functional cardiac pathology, including valvular heart disease, hypertension or viral cardiomyopathy. Dyspnoea is the predominant symptom, although chronic condition heart failure may be relatively asymptomatic in the early stages. It may also present as a medical emergency (acute life-threatening pulmonary oedema). There is a broad spectrum of severity between these extremes and symptomatic heart failure is a relatively common cause of attendance to emergency departments.

Heart failure has an overall prevalence of approximately 2%, although this is markedly higher in the elderly, affecting up to 15% of those aged over 85 years. It is likely to increase in prevalence with 'ageing of the population'. It is more common in men than women at all ages. The condition is progressive, and patients with heart failure have a shortened life expectancy and impaired quality of life. In the UK, over 40% of patients do not survive 18 months from the time of diagnosis.

Both mortality and morbidity can be improved with appropriate treatment (e.g. ACE inhibitors and certain β -blockers), which relies on accurate diagnosis. Clinical uncertainty is known to contribute to poorer outcome in patients presenting with dyspnoea. However, diagnostic certainty is not always straightforward. Two-dimensional and Doppler echocardiography are widely used and in addition to demonstrating left or right systolic or diastolic ventricular impairment may also provide information on aetiology. However, in many healthcare systems, access to such tests may be limited and there has therefore been considerable interest in biochemical tests for screening, diagnosis, prognosis and monitoring of treatment.

Natriuretic peptides

There has been much interest in the natriuretic peptides (NPs) that are secreted by the myocardium, as potential markers for HF. B-type natriuretic peptide (BNP) was originally identified in the brain but is now known to be released primarily by the heart, particularly the ventricles. It is synthesized as a prohormone, the C-terminal of which is cleaved on release from the

myocardium to produce BNP (a 32-amino acid biologically active peptide) and an N-terminal fragment of the prohormone called NT-proBNP (76-amino acid and biologically inert). Both can be measured in plasma, and in normal subjects, the plasma concentrations of BNP and NT-proBNP are similar (approximately 10 pmol/L). However in both systolic and diastolic heart failure, plasma concentrations of both rise, plasma NT-proBNP proportionately more than BNP, with NT-proBNP concentrations approximately four-fold higher than BNP concentrations.

Critical values

Measurement of either BNP or NT-proBNP helps to discriminate between HF and other causes of dyspnoea. A normal value of either (BNP <100 ng/L [29 pmol/L] or NT-proBNP <400 ng/L [47 pmol/L]) makes decompensated heart failure highly unlikely ('rule-out' values) and suggests a respiratory or other cause of dyspnoea. High plasma concentrations (BNP >400 ng/L or NT-proBNP >2000 ng/L) strongly support a diagnosis of abnormal ventricular function ('rule-in values'). Intermediate values (BNP 100–400 ng/L [29–116 pmol/L] or NT-proBNP 400–2000 ng/L [47–236 pmol/L]) should prompt a search for a non-cardiac cause of dyspnoea: for example, COPD. Approximately 75% of patients in this grey zone will have HF, which is relatively mild and has a good prognosis.

Non-HF factors influencing NPs

Measurements vary with the assay used and with age, gender, and body mass index: normal values tend to increase with age and to be higher in women than men and, for BNP, lower in obese individuals. Plasma concentrations of both tend to be less elevated in heart failure with preserved ejection fraction (EF) than in heart failure with low EF. A raised concentration may occur in other conditions such as hypoxia (e.g. pulmonary embolism, chronic obstructive pulmonary disease), myocardial ischaemia, tachycardia, atrial fibrillation, left ventricular hypertrophy, right ventricular overload, renal impairment (particularly NT-proBNP), liver cirrhosis, diabetes and sepsis. It is not necessary to adjust rule-out values for age or gender, but it has been suggested that obese (BMI >30 kg/m²) individuals should have their BNP doubled to use the cut-off points above. To date, no correction has been suggested for NT-proBNP in obesity. Plasma concentrations of both, but particularly NT-proBNP, should be interpreted in conjunction with an estimate of renal function.

Clinical utility

When raised concentrations are due to heart failure they are a useful prognostic indicator. Trials with either of these diagnostic biomarkers suggest that their use may reduce both the length of hospital stay and the overall cost of treatment. Both markers provide prognostic information in patients with acute and chronic HF, and plasma BNP also has prognostic value in patients with asymptomatic or minimally symptomatic LV dysfunction.

Guidance from the UK National Institute for Health and Care Excellence (NICE) (2010) suggests measurement of BNP or NT-proBNP as first line investigation in patients clinically suspected of having HF, where there has not been a previous MI (Fig. 38.9). It also suggests that patients with high concentrations (BNP >400 ng/L or NT-proBNP >2000 ng/L) should be referred within two weeks for echocardiography and specialist advice, because of the implications for poor prognosis. A raised BNP or NT-proBNP is also an independent prognostic indicator of mortality in patients at high risk of CHD and in those with established CHD. The value of serial measurements to guide management of acute HF has not yet been conclusively demonstrated, possibly due to the considerable intra-individual biological and analytical variability.

Work is also currently underway to assess diagnostic and prognostic benefits of mid-regional pro-atrial natriuretic peptide (MR-proANP) in HF.

CARDIOVASCULAR RISK FACTORS

Cardiovascular risk assessment

Assessment of cardiovascular risk is important to allow targeting of preventative measures to those who will achieve the greatest benefit. The most widely used cardiovascular risk prediction equation was developed from data collected in the Framingham Heart Study which was initiated in 1948 in the town of Framingham, near Boston, USA. It set out to identify the factors contributing to coronary disease using a cohort design in patients initially without coronary disease. The Framingham Risk Score has proved remarkably useful in diverse populations considering that it was derived from data on a predominantly middle-class, middle-aged, Caucasian population, and therefore underestimates overall lifetime risk and risk in the elderly. It is reasonably accurate at predicting

Diagnosing heart failure

FIGURE 38.10 ■ Receiver operating characteristic (ROC) curves for the Framingham algorithm in men (upper graph) and women (lower graph) using National Health and Nutritional Examination Survey (NHANES) follow-up data. Adapted from Liao Y, McGee D L, Cooper R S, Sutkowski M B 1999 How generalizable are coronary risk prevention models? Comparison of Framingham and two national cohorts. *American Heart Journal* 137: 837–845, with permission.

coronary events, with an area under the receiver operating characteristic (ROC) curve of 0.71–0.76 in males and 0.76–0.81 in females (Fig. 38.10).

The Framingham risk score continues to be used in the UK, although it somewhat overestimates cardiovascular risk in most subjects. In recent years, it has been surpassed in terms of accuracy by the QRISK and QRISK2 scores, which are derived from the UK general practice database and it is likely that QRISK2 or its future iterations will become the generally used cardiovascular risk prediction equation in the UK. QRISK2 employs the same core set of risk factors as Framingham but assigns different weightings to some and incorporates additional risk factors (notably postcode as a marker of social class), which impact significantly on cardiovascular risk in the UK. Alternative risk scores have been developed for use in other populations, notably EUROSCORE, which is widely used across Europe and the Reynolds risk score, which incorporates CRP as an additional risk factor. The major risk factors for cardiovascular disease are similar across all populations, although their relative importance may differ.

Unmodifiable risk factors

Age

Although post-mortem studies have demonstrated that fatty streaks and more advanced lesions are present in the second decade of life, these do not usually

become clinically evident until the fifth or sixth decades. Experimental models of atherosclerosis suggest that some of these early lesions are, to some extent, reversible. Atherosclerosis becomes increasingly prevalent after the age of 20 years. This may be partly associated with the increase in plasma cholesterol concentration and other coronary risk factors with age. The extent of coronary and aortic atherosclerosis increases with age (Fig. 38.11) and risk factor burden (Fig. 38.12). Although the absolute risk of CHD rises with age, the relative risk with increasing cholesterol is steeper in the younger age groups.

Gender

The risk of CHD in premenopausal women is approximately 30% of that in men at any particular age, irrespective of smoking status and the presence of

FIGURE 38.11 ■ Prevalence of atherosclerosis identified by intravascular ultrasound in the coronary arteries of heart donors by age. From: Tuzcu E M et al. 2001 High prevalence of coronary atherosclerosis in asymptomatic teenagers and young adults. *Circulation* 103: 2705–2710, with permission.

FIGURE 38.12 ■ Effects of cumulative risk factors on coronary and aortic lesion development in children and young adults. Data from Berenson G S et al. 1998 Association between cardiovascular multiple risk factors and atherosclerosis in children and young adults. hypertension. In women, a greater proportion of cholesterol is present as high density lipoprotein (HDL) cholesterol and this may be protective. Furthermore, it is possible that oestrogens have a direct protective effect on the vasculature. After the menopause, plasma LDL-cholesterol concentrations rise, HDL-cholesterol (HDL-C) falls, there is an increase in visceral adiposity and the risk of CHD rises considerably.

Race

The incidence of CHD and stroke varies with race. In the USA, black people have a higher risk of CHD than white people, while Hispanic groups have lower rates than either group. In the UK, men and women of South Asian descent have a particularly high incidence of CHD (approximately 50% higher rates of premature CHD death compared with the Caucasian population). The difference is widening, as rates do not appear to be falling as fast among this subgroup as for the UK as a whole. This may relate, in part, to a higher prevalence of diabetes in this group. Other factors contributing to this excess mortality may be socioeconomic status, a proatherogenic diet, lack of exercise, enhanced inflammatory status and high plasma concentrations of homocysteine and Lp(a). QRISK2 performs significantly better than the Framingham risk equation for estimating cardiovascular risk in South Asian subjects providing ethnicity is appropriately coded.

Family history

A family history of premature CVD is an important risk factor. In some cases this may be attributable to a single gene effect such as is observed in familial hypercholesterolaemia (see below), although, in most cases, the basis of the underlying genetic predisposition remains unknown and is likely to be polygenic. Family history is a particularly important contributor to risk in men in the lowest quintiles for calculated CHD risk. In women, age-adjusted risk is increased almost three-fold if either parent has CHD before 60 years of age.

Genetic factors

There are a number of inherited traits that are associated with increased CHD susceptibility. Familial hypercholesterolaemia (incidence ~ 1 in 500 in the UK) and familial combined hyperlipidaemia (1 in 100) account for a large proportion of cases. More common genetic variants have a more subtle effect on coronary risk. For example, the apolipoprotein E gene polymorphism is associated with a modest effect on serum cholesterol concentrations, and compared with individuals with the *E-3/E-3* genotype, carriers of the *E-4* allele have a 42% higher risk of CHD, whereas the apo E-2 allele appears not to confer significantly increased risk. The apolipoprotein (a) (apo(a)) gene polymorphism, due to tandem repeat within the kringle 4 region, affects the concentration and molecular weight of plasma Lp(a), and high plasma concentrations of Lp(a) are found more commonly among patients with coronary disease.

Low birth weight

Barker and colleagues have demonstrated that a low birth weight is associated with an increased risk of CVD and type 2 diabetes mellitus. This may reflect a permanent metabolic change resulting from undernutrition during critical stages of early development, which may become manifest as impaired endothelial function later in life. Low birth weight and high body mass in adulthood appear to interact to predict CHD.

Potentially modifiable risk factors

Smoking

The seminal studies of Doll and colleagues were the first to identify the dangers of cigarette smoking with regards to CHD risk and death: approximately 20% of cardiovascular deaths can be attributed to smoking. The injurious agents in cigarette smoke probably include tar, carbon monoxide and free radicals. The assessment of the risk of cigarette smoking is confounded by a number of other variables including social class, ethnicity and gender, but it remains important even when allowance is made for them. The relative risk of CHD in smokers is particularly high in young adults, especially women. Smoking rates differ regionally and, to some degree, contribute to the geographical, racial and socioeconomic differences in CHD rates. Furthermore, smoking also has effects on other risk factors such as plasma lipid concentrations, particularly HDL-C, clotting factors and fasting glucose concentrations. Cross-cultural studies indicate that smoking by itself is insufficient to cause CHD, but increases susceptibility to other risk factors. Passive smoking is also associated with an increased risk of coronary disease (~15–50%). The prevalence of cigarette smoking in the UK has fallen over the past three decades, as has overall tobacco consumption. Smoking cessation is associated with a substantial fall in coronary risk. The benefit of smoking cessation is particularly marked in patients who have already suffered an MI and is associated with a substantial reduction (36%) in mortality in patients with established CHD.

Lipids and lipoproteins

Numerous studies have demonstrated a positive association between CHD and plasma total cholesterol concentration. The association is continuous, exponential and shows no threshold, even at very low concentrations. However, the distributions of plasma total cholesterol concentrations among patients with and without CHD overlap to a considerable degree. Plasma apolipoprotein B (apo B) concentrations appear to be more discriminating: however, they are of less practical utility, as few clinical studies have used apo B concentrations as a basis for treatment (see also Chapter 37).

An inverse relationship between plasma HDL-C concentrations and CHD risk has also been demonstrated in various studies. HDL-C therefore forms an important component of risk prediction equations. However, the results of recent clinical trials using drugs to modify HDL-C levels have generally been disappointing, so

HDL-C is not currently a therapeutic target. Just as apoB may be more discriminating than total or LDL-C, so there is some evidence that apoA1 may be more discriminating than HDL-C.

Over recent years, the importance of triglycerides as a CHD risk factor has received increasing attention. There is a very strong inverse relationship between plasma HDL-C (particularly the HDL₂ fraction) and triglycerides, and, consequently, it has been difficult to demonstrate an independent relationship. However, recent data do support a role for triglycerides as an independent risk factor. Concentrations of plasma triglycerides above approximately 1.7 mmol/L are associated with the formation of the more atherogenic, small, dense LDL. However, triglycerides themselves also have proatherogenic effects by promoting a procoagulant state, being associated with enhanced factor VII activity.

Most primary (genetic) dyslipidaemias predispose to premature CHD, although hyperchylomicronaemia is associated with acute pancreatitis rather than CHD. However, while in the general population approximately 50% of the variability in plasma cholesterol is genetically determined, these monogenic disorders account for only a small proportion of it, and the basis of the greater part remains unknown.

Thrombogenesis, rheology and clotting factors

Thrombosis is the usual terminal event in coronary atherosclerosis. Several studies have revealed the importance of plasma clotting factor concentrations as risk factors for CVD. Fibrinogen forms the substrate for thrombin and represents the final step in the coagulation cascade. It is essential for platelet aggregation, modulates endothelial function and promotes smooth muscle proliferation. A recent systematic review has shown that plasma fibrinogen concentration is moderately strongly associated with CHD, stroke and vascular mortality in middle-aged adults. Fibrinogen concentrations are also related to risk of ischaemic stroke and CHD events in patients who have had a previous stroke. The relationship between plasma fibrinogen and coronary risk may underlie the positive association between plasma viscosity and CHD. However, it is unclear whether these associations are direct, or related to other risk factors such as smoking, so lowering fibrinogen may not itself reduce risk.

Endothelial injury causes the release of tissue factor that, in turn, activates the intrinsic clotting cascade. Platelet activation and aggregation are crucial processes in atherothrombogenesis, and platelet reactivity has been reported to be elevated in subjects with unstable angina and diabetes. The clinical benefit of antiplatelet drugs such as aspirin in patients at coronary risk is now well established.

There is a balance between the formation of clot and its inhibition and dissolution by factors such as proteins C and S and plasmin. The effectiveness of the fibrinolytic system depends on the balance between tissue plasminogen activator (tPA) and inhibitors of plasminogen activation including PAI-1. Tissue plasminogen activator converts plasminogen to plasmin, which acts on fibrin, causing clot dissolution. This process is inhibited by PAI-1, high

concentrations of which are associated with a high risk of reinfarction. Evidence from the Framingham study indicates that plasma PAI-1 concentrations rise with increasing systolic and diastolic blood pressure. Atherosclerotic lesions from diabetic subjects have been shown to contain high concentrations of PAI-1, and plasma PAI-1 is strongly associated with several CHD risk factors including body mass index (BMI), lipids and alcohol intake, and these effects appear to be cumulative.

Apolipoprotein(a) is a glycoprotein that has structural homologies with plasminogen. It is attached to apo B by a disulphide bond and, in some individuals, comprises the major cholesterol rich lipoprotein. High concentrations of Lp(a) have been shown to be associated with an increased risk of CHD, particularly when associated with raised concentrations of LDL-C or homocysteine. The structural similarities between apo(a) and plasminogen have led to the proposition that Lp(a) inhibits plasmin activity, leading to a prothrombotic state. Plasma concentrations of Lp(a) are largely genetically determined, but can be modified, to a limited degree, by dietary fatty acids, oestrogen, the lipid-lowering agent, nicotinic acid and alcohol.

Hypertension

Coronary heart disease risk increases both with increasing systolic and diastolic blood pressure (BP). Blood pressure, like plasma cholesterol, is a continuous variable and there is no clear cut-off value, but hypertension doubles the risk of CHD at any given concentration of cholesterol. Because intra-subject blood pressure measurements can vary so much over time, the diagnosis of hypertension relies on the measurement of blood pressure on several occasions. Blood pressure increases with age and its prevalence varies with ethnicity. Hypertension is also associated with obesity and dyslipidaemia, often as part of the metabolic syndrome.

Obesity

Obesity is an independent risk factor for CHD and is rising in prevalence throughout the developed and developing world (see Chapter 11). Body mass is positively related to fasting triglyceride concentrations, plasma cholesterol and blood pressure, and inversely related to HDL-C. The distribution of body fat appears to be particularly important. It is central or visceral obesity, measured as waist circumference, that is most strongly related to insulin resistance and CHD risk. Waist circumference is a significantly better index of insulin resistance than either waist/hip ratio or BMI. A cut-off value for waist circumference of <100 cm excludes insulin resistance in both sexes with optimal sensitivity and specificity. It has been proposed that hyperinsulinaemia stimulates 11 β -hydroxysteroid dehydrogenase in omental adipose tissue, generating cortisol and promoting a cushingoid fat distribution. Adipose tissue is now recognized to be a source of a number of inflammatory cytokines (interleukin-6, tumour necrosis factor α), growth factors (heparin binding epidermal growth factor) and hormone-like substances (leptin, adiponectin, resistin).

Weight loss is associated with an improvement in a number of coronary risk factors including LDL, HDL, triglycerides, systolic BP and fasting blood glucose. Rapid weight gain in childhood (between 2 and 11 years) appears to predict coronary disease in adulthood.

Impaired glucose tolerance and diabetes

Both diabetes mellitus and impaired glucose tolerance are important risk factors for CVD (Fig. 38.13) and epidemiological data have led to the notion that diabetes confers a similar risk of a cardiovascular event to a prior myocardial infarction (Fig. 38.14). In patients with diabetes, a high haemoglobin A_{1c} (HbA_{1c}) (>10mmol/mol) is associated with an increased risk of CHD; relative risk increases by 1.2-fold for each percentage point increase of HbA_{1c}. However, the value of tight glucose control in preventing macrovascular disease is less clear than its benefits in the prevention of microvascular complications. This may be in part because the atherogenic lipid profile typically associated with type 2 diabetes tends to persist even with excellent glycaemic control.

FIGURE 38.13 ■ The effects of glucose tolerance on CHD mortality rates. From: Hsueh W A, Law R E 1998 Cardiovascular risk continuum: implication of insulin resistance and diabetes. American Journal of Medicine 105: 4s–14s, with permission.

FIGURE 38.14 ■ Diabetes mellitus confers a similar risk for a cardiovascular event as a prior myocardial infarction (MI). Data from Haffner S M et al. 1998 Mortality from coronary heart disease in subjects with type 2 diabetes mellitus and in non diabetic subjects without prior myocardial infarction. New England Journal of Medicine 339: 229–234, with permission.

Although the absolute CHD mortality is higher for diabetic men than for diabetic women, the gender-related protection in women is lost if they have diabetes.

Metabolic syndrome

The clustering of several coronary risk factors (high triglycerides, low HDL, obesity, hyperuricaemia, hyperinsulinaemia and hypertension) has been known for several decades, and led Reaven and others to propose the existence of a syndrome with a common underlying metabolic defect. The genetic basis for this, if one exists, has yet to be identified. This is further complicated by the many synonyms and definitions in common use. These include definitions developed by the World Health Organization (WHO), International Diabetes Federation (IDF), American Diabetic Association, American Association of Clinical Endocrinologists (AACE), American Heart Association and the National Cholesterol Education Programme Adult Treatment Panel III (NCEP-ATPIII) (Table 38.1). Insulin resistance and hyperinsulinaemia appear to be characteristic features of the syndrome. The latter has also been shown to be associated with coronary events (Fig. 38.15). No matter how defined, there is a high prevalence of metabolic syndrome in westernized populations, with particularly high rates in some ethnic groups. Recent definitions have included ethnic-specific criteria. The prevalence of metabolic syndrome is approximately 22–39%, dependent on the definition. At any particular level of coronary risk, patients with metabolic syndrome appear to have higher event rates than predicted. Furthermore, the metabolic syndrome also predicts the future development of diabetes mellitus, and is associated with a raised concentration of inflammatory markers, such as C-reactive protein (CRP).

Physical activity

A high level of physical activity protects against CHD and probably does so by a number of different mechanisms. For example, it is associated with a reduction in blood pressure and improved lipid profile. Recent data indicate that approximately 30 min/day of moderate exercise is required to have a significant impact on coronary risk. Exercise-based rehabilitation for patients with CHD is effective in reducing total mortality and lipid concentrations. High levels of physical activity also decrease the risk of stroke in a dose-dependent manner. Reduction in fitness predicts cardiovascular death in middle-aged men.

Psychological factors

Data from the mid-1970s indicated that a type A personality, characterized by high achievement and drive, was associated with increased risk of CHD. However, more recent data do not support these findings. Stress adversely affects blood pressure, sleeping patterns and plasma lipid concentrations and there is clearly a plausible interaction between stress and personality. Some studies have demonstrated an increased risk of CHD in patients with depressive illness, though the basis of the association is unclear.

TABLE 38.1 Definitions of the metabolic syndrome/insulin resistance syndrome

	NCEP-ATPIII	WHO	AACE	IDF
Waist circumference (cm)				
Men	>102	–	–	≥94 (≥90 ^a)

Inflammation and infection

Atherosclerosis bears many hallmarks of a chronic inflammatory disease, and at every stage of its evolution is characterized by macrophage and T lymphocyte infiltration. The possible stimuli for this inflammatory process include oxidized LDL, homocysteine, free radicals generated from cigarette smoking and infectious microorganisms. If the original insult were not adequately neutralized, the inflammation might persist, causing the local and systemic release of growth factors and cytokines. These can cause intimal thickening by stimulating smooth muscle cell migration, proliferation and extracellular matrix elaboration. The release of IL-1 β and IL-6 from activated leukocytes may also lead to an induction of hepatic CRP synthesis.

Over the past few years, there has been an increasing interest in the use of inflammatory markers to estimate the risks of acute events in patients with established

coronary disease. In part, the predictive value of these markers may be related to their ability to identify patients with vulnerable plaques, which are rich in activated leukocytes. The risk associated with a high plasma CRP concentration is stronger than that associated with raised von Willebrand factor or erythrocyte sedimentation rate (ESR) but is estimated to be weaker than an increased cholesterol or positive smoking habit. It has also been reported that plasma concentrations of CRP are positively associated with subclinical carotid and femoral atherosclerosis, and a number of established coronary risk factors in healthy, middle-aged men. Among these factors were smoking habit, indices of adiposity, blood pressure, triglycerides and HDL. Of these, smoking habit showed the strongest association with plasma CRP. C-reactive protein is deposited in lipid rich regions of human coronary arteries, and its accumulation may precede monocyte recruitment. It is chemotactic for monocytes, and may also be involved in the activation of complement. A relationship between plasma concentrations of CRP and basal endothelial cell nitric oxide (NO) synthesis has also been reported, suggesting that CRP may indeed be involved early in the pathogenesis of atherosclerosis.

It remains unclear whether CRP is a risk marker or risk factor for atherosclerotic cardiovascular disease. Mendelian randomization studies suggest that genetic variation associated with increased CRP levels is not associated with increased cardiovascular risk, suggesting that CRP is a risk marker. However, it is now recognized that a range of conditions associated with chronic inflammation and elevated CRP, such as rheumatoid arthritis and psoriasis, are associated with a significant increased risk of atherosclerotic vascular disease.

Relative importance of coronary risk factors

Although many risk factors for CHD have been described, and others no doubt will become recognized in the future, the contribution of many of them is relatively

minor, certainly in comparison with diabetes, cigarette smoking, hypertension and hypercholesterolaemia. It is to these risk factors that the greatest effort should be directed in seeking to ameliorate an individual's risk of CHD.

Dietary factors

Diet is known to modulate several established coronary risk factors, and dietary change is an important element of coronary risk management as outlined by various dietary guidelines. These are targeted at optimizing the lipid profile, attaining ideal body weight and reducing blood pressure.

Salt

In experimental models, an increased dietary intake of sodium chloride raises blood pressure. This appears to be confirmed by clinical studies such as the INTERSALT study. Sodium excretion has been found to be related to median systolic and diastolic BP. A 5.9 g difference in intake of salt was associated with a 3–6 mmHg difference in blood pressure. A reduction of dietary salt causes a significant reduction in blood pressure, although sensitivity to salt intake varies between individuals. Up to 50% of hypertensive subjects are sensitive to salt loading, an effect that varies with ethnicity. The intake of other minerals also appears to modify blood pressure; these include potassium, calcium and magnesium, the intakes of which are inversely related to blood pressure.

Simple sugars

Dietary simple sugars (sucrose, lactose, glucose and fructose) comprise approximately 25% of total energy intake. An association between sucrose intake and CHD risk was first proposed in the 1960s, but this has not been supported by recent studies. Carbohydrates differ in their effects on blood sugar and insulin concentrations. Low glycaemic index (GI) foods have less effect on postprandial blood glucose and insulin. The Nurses' Health study has shown that a high glycaemic load is associated with an increased risk of CHD. This may be related to adverse effects on HDL and triglycerides, and increased risk of diabetes. However, low-GI diets appear to have only a modest impact on CHD risk. Low-GI diets also appear to have little effect on lipid concentrations or HbA_{1c}, although most studies to date have been short term. Diets rich in protein or unsaturated fat have been found to reduce blood pressure more than diets high in carbohydrate in obese subjects with mild hypertension.

Ethanol

Several population studies have reported that the relationship between ethanol consumption and CHD risk is J-shaped, with a nadir for risk at approximately three units (30 mL) of ethanol per day. However, confounding factors make it difficult to interpret the relative benefits of moderate drinking. People who never drink

alcohol appear to have a higher prevalence of several other cardiovascular risk factors. Although systolic blood pressure rises with increasing alcohol intake (>3 units/day is associated with a significant increase in systolic blood pressure and other adverse events), alcohol intake is positively associated with HDL-cholesterol, particularly the HDL₂ subfraction. Plasma triglycerides also increase with alcohol consumption, but this is associated with an increase in VLDL and the large, buoyant LDL subfraction, rather than small, dense LDL. The relative benefits of various alcoholic beverages have been debated, and related to their antioxidant content. However, the form of alcohol consumed is likely to be confounded by lifestyle, diet and cultural factors. For example, the prevalence of wine drinking varies with age, race, smoking, ethnicity and educational background.

Fish and fish oils

A relationship between fish consumption and protection against CVD was first mooted in the 1960s because of the low rates of coronary disease observed in the Inuit people. Subsequent epidemiological studies have shown that consuming more than 35 g of fish per day is associated with a substantial reduction in CHD risk. This effect is dose dependent, each 20 g increase in fish intake being associated with a 7% lower risk for CHD mortality. The Nurses' Health Study population revealed similar findings with up to 34% lower CHD mortality when fish was eaten more than five times per week.

It has been proposed that the protection conferred by increasing fish consumption may relate to the original risk status of the population concerned, and the kind of fish consumed.

Soy protein

Soy is an edible protein component of soya bean. A meta-analysis of 38 clinical studies has shown that consumption of soy protein can lower plasma LDL-cholesterol by as much as 13% and triglycerides by 10%, but only in subjects with higher starting concentrations. Several mechanisms for this have been proposed but both soy proteins and isoflavones appear to be required. It is noteworthy that the per capita consumption in Japan (where the incidence of CHD is low) is as much as 55 g/day, whereas in the USA (where it is much higher), it is <5 g/day. An intake of >25 g/day is required to significantly improve the lipid profile.

Fatty acids

Changing the fatty acid composition of the diet can have a substantial effect on plasma cholesterol concentrations and on coronary risk. Dietary fatty acids can have a profound effect on the inflammatory process and consequently may also affect plaque composition and stability. A high intake of α -linolenic acid is associated with reduced risk of fatal CHD, but in men, an increased risk of prostate cancer has also been reported.

Plant sterols

Sterols are alcohol derivatives of cyclopentanoperhydrophenanthrene, and are essential constituents of all cell membranes. Cholesterol is a mammalian sterol, containing 27 carbon atoms, whereas sitosterol, campesterol and stigmasterol are plant sterols with 28 and 29 carbon atoms, due to the presence of an additional methyl or ethyl side chain, respectively. Dietary cholesterol has a modest effect on plasma cholesterol concentrations, and an intake of <300 mg/day is recommended for the general population (<200 mg/day in patients with CVD). Plant sterols are normally poorly absorbed by the human intestine and inhibit cholesterol absorption. Five g/day of sitostanol ester reduces plasma cholesterol concentration by approximately 10–20%.

Fibre

Dietary fibre intake is inversely related to CHD risk. A 10 g/day increase in fibre has been shown to be associated with a 14% decrease in coronary events and a 27% decrease in coronary deaths. Intake of whole grain wheat is associated with a 26% reduction in coronary disease, which may be related to a reduction in LDL and triglycerides. High dietary fibre intake is also associated with a reduced prevalence of diabetes, hypertension and obesity. It has been proposed that the fibre content of soy may account for some of its cholesterol-lowering properties. However, the effect of fibre on cholesterol is a modest one: there is approximately a 0.045 mmol/L fall in plasma cholesterol per gram of dietary fibre. The mechanisms of action are thought to include: bile salt binding, in much the same way that resins work; altered gut motility; an effect on satiety, and increased insulin sensitivity. Overall, high dietary fibre intake is associated with a substantially lower relative risk of fatal and non-fatal CVD. It should also be noted that soy contains phyto-oestrogens, and whole grain wheat is rich in selenium, so that the beneficial effects of these foods may not be entirely attributable to their fibre content.

Fruit and vegetables, tea and coffee

Higher rates of coronary disease have been found in regions with low fruit and vegetable consumption, and a diet rich in fruit and vegetables is associated with a 5% reduction in stroke risk per portion of fruit and vegetables per day. Vegetarians have been reported to have a lower rate of CHD, although these data are confounded by other associated patterns of lifestyle, including a lower fat and tobacco consumption and higher socioeconomic class. The Dietary Approaches to Stop Hypertension (DASH) trial found that a diet high in fruit and vegetables and low in fat reduced systolic blood pressure by 5.5 and diastolic blood pressure by 3 mmHg. Fruit and vegetables are also a rich source of antioxidants, such as vitamins C and E, carotene and polyphenols.

Green and black teas contain a complex mixture of polyphenolic compounds that include tannins. This spectrum of components and their relative content depends on the conditions of brewing and their bioavailability depends on whether the tea is taken with milk. However,

drinking tea more than three times per day is associated with reduced stroke and CHD. Drinking boiled coffee is associated with an increase in plasma cholesterol. Plasma homocysteine concentrations are also increased in subjects with a high coffee consumption. However, there is little evidence that coffee intake is related to overall cardiovascular risk.

Dietary pattern

While individual dietary constituents may ameliorate cardiovascular risk as outlined above, increasing emphasis is placed on having a healthy dietary pattern rather than individual dietary components. Healthy diet is one which, first, maintains BMI in the normal range and minimizes the risk of overweight or obesity. A number of scores of been developed to identify a healthy or prudent dietary pattern. However, one dietary pattern that has considerable evidence to support benefits for cardiovascular health and that is currently recommended in NICE cardiovascular disease prevention guidelines is the Mediterranean diet. The Lyon Heart Study examined the effects of a Mediterranean diet (30% of calories from fat, of which 8% were saturated) compared with a prudent Western diet (34% of calories from fat of which 12% was saturated fat) on coronary events in patients with established coronary disease. The Mediterranean diet contained more bread, fruit, root and green vegetables, poultry and fish, and less red meat; dairy products were replaced with a high α -linolenic acid margarine. After a 46-month follow-up period, there was a 50–70% lower risk of cardiovascular events in the Mediterranean diet group.

HYPERTENSION

Hypertension, or raised blood pressure, is one of the single most common and preventable causes of premature morbidity and mortality. It is a major risk factor for myocardial infarction; heart failure; left ventricular hypertrophy; stroke (both ischaemic and haemorrhagic); chronic kidney disease; peripheral vascular disease; cognitive decline, and premature death. It can also (rarely) present as malignant hypertension, an acute, life-threatening emergency (see below).

The laboratory is involved in:

- assessment of end-organ damage in all hypertensive patients
- monitoring for complications of some commonly used antihypertensive drugs
- investigation for causes of secondary hypertension, particularly screening for renal disease (all) and investigation of endocrine causes (a selected sub-group).

Definition

Blood pressure is measured as diastolic and systolic pressures, measured in millimetres of mercury (mmHg). Systolic pressure represents the peak blood pressure during ventricular contraction (systole); diastolic pressure represents the pressure during ventricular relaxation (diastole).

The blood pressure of individuals within a population is continuously distributed in a Gaussian (normal) manner. Although it would be possible to define a reference interval or range that comprised 95% of an apparently healthy population, this range (as with that for plasma cholesterol concentration) would include significant numbers of people whose blood pressure would cause increased risk of the long-term complications. There is no cut-off value above which hypertension definitively exists; thus any definition of hypertension is to some extent arbitrary.

Epidemiological studies demonstrate increased risk of adverse effects above blood pressures of 115/70 mmHg in all age groups. The relationship is continuous and progressive: for every 2 mmHg rise in blood pressure, the risk of death due to IHD increases by 7% and the risk of death from stroke by 10%. However, this observed association does not prove causality, which would require randomized trials demonstrating risk reduction with blood pressure reduction. Thus, the level of blood pressure determining the presence of hypertension is defined as the level of blood pressure above which treatment has been shown to reduce the development or progression of disease. This is currently generally accepted by most bodies internationally to be 140/90 mmHg.

Blood pressure measurement outside a clinic environment has been shown to correlate more strongly with hypertension-related morbidity and mortality than that measured in the clinic setting, and the latest (2011) NICE guidance recommends that home ambulatory blood

pressure monitoring be used to confirm hypertension detected in the clinic.

Hypertension is usually asymptomatic, and diagnosed incidentally, either as part of routine assessment in primary care, as part of a general medical examination when a patient presents with an unrelated condition or as a result of one of its complications (e.g. angina due to coronary atherosclerosis, breathlessness due to cardiac failure). Presenting features in malignant hypertension (see below) include headache, visual disturbances and fits.

Cause

In at least 90% of individuals with sustained hypertension, no primary cause is identifiable, and the condition is termed 'primary hypertension' (previously 'essential hypertension'). Up to 10% have 'secondary hypertension', for which it is possible to identify a specific cause, such as renovascular disease, phaeochromocytoma or hyperaldosteronism. The clinical picture can help target investigation appropriately (Table 38.2).

Primary hypertension

Primary hypertension is very common in Western populations and its prevalence is strongly influenced by age as well as lifestyle factors. Blood pressure tends to rise with age (to a greater extent in men than in women), although, over the age of 70 years, diastolic blood pressure may decline. It is estimated that at least 25% of the UK adult

TABLE 38.2 Clinical pointers to secondary hypertension

Clinical feature	Condition
Drug-resistant hypertension	Any
Acute hypertension with previously stable values	
Diagnosis before age 30 in non-obese	
Severe hypertension with evidence of end-organ damage	
Raised creatinine/reduced eGFR	Renal impairment
Acute rise in serum creatinine (>30%) with ACE inhibitor or angiotensin II receptor blockade	Renovascular hypertension
Moderate to severe hypertension with known vascular disease, asymmetry on renal ultrasound, flash pulmonary oedema	
Abdominal bruit (low sensitivity)	
Hypokalaemia (mild or easily-induced)	Primary aldosteronism (serum potassium more often normal)
Mild hypernatraemia	Primary aldosteronism
Cushingoid facies, truncal obesity, proximal myopathy, bruising	Cushing syndrome
Adrenal 'incidentaloma'	Primary aldosteronism
	Cushing disease
	Drug-induced
Oral contraceptives	
Glucocorticoids	
Ciclosporin	
Erythropoietin	
Illicit drug use (esp. cocaine, ecstasy)	
Excessive alcohol consumption	
Paroxysmal hypertension, esp. with headaches, sweating, palpitations	Phaeochromocytoma (rarely asymptomatic)
Obesity (particularly men)	Sleep apnoea syndrome
Heavy snoring	
Daytime drowsiness / headache	
Delayed or reduced femoral pulse	Coarctation of aorta
Aortic 'machinery' murmur	
Symptoms of hypothyroidism	Primary hypothyroidism
Raised TSH	
Hypercalcaemia	Primary hyperparathyroidism

population have hypertension, as well as more than 50% of those aged more than 60 years. Systolic pressure is more commonly elevated in patients in older patients, while raised diastolic pressure is a more prevalent feature of hypertension in those aged less than 50 years.

The aetiology of primary hypertension is poorly understood but is likely to be complex and multifactorial, including genetic, intrauterine and lifestyle factors. Increased sympathetic neural activity and increased angiotensin II activity have both been implicated, although no abnormalities have consistently been identified.

Blood pressure tends to exhibit a familial concordance, to an extent that cannot be explained by a shared environment: having one or more hypertensive parent approximately doubles an individual's risk of hypertension. An influence of intrauterine environment is indicated by the fact that babies born at term with lower birth weights tend to have higher blood pressure as adults, possibly as a result of reduced nephron mass.

Important lifestyle factors include obesity, high sodium intake and a high alcohol intake (though individuals who consume moderate alcohol tend to have slightly lower blood pressures than abstainers). A meta-analysis of 18 studies has recently indicated an association between hypertension and vitamin D deficiency.

The 'metabolic syndrome' comprises hyperinsulinaemia, glucose intolerance, central obesity and dyslipidaemia (all secondary to insulin resistance) and hypertension; insulin resistance and hypertension also frequently co-exist in patients with polycystic ovary syndrome, but in neither case is the mechanism linking insulin resistance and hypertension fully understood. Dyslipidaemia also shows an association with higher blood pressure, which is independent of body mass. Blood pressure also varies between populations, tending to be higher in black Africans than in white Europeans.

The prevalence of primary hypertension will continue to rise with increasing longevity, particularly with the concurrently rising prevalence of obesity. Lifestyle modification is an important aspect of the management of hypertension.

Secondary hypertension

Kidney disease. Hypertension is an important complication of both acute and chronic kidney disease, most commonly glomerular or vascular. It is detected by blood testing (elevated serum creatinine and urea) and/or dipstick urinalysis which may show proteinuria or haematuria. Disease is usually bilateral. Both activation of the renin-angiotensin-aldosterone axis and retention of sodium and water may contribute, the latter becoming more important with deteriorating renal function, and peripheral oedema may be observed. Less frequently, unilateral renovascular disease is responsible.

Endocrine disease. Pheochromocytoma, hyperaldosteronism and Cushing syndrome are all well-recognized (though individually relatively uncommon) causes of hypertension. Patients with thyrotoxicosis and hypothyroid patients may both have hypertension. There is also an association between primary hyperparathyroidism and

hypertension. Hypertension is present in some 40% of patients with acromegaly, although some of this is likely to be essential hypertension. In addition, there are several rare, inherited endocrine conditions whose manifestations include hypertension: these are summarized in [Table 38.3](#).

Laboratory assessment of hypertension

All patients should have formal cardiovascular risk prediction using one of the risk prediction equations discussed above. Electrolytes and creatinine (with estimation of glomerular filtration rate) should be measured as baseline before treatment is started with drugs which are potentially nephrotoxic or associated with deranged electrolytes. Renal damage can also both cause hypertension and be affected by target organ damage, and all newly diagnosed hypertensive patients should also be tested for haematuria using a reagent strip at the clinic, and for microalbuminuria with a urinary albumin:creatinine ratio.

Investigation for secondary causes

Comprehensive investigation of every patient with newly diagnosed hypertension is not an efficient use of health-care resources, since approximately 90% of patients will have primary hypertension and by definition no cause will be found. It is important to bear in mind and target patients with signs and symptoms suggesting a secondary cause of hypertension for specialist endocrine or radiological investigations. Specific clinical features that may suggest specific diagnoses are given in [Table 38.2](#). General features which should prompt comprehensive investigation include:

- severe or resistant hypertension. (Resistant hypertension is the persistence of hypertension despite concurrent use of adequate doses of three antihypertensive agents from different classes, including a diuretic. It is important to try to ascertain compliance, which is a common cause of apparently resistant hypertension.)
- an acute rise in blood pressure in a patient with previously well-controlled measurements
- aged less than 40 years in a Caucasian patient without a family history of hypertension or other risk factor such as obesity
- prepubertal onset
- malignant or accelerated hypertension (e.g. severe hypertension plus signs of end-organ damage such as retinal hemorrhages or papilloedema, heart failure or acute kidney injury).

Renovascular hypertension

A proportion of the 10% of all hypertensive patients who have secondary hypertension present with chronic kidney disease which, if not clinically apparent, will be obvious on initial laboratory screening. Renovascular hypertension is the most common remediable cause of secondary hypertension. It may occur in the setting of a patient with other known vascular disease such as CHD or peripheral vascular disease. Particularly suggestive clinical clues include:

TABLE 38.3 Inherited disorders causing hypertension

Condition	Inheritance	Plasma renin	Plasma aldosterone	Cause	Other features	Treatment
Glucocorticoid suppressible hyperaldosteronism	Autosomal dominant	Normal/↓	↓	Mutation causes fusing of regulatory sequence of steroid 11 β -hydroxylase with aldosterone synthase: aldosterone synthesis is controlled by ACTH rather than angiotensin II	Variable hypokalaemic alkalosis; ↑ plasma 18-hydroxycortisol	Dexamethasone
Liddle syndrome	Autosomal dominant	↓	↓	Activating mutation in distal renal tubular sodium transporter leads to sodium retention and ↑ ECF volume	Variable hypokalaemic alkalosis	Amiloride, triamterene
Gordon syndrome (pseudohypoaldosteronism type II)	Autosomal recessive	↓	↓	Mutation leading to increased distal renal tubular chloride reabsorption; hence increased sodium reabsorption and ↑ extracellular fluid volume	Hyperkalaemia, renal tubular acidosis	Thiazide diuretics; dietary salt restriction
Syndrome of apparent mineralocorticoid excess	Autosomal recessive	↓	↓	11 β -Hydroxysteroid dehydrogenase ^a deficiency, causing decreased metabolism of cortisol to cortisone; allows cortisol to act as a major mineralocorticoid, causing sodium retention	Hypokalaemic acidosis	Dexamethasone or high-dose spironolactone
Steroid 11 β -hydroxylase deficiency	Autosomal recessive	↓	↓	Enzyme deficiency leads to ↑ plasma 11-deoxycortisol and 11-deoxycorticosterone; the latter has mineralocorticoid activity	Hypokalaemic alkalosis; masculinization in females; premature virilization in males	Cortisol
Steroid 17 α -hydroxylase deficiency	Autosomal recessive	↓	↓	Enzyme deficiency leads to ↑ plasma 11-deoxycorticosterone and corticosterone; the former has mineralocorticoid activity	Hypokalaemic alkalosis; feminization in males; lack of normal sexual maturation in females	Cortisol

^aThis enzyme converts cortisol to cortisone (inactive) but does not metabolize aldosterone; its activity normally limits the mineralocorticoid activity of cortisol. Carbenoxolone (glycyrrhetic acid) and liquorice (which contains glycyrrhizic acid) are inhibitors of this enzyme and can cause hypertension and hypokalaemia.

- the development of an acute sustained rise in serum creatinine (>50%) within a week of starting treatment with an angiotensin-converting-enzyme inhibitor or angiotensin II receptor blocker
- severe hypertension in a patient with asymmetric kidneys or an unexplained atrophic kidney seen on renal ultrasound
- severe hypertension in a patient with recurrent acute pulmonary oedema, or severe heart failure with impaired renal function
- severe hypertension in conjunction with a systolic–diastolic abdominal bruit that lateralizes to one side.

Any of these features should trigger prompt discussion with the local nephrology service and imaging of the renal arteries.

Primary aldosteronism (hyperaldosteronism)

Primary aldosteronism (PA) is the commonest identifiable, specifically treatable and potentially curable form of hypertension. The triad of hypertension, unexplained hypokalaemia, and an aldosterone-producing adenoma (APA) of the adrenal gland, was first described in 1955 by Jerome Conn, in a 34-year-old female who had a seven-year history of intermittent muscle weakness, muscle

spasms and cramping of her hands. This clinical picture is not specific for Conn adenoma but is associated with any cause of mineralocorticoid excess. Metabolic alkalosis is also a common feature.

Primary aldosteronism comprises a group of disorders characterized by inappropriately high secretion of aldosterone, which is autonomous and is not suppressed by saline. A growing body of research has implicated aldosterone in the pathogenesis of vascular disease independently of blood pressure, possibly via promotion of systemic inflammation and oxidative stress, which contribute to insulin resistance and vascular abnormalities. The recognition that most patients with PA (>75%) are actually normokalaemic has led to an appreciation that it is much more common than previously recognized. As many as 5–13% of patients with hypertension are currently thought to have PA.

Forms of PA

Around 30% have a unilateral APA, which is potentially resectable by laparoscopic adrenalectomy (hypokalaemia is more common in this group). Most of the remainder have bilateral idiopathic hyperaldosteronism (IHA), which responds best to aldosterone-antagonist drugs. A rare cause is glucocorticoid-suppressible aldosteronism (GRA). Very rarely, an adrenal carcinoma is responsible, and it is occasionally a component of multiple endocrine neoplasia (MEN) type 1. In general, hypertension and hypokalaemia are more severe in patients with APA than bilateral forms.

The diagnosis of PA should be considered in:

- hypertensive patients with spontaneous or diuretic-induced hypokalaemia (see Table 38.4 for differential diagnoses)

TABLE 38.4 Differential diagnosis of primary aldosteronism (PA)

Hypertensive condition	Differentiating clinical features	Differentiating tests
Primary hypertension	None	Aldosterone/renin ratio normal <i>off interferent drugs</i> × 2–4 weeks. Normal ratio on drugs that can potentially cause false positives makes PA highly unlikely Hypokalaemia not a feature of primary HT (only infrequently seen in PA)
Diuretic-induced hypokalaemia in patient with primary hypertension	Drug history	Aldosterone/renin ratio normal after correction of hypokalaemia and diuretic withdrawal for at least six weeks
Secondary hypertension	Known vascular disease or risk factors; known renal artery stenosis	Aldosterone/renin ratio normal or low Imaging studies (to demonstrate renal artery stenosis or reninoma)
Ectopic ACTH syndrome	Features of underlying malignancy (usually bronchial small cell tumour; rarely thymus pancreas or bronchial carcinoid) Rarely Cushingoid features (may be present if slow-growing tumour)	Aldosterone/renin ratio usually normal despite hypokalaemia and suppressed renin (aldosterone also low) Evidence of malignancy on imaging studies Cortisol and ACTH levels elevated and non-suppressible with high-dose dexamethasone
Liddle syndrome	Childhood presentation. Family history (autosomal dominant)	Aldosterone/renin ratio usually normal despite hypokalaemia and suppressed renin (aldosterone also low)
Syndrome of apparent mineralocorticoid excess	Childhood presentation of primary form. Family history (autosomal recessive) May be acquired due to excessive liquorice consumption	Aldosterone/renin ratio usually normal despite hypokalaemia and suppressed renin (aldosterone also low) Raised urinary free cortisol/cortisone ratio
Hypertensive forms of congenital adrenal hyperplasia	Childhood presentation. History of either virilization (in 11 β -hydroxylase deficiency) or feminization (in 17 α -hydroxylase deficiency) Family history of congenital adrenal hyperplasia due to 11 β -hydroxylase or 17 α -hydroxylase deficiency (autosomal recessive)	Aldosterone/renin ratio usually normal despite hypokalaemia and suppressed renin (aldosterone also low) 11 β -hydroxylase deficiency: low plasma cortisol and corticosterone; raised basal or ACTH-stimulated levels of deoxycorticosterone and 11-deoxycortisol 17 α -hydroxylase deficiency: low plasma 17 α -hydroxyprogesterone, 11-deoxycortisol, and cortisol; increased gonadotrophins (LH and FSH)
Primary glucocorticoid resistance	Family history (although may be acquired) May be associated with androgenization	Aldosterone/renin ratio normal despite hypokalaemia and suppressed renin (aldosterone also low) Raised ACTH and cortisol; resistance of cortisol to dexamethasone suppression in absence of clinical features of Cushing syndrome
Activating mutations of the mineralocorticoid receptor	Family history Pregnancy-induced worsening of HT and development of hypokalaemia	Aldosterone/renin ratio usually normal despite hypokalaemia and suppressed renin (aldosterone also low)
Pseudohypoaldosteronism type II (Gordon syndrome)	Family history (autosomal dominant) Hyperkalaemia; mild normal anion gap metabolic acidosis Increased distal tubular Cl ⁻ reabsorption	Low renin, normal aldosterone; often raised aldosterone/renin ratio

- patients with moderate, severe or resistant hypertension (less common in mild hypertension)
- patients with adrenal incidentaloma and hypertension
- patients with the onset of hypertension under the age of 20
- patients with hypertension and a family history of young-onset hypertension or CVA at young age (<40 years), who may have the rare, inherited glucocorticoid-remediable form of PA.

Biochemical investigation

Determination of the ratio of plasma aldosterone concentration to plasma renin activity is widely accepted as the optimal test for screening, after controlling for factors (including medicines) that may confound results. (See Appendix 1 for detailed protocol.)

Confounding factors

Posture. Assuming upright posture effects a rise in plasma aldosterone via increased renin, released from the juxtaglomerular apparatus in response to a slight fall in renal perfusion. All APA, and most with IHA, retain normal responsiveness to upright posture, and measurement in a sample taken when upright may be the most sensitive in detecting raised aldosterone. In practice, a mid-morning upright sample, taken after sitting for 5–15 min appears to be sensitive as well as pragmatic.

Time of day. In PA patients, suppression of renin makes aldosterone more strongly influenced by ACTH, which has a circadian rhythm, being highest in the morning, then falling rapidly. Thus, morning samples are most likely to show elevated aldosterone.

Drugs. See Box 38.4.

Relevant drugs should be withdrawn at least two weeks before testing, or for diuretics, at least four weeks. Where antihypertensive drugs cannot be safely withheld, verapamil slow-release, hydralazine and/or prazosin have lesser effects on the aldosterone–renin system.

BOX 38.4 Drugs known to potentially interfere with aldosterone:renin ratio

Drugs potentially causing false positive aldosterone:renin ratio

- β -Adrenergic receptor blockers
- Methyldopa
- Clonidine
- Non-steroidal anti-inflammatory drugs
- Renin inhibitors (if plasma renin activity measured)
- Oestrogen-containing drugs (if direct active renin measured)

Drugs potentially causing false negative aldosterone renin ratio

- Diuretics (all classes)
- Dihydropyridine Ca-channel antagonists
- Angiotensin-converting-enzyme (ACE) inhibitors
- AII receptor blockers (ARBs)
- Renin inhibitors (if direct active renin measured)

Dietary sodium. Salt restriction stimulates renin production, which may lower the aldosterone:renin ratio, thus patients are advised to maintain a liberal salt intake before testing.

Plasma potassium. Hypokalaemia suppresses aldosterone secretion and may cause a false negative result, thus any hypokalaemia should be corrected as far as possible with oral potassium supplements for several days prior to testing.

Phase of menstrual cycle. Higher aldosterone concentrations seem to be measured in the luteal phase relative to the follicular phase, almost certainly mediated by sex hormones, and it may thus be preferable to screen premenopausal women early in the menstrual cycle. More research is required in this area before firm recommendations can be given.

Renal impairment/elderly patients. Renin levels are lower in renal impairment due to reduced nephron mass as well as sodium and water retention. Similarly elderly patients secrete less renin and false positive ratios may result in both circumstances.

Other conditions. Co-existing conditions, which may give rise to false negatives, include pregnancy, renal artery stenosis and malignant hypertension.

Differences between laboratories in assays used and units reported give rise to variability in cut-off values used by different groups; this makes standardization of diagnostic criteria difficult. Renin measurement can be in terms of its enzymatic activity (plasma renin activity, PRA) or its mass (direct active renin concentration, DAR). Automated immunometric assays for measuring DAR have been widely adopted as they are faster and more convenient than PRA. However, considerable work is required to validate these methods, and in the meantime, PRA remains the preferred measurement.

Because of inherent variability in both renin and aldosterone, measurements should be repeated at least once for confirmation. In patients with repeatedly elevated aldosterone/renin ratios, definitive confirmation or exclusion of diagnosis involves careful suppression testing with measurement of aldosterone response to fludrocortisone or to salt loading.

Genetic testing for the hybrid gene causing familial hyperaldosteronism type I (glucocorticoid-remediable aldosteronism (GRA)) allows subtype differentiation, which allows treatment to be tailored. However this is rare, and the majority of genetic tests will be negative.

Localization

The next step should be to differentiate unilateral APA amenable to surgery from bilateral forms of PA which respond to drugs. Computerized tomography (CT) and MRI scanning are both used. Adrenal CT on its own is unreliable, as it may miss small secreting APAs, and misdiagnose larger non-functional adrenal tumours ('incidentalomas') as APA, leading to unnecessary surgery. The most sensitive technique for the localization of an isolated adenoma is selective adrenal vein blood sampling with measurement of the aldosterone/cortisol ratio, although this is a technically demanding technique.

The investigation of Cushing syndrome is discussed in Chapter 18.

Phaeochromocytoma

Phaeochromocytoma and functional paraganglioma (PGL) are catecholamine-secreting tumours of the adrenal medulla and extra-adrenal sympathetic nervous tissue (e.g. sympathetic ganglia), respectively. Because of their similarity in presentation and management principles, the term phaeochromocytoma is often used to referred to both, and this convention is also used here. Approximately 10% of phaeochromocytomas are extra-adrenal.

A patient identified with phaeochromocytoma is usually symptomatic. The classical triad of paroxysmal headache, sweating and palpitations is due to excess tumoral secretion of noradrenaline, adrenalin, and dopamine, and is said to have high predictive value. Pallor, lethargy, tremor, nausea, flushing and orthostatic hypotension can also occur. Episodes last from minutes up to an hour and are self-limiting. Symptoms are characteristically made worse by β -blockade because their use permits unopposed α -adrenergic stimulation.

Prevalence in the general population is uncertain, but it accounts for fewer than 0.2% of patients with hypertension. Its importance lies in its being malignant in about 10% of patients (more frequently in the context of multiple endocrine neoplasia, MEN, type 2) and being potentially curable. Malignant tumours biochemically and histologically resemble benign tumours, and can only be diagnosed for certain by the presence of local or distant spread which may occur many years after the primary tumour is resected.

Approximately 90% of phaeochromocytomas are sporadic: these are usually single adenomas. Approximately 10% are inherited: these are often bilateral and multiple. Inherited phaeochromocytomas may be isolated (inherited as an autosomal dominant trait) or be a component of multiple endocrine neoplasia (MEN 2A and 2B, in which they have a combined prevalence of 40%). They also occur as the sole manifestation of MEN 2A in approximately 25% of heterozygotes for this condition. (See Chapter 41 for further details of inherited phaeochromocytomas.)

Patients with phaeochromocytomas may come to medical attention because of their hypertension (paroxysmal in about one-third of patients, but more often sustained though variable) or because of the clinical features of increased secretion of catecholamines.

The diagnosis should be suspected in individuals with one or more of the following:

- paroxysmal self-limiting episodes of typical adrenergic symptoms (see above)
- resistant or labile hypertension (although 5–15% are normotensive at diagnosis)
- familial syndrome predisposing to catecholamine-secreting tumours (e.g. MEN2)
- family history of phaeochromocytoma
- incidentally discovered adrenal mass (25% of diagnoses)
- onset of hypertension at a young age (e.g. <20 years)
- hypertension with new onset or atypical diabetes mellitus
- hypertensive response during anesthesia, surgery or angiography

- idiopathic dilated cardiomyopathy
- history of gastric stromal tumour or pulmonary chondromas (Carney triad).

Biochemical investigation

Diagnosis of phaeochromocytoma involves first, demonstrating excessive secretion of catecholamines, followed by radiological localization of the causative tumour(s). Consideration of the diagnosis and a low threshold for investigation are key initial factors in successful diagnosis. Because the symptoms are so non-specific, diagnosis is rarely confirmed biochemically in patients with suggestive symptoms. The investigation strategy in a particular patient will be dictated by the availability of biochemical tests in any centre. However, as it is so important not to miss the diagnosis, testing with a high diagnostic sensitivity is critical, particularly when screening asymptomatic patients with an inherited risk of phaeochromocytoma.

Traditional measurement of urinary catecholamines is gradually being superseded by HPLC measurement of fractionated metanephrines (metabolites of catecholamines), either in a 24 h urine collection or in plasma, both of which offer better diagnostic sensitivity and specificity (Table 38.5). The improved sensitivity is a result of continuous production of metanephrines by the tumour, which contains a high concentration of catechol-O-methyltransferase. Even when the tumour release of catecholamines by the tumour is sporadic, this enzyme ensures continued metabolism of catecholamines to metanephrines. The sensitivity of metanephrine measurement to detect phaeochromocytoma is 99% for plasma and 97% for urine, which compare favourably with 86% for urinary catecholamines, among symptomatic patients, those with a previous phaeochromocytoma or a family history, and those with an incidental adrenal mass. The diagnostic specificities for plasma and urinary metanephrines are 89% and 93%, respectively, compared with 88% for urinary catecholamines. False positive results are common owing to the presence of other medical conditions (such as obstructive sleep apnoea) and medications (Table 38.6) that can cause elevation of metanephrines. The relative infrequency of phaeochromocytoma in those tested also contributes to the high rate of false positives. In addition,

TABLE 38.5 Sensitivities and specificities of biochemical tests for phaeochromocytoma in 214 patients

	Sensitivity (%)	Specificity (%)
P free metadrenalines	99	89
U fractionated metadrenalines (HPLC)	97	64
P catecholamines	81	81
U catecholamines	85	86
U total metadrenalines (spectrophotometry)	74	93
U vanillylmandelic acid (VMA)	62	93

Data from Lenders et al. JAMA 2002; 287:1427–1434. P, plasma; U, urine.

TABLE 38.6 Some drug interferences with measurement of catecholamines and metadrenalines

Interferent	Effect
Tricyclic antidepressants	↑ catecholamines and metadrenalines in U and P
Phenoxybenzamine	↑ catecholamines and metadrenalines in U and P
Monoamine oxidase inhibitors	↑ metadrenalines in U and P
Buspirone	↑ metadrenalines in U
Calcium-channel blockers	↑ catecholamines in U and P
Nicotine	↑ catecholamines in U and P
Caffeine	↑ catecholamines in U and P Analytical interference with HPLC assays
Methyldopa	Analytical interference with HPLC assays
Labetalol	Analytical interference with HPLC assays
Levodopa	Analytical interference with HPLC assays ↑ catecholamines and metadrenalines in U and P?

U, urine; P, plasma.

physical and psychological stress (e.g. surgery, severe pain or anxiety) can potentially increase catecholamine secretion, leading to false positive results.

Concentrations of metanephrines that are over four times normal are associated with a very high probability of pheochromocytoma; however, intermediate raised levels will require further biochemical investigation, which may include repeat testing after withdrawal of implicated medication. By contrast with the, now infrequently used, measurement of urine vanillylmandelic acid, dietary restrictions are not needed when performing these investigations.

Localization

The purpose of localization is to guide surgical intervention after biochemical confirmation, as well as to look for possible metastatic disease. Direct anatomical imaging methods by computed (CT) tomography or magnetic resonance imaging (MRI) should be used as first-line to locate the primary tumours and is particularly helpful in the relatively large, sporadic, symptomatic tumours. Both techniques have high sensitivity but lower specificity, due to the high prevalence of the benign adrenal cortical adenoma ('adrenal incidentaloma'). Meta-iodobenzylguanidine (MIBG) scintigraphy is particularly helpful for detecting smaller, presymptomatic tumours, extra-adrenal tumours, including metastases and recurrent tumours. However, false positive results may occur in patients with carcinoid tumours and, because the isotopes are excreted in the urine, false negatives can occur with tumours in the bladder or head of the pancreas (which is closely related to the right kidney). Overall, MIBG scanning has higher specificity than anatomical imaging. Newer functional imaging techniques include ¹⁸F-fluorodopamine positron

emission tomography (PET) and ¹¹¹In-octreotide single photon emission computed tomography (SPECT) scanning.

Management

It is beyond the scope of this book to discuss the management of pheochromocytoma in any detail. Even following apparently successful surgical resection, patients should be followed-up long term, both clinically (blood pressure measurements) and biochemically. Hypertension may persist and tumours may recur.

Malignant hypertension

Malignant hypertension is defined as markedly elevated blood pressure (diastolic BP often >140mmHg) with retinal haemorrhages, exudates or papilloedema with or without evidence of target organ damage, typically acute and progressive kidney injury with proteinuria and haematuria ('malignant nephrosclerosis'). Its management is a medical emergency and should take precedence over investigations to determine whether there is an underlying cause. Neurological signs in malignant hypertension may be due to intracerebral or subarachnoid haemorrhage or lacunar infarct, or to hypertensive encephalopathy. The latter is associated with insidious onset and non-lateralizing symptoms, such as headache, vomiting, restlessness, confusion. It may be confirmed radiologically on the basis of MRI, which shows oedema of the white matter in the occipito-parietal regions, termed 'reversible posterior leucoencephalopathy'. (The distinction is important as hypertensive encephalopathy mandates aggressive reduction of blood pressure, not usually indicated for haemorrhage or infarct.)

Hypertension in pregnancy

Hypertension developing in pregnancy constitutes a significant risk to the mother and the fetus. Pre-eclampsia is the development of new hypertension and proteinuria in the second half of pregnancy. It is a multisystem disorder and if untreated, the condition can progress to severe hypertension, acute kidney injury and seizures (eclampsia) and with high fetal and maternal morbidity and mortality. An increase in plasma urate concentration can be a sensitive indicator of deteriorating renal function in this condition. Low platelet count, microangiopathic haemolysis seen on blood film examination, rising creatinine and liver transaminases appear to be particularly predictive of adverse outcome. Pre-eclampsia may sometimes be a feature of the haemolysis, elevated liver enzymes and low platelet (HELLP) syndrome, which is discussed in Chapter 22.

Management of hypertension

Except in malignant hypertension, or in secondary causes of hypertension for which there are specific treatments, management should always begin with efforts to bring about appropriate lifestyle changes, for example attainment of ideal body weight, reduction in any excessive

alcohol intake, reduction in dietary salt intake and attention to other cardiovascular risk factors.

The classes of drugs available include diuretics, calcium channel antagonists, α - and β -blockers, ACE inhibitors and angiotensin receptor antagonists, and centrally acting agents. Combinations of drugs are often required to achieve adequate control of blood pressure; if three or more are required in a young (<40 years) patient with normal renal function, a secondary cause of hypertension should be considered. Compliance with treatment can pose a considerable challenge, particularly because hypertension is generally asymptomatic but also because drug treatment may cause significant adverse effects.

CONCLUSION

Biochemical investigations play a key role in the management of several distinct areas of cardiovascular disease.

Plasma concentrations of markers of myocyte necrosis form the basis of evidence-based criteria that influence decisions in the management of acute coronary syndrome. Increase in cardiac troponin concentrations is embedded in the universal definition of myocardial infarction, and new cardiac biomarkers, as well as panels of biomarkers with complementary timeframes, are currently being developed and evaluated.

The diagnostic and prognostic value of natriuretic peptides in heart failure is reflected in their inclusion as recommended first-line investigations, although they have limitations including lack of specificity.

Measurement of plasma lipids is well-established as a key component of the estimation of cardiovascular risk, and work is currently underway to examine the potential role of inflammatory markers in further stratifying this risk.

The biochemistry laboratory is involved in investigation of end-organ damage in hypertension, monitoring for side-effects of antihypertensive agents, and in the diagnosis of causes of secondary hypertension. A low threshold for investigation is necessary to avoid missing disorders such as pheochromocytoma and primary aldosteronism, which are probably underdiagnosed.

Cardiovascular disorders are associated with high morbidity and mortality. They contribute significantly to the workload of modern routine clinical biochemistry laboratories in developed countries, and are likely to continue to do so for the foreseeable future.

APPENDIX 1: PROTOCOL FOR INVESTIGATION OF ALDOSTERONISM: SCREENING AND CONFIRMATORY TESTS

Patient preparation

Ideally, all drugs that have an effect on the renin–aldosterone system should be discontinued for two weeks before samples are collected. Aldosterone antagonists (e.g. spironolactone) and oestrogens must be discontinued for at least six weeks. Where antihypertensive drugs cannot safely be withheld, verapamil (slow-release), hydralazine, doxazosin or prazosin can be used as these have minimal effect on the renin–aldosterone system. If essential to continue other drugs to control blood pressure, as a minimum, β -blockers and ACE inhibitors should be stopped for two weeks and calcium channel blockers withheld on the day of the test until after its completion. The potential effects of interfering drugs must be taken into account in the interpretation of the renin and aldosterone results if they have to be continued (see Box 38.4).

The patient must be encouraged to take a liberal amount of dietary sodium (typically 100–150 mmol/day). Administer potassium salts orally, or if necessary intravenously, to restore plasma potassium concentration to within the reference range or, if this is not attainable, to the maximum concentration possible. Discontinue this supplementation 24 h before blood samples are taken. The patient must be well hydrated at the time of the test.

Screening procedure

Collect blood mid-morning, after the patient has been up (sitting, standing or walking) for at least two hours and then seated for 5–15 min.

Draw blood into a tube containing anticoagulant (type required is assay dependent). The sample should be taken rapidly to the laboratory, but **not** on ice as cooling of the sample promotes conversion of inactive renin precursor to active renin. Care must be taken to avoid haemolysis, which will result in an artefactual increase in plasma potassium concentration.

Measure plasma aldosterone, renin and electrolytes.

Interpretation of results of screening test

A high aldosterone:renin ratio indicates probable primary aldosteronism (PA). The particular decision limits used are method dependent and therefore vary from laboratory to laboratory, although if the ratio of aldosterone (in pmol/L) to PRA (in pmol/mL/h) is >2000 , the patient almost certainly has PA. Patients with a positive screening test should proceed to a confirmatory test before further investigations are undertaken to determine the cause and location of the disease. If either aldosterone or renin results are abnormal but the ratio is not clearly diagnostic, the screening test should be repeated after a further period off-treatment from all potentially interfering drugs, if some had initially been continued. Other causes of abnormal aldosterone or renin results should be reviewed (see Table 38.4).

CONFIRMATORY TESTS

A number of different confirmatory tests have been described, and there is no definitive evidence as to which has the best diagnostic performance. Of the two tests most commonly used in the UK, the saline suppression test is more convenient and safer to perform than the fludrocortisone suppression test.

Saline suppression test

The test is only indicated when the screening test demonstrates a high aldosterone:renin ratio. The same patient preparation requirements as for the screening test apply. The saline suppression test is contraindicated in patients with severe uncontrolled hypertension, chronic kidney disease, heart failure, cardiac arrhythmia or severe hypokalemia.

Procedure

1. Start test between 08.00 and 09.30 h.
2. Place indwelling catheter in antecubital fossa for infusion of 0.9% saline.

3. Place indwelling catheter in opposite arm for blood sampling.
4. Position patient in recumbent position for 1 h prior to commencing the infusion, and throughout test. Blood pressure and heart rate must be monitored throughout the test.
5. Draw blood into a tube containing anticoagulant (type required is assay dependent), for aldosterone, renin and electrolytes – do not place on ice but send to the laboratory immediately.
6. Infuse 2 L of 0.9% saline over 4 h.
7. At completion of infusion, immediately (with patient still recumbent) draw another blood sample for measurement of aldosterone and renin – do not place on ice but send to the laboratory immediately.

Interpretation

Plasma aldosterone concentration of >140 pmol/L at the end of the test confirms a diagnosis of PA.

Fludrocortisone suppression test

The test is only indicated when the screening test demonstrates a high aldosterone:renin ratio. The same patient preparation requirements as for the screening test apply. The fludrocortisone suppression test is contraindicated in the elderly and those with severe hypertension owing to the risks associated with sodium retention. This test should be performed on an in-patient basis.

Procedure

1. Day 1 (mid-morning). Ensure that the patient is upright for at least 30 min then draw blood into a tube containing anticoagulant (type required is assay dependent), for aldosterone, renin and electrolytes – do not place on ice but send to the laboratory immediately.
2. Administer fludrocortisone 0.1 mg 6-hourly for four days.
3. Administer oral slow-release sodium tablets 30 mmol 8-hourly with meals for four days.
4. Administer slow-release potassium tablets in sufficient quantity to maintain plasma potassium concentration close to 4.0 mmol/L. Monitor plasma potassium concentration at least twice daily.
5. Day 4 (mid-morning). Ensure that the patient is upright for at least 30 min and repeat blood sample as on day 1.

Interpretation

Upright plasma aldosterone >170 pmol/L on day 4 confirms PA, provided renin is fully suppressed.

APPENDIX 786

INTRODUCTION

The aim of therapeutic drug monitoring (TDM) is to aid the clinician in the choice of drug dosage in order to provide the optimum treatment for the patient and, in particular, to avoid iatrogenic toxicity. It can be based on pharmacogenetic, demographic and clinical information alone (*a priori* TDM), but is normally supplemented with measurement of drug or metabolite concentrations in blood or markers of clinical effect (*a posteriori* TDM). Measurements of drug or metabolite concentrations are only useful where there is a known relationship between the plasma concentration and the clinical effect, no immediate simple clinical or other indication of effectiveness or toxicity and a defined concentration limit above which toxicity is likely. Therapeutic drug monitoring has an established place in enabling optimization of therapy in such cases.

Pharmacokinetics and pharmacodynamics

Before discussing which drugs to analyse or how to carry out the analyses, it is necessary to review the basic

elements of pharmacokinetics and pharmacodynamics. Essentially, pharmacokinetics may be defined as what the body does to drugs (the processes of absorption, distribution, metabolism and excretion), and pharmacodynamics as what drugs do to the body (the interaction of pharmacologically active substances with target sites (receptors) and the biochemical and physiological consequences of these interactions). The processes involved in drug handling are summarized in [Figure 39.1](#), which also indicates the relationship between pharmacokinetics and pharmacodynamics, and will now be discussed briefly. For a more mathematical treatment, the reader is referred to the pharmacokinetic texts listed in Further reading.

Adherence

The first requirement for a drug to exert a clinical effect is obviously for the patient to take it in accordance with the prescribed regimen. Patients are highly motivated to comply with medication in the acute stages of a painful or debilitating illness, but as they recover and the purpose of medication becomes prophylactic, it is

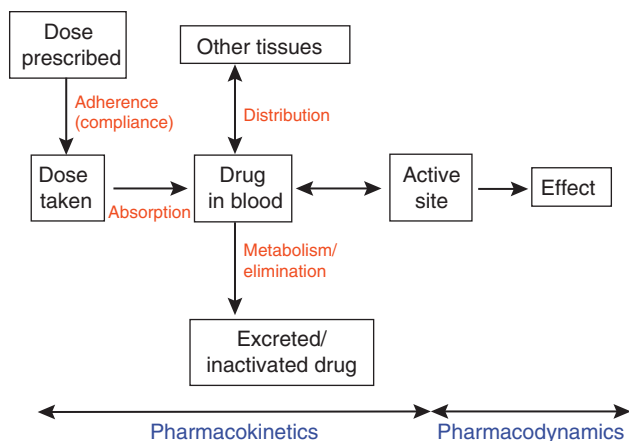

FIGURE 39.1 ■ Processes involved in drug handling.

easy for them to underestimate the importance of regular dosing. ‘Compliance’ is the traditional term used to describe whether the patient takes medication as prescribed, though ‘adherence’ has become the preferred term in recent years as being more consistent with the concept of a partnership between the patient and the clinician. ‘Compliance’, however, remains in widespread use. In chronic disease states such as asthma, epilepsy or bipolar disorder, variable adherence is widespread. The fact that a patient is not taking a drug at all is readily detectable by measurement of drug concentrations, although variable adherence may be more difficult to identify by monitoring plasma concentrations.

Absorption

Once a drug has been taken orally, it needs to be absorbed into the systemic circulation. This process is described by the pharmacokinetic parameter *bioavailability*, defined as the fraction of the absorbed dose that reaches the systemic circulation. Bioavailability varies between individuals, between drugs and between different dosage forms of the same drug. In the case of intravenous administration, all of the drug goes directly into the systemic circulation and bioavailability is 100% by definition, but different oral formulations of the same drug may have different bioavailability depending, for example on the particular salt or packing material that has been used. Changing the formulation used may require dosage adjustment guided by TDM to ensure that an individual’s exposure to drug remains constant. Other routes of absorption such as intramuscular, subcutaneous or sublingual may exhibit incomplete bioavailability. The total amount of drug absorbed can be determined from the area under the plasma concentration/time curve (see Fig. 39.2).

Distribution

When a drug reaches the bloodstream, the process of distribution to other compartments of the body begins. The extent of distribution of a drug is governed by its relative solubility in fat and water, and by the binding capabilities of the drug to plasma proteins and tissues. Drugs that are strongly bound to plasma proteins and exhibit

FIGURE 39.2 ■ Concentration/time curve for a drug administered by any route other than intravenously. Line A represents the absorption phase; line B indicates the distribution half-life and line C the elimination half-life. At point X, absorption, distribution and metabolism are all in progress. The areas of the rectangles can be summed to estimate the total amount of drug absorbed, the ‘area under the curve’ (AUC) (hatched area).

low lipid solubility and tissue binding will be retained in the plasma and show minimal distribution into tissue fluids. Conversely, high lipid solubility combined with low binding to plasma proteins will result in wide distribution throughout the body. The relevant pharmacokinetic parameter is the volume of distribution, which is defined as the theoretical volume of a compartment necessary to account for the total amount of drug in the body if it were present throughout the compartment at the same concentration found in the plasma. High volumes of distribution thus represent extensive tissue binding.

After reaching the systemic circulation, many drugs exhibit a distribution phase during which the drug concentration in each compartment reaches equilibrium, represented by Line B in Figure 39.2. This may be rapid (~15 min for gentamicin) or prolonged (at least six hours for digoxin). There is generally little point in measuring the drug concentration during the distribution phase, especially if the site of action of the drug for clinical or toxic effects lies outside the plasma compartment and the plasma concentration in the distribution phase is not representative of the concentration at the receptor.

Between-patient variations in volume of distribution caused by differences in physical size, the amount of adipose tissue and the presence of disease (e.g. ascites) can significantly weaken the relationship between the dose of drug taken and the plasma concentration in individual patients and hence increase the need for concentration monitoring.

Elimination (metabolism and excretion)

When a drug has been completely distributed throughout its volume of distribution, the pharmacokinetics enter the elimination phase (line C in Fig. 39.2). In this phase, the drug concentration falls owing to metabolism of the drug (usually in the liver) and/or excretion of the drug (usually via the kidneys into the urine or via the liver into the

bile). These processes are described by the pharmacokinetic parameter *clearance*, which is a measure of the ability of the organs of elimination to remove active drug. The clearance of a drug is defined as the theoretical volume of blood that can be completely cleared of drug in unit time (*cf.* creatinine clearance, see Chapter 7). Factors affecting clearance and hence the rate of elimination include body weight, body surface area, renal function, hepatic function, cardiac output, plasma protein binding and the presence of other drugs which affect the enzymes of drug metabolism including alcohol and nicotine (tobacco use). Pharmacogenetic factors may also have a profound influence on clearance.

Rate of elimination is often expressed in terms of the *elimination rate constant* or the *elimination half-life*, which is the time taken for the amount of drug in the body to fall to half its original value and is generally easier to apply in clinical situations. Both the elimination rate constant and the elimination half life can be calculated from the clearance and the volume of distribution (see Pharmacokinetic texts in Further reading).

With some drugs (e.g. phenytoin), the capacity of the clearance mechanism is limited, and once this is saturated there may be large increments in plasma concentrations with relatively small increases in dose. This phenomenon makes these drugs very difficult to use safely without access to concentration monitoring.

Protein binding

Many endogenous constituents of plasma are carried on binding proteins in plasma (e.g. bilirubin, cortisol and other hormones), and drugs are also frequently bound to plasma proteins (usually albumin and α_1 -acid glycoprotein). Acidic drugs (e.g. phenytoin) are, in the main, bound to albumin, whereas basic drugs bind to α_1 -acid glycoprotein and other globulins.

The proportion of drug bound to protein can vary from zero (e.g. lithium salts) to almost 100% (e.g. mycophenolic acid). The clinical effect of a drug and the processes of metabolism and excretion are related to the free concentration of a drug, with drug bound to protein effectively acting as an inert reservoir. Variations in the amount of binding protein present in plasma can thus change the total measured concentration of the drug in the blood without necessarily changing the free (active) concentration, and this is a further reason why measured plasma concentrations may not relate closely to clinical effect. Other drugs or endogenous substances that compete for the same binding sites on protein will also affect the relationship between free and bound drug. For these reasons, it has been suggested that the free concentration of a drug rather than the total (free + protein-bound) concentration should be measured by a TDM service, at least for those drugs exhibiting significant protein binding, e.g. phenytoin. Despite the apparent logic of this idea, it has not been widely adopted because of methodological difficulties and continuing controversy about whether the theoretical benefits are realized in clinical practice. It is nonetheless important to be aware of the effects of changes in protein binding when interpreting total drug concentrations in plasma, especially:

- when the free fraction of a drug may change within an individual over time, e.g. in pregnancy (with falling albumin concentration) or when other drugs bound at the same binding site are added or withdrawn
- when there is a highly abnormal binding protein concentration in plasma; for example, in severe hypoalbuminaemia
- when a pathological state (e.g. uraemia) results in the displacement of drug from the binding sites.

The discussion above has outlined the pharmacokinetic factors that govern the relationship between dose and the drug concentration in the plasma or at the active site, and has indicated how these may vary between patients to produce poor correlation between the dose prescribed and the effective drug concentration at the site of action. In general, once steady-state has been reached, plasma concentrations in the individual should exhibit a constant relationship to the concentration at the site of action governed by the distribution factors discussed above, but this may not be the case if blood supply to target tissues is impaired (e.g. for poorly vascularized tissues or a tumour that has outgrown its blood supply (cytotoxic drugs)) or a site of infection that is not well perfused (antibiotics)).

Pharmacodynamic factors

Pharmacodynamics is the study of the relationship between the concentration of drug at the site of action and the biochemical and physiological effect. The response of the receptor may be affected by the presence of drugs competing for the same receptor, the functional state of the receptor or pathophysiological factors such as hypokalaemia. Interindividual variability in pharmacodynamics may be genetic or reflect the development of tolerance to the drug with continued exposure. High pharmacodynamic variability severely limits the usefulness of monitoring drug concentrations as they are likely to give a poor indication of the effectiveness of therapy.

Which drugs should be measured?

The above discussion provides a basis for determining which drugs are good candidates for therapeutic drug monitoring. As stated at the beginning of this chapter, the aim of TDM is the provision of useful information that may be used to modify treatment. For this reason, it is generally inappropriate to measure drug concentrations where there is a good clinical indicator of drug effect. Examples of this are the measurement of blood pressure during antihypertensive therapy; glucose in patients treated with hypoglycaemic agents; clotting studies in patients treated with heparin or warfarin, and cholesterol in patients treated with cholesterol-lowering drugs. While plasma concentration data for such drugs are valuable during their development to define pharmacokinetic parameters and dosing regimens, TDM is not generally helpful in the routine monitoring of patients. It may have a limited role in detecting poor adherence or poor drug absorption in some cases. However, where there are no such clinical markers of effect or where

symptoms of toxicity may be confused with those of the disease being treated, concentration monitoring may have a vital role.

Therapeutic drug monitoring is useful only for drugs that have a poor correlation between dose and clinical effect (high pharmacokinetic variability). Clearly, if dose alone is a good predictor of pharmacological effect, then measuring the plasma concentration has little to contribute.

However, clinically useful TDM does require that there is a good relationship between plasma concentration and clinical effect. If drug concentration measurements are to be useful in modifying treatment, then they must relate closely to the effect of the drug or its toxicity (or both). This allows definition of an effective therapeutic 'window' – the concentration range between the minimal effective concentration and the concentration at which toxic effects begin to emerge – and allows titration of the dose to achieve concentrations within that window. Demonstration of a clear concentration–effect relationship requires low between-individual pharmacodynamic variability (see above), the absence of active metabolites that contribute to the biological effect but are not measured in the assay system and (usually) a reversible mode of action at the receptor site. Reversible interaction with the receptor is required for the intensity and duration of the response to the drug to be temporally correlated with the drug concentration at the receptor.

Many drugs have active metabolites, and some drugs are actually given as pro-drugs, in which the parent compound has zero or minimal activity and pharmacological activity resides in a product of metabolic transformation. For example, mycophenolate mofetil is metabolized to the active immunosuppressant mycophenolate. It will be clear that useful information cannot be obtained from drug concentration measurements if a substantial proportion of the drug's effect is provided by a metabolite that is not measured and whose concentration relationship to the parent compound is undefined. In some cases (e.g. amitriptyline/nortriptyline), both drug and metabolite concentrations can be measured and the concentrations added to give a combined indication of effect, but this assumes that drug and metabolite are equally active. In other cases (e.g. carbamazepine and carbamazepine 10,11-epoxide), the active metabolite is analysed and reported separately.

Therapeutic drug monitoring is most valuable for drugs which have a narrow therapeutic window. The therapeutic index (therapeutic ratio, toxic-therapeutic ratio) for a drug indicates the margin between the therapeutic dose and the toxic dose – the larger, the better. For most patients (except those who are hypersensitive), penicillin has a very high therapeutic ratio and it is safe to use in much higher doses than those required to treat the patient, with no requirement to check the concentration attained. However, for other drugs (e.g. immunosuppressives, anticoagulants, aminoglycoside antibiotics and cardiac glycosides), the margin between desirable and toxic doses is very small, and some form of monitoring is essential to achieve maximal efficacy with minimal toxicity.

The criteria for TDM to be clinically useful are summarized in [Box 39.1](#).

BOX 39.1 Criteria for clinically useful TDM

- Absence of good clinical markers of drug effect
- Poor correlation between dose and clinical effect (high pharmacokinetic variability)
- Good correlation between plasma drug concentration and clinical effect (low pharmacodynamic variability, no active metabolites)
- Narrow concentration interval between therapeutic and toxic effects

The list of drugs for which TDM is of proven value is relatively small ([Box 39.2](#)). Phenytoin and lithium are perhaps the best and earliest examples of drugs that meet all the above criteria and for which TDM is essential. The aminoglycoside antibiotics, chiefly gentamicin and tobramycin, also qualify on all counts. A number of other drugs that are frequently monitored fail to meet one or more of the criteria completely, and the effectiveness of TDM as an aid to management is therefore reduced. The evidence for the utility of monitoring many drugs is based more on practical experience than well-designed studies. However, for newer agents such as the

BOX 39.2 Drugs for which there is a clear indication for measurement

- Aminoglycoside antibiotics (e.g. gentamicin, tobramycin)
- Carbamazepine
- Ciclosporin
- Digoxin
- Lamotrigine
- Lithium
- Methotrexate
- Phenytoin
- Sirolimus
- Tacrolimus
- Theophylline

Drugs whose measurement may be useful in some circumstances but not generally practised

- Amiodarone
- Antiretroviral drugs (protease inhibitors, NNRTIs)
- β -Blockers
- Caffeine
- Chloramphenicol
- Clozapine
- Disopyramide
- Flecainide
- Flucytosine
- Methadone
- Morphine
- Mycophenolic acid
- Olanzapine
- Phenobarbital
- Procainamide (and N-acetylprocainamide)
- Teicoplanin
- Tricyclic antidepressants (amitriptyline/nortriptyline, imipramine/desipramine, dothiepin)
- Valproate
- Vancomycin

immunosuppressants and antiretroviral drugs, there is good evidence supporting the benefits of TDM in improving clinical outcomes. (Further information is given in Individual Drugs, below.)

USE OF THERAPEUTIC DRUG MONITORING

Once the narrow range of drugs for which TDM can provide useful information has been defined, it should not be assumed that TDM is necessary for every patient on these drugs at every visit. For TDM to be used for maximum patient benefit and optimal cost-effectiveness, six important criteria must be satisfied each time a sample is taken. These are summarized in [Box 39.3](#) and will now be discussed briefly.

Appropriate clinical question

The first essential for making effective use of any laboratory test is to be clear at the start what question is being asked. This is particularly true for TDM requests, and much time, money and effort is wasted on requests where the indication for analysis has not been clearly defined. If the question is uncertain, the answer is likely to be unhelpful.

The two main reasons for monitoring drugs in blood are to ensure effective therapy and to avoid toxicity. Effective therapy requires that sufficient drug reaches the drug receptor to produce the desired response (which may be delayed in onset). Where a drug is prescribed and the desired effect is not achieved, this may or may not be due to insufficient dosage, since there may be other reasons (individual idiosyncrasy, drug interactions etc.) for the lack of effect. Those at the extremes of age – neonates and the very elderly – have metabolic processes that render them differently susceptible even to weight-adjusted doses. For example, in neonates, the metabolism of theophylline is qualitatively as well as quantitatively different from that in older children. In the very elderly, there may be considerable alterations in absorption and also renal clearance. Drug interactions may also produce a reduced clinical effect for a given dose.

In patients on long-term therapy, once a steady-state concentration that produces a satisfactory clinical effect has been obtained, this concentration can be documented as an effective baseline for the individual patient. If circumstances subsequently change, then changes in response can be related back to both the dose and the plasma concentration of the drug. This is particularly important for psychotropic drugs. ‘Baseline’ concentrations

may however change over time as disease processes develop, or gradually with increasing age or changes in drug metabolism.

The avoidance of iatrogenic toxicity is probably the most pressing case for the practice of TDM. The aim is to ensure that drug (or metabolite) concentrations are not so high as to produce symptoms/signs of toxicity. Since a narrow therapeutic index is a prerequisite for drugs suitable for TDM, it is inevitable that toxicity will occur in a small proportion of patients, even with all due care being exercised. Toxicity can never be diagnosed solely from the plasma drug concentration, and it must always be considered in conjunction with the clinical circumstances since some patients will show toxicity when their concentrations are within the generally accepted therapeutic range and others will tolerate concentrations outside the range with few or no ill-effects. The advantage of regular monitoring is that such circumstances may be recorded and the range for that individual adjusted accordingly.

There are two main factors that may lead to inappropriately high plasma drug concentrations. The first is an inappropriate dosing regimen, either due to a single gross error or (more often) a gradual build-up of plasma concentration either because the dose is slightly too high for the individual or because of the development of hepatic or renal insufficiency.

The second factor leading to toxicity is pharmacokinetic drug interactions. Patients are often treated with more than one drug, which can interfere with each other's actions in a number of ways, for example:

- displacement from protein binding sites
- competition for hepatic metabolism
- induction of hepatic metabolizing systems
- competition for renal excretory mechanisms.

Examples of the more commonly encountered drug interactions involving drugs measured for TDM purposes are given in [Table 39.1](#). There are, however, numerous other examples and the analyst faced with an unusual response or an inappropriate plasma concentration should seek a full drug history to assist in determining the explanation. This history should include specific enquiry about the use of alternative therapies, since many herbal and other non-pharmaceutical remedies (which may not be immediately mentioned by patients) may have significant effects on drug concentrations due to the induction of drug metabolizing enzymes. St John's wort (*Hypericum perforatum*), a perennial herb with bright yellow flowers, is one example. It has been shown to induce the hepatic drug-metabolizing enzymes CYP3A4 and CYP2B6, and hence reduce the steady-state concentrations of many drugs.

Therapeutic drug monitoring is particularly useful in confirming toxicity when both under- and overdosage with the drug in question give rise to similar clinical features, for example arrhythmias with digoxin, or fits with phenytoin, and where high drug concentrations give rise to delayed toxicity, for instance high aminoglycoside concentrations, which may give rise to irreversible ototoxicity if prompt action is not taken.

Where a patient is known to be suffering from toxicity and the plasma drug concentration is high, monitoring is often required to follow the fall in concentration

BOX 39.3 Criteria for effective drug monitoring

- Appropriate clinical question
- Accurate patient information
- Appropriate sample
- Accurate analysis
- Relevant clinical interpretation
- Effective action taken

TABLE 39.1 Common drug interactions encountered in therapeutic drug monitoring

Effector	Drug(s) affected (examples)
Interactions due to induction of metabolism	
Phenytoin	Phenytoin, phenobarbital, digoxin
Phenobarbital	Phenobarbital, phenytoin, prednisolone, warfarin, digoxin
Rifampicin	Cortisone, digoxin, methadone, quinidine, theophylline
St John's wort	Ciclosporin, tacrolimus, digoxin, theophylline, antiretrovirals
Interactions due to inhibition of metabolism	
Chloramphenicol	Phenytoin, tolbutamide
Cimetidine	Diazepam, phenytoin, theophylline, warfarin
Ethanol	Diazepam
Erythromycin	Theophylline
Isoniazid	Carbamazepine, phenytoin
Oral contraceptives	Theophylline
Quinidine	Digoxin
Valproate	Phenobarbital
Interactions due to effects on excretion	
Cimetidine, ranitidine	Procainamide
Verapamil	Digoxin
Amiodarone	Digoxin
Spironolactone	Digoxin
Quinidine	Digoxin
Interactions due to displacement from protein binding	
Valproate	Phenytoin
Salicylate	Warfarin, sulphonylureas, methotrexate
Interactions due to enhanced absorption	
Erythromycin	Digoxin

following cessation of treatment. For example, in anti-convulsant overdose, it is important for the clinician to know when drug concentration(s) are likely to reach the therapeutic range, since reinstatement of therapy will then be required to prevent seizures.

Other important reasons for therapeutic drug monitoring include guiding dosage adjustment in clinical situations in which the pharmacokinetics are changing rapidly (e.g. neonates, children or patients in whom hepatic or renal function is changing) and defining pharmacokinetic parameters and concentration–effect relationships for new drugs.

The use of TDM to assess adherence (compliance) is to some extent controversial. Clearly, assessment of adherence could provide justification for monitoring every drug in the pharmacopoeia, at enormous cost and for little clinical benefit. Further, application of TDM in this situation is not simple. A patient with a very low or undetectable drug concentration is usually assumed to be non-compliant, but the situation is much less clear when a concentration that is only slightly low (based on population data) is found. Is the patient non-compliant or are other factors (such as poor absorption, induced metabolism or altered protein binding) leading to the low concentration? Much harm may be done in these situations by assumptions of poor adherence to therapy. Adherence can be assessed in other ways, by tablet-counting, supervised medication in hospital or the use of carefully posed

questions that are non-judgemental, for example ‘How often do you forget to take your tablets?’ Such approaches are likely to be more effective than TDM in detecting and avoiding poor adherence to therapy, though TDM may have a role in patients with poor symptom control, who deny poor adherence despite careful questioning and interventional reinforcement.

Accurate patient information

Proper interpretation of TDM data depends on having some basic information about the patients and their recent drug history. The importance of this requirement has led many laboratories to design specific request forms for TDM. These are now being superseded by computerized request ordering systems that allow collection of essential items of information at the time of making the request, although it remains important to keep the requesting interface user-friendly and not too complex. Intelligent system design is necessary. Basic information requirements for TDM requests are summarized in [Table 39.2](#).

Appropriate sample

The vast majority of TDM applications require a blood sample. In general, serum or plasma can be used, although for a few drugs that are concentrated within red cells, for example, ciclosporin, whole blood is preferable as concentrations are higher and partition effects are avoided. The literature is poor on the differentiation between serum and plasma samples and careful selection of sample tubes is necessary to avoid interferences by anti-coagulants, plasticizers, separation gels etc, either in the assay system or by absorption of sample drug onto the gel or the tube, reducing the amount available for analysis. If in doubt, serum collected into a plain glass tube with no additives is usually safest. Haemolysis should be avoided, as it may cause in vivo interference if the drug is concentrated in erythrocytes, or in vitro interference in immunoassay systems. For drugs that are minimally protein bound, there need be no restrictions on the use

TABLE 39.2 Information requirements for TDM requests

	Essential	Desirable
Patient	Name Age	Weight Renal/hepatic function
	Gender Hospital/health system ID number	
Problem	Pathology/clinical details Reason for request (e.g. poor response, ?toxic)	
Therapy	Drug of interest dose formulation and route of administration duration of therapy date/time last given	Other drugs – list all

of tourniquets; however, stasis should ideally be avoided for drugs which are highly bound to albumin, e.g. phenytoin. Care should also be taken to avoid contamination with local anaesthetics, for example lidocaine, which are sometimes used before venepuncture. Where intravenous therapy is being given, care must be taken to avoid sampling from the limb into which the drug is being infused.

Urine is of no value for quantitative TDM. Saliva may provide a useful alternative to avoid venepuncture (especially in children) or when an estimate of the concentration of free (non-protein-bound) drug is required. Saliva is effectively an *in vivo* ultrafiltrate and concentrations reflect plasma free drug concentrations quite well for drugs that are essentially unionized at physiological pH. Salivary monitoring is unsuitable for drugs that are actively secreted into saliva (e.g. lithium) and drugs that are strongly ionized at physiological pH (e.g. valproic acid, quinidine) as the relationship between salivary and plasma concentrations becomes unpredictable. Careful collection of the sample is required, and the mouth should be thoroughly rinsed with water prior to sampling. Sapid (taste related) or masticatory (chewing on an elastic band) stimulation of saliva flow is used to increase volume. The mucoproteins in saliva make the sample difficult to handle, and centrifugation is usually necessary to remove cellular debris. These and other problems have meant that salivary analysis has not been widely adopted for routine TDM.

It is normally necessary for the patient to be at steady-state on the current dose of drug, i.e. when absorption and elimination are in balance and the plasma concentration is stable. This is true except when suspected toxicity is being investigated, when it is clearly inappropriate to delay sampling until steady-state has been reached. The time taken to attain the steady-state concentration is determined by the plasma half-life of the drug, and the relationship between the number of half-lives which have elapsed since the start of treatment and the progress towards steady-state concentrations is shown in Table 39.3.

It is frequently stated that five half-lives must elapse before plateau concentrations are achieved, unless loading doses are employed when they are achieved much more rapidly. As shown in Table 39.3, the plasma concentration after 3.3 half-lives is 90% of the predicted steady-state concentration, and this may be taken as the minimum time for sampling for routine purposes after starting a drug or changing the dose. For drugs with a long half-life (e.g. digoxin or phenobarbitone), two weeks

or more may be required before steady-state is achieved, especially if the drug is renally excreted and renal function is poor.

In neonates, the rapidly changing clinical state, degree of hydration and dosage requirements make the concept of steady-state a theoretical ideal rather than an attainable goal and there is little value in delaying measurements in the hope of attaining steady-state.

A further requirement for many drugs is for samples to be taken at the appropriate time following the last dose. The size of the fluctuations in plasma concentration between doses depends on the dosage interval and the half-life of the drug. Frequent dosing avoids large peaks and transient toxic effects but is unpopular with patients, difficult to comply with and more likely to lead to medication errors. Less frequent dosing can give rise to large fluctuations in plasma concentration. To some extent, these opposing considerations can be reconciled with the use of sustained-release preparations.

There is no single optimum time for taking samples in relation to dose. The most reproducible for sampling is immediately (<30 min) before a dose (trough concentration), when the lowest concentrations in the cycle will be obtained. This is the optimum time if an indication of drug efficacy is required, and will show least between-sample variation in patients on chronic therapy. The use of peak and trough concentrations for detecting toxicity of aminoglycoside antibiotics has become less relevant with the advent of once-daily dosing regimens, but sampling at two hours post-dose for ciclosporin can give an excellent estimate of the probable area under the curve and has become a common and effective TDM technique, though sampling in the middle of the absorption/distribution phase in this way does require very accurate standardization of sampling time in relation to the last dose. In the case of digoxin, a specimen should not be taken within 6 h of the dose, since the digoxin absorption and distribution peak may be extremely sharp and high (Fig. 39.3) and serum digoxin concentrations in this period do not reflect tissue concentrations.

TABLE 39.3 Percentage of steady-state plasma concentration attained at various times after starting/changing therapy

Time (drug half-lives)	% steady-state
0.5	29
1.0	50
2.0	75
3.0	88
3.3	90
4.0	94
5.0	97
7.0	99

FIGURE 39.3 ■ The concentration/time curve for a patient given digoxin orally. Note the sharp peak and relatively stable plateau concentration after 6 h.

Further details on optimal sampling times for individual drugs are given in the relevant sections of this chapter. When computer programmes are used for pharmacokinetic parameter optimization and dosage prediction, it becomes extremely important that dosage and sampling times are accurately known, as large prediction errors can result from inaccurate data.

Accurate analysis

Establishing a relationship between plasma drug concentrations and effect requires accurate, precise and reliable analytical methods. The choice of methods is vast, encompassing immunoassays (isotopic and optical), chromatography (e.g. gas liquid chromatography (GLC) and high performance liquid chromatography (HPLC)), increasingly with mass spectrophotometric detectors) and a variety of novel techniques involving dry chemistry.

Selecting the most appropriate analytical methods is often challenging, and the choice depends on the availability of staff, expertise and equipment, the anticipated batch sizes, the range of drugs to be measured and the turnaround time required. There is no 'best fit' for every situation. Some guidelines are given in Table 39.4. Assays used in routine TDM must be specific, showing no interferences from endogenous compounds, drug metabolites or exogenous sources, and must also work with small sample sizes (certainly <1 mL plasma/serum and ideally 10–100 μ L).

Most analytical methods determine the total concentration of drug in plasma or serum. As discussed above, it is sometimes useful to obtain an estimate of the free (non-protein-bound) drug concentration. The main methods for separation of bound and free drug prior to quantitation by conventional assays are equilibrium dialysis, ultrafiltration and centrifugation through a fine-mesh membrane. The latter two are non-equilibrium techniques and are therefore much quicker than equilibrium dialysis, which generally requires an overnight incubation. It is often difficult to assess the reliability of different procedures as no single method gives consistently accurate estimates of free drug concentration.

TABLE 39.4 Guidelines for choice of methods for therapeutic drug monitoring analyses

Purpose for which required	Most appropriate method(s)
On-site analyses in clinics	Point of care immunoassay devices
Urgent analyses	Optical immunoassays
Batch analyses, single drug	Optical immunoassays, HPLC, GC, HPLC/mass spectrometry (MS)
Batch analyses, multiple drugs	HPLC, GC (optical immunoassays become uneconomic)
Single analyses with metabolite patterns	HPLC/MS or LC/MS

For some drugs, no choice of method exists.

Relevant clinical interpretation

In the 40 years or so that TDM has been practised routinely, it has been shown that having drug concentration measurements available to clinicians does not in itself result in improved clinical care. Improved outcome depends on application of the analytical result to a specific clinical situation with appropriate expertise.

In particular, it is important to understand that the widely quoted (and just as widely misused) 'therapeutic ranges' for drugs represent a guide to the approximate concentrations that produce a therapeutic response in the majority of patients, rather than a set of inflexible concentration limits to which dosage regimens must be directed. 'Target ranges' has been suggested as a better term, which at least implies that these are aims, rather than that all concentrations within the specified range are therapeutic (and all outside are not). Many patients need plasma drug concentrations above the upper limit of the target range for effective therapy, and such concentrations must not provoke knee-jerk dosage reduction. Specialist clinicians usually appreciate this fact, but non-specialists frequently do not, and laboratory staff or pharmacists have an essential educational role here. Conversely, plasma drug concentrations below the lower limit of the target range may produce a satisfactory response in some patients, and arbitrary dose increases will merely increase the likelihood of toxicity without added benefit. In one of the earliest papers on TDM, Koch–Weser wrote: 'Therapeutic decisions should never be based solely on the drug concentration in the serum'. The cardinal principle, often repeated but still forgotten, is to treat the patient, not the drug concentration.

Effective action taken

As implied above, drug concentrations above the target range do not invariably require a reduction in dosage. If the patient is symptom-free, a careful search for signs of toxicity should be made. If there is no evidence of toxicity, the patient may be best served by doing nothing, although for some drugs (e.g. phenytoin) continued monitoring for the development of long-term undesirable effects is advisable. Similarly, drug concentrations below the target range in a patient who is well and free from symptoms do not necessarily require an increased dose, although in some cases (e.g. digoxin), they may provide evidence that the drug is no longer effective, and that stopping it under medical supervision may be worth trying.

For most drugs, there is a relatively linear relationship between dose and plasma concentration at steady-state, the major exception to this being phenytoin (see later); thus doubling the dose should double the plasma concentration. The difficulty, therefore, is in determining the initial dose to use, especially where a rapid effect, for example the prevention of cardiac arrhythmias, is required. The aim then is to achieve a steady-state concentration rapidly, without waiting for five half-lives to elapse, particularly for drugs with long half-lives. For this reason a 'loading' dose of several times the daily maintenance dose is given, effectively reaching steady-state over two half-lives (Fig. 39.4). The calculation of the doses required for

FIGURE 39.4 ■ The effect of a loading dose on the rate of achieving a steady-state concentration

loading and maintenance of a steady-state concentration is relatively straightforward and the relevant equations are given in [Appendix 39.1](#).

In practice, dosage prediction can be approached in two main ways. It can be estimated from average population parameter values using the equations in [Appendix 39.1](#), or the measurement of one or more drug concentrations at appropriate times in the specific individual allows calculation of patient-specific parameters, which then allows further dosage optimization – TDM-assisted dosage optimization. The details are beyond the scope of this chapter and specialist pharmacokinetic texts (see [Further reading](#)) should be consulted. Numerous nomograms and software packages are available for dosage optimization based on TDM data and Bayesian principles. It is vital to ensure that the baseline data are accurate, for example ensuring that the time the drug was actually taken in relation to the sampling time is known (rather than when it was supposed to be taken).

PROVISION OF A THERAPEUTIC DRUG MONITORING SERVICE

The basic essentials for an effective TDM service are the availability of appropriate analytical methods and quality assurance procedures, specialist expertise and the ability to produce results within a clinically relevant time.

Staff

A TDM service requires experienced analysts who understand the basis of the procedures involved and are competent to advise on the analytical sensitivity and specificity of the methods being used and to maintain exacting standards of accuracy, precision and document control. In addition, it is essential that the service has access to specialist clinical advice from someone who understands the principles of pharmacokinetics and therapeutics – an appropriately trained laboratory scientist, a pharmacist or a specialist clinician. The best service is generally obtained with a team approach in

which pharmacists, clinical scientists, technical and medical staff all play a role. Difficult cases can then be discussed before any samples are taken and advice obtained on whether concentration monitoring is indicated and on the appropriate timing of any samples required. Following analysis, results are scrutinized by members of the team and appropriate recommendations for action conveyed to the clinician.

However, this ideal degree of involvement is impractical in many hospital situations, and even more difficult for outpatient or primary care work. Provided the request form contains the necessary clinical information (see above), laboratory staff can check these details on receipt of the specimen and advise if the specimen or the reason for analysis is appropriate. Once the analysis is complete, all results (or just those which fall outside defined limits) can be assessed by specialist staff and communicated to the requesting clinician with the appropriate degree of urgency and with recommendations for action where appropriate.

Turnaround time

The ideal turnaround for TDM analyses requires that results are returned to the clinician before the next dose of the drug is due, in order that adjustments can be made immediately. This is not feasible in cases of three or four times daily dosage regimens but, provided that a responsive service is available, patients should not be exposed to inappropriate dosage regimens for more than 24 h after the specimen was taken.

Point-of-care testing

Point-of-care testing is appropriate in some clinical situations since the availability of a plasma drug concentration at the time of consultation allows the clinician to make immediate decisions on dosage adjustments based on objective data. The savings in patient time and improvements in clinic throughput have been shown to outweigh the extra costs of on-site testing in a number of settings. Several methods are available for on-site TDM testing, but need to be carefully evaluated to ensure that their analytical performance is adequate in the setting in which they are used.

Reporting

The reporting of a plasma concentration alone is of limited value to the clinician who is not fully familiar with TDM. Reports that contain information on the reason for the request, the dosage and timing along with the result and appropriate interpretative comments are much more useful. All urgent results should be telephoned and the fact noted. The provision of cumulative reports improves liaison between the laboratory and the clinician, and has been shown to improve patient care.

Units

There has been considerable debate about the appropriate units (mass or molar) for reporting measurements of

drug concentration. Most of the toxicological literature has been in mass units, but molar units have theoretical advantages in making it easier to equate drug and metabolite concentrations. Uniformity of reporting is important for patient safety reasons, as confusion over units can result in dangerous misinterpretations. Within the UK, at least, there is now agreed consensus that SI mass units with the litre as the unit of volume should be used for all therapeutic drug assays, except for a specified few which have always been reported in molar units (methotrexate, lithium, thyroxine and iron).

Quality assurance

Measurements of plasma drug concentrations can only be used effectively to diagnose toxicity or under-dosage and to monitor treatment if the measurements are accurate and reproducible. The need for effective internal quality control and external quality assessment procedures for all methods used to produce results is therefore as great as in other areas of clinical biochemistry. Analytical laboratories should be accredited to ISO 15189.

Continuing education

A good TDM service provides an environment for education of trainee staff, not only from biochemistry but from clinical pharmacy and clinical pharmacology. The involvement of staff from other disciplines and their exposure to the analytical and interpretational aspects should be encouraged. Insistence on the provision of full clinical information and the feedback of interpretation on correctly documented cases can lead to considerable improvements in the effectiveness of the service.

PHARMACODYNAMIC MONITORING, BIOMARKERS AND PHARMACOGENETICS

Classic TDM uses drug concentration measurements in body fluids to guide optimization of therapy and minimize adverse consequences. In recent years, other methods of guiding drug therapy have been introduced, and though they do not fit the strict definition of TDM they merit discussion as they are becoming increasingly relevant to the provision of effective drug therapy.

Pharmacodynamic monitoring is the study of the biological effect of a drug at its target site, and has been applied to areas of immunosuppressive therapy and cancer chemotherapy. For example, the biological effect of the immunosuppressive calcineurin inhibitors ciclosporin A and tacrolimus can be assessed by direct measurement of calcineurin phosphatase activity. The main disadvantage of pharmacodynamic monitoring that has emerged to date is that the assays involved are often significantly more complex and time-consuming than the measurement of a drug by chromatography or immunoassay.

Any biochemical measurement that can be used to determine efficacy, extent of toxicity or individual pharmacodynamics for a therapeutic agent is called a *therapeutic biomarker*. Hitherto, most such markers have been markers of toxicity rather than of therapeutic efficacy

(e.g. urinary N-acetylglucosaminidase as an index of tubular damage caused by nephrotoxic drugs), but there is increasing interest in biomarkers that give direct information about drug efficacy, for example red cell 6-thioguanine nucleotide concentrations in the assessment of thiopurine drug efficacy or measurement of inosine 5'-monophosphate dehydrogenase (IMPDH) activity as a marker of the IMPDH inhibitor mycophenolic acid. Biomarker monitoring can provide an integrated measure of all biologically active species (parent drug and metabolites) present, so that therapeutic ranges can be defined more closely. It is also often free from the matrix and drug disposition effects that frequently complicate drug concentration measurements.

Pharmacogenetic studies (studies of genetic influences on pharmacological responses) have wide-ranging clinical relevance. The enzymes responsible for metabolizing drugs exhibit wide interindividual variation in their protein expression or catalytic activity, resulting in quantitative and qualitative differences in drug metabolism between individuals. This variation may arise from transient effects on the enzyme, such as inhibition or induction by other drugs or metabolites, or may result from specific mutations or deletions at the gene level. Pharmacogenetic polymorphism is defined as the existence in a population of two or more alleles at the same locus that result in more than one phenotype with respect to the effect of a drug, the rarest of which occurs with a significant frequency (usually taken as 1%). The term *pharmacogenomics* is used to describe the range of genetic influences on drug metabolism, and the application of this information to the practice of tailoring drugs and dosages to specific individuals to enhance safety and/or efficacy. This practice, often referred to as 'Personalized Medicine', is a major growth area for 21st century medicine.

Determination of an individual's ability to metabolize a specific drug may be performed either by administering a test dose of the drug or a related compound and measuring the metabolites formed (phenotyping), or by specific genetic analysis (genotyping). The information obtained can dramatically improve the clinician's ability to select a drug dose appropriate to the specific requirements of the individual. For example, many of the isoenzymes of the cytochrome P450 superfamily responsible for drug oxidation show genetic polymorphisms that affect the extent of drug metabolism and produce differences in clinical response. The CYP2D6 isoform has more than 100 allelic variants, and metabolizes about a quarter of all drugs used in medicine, including many antiarrhythmics and psychoactive drugs. The rate of metabolism of a test dose of debrisoquine or dextromethorphan has been widely used for the determination of CYP2D6 phenotype and the differentiation of poor metabolizer (PM), extensive metabolizer (EM) and ultra extensive metabolizer (UEM) phenotypes. Alternatively, genetic analysis can be used to define the CYP2D6 genotype and identify the alleles associated with the PM phenotype (of which the most common are CYP2D6*3, *4, *5 and *6). Once determined, the phenotype can be used to guide dosing for any of the wide range of drugs metabolized by the CYP2D6 isoform, and ensure that lower doses are used for individuals with the PM phenotype, avoiding toxicity. The PM phenotype

is found in 7–10% of Caucasians but less frequently in people of Asian origin.

Pharmacogenetic data have many other clinical applications, including anticoagulation (polymorphisms of the CYP2C9 isoform and the *VKORC1* genes in assessing susceptibility to warfarin), oncology/immunosuppression (thiopurine methyltransferase polymorphisms and azathioprine therapy), psychiatry (CYP2D6 isoforms and rate of metabolism of some antidepressants), epilepsy, pain control and other areas. (See Chapter 43 for a further discussion of this topic.)

Integrating information

Pharmacogenetics and new biomarkers provide invaluable adjuncts to conventional drug concentration monitoring, and promise to deliver the ability to create individualized therapeutic regimens. However, integrating the information from all three strands is complex, and will require developments in decision support software and effective strategies for presenting the information in an accessible and comprehensible format to those involved in the provision of care. Pre-treatment pharmacogenetic profiling will allow identification of individuals who are likely to be particularly susceptible or resistant to a proposed regimen, allowing better selection of drug and initial dose. However, the effect of factors such as disease, age or drug interactions means that pharmacogenetics can never tell the whole story, and measuring the concentrations of drugs, metabolites or other biomarkers will still be necessary to complete the picture and deliver truly personalized medicine.

INDIVIDUAL DRUGS

Analgesic/anti-inflammatory drugs

Aspirin (acetylsalicylic acid)

Aspirin (acetylsalicylic acid) is a widely available drug used as a self-prescribed analgesic and as a prophylactic (at low dose) for thromboembolic disease. It is prescribed in relatively high doses for inflammatory arthropathies, since it has both analgesic and anti-inflammatory properties. Aspirin causes gastric erosions and, for this reason, is available in a variety of formulations designed to reduce this side-effect. Once absorbed, aspirin is rapidly converted to salicylate. Salicylate metabolism is complex and variable and its excretion is highly dependent upon urinary acidity, hence the concurrent ingestion of antacids can lead to lower plasma concentrations. The commonest symptom of toxicity is tinnitus, which occurs in the majority of patients once the plasma concentration exceeds 400 mg/L (2.9 mmol/L). Plasma salicylate concentrations may need to be monitored in a minority of patients to avoid toxicity. When used as an anti-inflammatory agent, plasma concentrations should lie between 150 and 300 mg/L (1.1–2.2 mmol/L), measured just before a dose. The half-life of salicylate varies widely between 3 and 20 h, depending on the dose and duration of therapy.

Value of monitoring: low.

Antiarrhythmics and cardiac glycosides

Amiodarone

Amiodarone is used in the treatment of intractable arrhythmias. It can be given intravenously or orally. It is strongly tissue bound and has a very high volume of distribution (about 5000 L), leading to a plasma half-life of approximately 50 days. There is considerable interpatient variability. Effective combined plasma concentrations of amiodarone and its active metabolite, desethylamiodarone, are in the range 0.5–2.5 mg/L (0.7–3.7 µmol/L). Most patients do not require concentration monitoring, but in some patients it may be useful to differentiate treatment failure from poor adherence or suboptimal dosing, while in others it may assist in the confirmation of concentration-related side-effects.

Value of monitoring: moderate.

Digoxin and digitoxin

The cardiac glycosides digoxin and digitoxin increase the force of cardiac contraction and increase cardiac output, and are used in the treatment of cardiac failure. They are also useful in the management of certain supraventricular arrhythmias. Digitoxin is structurally and functionally similar to digoxin, but is less frequently used in the UK.

Digoxin has a long half-life (20–60 h) and is usually given once daily. Clearance is primarily by the kidneys and a reduced glomerular filtration rate (GFR) can lead to toxicity. Effective plasma concentrations are 0.5–2.0 µg/L (0.6–2.6 nmol/L), with concentrations at the lower end of this range (0.5–1.0 µg/L; 0.6–1.3 nmol/L) recommended for the treatment of heart failure. Blood samples should be taken at least 6 h post-dose to allow time for distribution into tissues. Digoxin acts by inhibition of the Na⁺,K⁺-ATPase pump in the membranes of cardiac myocytes. Studies on red blood cells have shown that patients on long-term therapy adapt by production of additional pump activity. As a result, the interpretation of plasma concentrations is different depending upon whether therapy is newly instituted or long term. There is no clear relationship between digoxin concentration and therapeutic effect, but toxicity is a major problem and is more likely at plasma concentrations >2.3 µg/L (3.0 nmol/L). Toxicity at any digoxin concentration is inversely proportional to plasma potassium concentration and, in the presence of hypokalaemia, toxicity may be observed at plasma digoxin concentration as low as 1.2 µg/L (1.5 nmol/L). The patient's age and the severity of heart disease are independent risk factors for development of toxicity. Although the most common presentation of digoxin toxicity is bradycardia, there may also be other cardiac arrhythmias which, coupled with underlying cardiac pathology, may give rise to a confused clinical picture that may be clarified by the measurement of digoxin concentrations. Significant numbers of patients die with digoxin concentrations >2.3 µg/L. The possible contribution of digoxin to the cause of death is not always suspected. It should be noted that, if a patient is treated with anti-digoxin antibodies to reverse toxicity (see Chapter 40), further measurements of

digoxin concentration will not be possible using the commonly available immunoassays until the antibodies have been cleared, which may take up to a week.

It should be noted that in some patients, notably neonates, there exist in the plasma digoxin-like interfering substances (DLIS) that can lead to falsely elevated 'digoxin' concentrations when measured by immunoassay. Elevated DLIS concentrations are encountered in patients with volume-expanded conditions such as uraemia, essential hypertension, liver disease and pre-eclampsia, suggesting that DLIS may be a hormone involved in natriuresis. Falsely low digoxin values due to the presence of DLIS have also been reported. Commercially available immunoassays for digoxin vary in their specificity for DLIS and their ability to differentiate DLIS from exogenous digoxin. The presence of DLIS should be considered if digoxin concentrations are unexpectedly high.

Value of monitoring: moderate to high.

Disopyramide

Disopyramide is effective in controlling supraventricular and ventricular arrhythmias after myocardial infarction. Its use is limited by anticholinergic side-effects including dry mouth, blurred vision and difficulty in urination, and it is contra-indicated in prostatic enlargement. Monitoring can be helpful in ensuring efficacy and avoiding toxicity, though variable protein binding complicates the picture. Monitoring of free disopyramide concentration is recommended, although the assay is not always easily available. Target ranges for trough values are 1.5–5.0 mg/L (4.4–14.7 $\mu\text{mol/L}$) for total disopyramide and 0.5–2.0 mg/L (1.5–5.9 $\mu\text{mol/L}$) for free disopyramide.

Value of monitoring: moderate.

Flecainide

Flecainide is used to control serious symptomatic arrhythmias, junctional re-entry tachycardia and paroxysmal atrial fibrillation. It is eliminated via the kidneys (40–45%) and metabolized in the liver, where it is a substrate for the CYP2D6 isoform. The half-life is shortened and plasma concentrations are lower in extensive metabolizers. The usual target range is 0.2–1.0 mg/L (0.5–2.4 $\mu\text{mol/L}$), with most patients responding in the lower half of the range.

Value of monitoring: moderate.

Procainamide

Procainamide is used to control ventricular arrhythmias after myocardial infarction and atrial tachycardia. It is metabolized in the liver to N-acetylprocainamide (NAPA), which is also active, though slightly less potent. The rate of acetylation of procainamide to NAPA is genetically determined with a bimodal distribution, patients being classified as either slow or fast acetylators. Procainamide has a relatively short half-life (2–5.5 h) and is rapidly cleared. N-acetylprocainamide has a longer half-life (6–12 h) than the

parent drug and renal impairment can result in the accumulation of toxic concentrations of the metabolite. Monitoring of procainamide should therefore include quantitation of both procainamide and NAPA. Trough samples are preferable. Procainamide concentrations should fall between 4 and 10 mg/L (17–42 $\mu\text{mol/L}$). Procainamide and NAPA concentrations combined should not exceed 30 mg/L (100 $\mu\text{mol/L}$).

Value of monitoring: moderate.

Anticonvulsants (antiepileptics)

Carbamazepine/oxcarbazepine

Carbamazepine is a drug of choice for the treatment of simple and complex focal seizures and generalized tonic-clonic seizures. It is also used for the prophylaxis of bipolar affective disorder and mania, and for pain relief in trigeminal neuralgia. Metabolism is primarily by hepatic oxidation. The major metabolite, the 10,11-epoxide, is active but is seldom measured routinely, which complicates the interpretation of plasma carbamazepine concentrations. The best available information suggests that carbamazepine, when prescribed alone, is effective at plasma concentrations of 4–12 mg/L (17–50 $\mu\text{mol/L}$). Nystagmus, ataxia and drowsiness may occur at concentrations >12 mg/L and more serious toxicity >15 mg/L (60 $\mu\text{mol/L}$). Protein binding is variable and drug concentrations in saliva have been studied but have not proved to be widely useful. A troublesome erythematous rash occurs in about 4% of patients, and other chronic side-effects including hepatic and haematological problems may occur, although these are not dose related. Carbamazepine induces its own metabolism, and therapy needs to be initiated at a low dose and built up slowly over weeks. The unpredictable relationship between dose and concentration, the narrow therapeutic index and the presence of numerous drug interactions that alter the pharmacokinetics support the requirement for therapeutic drug monitoring until stable therapy is established.

Oxcarbazepine is also licensed for the same indications as carbamazepine. It is effectively a pro-drug for 10-hydroxycarbazepine, which is active. The role of therapeutic monitoring has not been established.

Value of monitoring: high (carbamazepine); low (oxcarbazepine).

Ethosuximide

Ethosuximide is used in the treatment of absence seizures and is administered once daily as it has a long half-life. In most patients, therapy can be optimized on the basis of clinical response and EEG checks. Toxicity is readily recognizable clinically as anorexia, nausea, vomiting and dizziness. There is therefore no real need to measure plasma concentrations except in patients receiving multiple therapy to decide which drug is responsible for symptoms of toxicity. The therapeutic range is usually taken as 40–100 mg/L (280–710 $\mu\text{mol/L}$) with toxicity likely at concentrations >150 mg/L (1060 $\mu\text{mol/L}$).

Value of monitoring: low to moderate.

Phenobarbital/primidone

Phenobarbital (phenobarbitone) is an anticonvulsant drug in its own right and also the active metabolite of primidone. It is effective but may be sedative in adults and cause behavioural disturbances in children, and is therefore not a recommended first- or second-line drug. Phenobarbital has a relatively long half-life and is cleared by both the renal and hepatic routes. There is a wide inter-individual variation in handling and, for this reason, there are no well-defined therapeutic limits for plasma phenobarbital concentrations. The majority of well-controlled patients have plasma concentrations of 10–40 mg/L (40–160 $\mu\text{mol/L}$), although some individuals may require much higher concentrations owing to the development of tolerance. The toxic symptoms associated with inappropriately high dosage progress from increasing drowsiness to coma. Primidone therapy can be monitored by the phenobarbital concentration if required.

Value of monitoring: moderate (phenobarbital); low (primidone).

Phenytoin

Phenytoin is still widely used and is effective for the treatment of tonic-clonic and focal seizures, but is no longer a first- or second-line drug for the treatment of epilepsy. It is well absorbed, has a long elimination half-life and is cleared mainly by oxidation in the liver. Its enzymatic removal is, however, saturable and the concentration at which this occurs varies between individuals. Once saturation has occurred, there is an exponential (zero order) increase in plasma concentration (Fig. 39.5); saturation can occur within the therapeutic range, so small increments in dose can lead to large increments in plasma

FIGURE 39.5 ■ The relationship between dose and plasma concentration for phenytoin as compared with most other drugs (dotted line). The point where hepatic metabolism is saturated (at which divergence occurs) is specific to the individual.

concentration and severe toxicity. In addition, phenytoin induces its own metabolism, leading to increased clearance and lower plasma concentrations after some weeks. Interaction with other drugs, particularly valproate, can also cause changes in clearance. The drug is highly protein-bound, and, at a given plasma total drug concentration, the lower the plasma protein concentration, the higher will be the free (effective) drug concentration. The unpredictable relationship between dose and plasma concentration, the narrow therapeutic index and the many clinically significant drug interactions mean that monitoring is essential for safe and effective use of the drug. The usual target range is 5–20 mg/L (20–80 $\mu\text{mol/L}$) but higher concentrations may be required in severe epilepsy. Neurotoxicity (nystagmus, dysarthria, ataxia) is usually concentration-dependent, though signs of chronic toxicity, for example gum hyperplasia, are not so clearly linked to concentration.

Value of monitoring: high.

Valproate

Sodium valproate is a popular drug because it does not give rise to drowsiness or the CNS side-effects associated with other anticonvulsants, although it carries a higher risk of congenital malformation and should be used with caution in women of childbearing age. It is recommended as a first-line drug in most types of epilepsy and is used widely in children. It is also used in the treatment of bipolar disorder. However, there is no well-documented relationship between plasma valproate concentration and relief from seizures; indeed, seizures appear to be absent for some time following a dose of valproate when plasma concentrations are too low to measure. A number of cases of severe hepatocellular damage, some fatal, have been reported in patients receiving valproate alone. These appear to be idiosyncratic and are not related to plasma concentration. There is, therefore, no reason to measure plasma valproate in order to avoid hepatotoxicity; however, where the risk of liver damage is high, for example in young children or those with seizure disorders associated with metabolic or degenerative disorders, learning disorders or organic brain disease, baseline and follow-up liver enzyme measurements are indicated.

Valproate is highly protein bound (90–95%) and, when given together with other anticonvulsant drugs, for example phenytoin, can give rise to a (transient) increase in the concentration of free phenytoin. There may, on occasion, be some value in analysing valproate in order to adjust phenytoin or carbamazepine therapy or in the management of complex regimens, but the vast majority of valproate measurements are an unnecessary drain on resources.

Value of monitoring: low.

Newer anticonvulsant drugs

There is now a plethora of newer antiepileptic drugs such as clobazam, clonazepam, felbamate, gabapentin, lamotrigine, levetiracetam, piracetam, retigabine,

rufinamide, topiramate, vigabatrin and zonisamide. Data on concentration–effect relationships are limited, and TDM is not widely used outside specialist centres, since there are no accepted target ranges and most have a wide therapeutic range with overlap of toxic and non-effective concentrations. Tentative target ranges are available in the literature (see [Further reading](#)). Routine monitoring cannot be recommended at present, except for monitoring of lamotrigine concentrations on combination therapy because of the marked effect of drug interactions.

Value of monitoring: low to moderate.

Antidepressants and antipsychotic drugs

Tricyclic antidepressants (amitriptyline, clomipramine, dosulepin, doxepin, imipramine, lofepramine, nortriptyline, trimipramine)

The tricyclic antidepressants show wide interindividual genetic differences in metabolism, and for many of them a good relationship between plasma concentration and clinical effectiveness has been shown. Their use is diminishing in favour of selective serotonin release inhibitors (SSRIs), which are better tolerated and less toxic in overdose. Monitoring is potentially valuable to reduce the incidence of toxicity in susceptible patients.

Value of monitoring: moderate.

Selective serotonin release inhibitors (SSRIs) (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine and sertraline)

Therapeutic drug monitoring for SSRIs is of little clinical importance in routine practice, primarily because of their much lower toxicity.

Value of monitoring: low.

Lithium

The lithium cation is of great clinical use in the management of bipolar disorder. Lithium is, however, extremely toxic, with a low therapeutic index. It is prescribed orally as uncoated lithium carbonate or as a slow-release preparation. The usual therapeutic range is 0.4–1.0 mmol/L in samples taken 12 h post-dose, with an upper limit of 0.8 mmol/L in the elderly. Concentrations up to 1.2 mmol/L may be required for the acute treatment of mania in younger patients. Since lithium is nephrotoxic and is excreted renally, excessive dosing can produce a vicious circle in which plasma concentrations increase, causing renal damage, excretion is reduced and concentrations increase further. Plasma concentrations >1.5 mmol/L require intervention, and concentrations >3.0 mmol/L on chronic therapy are potentially fatal. High concentrations in acute overdose are less serious than on chronic therapy, since the tissues are not saturated and distribution will lead to a rapid fall in plasma concentration.

Patients newly started on lithium should be monitored regularly until the relationship between dose and plasma concentration is established. Thereafter, monitoring can be less frequent. Lithium competes with sodium for reabsorption in renal tubules, and alterations in sodium balance or fluid intake may precipitate toxicity. Patients on lithium who start diuretics, or develop diarrhoea and vomiting or renal problems should be assessed and their serum lithium measured. Lithium should not be stopped completely since acute withdrawal can give rise to severe psychiatric symptoms. Thyroid dysfunction (most often hypothyroidism), hyperparathyroidism and nephrogenic diabetes insipidus are recognized side-effects of lithium therapy. Lithium has a half-life of 20–40 h depending on the duration of treatment; steady-state concentrations are therefore obtained approximately seven days after the start of therapy.

Value of monitoring: high.

Other antidepressants

There is no good evidence for a significant relationship between drug concentration and therapeutic outcome for the tetracyclic antidepressants maprotiline, mianserin and mirtazapine, the monoamine oxidase inhibitors moclobemide and tranlycypromine or for trazodone and reboxetine.

Value of monitoring: low.

Antipsychotic drugs

The first-generation antipsychotic drugs such as haloperidol and the phenothiazines chlorpromazine, fluphenazine and perphenazine show marked variation in metabolism between individuals according to their CYP2D6 genotype. Drug and metabolites accumulate in poor metabolizers and overdosing leading to extra-pyramidal side effects and irreversible tardive dyskinesia may occur. If CYP2D6 genotyping is not available, TDM may be useful in assessing phenotype and guiding therapy.

The development of second generation antipsychotic agents, for example clozapine, olanzapine, quetiapine, amisulpride, aripiprazole and risperidone, has proved to be a significant advance in the treatment of schizophrenia. The atypical (or second-generation) antipsychotics have several therapeutic properties in common; however, they can differ significantly with regard to clinical potency and side-effects.

Therapeutic drug monitoring may assist in avoidance of extrapyramidal side-effects by maintaining minimum effective concentrations during chronic treatment, although for the majority of patients this is a matter of quality of life rather than safety. Monitoring is available from specialist centres in difficult cases. In the case of clozapine, there is a strong correlation between clozapine plasma concentrations and the incidence of seizures. Clozapine also carries a significant risk (~3%) of agranulocytosis and regular (weekly at the start of therapy) differential white blood cell monitoring is required.

Value of monitoring: moderate (haloperidol, clozapine) to low.

Antimicrobial drugs

Most antimicrobial drugs are well tolerated and do not require therapeutic drug monitoring. The exceptions to this general principle include the aminoglycoside antibiotics, the glycopeptides vancomycin and teicoplanin, and chloramphenicol.

Aminoglycosides (amikacin, gentamicin, tobramycin)

The aminoglycosides are an important group of antimicrobial drugs used in the treatment of severe systemic infection by some Gram-positive and many Gram-negative organisms. Amikacin, gentamicin and tobramycin are also active against *Pseudomonas aeruginosa*. Streptomycin is active against *Mycobacterium tuberculosis* and is now generally reserved for tuberculosis (see below). Neomycin is too toxic for systemic use and can only be used for topical application (skin, mucous membranes). The parent compounds are produced by moulds of the *Streptomyces* family (streptomycin, tobramycin, neomycin) or the *Micromonospora* family (gentamicin). The different host organisms account for the variation in spelling of the suffix.

The aminoglycoside antibiotics exhibit relatively simple pharmacokinetics. They are large, highly polar molecules with very poor oral bioavailability, and must be given parenterally. They are not protein bound and not metabolized, and are excreted through the kidneys. The plasma half-life is 2–3 h, except when renal function is impaired, but the drug may accumulate in tissues. If therapy is continued for longer than a week, tissue sites become saturated and plasma concentrations may rise.

These drugs exhibit significant systemic toxicity at plasma concentrations just above those necessary for bactericidal activity. The main toxic effects are nephrotoxicity and ototoxicity. Nephrotoxicity further reduces the ability to excrete aminoglycosides, and a vicious cycle may be precipitated. Nephrotoxicity is often reversible, as is mild ototoxicity, but severely damaged cochlear hair cells cannot be replaced and patients may be left with irreversible hearing loss and disturbed balance.

The drug concentration at which bactericidal effects are achieved (the minimum inhibitory concentration, MIC) is relatively easy to determine in vitro but often has little relevance in vivo, owing to variable penetrance of the drug to the site of infection and differing conditions at the infection site. Aminoglycosides also show a marked post-antibiotic effect – suppression of bacterial growth persists for some time after the drug is no longer present in the plasma. This makes definition of target plasma concentrations difficult, and this difficulty has been compounded in recent years by changes in the ways in which aminoglycosides are administered.

Until the mid-1990s, aminoglycosides were administered every 8 or 12 h, to give relatively stable plasma concentrations in view of their short half-life. It has become clearer that less frequent dosing (every 24 h or more) produces higher peak concentrations, which enhance bacterial kill, and lower trough concentrations, which reduce the systemic toxicity. Such regimens are more convenient,

less toxic, reduce adaptive resistance and are generally more suitable in patients with normal renal function. The approach was originally devised as once daily dosing, but a more accurate term is probably 'extended dosing interval', in which a plasma concentration measurement is used to design an individual dosing interval which reflects the patient's needs and renal function. The Hartford nomogram (Nicolau et al. 1995, see [Further reading](#)) is an example of this approach, but local guidelines should be consulted on dosage and serum concentrations. Monitoring is essential to achieve effective therapy while avoiding toxicity, particularly in infants, the elderly, the obese and patients with cystic fibrosis, if high doses are being used or if renal function is impaired.

Value of monitoring: high.

Glycopeptides (vancomycin and teicoplanin)

The glycopeptide antibiotic vancomycin is used intravenously in endocarditis and other serious infections caused by Gram-positive cocci including multi-resistant *Staphylococci* (MRSA). It is also used orally in the treatment of antibiotic-associated (pseudomembranous) colitis. Like the aminoglycosides, the glycopeptides are poorly absorbed, not metabolized, excreted renally and are potentially nephrotoxic and ototoxic. Indications for monitoring have been controversial, but there is definitely a role for monitoring in patients with poor renal function to achieve maximum effect with minimal toxicity. Teicoplanin is similar to vancomycin, but has a longer duration of action such that once-daily dosing is sufficient. No relationship between plasma concentration and toxicity has been established, and teicoplanin is not normally monitored.

Value of monitoring: moderate (vancomycin), low (teicoplanin).

Chloramphenicol

Chloramphenicol is a powerful broad-spectrum antibiotic that carries a risk of serious haematological side-effects when given systemically. It is used to treat life-threatening infections such as cholera, typhoid fever, resistant *Haemophilus influenzae*, septicaemia and meningitis. Chloramphenicol is metabolized in the liver to the active glucuronide, and peak plasma concentrations (2 h post-dose) in the range 10–25 mg/L (30–77 µmol/L) are desirable. Concentration monitoring is essential in neonates and recommended in children under four years, the elderly and patients with hepatic impairment.

Value of monitoring: moderate.

Antifungal drugs

The successful management of invasive fungal infections remains challenging to clinicians, and the incidence of invasive mycosis has risen in parallel with the rise in the population of immunocompromised patients. The morbidity and mortality caused by these infections remains

high, and TDM has a role in ensuring that adequate drug concentrations are attained at the site of infection without systemic toxicity. Four triazole antifungal drugs (fluconazole, itraconazole, posaconazole and voriconazole) have been approved for use. They show marked inter- and intraindividual variations in blood drug concentrations after dosing, owing to variable absorption from the gut (itraconazole, posaconazole) and polymorphism in the CYP2C19 enzyme (voriconazole). The pyrimidine analogue flucytosine also exhibits wide interpatient variation in blood concentration owing to variation in renal elimination. The high pharmacokinetic variability and need for optimal adjustment of drug exposure to ensure that infections are treated adequately are arguments in favour of TDM, but although concentration–effect relationships have been demonstrated for the triazoles and flucytosine, optimal target blood concentrations have not been definitively established and concentration measurements in clinically relevant timescales are not yet readily available. Itraconazole and flucytosine concentrations should be measured routinely in all patients during the first week of therapy and in patients with poor responses. Monitoring of posaconazole and voriconazole should be considered in patients who are not responding to therapy, those with gastrointestinal dysfunction, children and those taking drugs which interact with triazole antifungal agents.

Value of monitoring: moderate.

Antitubercular drugs

The treatment of active tuberculosis (TB) always requires the use of multiple antibacterial agents. It is usually treated in two phases – an initial phase using four drugs and a continuation phase using two drugs. The most frequently used regimen is isoniazid, rifampicin, pyrazinamide and ethambutol (or, rarely, streptomycin), followed by isoniazid and rifampicin. Isoniazid and rifampicin are the key components of this regimen, and both drugs show significant pharmacokinetic variability. The majority of patients are completely cured by standard regimens, and TDM has no role in dosage optimization in these patients. However, patients who are slow to respond to treatment, have drug-resistant TB, are at risk of drug–drug interactions or have concurrent disease states (e.g. acquired immunodeficiency syndrome) that significantly complicate the clinical picture may require individualization of drug therapy, and may benefit from TDM. Early intervention guided by concentration monitoring may prevent the development of further drug resistance. The pharmacokinetic interactions between antitubercular drugs and other medications can often be of considerable clinical concern. Rifampicin is a potent inducer of cytochrome P450 CYP3A and decreases plasma concentrations of the HIV-protease inhibitors significantly; isoniazid is a P450 enzyme inhibitor. Patients with HIV are at particular risk for drug–drug interactions.

When TDM is justified, the 2 h post-dose concentrations of isoniazid, rifampicin, pyrazinamide and ethambutol are usually most informative. Unfortunately, low 2 h values do not distinguish between delayed absorption or malabsorption and non-adherence. In such cases, a

second sample, often collected at 6 h post-dose, provides additional information. Trough concentrations of many anti-TB drugs are below the limit of detection of current assays and have limited relevance. Plasma concentrations required for effective therapy, especially on multi-drug regimens, are only partially known, as detailed pharmacokinetic and pharmacodynamic information in humans is lacking. There is a clear dose–response relationship for rifampicin and pyrazinamide and low isoniazid concentrations are also associated with poorer outcomes. Second-line TB drugs such as *p*-aminosalicylic acid, cycloserine and ethionamide are not usually monitored. Streptomycin is used against resistant organisms. It is nephrotoxic and should be used with great care in patients with renal impairment; concentration monitoring is essential in such patients.

Value of monitoring: moderate.

Antiretroviral drugs

Several classes of antiretroviral drugs are used in the management of infection by HIV:

- nucleoside reverse transcriptase inhibitors, e.g. zidovudine, abacavir, didanosine, emtricitabine, lamivudine, stavudine and tenofovir
- non-nucleoside reverse transcriptase inhibitors, e.g. efavirenz, etravirine and nevirapine
- protease inhibitors, e.g. atazanavir, darunavir, fosamprenavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir and tipranavir
- fusion inhibitors, e.g. enfuvirtide
- entry inhibitors, e.g. maraviroc
- integrase inhibitors, e.g. raltegravir.

The nucleoside reverse transcriptase inhibitors (NRTIs) are pro-drugs that require activation by intracellular phosphorylation. Plasma NRTI concentrations therefore do not correlate with clinical effect and NRTIs are not suitable for TDM.

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) display highly variable pharmacokinetics; the cytochrome P450 isoenzyme involved in their metabolism (CYP2B6) has a polymorphic variant resulting in slower metabolism and higher plasma concentrations. The protease inhibitors (PIs) also have highly variable pharmacokinetics, but their plasma concentrations have been shown to correlate with virological response. Therapeutic drug monitoring for NNRTIs and PIs may have an important adjunctive role in individualizing therapy in high-risk patients or those with PI resistance. Adherence remains a major problem, especially in developing countries where patient understanding is often poor. Concentrations are normally monitored 1 h post-dose. Protease inhibitors and NNRTIs can be quantitated by liquid chromatography tandem mass spectrometry (LC-MS) in a single run.

Value of monitoring: low to moderate.

Antineoplastic drugs

Despite their considerable toxicity, there are no controlled trials that indicate clear advantages to routine

concentration monitoring of anticancer drugs, with the exception of methotrexate (see below). Antineoplastic agents are often used in combinations of up to four drugs, which makes the establishment of therapeutic ranges difficult. Areas under the concentration–time curve give a better indication of total exposure to the drug than isolated plasma concentrations, but are more difficult to apply routinely. Pharmacokinetic optimization protocols for many classes of cytotoxic compounds have been used in some specialized centres and a role for monitoring has been proposed for some newer drugs such as the tyrosine kinase inhibitor imatinib in chronic myeloid leukaemia.

Value of monitoring: low (except methotrexate – see below).

Methotrexate

Methotrexate is widely used in a variety of chemotherapeutic regimens for malignancies, where it is given in high doses by the intravenous route over periods of 6–12 h. It is also used orally at low dose (7.5–25 mg weekly) in Crohn disease, rheumatoid arthritis and as an antipsoriatic agent.

Methotrexate is an inhibitor of folic acid metabolism. The rationale behind high-dose therapy is that a short period of exposure to high concentrations of drug will eliminate rapidly dividing cells, while sparing those growing more slowly. At the end of the infusion, methotrexate concentrations should fall rapidly. Where this is not the case, or where the rate of infusion produces too high a plasma concentration, folinic acid (leucovorin) is infused to provide a source of folate and reverse toxic effects. Measurement of methotrexate concentrations may therefore be required in two circumstances – to allow adjustment of infusion to maintain a steady plasma concentration at 10^{-4} M and to ensure that the concentrations at 24 and 48 h after the start of the infusion have fallen to <5 – 10 $\mu\text{mol/L}$ and <0.5 – 1.0 $\mu\text{mol/L}$, respectively, depending on the protocol. A rapid turnaround time is required. Folinic acid may interfere in some assay systems, complicating measurements made after treatment has been given. Methotrexate is metabolized to 7-hydroxymethotrexate and both the parent drug and metabolite are excreted via the kidneys and are nephrotoxic due to their low solubility; prehydration, alkalization and good renal function are essential for the safe use of this drug. Hepatotoxicity has been reported in a number of patients. Monitoring of liver function and the plasma concentration of the N-terminal propeptide of collagen type III to detect hepatic fibrosis is advised in patients on long-term oral treatment; renal function and white blood cell counts should also be monitored. Methotrexate concentration monitoring is not usually necessary in patients on low-dose regimens.

Value of monitoring: high (on high-dose regimens).

Bronchodilator drugs

Theophylline/caffeine

Theophylline is a bronchodilator used for the relief of asthma that has a number of other pharmacological effects, notably the stimulation of cardiac output and the

dilatation of peripheral blood vessels. It is no longer a first- or second-line drug in asthma, but is still useful in patients who have difficulty with inhalers and those with predominantly nocturnal symptoms. Theophylline has a short half-life (3–13 h in adults), but the availability of sustained-release preparations compensates for this and allows dosing at 12 or 24 h intervals. It also has a narrow therapeutic window and wide pharmacokinetic variability, so it is important to have access to TDM if the drug is to be used effectively and safely.

In outpatients, adherence has been shown to be erratic, with as few as 30% of patients taking the drug as prescribed. In such cases, TDM can contribute little unless the patient is toxic or grossly non-compliant. However, in inpatients, and especially those receiving intravenous therapy, TDM can be of great assistance in dosage optimization and in confirming toxicity. Steady-state trough concentrations are the most reproducible for monitoring, except when toxicity is suspected.

Theophylline is metabolized in the liver by a variety of pathways, including oxidation via the cytochrome P450 system (CYP1A2/CYP2E1), which is subject to induction by drugs such as phenytoin. In addition to this, theophylline shows dose-dependent excretion. It is therefore preferable that those involved in its monitoring are familiar with the pharmacokinetic optimization programmes that are available.

The target range in adults is 10–20 mg/L (55–110 $\mu\text{mol/L}$). The range is lower in neonates (5–15 mg/L; 25–80 $\mu\text{mol/L}$). This is partly due to sensitivity and partly because babies under six months old metabolize theophylline in a different manner to adults, converting a proportion to caffeine, an active metabolite. After six months, caffeine production is replaced by the adult pattern of metabolism to a variety of methylated urates, including 3-methylxanthine, which is also active. Caffeine has now taken over as the drug of choice to treat neonatal apnoea, as dose regimens are simpler and the effects are more predictable. Caffeine concentrations in the range 5–20 mg/L (25–100 $\mu\text{mol/L}$) are generally associated with response in neonatal apnoea, but the lower toxicity and simpler pharmacokinetics mean that TDM is rarely required.

Side-effects of theophylline are relatively frequent – mild or moderate effects such as nausea, headache and jitteriness are common within the target range, and more serious effects (tremor, agitation, insomnia, diarrhoea, palpitations, seizures and cardiac arrhythmias) occur with increasing frequency at plasma concentrations >20 mg/L (110 $\mu\text{mol/L}$). Caffeine produces much less tachycardia and fewer fits.

Oral therapy with theophylline may involve the free base or any of a number of salts. For intravenous therapy, a water-soluble salt such as aminophylline (theophylline ethylenediamine) is used (aminophylline is approximately 80% w/w theophylline).

Value of monitoring: high (theophylline); low to moderate (caffeine).

Immunosuppressants

Monitoring of immunosuppressants has become an essential adjunct to drug therapy for organ transplant

patients because of the relatively narrow therapeutic index of these agents. Therapeutic drug monitoring is important for three of the major immunosuppressants in current use: ciclosporin, tacrolimus, and sirolimus. All three of these drugs are lipophilic and are concentrated in red cells, so whole blood samples are commonly used for analysis. The indications for and approach to monitoring of mycophenolic acid are more controversial.

Ciclosporin

Ciclosporin is a cyclic peptide, widely used for prevention of graft rejection following kidney, liver, heart, lung, heart–lung, bone marrow or pancreas transplants. It is also used in lower doses as an immunosuppressant in severe psoriasis, atopic dermatitis, nephrotic syndrome, ulcerative colitis and rheumatoid arthritis, and in the prophylaxis and treatment of graft-versus-host disease. Ciclosporin inhibits calcineurin phosphatase and limits T cell activation, producing immunosuppression without myelosuppression. However, it is nephrotoxic, and the major difficulty with its use lies in balancing the risks of undertreatment, leading to rejection of the organ, and overtreatment, which can cause kidney damage. This is particularly relevant in renal transplantation, where it is essential to determine whether a rising plasma creatinine concentration is due to nephrotoxicity or rejection.

The pharmacokinetics of ciclosporin vary widely between patients, and target plasma concentrations are dependent on the transplant type, time after transplantation, sample time post-dose, analytical method used and other drugs administered. It is not possible to give specific guidance here and local protocols should be consulted. The drug is highly lipophilic and accumulates in red cells, so EDTA whole blood is the preferred matrix for assay. Trough (pre-dose) concentrations have traditionally been used; although concentrations at 2 h post-dose (C₂) give a better indication of ciclosporin exposure, they do require precise timing. Immunoassays and LC-MS assays have been used. Ciclosporin is metabolized in the liver by CYP3A, producing more than 30 metabolites that have variable cross-reactivity in immunoassays, explaining some of the differences in apparent ciclosporin concentrations determined by different assays.

Value of monitoring: high.

Sirolimus

Sirolimus is a macrolide antibiotic, also known as rapamycin. It is structurally similar to tacrolimus, but has a different mode of action. Both sirolimus and tacrolimus bind to a binding protein (FK binding protein, FKBP), but the sirolimus-FKBP complex then binds to a protein kinase, mammalian target of rapamycin (mTOR). This interaction blocks signal transduction in the second phase of T cell activation. Sirolimus reduces acute rejection when co-administered with a calcineurin phosphatase inhibitor and steroids, and allows earlier withdrawal of ciclosporin. When sirolimus is given concurrently with the microemulsion formulation of ciclosporin, the absorption

of sirolimus is markedly enhanced, almost doubling the effective dose, so it is recommended to give sirolimus 4 h after ciclosporin. The drug is metabolized in the liver by CYP3A, and is also a substrate for the P-glycoprotein transporter system. Sirolimus is not nephrotoxic so is particularly useful in kidney transplantation, but has a range of other adverse effects, including lipid disturbances, anaemia, leukopenia and thrombocytopenia and impaired wound healing. Over-suppression of the immune system is associated with infection and neoplasia. Blood concentrations are a better guide to effect than dose is, and concentration monitoring is advised, particularly in patients with hepatic impairment or on interacting drugs. Pre-dose (trough) concentrations measured on EDTA whole blood should be in the region of 4–12 µg/L when the drug is being given with ciclosporin and 12–20 µg/L when ciclosporin has been withdrawn. Liquid chromatography or LC-MS are the preferred analytical methods, but an immunoassay is also available.

Value of monitoring: high.

Tacrolimus

Like ciclosporin, tacrolimus is a calcineurin phosphatase inhibitor used to prevent or treat graft rejection in kidney, liver and heart transplant patients. It is also metabolized in the liver by CYP3A and is concentrated in red blood cells, so EDTA whole blood samples are used for monitoring. Unlike ciclosporin, it is not intrinsically nephrotoxic, but does cause renal vasoconstriction, which leads to chronic graft dysfunction. Adverse effects are minimized by using the lowest dose consistent with efficacy and by the use of combined therapy with other drugs such as mycophenolic acid, allowing dose minimization for all drugs. Monitoring is essential, particularly in hepatic impairment and during or following treatment with drugs that induce or inhibit metabolism. Target concentration ranges vary with transplant type, other drug therapy and analytical method, but are typically in the range 5–15 µg/L. Immunoassays or LC-MS are used.

Value of monitoring: moderate to high.

Mycophenolic acid

Mycophenolic acid (MPA) is increasingly used in solid organ transplantation as an antiproliferative immunosuppressant. It is used for the prophylaxis of acute rejection in kidney, liver and heart transplantation in combination with calcineurin phosphatase inhibitors (ciclosporin/tacrolimus) and corticosteroids. It is given as the pro-drug mycophenolate mofetil (MMF), or as the enteric-coated sodium salt of MPA. It is rapidly absorbed and mainly excreted renally, with <10% hepatic metabolism to the inactive glucuronide. Concentrations in plasma are relatively high (1–3 mg/L; 3–9 µmol/L) and trough plasma (EDTA or heparin) samples are often used for monitoring, although the optimum measures of MPA exposure are still the subject of considerable debate as trough plasma concentrations vary widely. Limited-sampling strategies to

give a better estimate of the area under the concentration–time curve have been advocated. The general routine use of MPA monitoring in solid-organ transplantation is not currently recommended, though monitoring has a role in specific patient populations, including those at increased immunological risk or those with changing renal or hepatic function.

Value of monitoring: low to moderate.

Opiate and opioid drugs

Methadone/buprenorphine

Methadone and buprenorphine are synthetic opioids used as adjunct therapy in the treatment of opiate dependence. The primary requirement in this setting is to confirm that patients have been taking their medication, rather than selling it, since these drugs have a street value. Qualitative testing of urine is used to achieve this. For patients on methadone therapy, urine is often tested for the methadone metabolite EDDP (2-ethylidine-1,5-dimethyl-3,3-diphenyl pyrrolidine), as this guards against adulteration of urine specimens with the medication and confirms that drug has actually been ingested. Monitoring of plasma concentrations has not yet been shown to be routinely useful, despite significant pharmacokinetic variation and much recent interest in dosage optimization for opiate substitutes.

Value of monitoring: low.

Morphine

Morphine is used as a short-term analgesic, often as patient-controlled analgesia following surgical procedures, and for long-term analgesia in conditions with protracted pain, for example the later stages of malignant disease. Morphine kinetics are complex and absorption can be erratic. There is also an active metabolite, morphine 6-glucuronide (M6G), with analgesic properties superior to morphine. Heroin (diacetylmorphine) is converted rapidly to morphine via a short-lived monoacetylmorphine intermediate. Until recently, morphine was not part of the repertoire of drugs for which therapeutic monitoring was advocated, but there is now evidence that, in patients in whom analgesia is difficult to achieve, plasma morphine concentrations can be useful. The method of choice is high performance liquid chromatography – mass spectrometry, since the active metabolites M6G and codeine can also be determined; this is of particular use in patients with renal insufficiency in whom there may be accumulation of M6G.

Value of monitoring: low to moderate.

ACKNOWLEDGEMENT

I am grateful to Dr Michael J. Stewart who was the author of this chapter in previous editions of the book.

APPENDIX 39.1: CALCULATIONS FOR THE DETERMINATION OF DOSE REQUIREMENTS TO ACHIEVE STEADY-STATE CONCENTRATIONS

The loading dose depends on the volume of distribution (V_d). Hence, to calculate a loading dose use:

$$\text{Loading dose} = \frac{V_d \times \text{desired plasma concentration } (C_p)}{\text{Bioavailability } (F) \times \text{correction factor for formulation } (S)}$$

The maintenance dose required for steady-state depends on the clearance and is calculated by:

$$\text{Maintenance dose} = \frac{\text{Clearance } (Cl) \times \text{desired plasma concentration } (C_p) \times \text{interval between doses } (T)}{\text{Bioavailability } (F) \times \text{correction factor for formulation } (S)}$$

Average population values for clearance, volume of distribution, bioavailability and formulation correction factor (if relevant) may be found in reference texts.

CONCLUSION 807**APPENDIX 807****INTRODUCTION**

Poisoning can be defined as an interaction between a foreign chemical (toxin) and a biological system that results in damage to a living organism. In general, the medical profession has been more concerned with the acute effects of toxins and the clinical management of toxicity, but chronic effects of toxins have much more importance on a global scale. For example, acute ingestion of ethanol may result in intoxication, which can cause death directly from its acute depressant effects and also through intoxication-related accidents and violence. However, alcohol-related liver disease, myopathy, hypertriglyceridaemia and cancers are all effects of chronic alcohol abuse and together, cause far more deaths than the acute effects of alcohol. Other types of chronic or delayed effects of toxins include mutagenicity, carcinogenicity and teratogenicity. For example, many cases of bronchogenic carcinoma are a direct result of exposure to cigarette smoke. Increasing concerns about environmental contamination by chemicals has added a further dimension to toxicology, especially as many chemicals, such as pesticide residues, may be found in small amounts in the general population, who do not appear to be suffering any ill effects.

The interaction between a toxin and the biological system is highly complex. Once the biological system has

been exposed to the toxin, the toxin is subject to various processes. In the case of a drug, this is usually termed pharmacokinetics, but in the case of a poison, the term toxicokinetics may be used. This includes absorption, for which the route of administration is of great importance, as are the dose of the toxin and the duration of exposure. Once a toxin has entered the bloodstream, its distribution depends to a large extent, on its physicochemical characteristics, including its degree of lipid or water solubility and its degree of ionization. Metabolism is a further important process, which usually renders toxins inactive, but which may also convert some substances of low toxicity into highly toxic metabolites. Classic examples of this include paracetamol (acetaminophen), methanol and ethylene glycol. Finally, toxins are excreted, although some remain within the body for many years. All of these processes determine the amount of toxin that interacts with tissues to produce a toxic effect.

The study of the interaction between toxins and tissues is called toxicodynamics. An understanding of the nature of this interaction is essential for an intelligent approach to the diagnosis and management of poisoning. This interaction may cause functional and metabolic disturbances that produce the characteristic clinical features of poisoning and the laboratory changes that may be essential for diagnosis or management. These changes are summarized in [Figure 40.1](#).

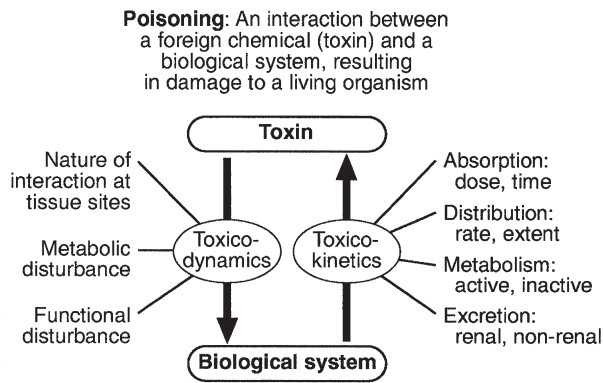

FIGURE 40.1 ■ The factors involved in poisoning.

This chapter covers several of the more common types of acute poisoning and also some aspects of chronic poisoning. Clinical features are given in some detail, as these frequently integrate with the metabolic and biochemical changes.

AETIOLOGY OF POISONING

Intrauterine

A number of drugs, such as tretinoin, should not be taken by women intending to become pregnant because of their known teratogenicity. Other drugs, such as phenytoin and several other anticonvulsants, are teratogenic but their continued use may be considered necessary during pregnancy. As far as poisoning and overdose during pregnancy are concerned, the fetus generally only suffers damage secondary to the mother's illness, and the management is no different from that of overdose in non-pregnant women. One exception is carbon monoxide, which has a higher affinity for fetal haemoglobin than adult haemoglobin; the mother should be treated aggressively even in apparently mild poisoning. Antidotes such as acetylcysteine or desferrioxamine should not be withheld because the patient is pregnant.

Neonates

During the neonatal period, particularly in premature infants, there is a risk of iatrogenic overdose because of the poor metabolic and excretory capacity relative to body weight. Particular care should be taken with drugs such as theophylline, digoxin, chloramphenicol and morphine.

Infants

The commonest cause of poisoning between the ages of one and four is termed accidental poisoning because of the natural exploratory activities of children at this stage of life. Each year, this results in 20 000 admissions to hospital in Britain, but only about ten fatalities. The commonest agents involved are paracetamol and oral contraceptives, but most fatalities occur from tricyclic antidepressants, salicylates, iron, methadone and quinine. Another form of poisoning in this age group is non-accidental injury,

which is usually inflicted by a carer such as the mother, and the child may present with repeated episodes of floppiness and collapse, depending on the substance responsible. This is most commonly with a drug prescribed for the mother, though salt and other readily available chemicals have been used (see Chapter 44).

Childhood

Later in childhood, substance abuse, particularly volatile substance abuse ('glue sniffing'), can cause serious problems. There are about 30 deaths each year in Britain from this cause. Acute and chronic alcohol toxicity are often underestimated in this age group. Intentional drug overdose is common, but suicide is rare.

Adult life

In early adult life, particularly in females, drug overdose in the form of parasuicidal gestures is common, though rarely fatal. In later adult life, suicidal intent is commoner and parasuicidal gestures are less frequent. The commonest causes of suicidal poisoning in England are tricyclic antidepressants, analgesic drugs and carbon monoxide. Male suicides are approximately three times as frequent as female suicides. Accidental poisoning in adults is usually domestic, the commonest agent being carbon monoxide, or industrial, in which a wide range of chemicals may be involved. Homicidal poisoning, though rare, may go undetected if it is not suspected.

TYPES OF LESION IN POISONING

Many types of poisoning involve a highly specific interaction between the toxin and one type of tissue. This has led to a 'target organ' oriented approach in toxicology, which is of great help in understanding poisoning, where damage to a single organ or tissue produces a characteristic clinical and pathological picture. Examples include poisoning with paracetamol, salicylates, cholinesterase inhibitors and cardiac glycosides. In other instances, the type of toxicity may be less clearly definable. The acute effects of ethanol are mainly due to its central nervous depressant effect. Cocaine, tricyclic antidepressants, many volatile substances, some β -adrenergic blocking drugs and dextropropoxyphene can all produce cardiotoxicity due to a quinidine-like sodium channel blocking effect. However, the clinical features are definable as a toxic effect on the heart.

An important way in which many poisons can affect the organism is by interference with the oxygen pathway from the inspired air to cellular respiration. Thus, a reduction in the oxygen content of the inspired air may cause acute hypoxaemia, rapidly leading to collapse and coma. Interference with the mechanics of respiration by poisons may result in hypoxaemia and hypercapnia (type II respiratory failure), while disturbances of oxygen transfer produce hypoxaemia alone (type I respiratory failure). Even if the oxygen content of the air is not diminished and respiration is functioning adequately,

disturbances to other processes may prevent oxygen reaching its site of action (see Chapter 5). The oxygen-carrying capacity of the blood may be reduced by the presence of carboxyhaemoglobin or methaemoglobin or, more rarely, by acute haemolysis. Cardiac output may be reduced by a number of poisons that cause cardiac arrhythmias, depress the contractility of the heart or cause extreme vasodilatation. The final step where poisons may interfere with the oxygen pathway is blockage of the cytochrome enzyme chain as occurs with toxins such as cyanide and hydrogen sulphide. These effects and the main poisons involved are summarized and outlined in Table 40.1.

DIAGNOSIS AND MANAGEMENT OF POISONING: GENERAL PRINCIPLES

Diagnosis

In most cases of poisoning, the diagnosis is provided by the history and clinical examination. In some patients, however, there may be no history, though poisoning may be suspected because of the circumstances or the clinical features. In rare cases, the clinical presentation may mimic other medical conditions and it is necessary to consider the diagnosis of poisoning, especially when there are unusual features of the illness. Examples of these conditions include carbon monoxide, lead and paraquat poisoning, and drug and substance abuse.

The clinical features of poisoning depend most of all on the type of agent involved, but also on the route of exposure (oral, intravenous, percutaneous or inhaled), the duration of exposure and time elapsed since exposure, and also the patient's age and medical background

(conditions such as diabetes, asthma, chronic renal failure and epilepsy). Clinical examination may reveal signs of injection marks, cutaneous burns, buccal corrosion, tablet residues in the mouth or cutaneous blisters. These blisters (originally called 'barbiturate blisters') may be found following overdose with barbiturates, benzodiazepines, tricyclic antidepressants or chloral hydrate, or exposure to carbon monoxide. There may be evidence of pulmonary aspiration or secondary hypostatic pneumonia in comatose patients.

Clinical examination may indicate that a specific agonist/receptor pathway has been either over-stimulated or blocked by a poison. These syndromes are termed toxidromes and provide a useful initial guide to poison identification when the agent involved is unknown (Table 40.2).

In the severely ill patient, baseline haematological and biochemical investigations will be necessary and arterial blood gas estimations will also be required. A chest radiograph is usually indicated. The results of haematological and biochemical investigations may be of great assistance in making the diagnosis and monitoring the response to treatment. The tests to be carried out and their frequency depend very much on the poison involved. Many of these are given later in this chapter, and a general summary is given in Table 40.3. Toxicological investigations may also be required: in some cases, these may only be available in specialized laboratories. The usual samples required are blood (note that whole blood is required for measurement of carboxyhaemoglobin, methaemoglobin, cyanide and several metals) and urine (50 mL in a universal container with no preservative). Urine should always be provided where possible, since many types of analysis, such as drugs of abuse, are more efficiently carried out on urine samples. Some of these assays are qualitative,

TABLE 40.1 Some typical causes of blockade of the oxygen pathway due to poisoning, with mechanisms and typical values

Note that whatever the initial effect of a poison, there may be subsequent progression down the list of effects towards cell death. The effects of two or more poisons may be additive

Cause	Mechanism	Effect
Asphyxiant gases (e.g. butane, methane, carbon dioxide, nitrogen)	Hypoxic gas mixture	Reduced inspired oxygen fraction (F_{iO_2}) (normal ~0.21)
Respiratory depression (e.g. opioids, barbiturates, other sedatives and hypnotics). Respiratory muscle disorders: paralysis (e.g. organophosphates, botulinum toxin) or spasm (e.g. strychnine, phencyclidine)	Failure of ventilation (type II respiratory failure)	Reduced alveolar oxygen tension (P_AO_2) (normal ~13.3 kPa)
Aspiration pneumonitis Adult respiratory distress syndrome (e.g. paraquat)	Failure of oxygen transfer (type I respiratory failure)	Reduced arterial oxygen tension (P_aO_2) (normal 10–13.3 kPa)
Carboxyhaemoglobin (carbon monoxide); methaemoglobin (e.g. nitrites); haemolysis (e.g. arsine, stibine)	Loss of functioning haemoglobin	Reduced arterial oxygen content (CaO_2) (normal 18–21 volumes %)
Myocardial depressants (e.g. β -blockers, calcium antagonists, tricyclic antidepressants, dextropropoxyphene, cocaine)	Reduced cardiac output	Reduced tissue oxygen delivery (QO_2) (normal 12–16 mL/kg per min)
Chemical asphyxiants (cyanide, hydrogen sulphide)	Block of cytochrome enzyme chain	Reduced tissue oxygen consumption (VO_2) causing failure of oxidative metabolism (normal 3–4 mL/kg per min). Cell death

TABLE 40.2 Syndromes caused by poisoning

Clinical features	Example agent(s)
Anticholinergic syndrome (muscarinic antagonist) Dry skin Hyperthermia Thirst Dry mouth Dilated pupils Tachycardia Urinary retention Decreased bowel sounds	Tricyclic antidepressants (TCA) Antipsychotics Antihistamines <i>Atropa belladonna</i> Inocybe mushrooms
Antimitotic syndrome (cytotoxic to dividing cells) Bone marrow suppression (aplastic anaemia, leucopenia, thrombocytopenia) Alopecia Vomiting, diarrhoea, mucositis	Antineoplastic drugs Colchicine Radiation exposure
Cholinergic syndrome (nicotinic and muscarinic agonist) Defaecation Urination Miosis Bradycardia Tachycardia Emesis Lacrimation Hyperhidrosis Muscle paralysis and respiratory failure	Organophosphates Carbamate insecticides Nicotine Laburnum species Hemlock species
Corrosive poisoning GI tract pain Vomiting Haematemesis Dyspnoea Drooling Aspiration/inhalation causing stridor/pneumonitis Skin contact causing pain, ulceration, necrosis Eye contact causing inflammation of all layers	Hydrofluoric acid Sodium hydroxide Paraquat
Fume fever History of unpleasant smells Chills Cough Dyspnoea Headache Myalgia Malaise	Metal oxides (esp zinc oxide) Polymer fumes Other toxic industrial chemicals
Metabolic acidosis Deep and rapid (Kussmaul) breathing Obtunded consciousness Tachycardia Hypotension	Ethylene glycol Methanol Aspirin Paracetamol Iron Cyanide Carbon monoxide
Methaemoglobinaemia Blue-grey 'apparent' central cyanosis (blue to grey lips, tongue and mucus membranes, and slate grey skin) Persistent cyanosis despite oxygenation Fatigue, dizziness, headaches Depressed consciousness Seizures Urine may be discoloured black or brown	Benzene derivatives (phenols, cresols, aniline) Sodium nitrite Organic nitrites Chlorates Copper salts Prilocaine
Opioid syndrome Depressed consciousness Hypoventilation Pinpoint pupils Naloxone response Hypotension Pulmonary oedema	Opioids

(Continued)

TABLE 40.2 Syndromes caused by poisoning (Continued)

Clinical features	Example agent(s)
Sedative – hypnotic poisoning Depressed consciousness Ataxia Dysarthria Nystagmus	Ethanol Benzodiazepines and related drugs Gamma hydroxybutyrate (GHB) Gamma butyrolactone (GBL) Barbiturates
Serotonin agonist syndrome Restlessness Agitation Confusion Hyperreflexia Clonus Tremor Shivering Hypertonia Fever/hyperthermia Flushing Seizures	Serotonin-specific re-uptake inhibitors (SSRI) Monoamine oxidase Inhibitors (MAOI) Tricyclic antidepressants Venlafaxine Methylenedioxymetamphetamine (MDMA) Amfetamines Cocaine Tramadol Triptans Linezolid St John's wort 'Legal highs' Psilocybe mushrooms
Sympathomimetic syndrome Hyper/hypotension Tachycardia Neurological excitation Tremor Hyperreflexia Seizures	Cocaine Amfetamines 'Legal highs'
Vesicant poisoning (blistering agents) Conjunctivitis Keratitis Dermatitis Severe blistering	Nitrogen mustards Methyl bromide

but may be necessary in order to confirm the presence of compounds, which are not easily detectable in blood.

Poisons centres now exist in most countries, with specialized facilities for provision of information on the toxicity of substances and on the management of poisoning. Most hold stocks of specialized antidotes, such as snake antivenoms. Many also have an analytical laboratory and some have patient care facilities. They are usually accessible by telephone or e-mail. In the UK, there are several poisons centres that provide information on poisoning; see [Appendix 40.1](#).

Management

When an acutely ill patient presents, the first priority, regardless of the cause of the illness, is to establish the airway and provide immediate supportive treatment. Cardiopulmonary resuscitation or urgent ventilatory support may be needed. Depending on the patient's state, questioning about the possible agent involved, obtaining an antidote or taking diagnostic samples may waste valuable time. In view of the frequency of opioid abuse, naloxone (an opioid antagonist) may have both a diagnostic and a therapeutic role. Once any immediate life-threatening problems have been dealt with, full supportive care must

be provided while attempts are made to establish the diagnosis and treat the poisoning.

Respiratory support

In comatose patients, the most important measure is to maintain the airway and support ventilation as required, since respiratory complications are the commonest causes of death in unconscious poisoned patients. The unconscious patient should be placed in the left lateral (recovery) position in order to keep the airway patent and to minimize the risk of aspiration of gastric contents. Regular observation is essential as mechanical ventilation is not infrequently required.

Cardiovascular support

The circulation must be supported in order to maintain tissue perfusion and the electrocardiogram should be monitored, since cardiac dysrhythmias are common in poisoning. Antiarrhythmic agents and inotropic agents may be necessary.

Central nervous system complications

A brief convulsion due to cerebral hypoxia or to a toxic effect of the poison is not an indication for anticonvulsant

TABLE 40.3 Indications for measurement of drugs and poisons or other biochemical tests in actual or suspected poisoning

Toxin or measurement	Indications for measurement	Interpretation
Amfetamines (including MDA and MDMA)	Abuse	Tests can confirm exposure
Carbamazepine	1. Overdose	Ataxia >12 mg/L (50 µmol/L) Severe poisoning >40 mg/L (170 µmol/L)
Carboxyhaemoglobin	2. Therapeutic monitoring	Therapeutic range 5–10 mg/L (20–40 µmol/L)
	1. Carbon monoxide inhalation	May confirm exposure and indicate severity (normal <1%; <5% in smokers)
	2. Smoke-exposed fire victims	Carboxyhaemoglobin >12% indicates potential for pulmonary damage
Chloroquine	3. Methylene chloride exposure	Carbon monoxide is a metabolite of methylene chloride (dichloromethane)
	Accidental or deliberate overdose	May confirm ingestion and indicate potential toxicity
Cholinesterase (red blood cell, RBC)	1. Acute poisoning with organophosphates	RBC cholinesterase <20% of normal indicates significant exposure (usually by ingestion)
	2. Chronic exposure to organophosphates	Plasma pseudocholinesterase <50% of normal helps to confirm exposure but is a poor guide to severity
Digoxin	1. Digoxin or digitoxin overdose	In patients with severe poisoning blood digoxin concentration >6 h after overdose can be used to guide the dose of digoxin specific antibody
	2. Detecting digitalis immunoreactivity in cardiac glycoside plant ingestion	May be used to confirm ingestion but is not a guide to severity
	3. Detecting digitalis toxicity in therapeutic use	To confirm toxicity or undertreatment. Hypokalaemia may cause signs of toxicity with digoxin concentrations in the therapeutic range
Drug abuse screen	1. Suspected acute toxicity	May confirm diagnosis or need for treatment
	2. Medicolegal indications	May be used to confirm abstinence (sample collection must be supervised)
Ethanol	3. Employment screening	May exclude from certain types of employment
	1. Severe intoxication	Very high concentrations (>5000 mg/L) (110 mmol/L) in a severely obtunded patient may be an indication for haemodialysis
	2. Intoxication (actual or possible) in head-injured patients	Low concentrations (<1500 mg/L) (32 mmol/L) help to exclude ethanol as a cause of behavioural disturbance or altered consciousness level
Ethylene glycol	3. Monitoring of treatment of methanol or ethylene glycol intoxication	Blood ethanol should be maintained at 1000–2000 mg/L (22–43 mmol/L) to inhibit alcohol dehydrogenase
	Suspected toxicity	Confirm the presence of ethylene glycol in blood and monitor clearance with treatment
Iron	Overdose	Serum iron >3 mg/L (55 µmol/L) is associated with significant toxicity. In patients without features of severe poisoning, serial measurements are useful in determining need for treatment
Lead	1. Clinical suspicion of poisoning	May confirm toxicity and indicate need for antidote therapy. Patients with blood concentrations >50 µg/dL (2.4 µmol/L) should be considered for treatment
	2. Monitoring industrial exposure	Employers must reduce lead exposure if an employee's blood concentration is ≥50 µg/dL. If ≥60 µg/dL work may be suspended
Lithium	1. Acute overdose	Plasma concentrations may confirm ingestion and indicate possible toxicity, but clinical manifestations are the main guide to toxicity and need for haemodialysis (patient may be asymptomatic with plasma lithium >5 mmol/L, depending on time since ingestion)
	2. Therapeutic monitoring	Therapeutic range 0.4–1.2 mmol/L (but see text). Toxicity in therapeutic use can occur at 1.5–2 mmol/L (often due to interactions with diuretic or NSAID therapy). Severe toxicity >4 mmol/L
Methanol	Suspected toxicity	Confirm the presence of methanol in blood and monitor clearance with treatment
Opioids	1. Overdose	Tests can confirm exposure; treatment is based on clinical decision
Osmolality (plasma)	2. Abuse	Tests can confirm exposure
	3. Toxicity in renal failure patients	Requires measurement of morphine 6-glucuronide
	Suspected methanol or ethylene glycol ingestion	If methanol/ethylene glycol cannot be directly measured then the plasma osmolar gap can be used as a surrogate marker for the presence of toxic alcohol in blood. As the toxic alcohol is metabolized to acid, the osmolar gap falls and may be normal if the patient presents late after ingestion

(Continued)

TABLE 40.3 Indications for measurement of drugs and poisons or other biochemical tests in actual or suspected poisoning (Continued)

Toxin or measurement	Indications for measurement	Interpretation
Paracetamol	1. Paracetamol overdose	High concentrations are an indication for antidote administration according to nomogram To exclude co-ingestion of paracetamol
Paraquat	2. Comatose patient with suspected drug overdose 1. Suspected ingestion (or other route of exposure)	Plasma paraquat concentrations can confirm ingestion and severity of exposure. Positive urine dithionite test confirms exposure. Dithionite test can be carried out on plasma – if positive, confirms massive ingestion Severe toxicity >50 mg/L (215 µmol/L) Concentrations may be in the range 30–60 mg/L (130–260 µmol/L) with minimal impairment
Phenobarbital	1. Overdose 2. Abuse	Therapeutic range 19–37 mg/L (80–160 µmol/L) Ataxia may occur at plasma concentrations >30 mg/L. Dysarthria and lethargy at >40 mg/L. Plasma concentration needs to be corrected for albumin concentration
Phenytoin	3. Therapeutic monitoring 1. Overdose	
Salicylate (aspirin)	2. Following overdose to decide when therapy should be resumed 3. Therapeutic monitoring 1. Salicylate overdose	Therapeutic range 10–20 mg/L (40–80 µmol/L) Provides an indication of severity and action to be taken. May indicate need for haemodialysis if >900 mg/L (6.4 mmol/L) To exclude co-ingestion of salicylate
Solvents	2. Comatose patient with suspected drug overdose 1. Suspected poisoning in an unconscious patient 2. Behavioural disturbance or suspected abuse	May provide diagnosis May confirm exposure
Theophylline	3. Industrial exposure 1. Acute overdose	Tests can confirm excessive exposure High concentrations of >80 mg/L (440 µmol/L) in a severely symptomatic patient (convulsions, cardiac arrhythmias) may be an indication for haemoperfusion Toxicity may occur at 30 mg/L (170 µmol/L) in regular therapy. (Therapeutic range 10–20 mg/L)
Toxicology screen	2. Therapeutic monitoring	
	1. Suspected acute poisoning in an unconscious patient 2. Behavioural disturbance due to suspected abuse or poisoning 3. Confirmation of brain stem death when drug administration is known or suspected	May provide diagnosis May provide diagnosis Presence of potentially toxic drugs prevents diagnosis of brain stem death

MDA, 3,4-methylenedioxyamphetamine; MDMA, 3,4-methylenedioxymetamphetamine; NSAID, non-steroidal anti-inflammatory drug.

drug therapy. However, if convulsions are repeated or prolonged, diazepam is the first-line drug. Drugs such as phenytoin, clomethiazole and thiopental may be required if there is no response to diazepam. In tricyclic antidepressant poisoning, administration of sodium bicarbonate may relieve convulsions. Phenytoin is contraindicated in tricyclic poisoning because both tricyclics and phenytoin are sodium channel blockers and these increase the risk of cardiac arrhythmias.

Body temperature

The core temperature should be recorded with a low-reading thermometer, since hypothermia may complicate poisoning with sedative and antidepressant drugs. The patient should be wrapped in a space blanket, but active rewarming is not usually required. The prognosis is better than in accidental hypothermia from other causes, and temperatures as low as 22 °C are compatible with full recovery. In hyperthermia (rectal temperature >39 °C),

reduction of body temperature is a priority. Depending on the cause of the problem, different treatments may be required. Hyperthermic patients poisoned with agents that produce severe muscle rigidity may require elective paralysis with a muscle relaxant and mechanical ventilation. Malignant hyperthermia or neuroleptic malignant syndrome can be treated with intravenous dantrolene.

Renal complications

Renal function should be monitored (bladder catheterization may be necessary if there is oliguria or severe hypovolaemia). Acute kidney injury may occur as a result of a direct toxic effect or secondary to acute haemolysis with haemoglobinuria or rhabdomyolysis with myoglobinuria. There is controversy as to whether myoglobin and haemoglobin are directly toxic to the kidneys. Most probably they cause an obstructive lesion; alkalinization of the urine increases myoglobin excretion and may prevent acute kidney injury.

General supportive care

In the severely ill patient, general supportive care may be life saving. Regular turning will be needed to prevent pressure necrosis of tissues, and care of the eyes and mouth will also be required.

Intestinal decontamination

Decontamination of the gut following ingestion of poisons is controversial. Syrup of ipecacuanha to induce emesis is now obsolete; there is little evidence that it is effective in emptying the stomach. In the comatose patient, gastric lavage is still occasionally used. However, this procedure may wash some of the poison further down the gut, and it is now rarely recommended.

The most widely used method of gut decontamination is to administer activated charcoal, which adsorbs almost all drugs and poisons. The main exceptions are iron and lithium, which are poorly adsorbed, and alcohols and glycols, whose molar load usually exceeds the adsorptive

capacity of the charcoal. Repeated doses of activated charcoal may be used for sustained-release preparations that have delayed absorption, and may also be used to eliminate certain poisons from the body if there is significant enterohepatic recycling (e.g. carbamazepine and theophylline).

Antidotes

Antidotes form an important part of the management of certain poisons. In some cases (as with paracetamol, opioids, cardiac glycosides, organophosphates and snake bites), they may be life-saving. However, it should be noted that antidotal treatment is only required in a minority of poisonings. The most debated areas with regard to antidotes concern their effectiveness in 'late' paracetamol poisoning (when the patient presents more than 12 h after ingestion) and their effectiveness and use in the management of poisonings by metals. A list of commonly used antidotes is given in [Table 40.4](#).

TABLE 40.4 Commonly used antidotes

Poison	Antidote	Mechanism of action
Anticoagulants (warfarin type)	Vitamin K (phytomenadione)	Competitive antagonist at site of active prothrombin production in liver
Benzodiazepines	Flumazenil	Competitive antagonist at benzodiazepine receptors (often not recommended as may worsen toxicity by causing convulsions)
β -Blockers	Isoprenaline	Competitive antagonist at β -receptors.
Carbon monoxide	Glucagon Oxygen (normobaric or hyperbaric)	Stimulates myocardial adenylyl cyclase Competitive displacement of carbon monoxide from haemoglobin, myoglobin and cytochrome molecules
Cyanide	Dicobalt edentate Sodium nitrite	Chelates cyanide Forms methaemoglobin, which combines with cyanide
Digoxin, digitoxin	Sodium thiosulfate Hydroxocobalamin	Substrate for enzymatic detoxification of cyanide Combines with cyanide to form cyanocobalamin
Ethylene glycol	Fab antibody fragments Ethanol	Antidote forms an inert complex with drug Competitive substrate for alcohol dehydrogenase, slows toxic metabolite production
Heavy metals (lead, mercury, arsenic)	Fomepizole (4-methyl pyrazole)	Inhibits alcohol dehydrogenase, slows toxic metabolite production
Hydrofluoric acid	2,3-Dimercaptosuccinic acid (DMSA) 2,3-Dimercapto-1-propanesulfonate (DMPS)	Chelating agent Chelating agent
Iron salts	Sodium calcium edentate Dimercaprol	Chelating agent Chelating agent
Methanol	D-Penicillamine Calcium gluconate Desferrioxamine Ethanol	Chelating agent Forms an inert complex (calcium fluoride) Chelating agent Competitive substrate for alcohol dehydrogenase, slows toxic metabolite production
Methaemoglobin	Fomepizole (4-methyl pyrazole)	Inhibits alcohol dehydrogenase, slows toxic metabolite production
Narcotic analgesics (heroin, methadone etc.)	Methylthioninium chloride (methylene blue) Ascorbic acid	Cofactor for reduction of methaemoglobin by NADPH Reducing agent
Organophosphates	Naloxone	Competitive antagonist at opioid receptors
Paracetamol	Atropine Pralidoxime; obidoxime Acetylcysteine	Competitive antagonist at acetylcholine receptors Cholinesterase reactivators Accelerates detoxification of potentially toxic metabolite
Thallium	Berlin (Prussian) blue	Chelating agent

Elimination techniques

In some types of poisoning, active elimination techniques are indicated. This approach is most widely used in poisoning by salicylates, theophylline, ethylene glycol and methanol. The techniques include repeated oral doses of activated charcoal, enhanced renal elimination (by alkalization of the urine or diuresis), haemoperfusion and haemodialysis. Haemodialysis may be required for the elimination of the poison (most notably in the case of salicylates, ethylene glycol and methanol) or for the support of renal function. Exchange transfusion may be used in infants. Peritoneal dialysis, plasmapheresis and continuous arteriovenous haemofiltration are less useful in removing poisons, although the latter is an effective technique to support renal function.

SPECIFIC POISONS

Paracetamol (acetaminophen)

Although paracetamol is safe when taken in the recommended dose, it is potentially very toxic in overdose and, since it is widely available over the counter, it is currently the commonest cause of admissions to hospital for poisoning and also of acute hepatic necrosis. It causes approximately 150 deaths each year in Britain.

Mechanisms

Paracetamol is rapidly absorbed from the upper gastrointestinal tract and the majority is metabolized by conjugation with sulfate or glucuronate to non-toxic derivatives. However, a small proportion (approximately 8–10%) is metabolized by a specific cytochrome P450 enzyme, CYP2E1, to produce a highly reactive intermediate, N-acetyl-*p*-benzoquinoneimine (NAPQI). This reactive metabolite can be metabolized by conjugation to form non-toxic mercapturic acid conjugates, provided glutathione is present in the liver cell. When an overdose of paracetamol is taken, the rate of production of NAPQI may exhaust existing glutathione stores and the capacity of the liver to synthesize glutathione (Fig. 40.2). In this case, NAPQI covalently binds to sulfhydryl groups in hepatocytes, forming an irreversible complex, which can result in acute centrilobular necrosis of the liver. Since paracetamol is also metabolized in the cells of the renal tubules, a similar process can also occur in the kidneys, leading to acute kidney injury. There is usually a small amount of renal damage in the presence of hepatic damage, but occasionally renal damage predominates and acute kidney injury may rarely be the presenting feature of paracetamol poisoning.

Toxic dose

The upper therapeutic limit for an adult of 4g daily in divided doses is generally accepted as being safe, but doses above this can cause severe hepatotoxicity and possibly death. However, owing to the wide variation in the metabolic handling of paracetamol by the body, much larger overdoses (>50g) may have little effect in some

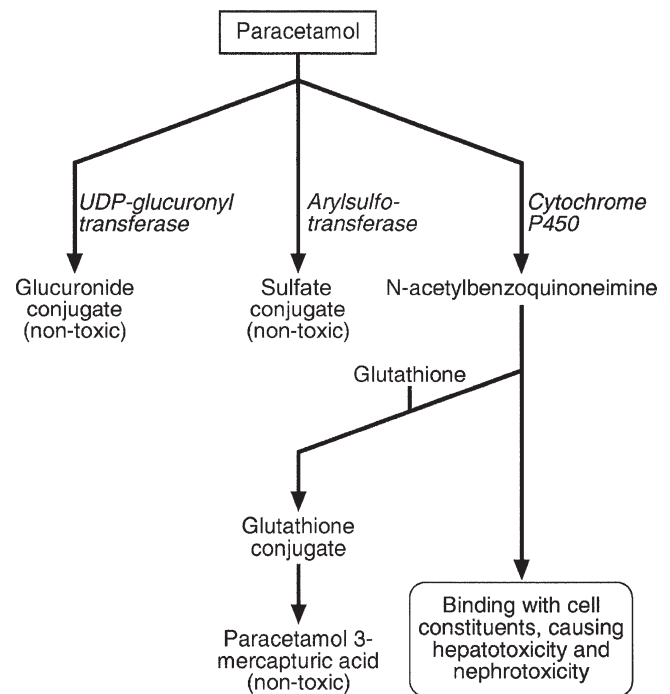

FIGURE 40.2 ■ Metabolism of paracetamol. Induction of the cytochrome P450 pathway increases the production of the toxic metabolite, N-acetyl-*p*-benzoquinoneimine, causing depletion of glutathione stores; a protein-depleted diet leading to deficiency of amino acids may make less glutathione available. In both cases, increased toxicity may result following an overdose.

individuals, producing nothing more than a minor rise in plasma aminotransferase activities.

Clinical features

In the first hours after ingestion of an overdose of paracetamol, symptoms may be minimal, unless it has been taken with some other drug, for example in a compound formulation with dihydrocodeine. There may be malaise, nausea and vomiting. A very large overdose may cause depression of consciousness or metabolic acidosis. By 24–36h, there may be pain in the right hypochondrium. Plasma aminotransferase activities will rise at this time, but the peak values are a poor indicator of prognosis. The prothrombin time (or international normalized ration, INR) is a reliable prognostic indicator of severe hepatotoxicity. Hypoglycaemia and coagulation defects may complicate the hepatic failure. By about 48h, the early signs of hepatic encephalopathy may appear. Death usually occurs after five or six days.

Management

Giving an antidote is more important than emptying the stomach or giving activated charcoal. After a single acute overdose, an antidote should be given if the patient's plasma paracetamol concentration is on or above the line on the treatment nomogram (Fig. 40.3). The need for treatment following repeated suprathreshold dosing (staggered overdose) cannot be assessed using the nomogram and treatment decisions are based on the dose ingested and the patient's body weight. Repeated plasma paracetamol

FIGURE 40.3 ■ UK nomogram for treatment of paracetamol poisoning.

estimations should not be performed routinely, but may be helpful in doubtful cases.

Acetylcysteine is the antidote of choice and the intravenous route is the only reliable method of treatment in a patient who is comatose or vomiting. Although the effectiveness of acetylcysteine diminishes considerably with time once 12 h have passed since ingestion, later administration improves outcome even in patients with established liver failure. Acetylcysteine should also be given if the time of the overdose is in doubt or not known. Its main adverse effect is anaphylactoid reactions, which respond to administration of antihistamines and discontinuation or slowing of the infusion.

Salicylate

Although the use of aspirin (acetylsalicylic acid) as an analgesic is decreasing, the management of salicylate poisoning remains a major challenge. The potentially lethal dose in adults is between 24 and 30 g, but death can occur in children under 18 months, from as little as 300 mg. Most fatal poisonings occur in elderly people, because they lack the metabolic reserves to cope with salicylate poisoning and also because attempted suicide with aspirin is commoner in old age. The use of aspirin preparations in children under 16 years of age is largely restricted to rheumatological indications because of the risk of Reye syndrome in children given aspirin for viral illnesses. However, this risk is very low.

Mechanisms

The mechanisms involved in salicylate poisoning are multiple and complex. The clinical features are mainly due to gastrointestinal irritation, stimulation of the respiratory

centre causing respiratory alkalosis and uncoupling of oxidative phosphorylation, leading to heat production and metabolic acidosis. Many other mechanisms are also involved in salicylate poisoning. These are summarized and correlated with the clinical features in Figure 40.4.

Clinical features

Salicylate poisoning usually presents with nausea and vomiting, increased rate and depth of respiration, sweating, tinnitus and sometimes deafness. Consciousness is preserved initially, but confusion, disorientation and loss of consciousness may occur, and usually indicate severe poisoning with a poor prognosis. The patient is often severely volume depleted because of vomiting, hyperventilation and sweating. Excess heat production usually causes compensatory sweating in adults but there may be hyperpyrexia in children. There is usually a combined compensated metabolic acidosis and respiratory alkalosis, with an arterial $[H^+]$ of 32–40 nmol/L (pH 7.4–7.5). Later, the $[H^+]$ rises (pH falls) as the alkali reserve diminishes, and this is a serious sign. In infants, metabolic acidosis may predominate from the start.

Salicylate overdose increases pulmonary capillary permeability, which, in severe poisoning, may cause non-cardiogenic pulmonary oedema. This presents initially as lowering of the arterial oxygen tension and subsequently becomes apparent on chest radiographs. Acute kidney injury is rare and is more likely to occur in children than in adults.

Laboratory measurements

Plasma salicylate concentration should be measured on presentation and at intervals of 4–6 h thereafter, until it has fallen below the toxic range. This is especially

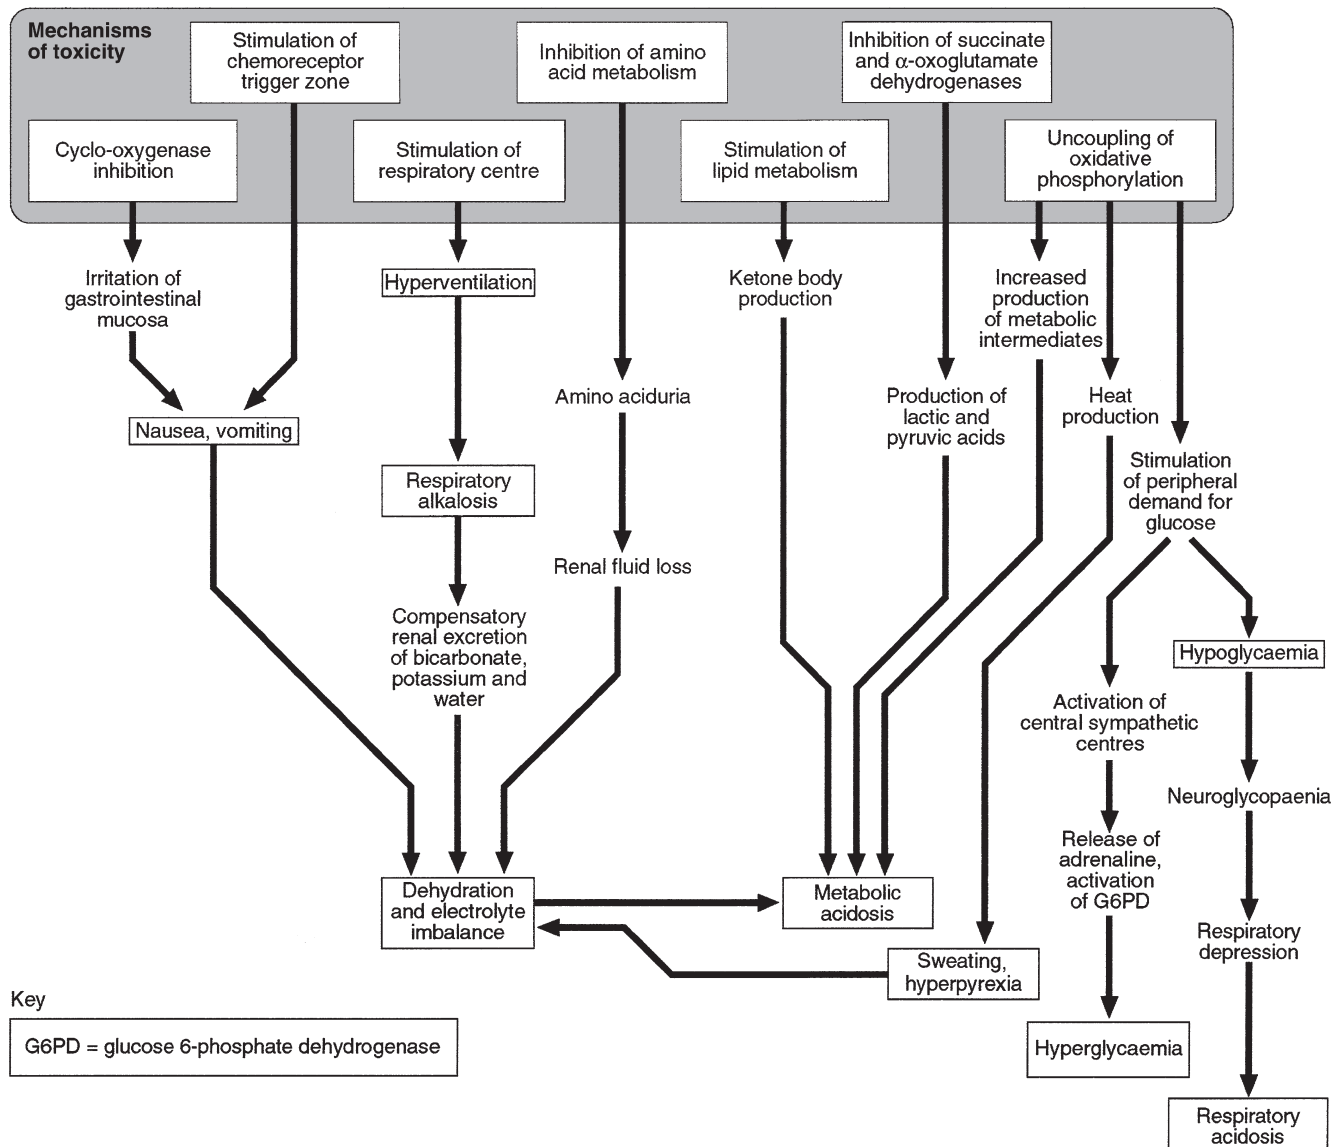

FIGURE 40.4 ■ Pharmacological and metabolic effects of salicylates, leading to biochemical disturbances and clinical effects.

important, since salicylates are precipitated in an acidic environment and may therefore be deposited in the stomach, resulting in delayed absorption. Plasma concentrations may continue to rise for many hours, particularly in serious overdoses. Experience has shown that in most cases with a fatal outcome, plasma salicylate concentrations have risen progressively following admission to hospital.

Management

Activated charcoal should be given to patients presenting to hospital soon after overdose (within 1 h) and a second dose may be given if plasma salicylate concentration continues to rise. Gastric lavage is rarely, if ever, indicated but may be considered if a patient has presented early to hospital after taking a massive overdose. All symptomatic patients should have central venous pressure monitored, and fluid replacement and correction

of electrolyte imbalances, especially hypokalaemia, are priorities. Hypoglycaemia may need to be corrected. Elimination of salicylate can be promoted by administration of sodium bicarbonate to produce a urine pH of >7.5 ($[H^+] < 32$ nmol/L). This has been clearly demonstrated, but the concept of 'forced diuresis' is now no longer used, since the excretion of salicylate is not influenced by urine volume. A urinary alkalization regimen is recommended if the plasma salicylate concentration is greater than 500 mg/L (3.6 mmol/L). Haemodialysis may be necessary in severe poisoning with a plasma salicylate concentration >900 mg/L (6.4 mmol/L), or lower than this if complications are present. As well as removing salicylate, haemodialysis can also correct acid-base and electrolyte imbalances and is therefore preferred to charcoal haemoperfusion. The prothrombin time should be measured; it is rarely prolonged, but if it is, phytomenadione (vitamin K) should be administered intravenously.

Chloroquine

In overdose, this drug can produce hypokalaemia ($[K^+]$ often <2 mmol/L), coma, convulsions and sudden cardiovascular collapse. An acute overdose of >5 g, systolic blood pressure <85 mmHg, a QRS complex duration >0.12 s and a blood chloroquine concentration >25 μ mol/L are all regarded as predictors of a fatal outcome. Active removal methods such as haemoperfusion and haemodialysis are ineffective. Aggressive resuscitation with the use of intravenous noradrenaline (norepinephrine) and diazepam may be life-saving. After treatment, severe hyperkalaemia may ensue, particularly if potassium salts have been given to correct hypokalaemia.

Digoxin

Clinical features

Digoxin and other cardiac glycosides, including plant toxins from oleander (*Nerium oleander*) and yellow oleander (*Thevetia peruviana*), increase the force of contraction of the myocardium. Overdose increases the irritability of ventricular muscle, resulting in extrasystoles, ventricular tachycardia and fibrillation. Conduction is depressed and sinus bradycardia and various degrees of block may also occur. Since digoxin inhibits Na^+, K^+ -ATPase, hyperkalaemia is a feature of digoxin poisoning. A plasma potassium concentration >5.3 mmol/L (in the absence of any other cause of hyperkalaemia) suggests severe poisoning with an increased likelihood of cardiac toxicity. Occasionally, the plasma potassium concentration itself may rise rapidly to life-threatening levels and require urgent treatment.

Other clinical features of acute poisoning include headache, nausea, vomiting, abdominal discomfort, confusion, disorientation and visual blurring or distorted colour vision.

Management

Activated charcoal effectively adsorbs digoxin and should be used if the patient is not vomiting. Atropine may reverse bradycardia. Marked hyperkalaemia should be reversed with intravenous insulin and glucose. There is a concern that administration of intravenous calcium to counteract the effects of hyperkalaemia could worsen digoxin toxicity: however, observational studies do not demonstrate any adverse effects. Whenever there is evidence of severe poisoning such as cardiovascular collapse or refractory hyperkalaemia, digoxin-specific Fab antibody fragments should be obtained urgently. Given intravenously in an appropriate dose, this treatment should produce reversal of signs of toxicity within 20–30 min. These Fab antibodies interfere with commonly available assays for digoxin, so measurements of serum digoxin concentration after treatment will not be reliable.

Iron

Toxicity

Iron absorption is normally regulated by the intestinal mucosa. In overdose, iron-containing medication is corrosive and damages the mucosa, so that iron ions are

absorbed in toxic amounts. When the plasma iron exceeds the iron binding capacity of transferrin, unbound iron circulates freely and may damage the liver, kidneys, cardiovascular system and central nervous system, leading to multi-organ failure.

Toxic doses in terms of elemental iron content are:

- mild-to-moderate poisoning: >20 mg/kg
- severe poisoning: >75 mg/kg
- lethal dose: >150 mg/kg.

Clinical features

The clinical course of iron poisoning can conveniently be divided into four phases. During the first 6 h there may be vomiting, abdominal pain and diarrhoea, resulting from direct irritation of the gastrointestinal mucosa. The vomitus or stools may be dark or blood stained and may smell metallic. Severe fluid loss can lead to lethargy, convulsions, coma, metabolic acidosis and shock. Leukocytosis ($>15 \times 10^9/L$) and hyperglycaemia (>8.3 mmol/L) indicate severe poisoning. This phase usually resolves after 6 h and the patient is often relatively well for the next 18 h. By about 24 h, the patient's condition may worsen: this indicates severe poisoning. Features in this third phase include lethargy, coma, convulsions, cardiovascular collapse, metabolic acidosis, hypoglycaemia and renal and hepatic failure with coagulation abnormalities. Finally, a fourth phase of poisoning may follow the acute episode; it consists of stricture formation that may lead to small bowel obstruction 2–5 weeks after poisoning.

Analysis

Blood should be taken 2–6 h after ingestion. Measurement of serum iron concentration after 6 h may underestimate the amount of free iron because of distribution into tissues. Serum iron concentrations in excess of total iron binding capacity indicate severe poisoning, but the estimation of iron binding capacity may be unreliable in overdose because of the shortcomings of the methods used. The serum iron concentration at 4 h after ingestion is the most reliable guide:

- <3 mg/L (55 μ mol/L): mild toxicity
- 3 – 5 mg/L (55 – 90 μ mol/L): moderate toxicity
- >5 mg/L (>90 μ mol/L): severe toxicity.

Treatment

Chelation therapy. Desferrioxamine binds free iron and the non-toxic complex is excreted by the kidneys. The decision to use it should be based upon the patient's clinical condition and on laboratory analysis. Once parenteral desferrioxamine has been given, colorimetric assay methods for iron are misleading because they measure both free and chelated iron.

Other metals

Poisoning with lead, mercury, bismuth, thallium or arsenic is uncommon, but may arise from deliberate, accidental or occupational exposure. Lead poisoning in children

may be due to pica or follow the use of surma eye make-up in Asian children; in adults it is usually the result of occupational exposure.

The characteristic features of lead toxicity are anaemia with punctate basophilia of the red cells, peripheral muscle weakness, abdominal pain, colic and constipation, and encephalopathy if concentrations are high. Chronic poisoning may produce learning difficulties in children. Chelating agents such as 2,3-dimercaptosuccinic acid (DMSA) and 2,3-dimercaptopropane sulfonate (DMPS) are more effective than the traditional sodium calcium edetate and other chelating agents. DMSA and DMPS are water-soluble analogues of dimercaprol. DMSA is more effective in chelating lead, while DMPS can be used for mercury. Important advantages of DMSA and DMPS over the older chelating agents are that they can be given orally as an outpatient treatment and do not interfere with zinc and copper metabolism.

Orthopaedic implants, such as hip replacements, may contain cobalt and chromium metal. If the implant is functioning well, blood metal concentrations will be very low. However, elevated concentrations >119 nmol/L (cobalt) or >134.5 nmol/L (chromium) are associated with a failing implant and may lead to local tissue reactions, with malignant tumours being described in case reports. In the UK, the Medicines and Healthcare Products Regulatory Agency has issued guidance about the follow-up of patients who have specific types of hip implants. They recommend at least annual assessment of patients during the life of the implant, with more frequent assessment if whole blood concentrations of either chromium or cobalt are above the defined limits. It is unclear if elevated blood cobalt or chromium concentrations produce systemic toxicity in the setting of a failing hip replacement. However, hip revision should be considered if they are persistently elevated.

Organophosphates

Organophosphate poisoning is a major public health issue worldwide resulting in 200 000 deaths each year. Most of these occur through ingestion with suicidal intent. In developed countries, however, the number of poisonings is low and deaths are very rare. The most serious poisoning occurs by ingestion; cutaneous absorption and inhalation of sprays rarely cause serious toxicity.

Toxicity

The acute toxicity of these compounds is due to the inhibition of the enzyme acetylcholinesterase by phosphorylation, resulting in an accumulation of acetylcholine at postganglionic parasympathetic nerve endings (muscarinic receptors), parasympathetic ganglia (nicotinic receptors) and neuromuscular junctions (nicotinic receptors). All the organophosphates inhibit both red cell acetylcholinesterase and plasma cholinesterase (pseudo-cholinesterase) and this provides the basis for biological monitoring of toxicity (red cell measurements being preferred for acute toxicity). For monitoring of occupational exposure, regular measurement of plasma cholinesterase

activity should be carried out: a reduction of the pre-employment value by 30% indicates excessive exposure and the worker should be removed from exposure pending recovery of enzyme activity.

Phosphorylated acetylcholinesterase is relatively stable, which means that the features of poisoning may persist longer than the presence of the organophosphate in the bloodstream. Spontaneous reactivation of the enzyme depends mainly on the chemical structure of the organophosphate. Exposure to compounds such as dimethylphosphates and dimethylphosphorothioates leads to dealkylation of the enzyme (a process referred to as 'ageing'), which makes the enzyme inaccessible to reactivation, either spontaneously or by administration of reactivating agents such as pralidoxime. In poisoning by carbamates, the affected acetylcholinesterase undergoes rapid spontaneous reactivation.

Clinical features and management

Early symptoms of acute exposure to organophosphates are non-specific but lead on to more characteristic features. In mild-to-moderate poisoning there may be headache, blurred vision, miosis, excessive salivation, lacrimation, sweating, wheezing and lethargy. The patient should be kept under observation for at least 24h. Severe poisoning may cause coma, convulsions, respiratory muscle paralysis, bradycardia and hypotension.

The first step is to maintain a clear airway and ensure adequate ventilation, after which atropine should be given until atropinization is achieved, that is, the heart rate is >80 /min, secretions are inhibited or pupils are enlarged.

Pralidoxime (a specific cholinesterase reactivator) should ideally be started within 4h of exposure. In patients who present late to hospital, enzyme inactivation becomes less reversible and pralidoxime is unlikely to have any effect if given after 24–36h.

The patient may relapse after apparent recovery, as a result of an acute myopathy that is distinct from the acute toxicity or the delayed neuropathy that may occur after several weeks. This has been called the 'intermediate syndrome'.

Alcohols and glycols

One of the important features about alcohols from the clinical chemistry point of view is that they all cause a raised osmolar gap; comparison of measured and calculated osmolality can be used for the early confirmation of the potential severity of poisoning by alcohols and glycols.

Ethanol (ethyl alcohol)

Ethanol is probably the best known of all toxins. There are 100 deaths per year in England and Wales from acute alcohol toxicity, but the numbers of deaths from other causes, including road accidents and accidents in the workplace and also from chronic hepatic damage and cancers, is considerably greater than this, with the total toll being over 25 000 deaths each year. When alcohol is taken acutely, effects on behaviour can be demonstrated

at blood concentrations as low as 200 mg/L (4.3 mmol/L). Intellectual performance, judgement and coordination are progressively impaired at increasing blood concentrations. The legal limit in the UK for being in charge of a motor vehicle is 800 mg/L (17.4 mmol/L). By 1600 mg/L (35 mmol/L), most people have marked impairment of coordination and are obviously drunk. However, tolerant individuals may have a blood alcohol concentration of >5000 mg/L (110 mmol/L), without apparent behavioural impairment. By contrast, death from acute toxicity may occur in non-tolerant individuals with blood ethanol concentrations in the range 2000–3000 mg/L (43–65 mmol/L). A fatal outcome from acute alcohol toxicity may result from cardiac or respiratory depression or from aspiration of vomit.

The effects of ethanol are increased by sedative and hypnotic agents, and deep coma may occur in a patient who has taken a combination of a relatively small amount of alcohol plus a small overdose of a benzodiazepine. The clinical assessment of a patient with a severe head injury may be confused by alcohol intoxication. In children, convulsions and hypoglycaemia may result from acute alcohol intoxication. Alcohol potentiates rebound hypoglycaemia and may also cause marked hypoglycaemia in adults. Alcoholic ketoacidosis may follow bouts of heavy drinking (see Chapter 5).

Dilute ethanol enhances gastric emptying, but high concentrations (e.g. at the strength found in spirits) may cause gastric irritation and can delay stomach emptying. In rare cases, haemodialysis may be indicated to remove ethanol from the bloodstream, but supportive care is usually sufficient.

Heavy ingestion of alcohol may lead to the clinical picture of alcoholic hepatitis, with fever, leukocytosis and hepatomegaly. More chronic ingestion can lead to hypertriglyceridaemia; hyperuricaemia is also common in chronic heavy alcohol drinkers. A pseudo-Cushing syndrome occurs in a proportion of alcoholics and may be accompanied by an alcoholic myopathy. The commonest pathological sequel of long-term alcohol abuse is alcoholic cirrhosis, which is accompanied by typical physical signs and the biochemical changes of hepatic impairment. Acute bleeding may occur from ruptured oesophageal varices. The most important tests for detecting chronic abuse, apart from the detection of alcohol in a morning blood or urine sample, are plasma γ -glutamyltransferase activity and carbohydrate deficient transferrin concentration (see Chapter 13).

The alcohol-dependent patient who discontinues drinking because of an accident or a hospital admission may develop the alcohol withdrawal syndrome, in which there is a risk of convulsions and death. Initial irritability may develop into frank hallucinations and infusion of a sedative drug such as clomethiazole may be needed.

Methanol (methyl alcohol)

Methanol is a common constituent of car engine antifreezes. Model aircraft fuel also contains methanol, as do some screenwashes, varnishes and thinners. As little as 10 mL of pure methanol in a child and 50 mL in an adult can be fatal, causing profound metabolic acidosis, coma, convulsions and blindness.

Plasma osmolality, acid–base status and renal function should be checked in all patients with methanol ingestion. Direct measurement of blood methanol concentration is preferable to measurement of plasma osmolality (which is a surrogate indicator), but may not be available in a clinically useful timeframe. If plasma osmolality is normal and there is no acidosis (normal osmolal and anion gap), treatment is not required. Enzymatic metabolism of methanol to toxic metabolites can be prevented by either fomepizole (4-methyl pyrazole) or ethyl alcohol administration. Fluid administration may be required to maintain an adequate urine output for elimination of methanol. Acidosis should be corrected with intravenous sodium bicarbonate. Haemodialysis is indicated if visual disturbance is present, there are features of CNS toxicity or severe metabolic acidosis or if the patient develops acute kidney injury.

Ethylene glycol

Ethylene glycol is a common constituent of automobile antifreezes. If ingested, it tends initially to cause signs of alcoholic intoxication followed later by tachycardia, pulmonary oedema, convulsions and then acute kidney injury (see Fig. 40.5). Metabolic acidosis, leukocytosis, hypocalcaemia and crystalluria are characteristic, owing mainly to the metabolic production of oxalate, which then combines with calcium. Oxalate deposition may lead to meningism and acute tubular injury. The presence of calcium oxalate crystals in the urine is typical and is a useful diagnostic feature.

The main principles of treatment are as for methanol poisoning: to delay the metabolism of ethylene glycol to toxic metabolites by administering fomepizole or ethyl alcohol, to correct the metabolic acidosis and to hasten the elimination of ethylene glycol by increasing urine output or, in severe cases, by using haemodialysis. In addition, plasma calcium concentration should be monitored (hypocalcaemia should be corrected if it occurs), as should renal function (acute kidney injury may require haemodialysis).

Drug and substance abuse

Many drugs and chemicals are widely abused and some cause serious medical complications. There are approximately 600 deaths from opioid abuse, 150 from cocaine and 30 deaths from volatile substance abuse each year in the UK and, although other abused substances cause fewer deaths, they remain an important cause of morbidity.

Apart from opioid toxicity, the management of poisoning with this group of agents is mainly symptomatic. Confirmation of exposure is often necessary for diagnostic or medicolegal reasons and Table 40.5 gives a guide to the typical times during which urine tests remain positive. Immunologically based point-of-care urine tests are commonly used for diagnosis of poisoning by drugs such as opioids, cocaine, cannabis, amphetamine and metamphetamine (usually includes 3,4-methylenedioxymetamphetamine, MDMA, see below). Tests are also available for benzodiazepines,

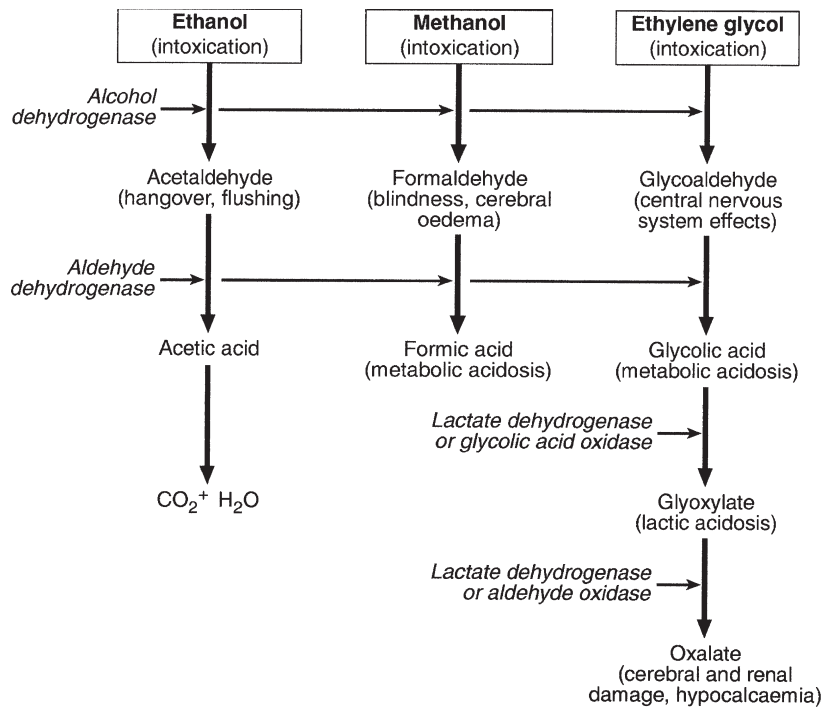

FIGURE 40.5 ■ Metabolism and clinical effects of ethanol, methanol and ethylene glycol. Clinical effects are given in brackets; *enzymes* are in italics. The higher affinity of ethanol for alcohol dehydrogenase is the rationale for its use as an antidote in poisoning with other alcohols. Fomepizole also inhibits metabolism of alcohols by its high affinity for alcohol dehydrogenase.

TABLE 40.5 Duration of positive results in urine after a typical dose taken by a drug abuser

Substance	Limit of detection	Time of detection
Amphetamine	0.25 mg/L	1–2 days
Barbiturates	0.5 mg/L	1–3 days (longer for phenobarbital)
Cannabis	50–300 µg/L	2 days to 3 weeks (depends on usage and limit set)
Cocaine	0.3 mg/L	2–3 days
Codeine	0.25 mg/L	1–2 days
Dihydrocodeine	0.25 mg/L	1–2 days
LSD	0.5 mg/L	2–3 days
MDMA ('Ecstasy')	0.1 mg/L	1–2 days
Methadone	0.25 mg/L	2–5 days
Morphine	0.5 mg/L	1–2 days
Propoxyphene	0.3 mg/L	2–4 days

LSD, lysergic acid diethylamide; MDMA, 3,4-methylenedioxyamfetamine.

methadone (which is structurally different to other opioids and does not give a positive result in tests for opioids), and phencyclidine (ketamine will cross-react in this test).

Amfetamines

The amfetamines are frequently abused for their stimulant effects. Amfetamine sulphate may be injected, inhaled or taken orally. Methylamfetamine ('crystal meth'

or 'ice') comes in the form of crystals that can be smoked and is about 20 times more potent than amfetamine sulphate, but has similar effects.

The main complications of amfetamine toxicity include agitation, convulsions, cardiac arrhythmias, hyperthermia and myoglobinuric acute kidney injury, which can be aggravated by volume depletion. There is no specific pharmacological antidote and management is generally supportive. Sedation and anticonvulsants will be needed for the patient who is agitated or fitting, and maintaining an acidic urine markedly increases the excretion of amfetamine and shortens its elimination half-life. However, if there is a suspicion of rhabdomyolysis, for example following repeated seizures, or if the plasma creatine kinase activity is raised or myoglobinuria is present, then alkalinization of the urine is recommended to prevent myoglobinuric kidney injury.

3,4-Methylenedioxyamfetamine (MDMA)

3,4-Methylenedioxyamfetamine, also known as 'Ecstasy' or 'E', is an amfetamine derivative with different properties from amfetamine; it typically produces euphoria, empathy and a subjective sense of increased energy, which is the reason why it has become popular as a 'dance drug'. First synthesized in 1914, it was briefly used as a mood-modifying agent, but was banned in the UK in 1977. In the usual doses (tablets or capsules contain 30–150 mg; users take between half and five orally during the course of an evening), it has few adverse effects in the majority of people. The commonest effects are

trismus, tachycardia, sweating and agitation. A small proportion of users develop muscle pain and stiffness, which may persist for a week. When the drug is taken before or during strenuous exercise such as dancing, it may lead, in rare cases, to collapse, convulsions and acute hyperthermia, rapidly followed by disseminated intravascular coagulation and rhabdomyolysis. Deaths have occurred after a single dose.

The reason for collapse is related to the combination of physical hyperactivity and inadequate fluid replacement, but it is not known why only a very small number of individuals are affected. Management initially should be directed to restoring fluid volume and reducing body temperature. Intravenous dantrolene may be effective. Ingestion of MDMA may also produce a serotonin syndrome, which is characterized by a triad of altered mental status (agitation, confusion), neuromuscular hyperactivity (clonus) and autonomic instability (hyperthermia, tachycardia). In order to prevent the hyperthermia becoming fatal, paralysis and ventilation may be required. Another complication of MDMA use is hyponatraemia, which usually occurs when excess fluid has been taken but there has been insufficient exercise to sweat off the fluid. This occurs because MDMA causes serotonin production, which in turn causes release of excess arginine vasopressin (antidiuretic hormone) from the posterior pituitary. The patient is likely to be confused and may have convulsions, but has a normal body temperature. Plasma sodium will be ≤ 125 mmol/L. The most important step in management is to avoid giving any fluids; most patients will recover spontaneously.

Although MDMA is taken because it causes the release in the nervous system of large amounts of serotonin, which is one of the neurotransmitters responsible for the 'high' caused by the drug, this leads to depletion of serotonin and a 'midweek low' is a well-known consequence of MDMA consumption. Serotonin neurotoxicity has been demonstrated in animals, and a reduction in cognitive abilities, particularly memory, has been demonstrated in humans following chronic intermittent use.

Heroin (diamorphine)

Heroin abuse is common in the UK, causing over 500 deaths per year. Many of these are from respiratory failure, which may occur after the first use of the drug. Experienced users may die from acute respiratory depression or aspiration of vomit following loss of tolerance after a period of abstinence. Tolerance is rapidly lost; the dose requirement may fall by 10-fold over a period of 2–3 days of abstinence, so that the dose which previously produced euphoria may prove fatal.

The classic signs of opioid toxicity consist of depressed consciousness, which may amount to profound coma, small or 'pinpoint' pupils (pethidine is an exception to this and the atropine in Lomotil[®], a mixture of diphenoxylate and atropine, may cause dilated pupils) and respiratory depression. The pattern of opioid induced respiratory depression is characteristic and consists of a slowing of respiration, whereas other respiratory depressants tend to decrease the depth of respiration with less effect on the rate. An adequate dose of naloxone

should reverse these symptoms; an initial dose may only produce a minimal or partial response and further doses may be required. The presence of other central nervous depressant drugs or other causes of coma may mask the response to naloxone.

Once the diagnosis of opioid toxicity has been confirmed by administration of naloxone, the choice can be made as to whether to continue reversal with an infusion of naloxone sufficient to maintain adequate spontaneous respiration or whether to ventilate the patient until the drug is metabolized. Diamorphine has a short elimination half-life of 2–4h, so that treatment may not need to be prolonged. Other opioid drugs such as buprenorphine, dihydrocodeine, methadone and dextropropoxyphene have considerably longer elimination half-lives and a longer period of recovery should be anticipated.

Complications of heroin overdose include a chemical pneumonitis owing to aspiration of vomit, non-cardiogenic pulmonary oedema and non-traumatic rhabdomyolysis. The question of provoking heroin withdrawal symptoms in an addict by administration of naloxone is often raised; opioid withdrawal is a non-fatal condition, which is, in any case, short-lived because of the short duration of effect of a single dose of naloxone (10–30 min).

Lysergic acid diethylamide (LSD)

Lysergic acid diethylamide is a synthetic hallucinogen, which may lead to a patient being admitted to an intensive therapy unit because of behavioural disturbances, accidents or suicide attempts. There is no specific antidote.

Cocaine

The hydrochloride is typically snorted through a straw or a rolled up bank note, while the free base form, in small crystals or 'rocks', is drawn directly into the lungs by flaming a rock with a cigarette lighter. Cocaine produces marked vasospasm and hypertension, and patients most frequently present to emergency departments with chest pain. They may also present with confusion, convulsions, myocardial infarction, acute heart failure or cerebral haemorrhage. There is no specific antidote, but intravenous diazepam relieves the chest pain and reduces the risk of convulsions. After this, blood pressure may be controlled with agents such as intravenous nitrates. Other management is supportive.

Cannabis

Tetrahydrocannabinol, the active ingredient of the cannabis plant, combines with receptors in the brain and periphery to cause mental effects together with vasodilatation and tachycardia. Effects last a few hours, but the drug can persist in tissues for a long time. Acute overdose is unlikely to be fatal, but heavy use is cumulative and can lead to agitation, hallucinations and paranoid behaviour.

The main psychoactive component of cannabis, Δ^9 -tetrahydrocannabinol (THC), reaches peak concentration in the blood within minutes of smoking, but rapid absorption by fatty tissues then leads to a rapid fall. However,

one of the main metabolites of cannabis, 11-nor- Δ^9 -tetrahydrocannabinol carboxylic acid (carboxy-THC), which is detectable in the blood shortly after use, persists in the blood for a week or more. Immunoassays do not distinguish between active THC and its inactive metabolites. For this reason, blood or urine tests may remain positive for a long time after cannabis consumption, and cannot be taken to indicate intoxication.

Solvents

Volatile substance abuse (solvent abuse, 'glue sniffing') is relatively common in teenagers. Most obtain a sensation of intoxication within seconds of inhalation and come to little harm. The commonest substance abused is toluene. However, if the dose is too high, coma and convulsions may ensue and inhalation of vomit is a possibility. Since volatile substances (particularly chlorinated hydrocarbons) sensitize the myocardium to catecholamines, cardiac arrhythmias may occur and cause a fatal outcome. Butane from cigarette lighter refills may be inhaled directly; the gas may cause asphyxia or its cooling effect may cause cardiac arrest through vagal inhibition.

Chronic complications of solvent abuse are unusual, but brain, liver and kidney damage have all been reported. Carcinogenesis has not been documented. Management is generally symptomatic; cardiac arrhythmias may respond to an intravenous dose of a β -blocker.

Benzodiazepines

The benzodiazepines are widely thought to be non-fatal in overdose, but about 200 deaths occur every year in the UK from respiratory depression, aspiration of vomit or hypothermia. Usually such deaths occur when benzodiazepines are combined with other agents such as ethanol. In most patients with an uncomplicated benzodiazepine overdose, the coma amounts to a deep sleep with an adequate gag reflex and preserved tendon reflexes and response to painful stimuli.

Patients rarely need management in an intensive therapy unit, but sometimes the drug has been co-ingested with ethanol, opioids, barbiturates or tricyclic antidepressants. The question may arise as to whether flumazenil should be given as a therapeutic or diagnostic test. Reversal of benzodiazepine toxicity could provoke convulsions due to simultaneously ingested tricyclic antidepressants. In general, it should only be used in carefully considered circumstances.

Theophylline

Clinical features

Most oral preparations of theophylline are sustained-release formulations. The patient may be asymptomatic on presentation. Symptoms usually take several hours to develop and include vomiting, abdominal pain, haematemesis, irritability and hyperventilation. A sinus tachycardia is usual and there may be hypotension, cardiac arrhythmias (most commonly supraventricular

tachycardia), convulsions, hypokalaemia and hyperglycaemia. Coma is not common. Rhabdomyolysis and acute kidney injury are rare complications.

Management

Activated charcoal in repeated doses is the treatment of choice for severe poisoning. This is indicated if the patient is clinically severely poisoned and/or has a plasma theophylline concentration $>40\text{mg/L}$. In life-threatening poisoning, charcoal haemoperfusion can be used, if available.

Antidepressants

Tricyclic antidepressants

Acute overdose with tricyclic antidepressants is the commonest cause of poisoning admissions to intensive therapy units in the UK. The mechanisms of toxicity are complex and are due to at least three pharmacological effects:

- an anticholinergic effect, which causes delayed gastric emptying, sinus tachycardia and mydriasis
- blockade of noradrenaline uptake at adrenergic synapses, which may produce hypotension
- a quinidine-like or membrane-stabilizing effect. In low doses, this last effect is antiarrhythmic, but in overdose, it delays conduction and depresses contractility. The quinidine-like effect slows sodium flux into cells and is the mechanism underlying cardiac toxicity. It may be aggravated by hypoxaemia (Fig. 40.6).

Clinical features. There may be initial nausea, vomiting, agitation and hallucinations, giving way to coma. Tendon reflexes may be equal and very brisk, with extensor plantar reflexes; as coma deepens, muscle tone becomes flaccid and reflexes are lost. The pupils are more often mid-sized than widely dilated. Convulsions are common and respiratory depression may occur.

The most serious and potentially fatal complications are cardiac arrhythmias (most commonly atrioventricular block, ventricular tachycardia or ventricular fibrillation, which may be followed by asystole) and profound hypotension, which may amount to electromechanical dissociation. Pulmonary oedema may occur. The electrocardiogram (ECG) shows a sinus tachycardia and there may be a right bundle branch block pattern. A QRS duration $>100\text{ms}$ is regarded as the best indicator of risk of cardiac toxicity.

Management. Cardiopulmonary status must be assessed urgently and resuscitation commenced if necessary. Poisoning is potentially reversible, provided hypoxic cerebral damage has not occurred. In significant poisoning, the most important treatment is alkalization with intravenous sodium bicarbonate, aiming for a blood $[\text{H}^+]$ of 32nmol/L (pH 7.5). This is indicated even in the absence of acidosis when there is prolongation of the QRS duration on ECG, there are cardiac arrhythmias or resistant hypotension. Seizures should be treated with benzodiazepines. If recurrent, phenobarbital or thiopentone may

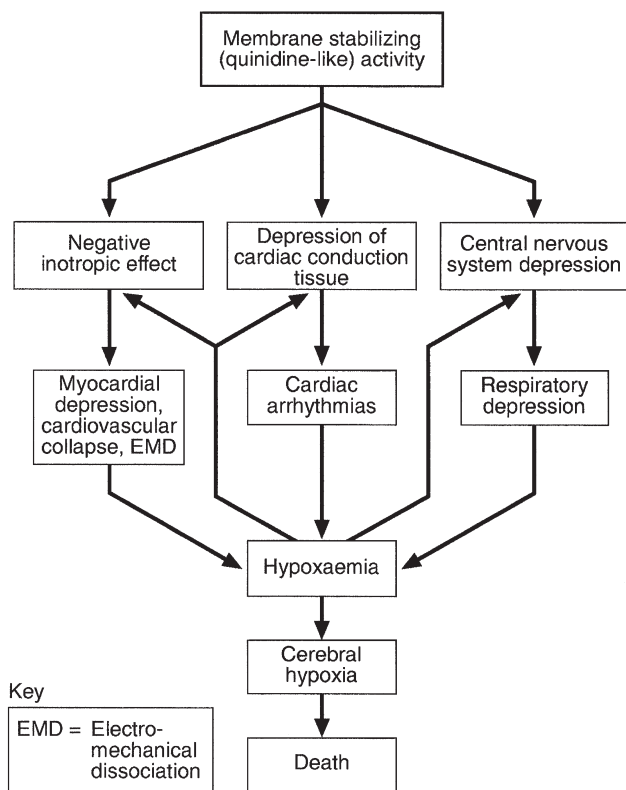

FIGURE 40.6 ■ Mechanisms by which the membrane-stabilizing activity of drugs can cause death.

be needed in a critical care setting. Phenytoin is contraindicated as both tricyclics and phenytoin block cardiac sodium channels. In life-threatening poisoning, lipid emulsion (e.g. intralipid) therapy may be considered; this acts as a lipid reservoir in the circulation that may 'trap' the drug and reduce the concentration at the receptor.

Monoamine oxidase inhibitors

Toxicity. Several drugs and foods are prohibited for patients taking monoamine oxidase inhibitors to prevent the well-known 'cheese' reaction, which consists of a sudden and severe rise in blood pressure owing to tyramine-provoked release of noradrenaline.

Overdose of monoamine oxidase inhibitors produces symptoms that build up over 12–24h, with muscle twitching progressing to widespread muscle spasms, trismus and opisthotonos. The blood pressure may vary between hypotension and moderate hypertension; there is usually a sinus tachycardia and the patient is warm to the touch, sweating profusely and has fixed dilated pupils. The core temperature may rise steeply, leading to death from hyperthermia. The muscle spasms may lead to rhabdomyolysis, which can cause acute kidney injury. Disseminated intravascular coagulation may occur as a complication of hyperthermia.

Management. If the rectal temperature rises above 39°C the patient should be electively paralysed with pancuronium and mechanically ventilated for 12–24h both to reduce heat generation through muscle spasm (and thus correct

hyperthermia) and prevent rhabdomyolysis. Hypotension is usually secondary to hypovolaemia, but dopamine may be tried if fluid replacement fails to restore blood pressure.

Other antidepressants

Lofepramine. This tricyclic drug is metabolized to desipramine, but toxicity in overdose is usually relatively mild and deaths are rare.

Trazodone. This drug is chemically unrelated to the tricyclic antidepressants. Toxicity is usually mild, with drowsiness, dizziness and occasionally coma.

Venlafaxine. This drug is less cardiotoxic than the tricyclic antidepressants, but may cause convulsions in overdose.

Fluvoxamine, fluoxetine, sertraline, paroxetine. These serotonin reuptake inhibitors rarely cause serious toxicity in overdose, though a mild serotonin syndrome may occur, and they can also interact with other drugs to produce a serotonin syndrome. Management is symptomatic.

Citalopram. This serotonin reuptake inhibitor is more cardiotoxic than others, producing QT interval prolongation.

Lithium

Toxicity

Lithium is eliminated by the kidneys and reduced renal function can lead to accumulation. The therapeutic range is narrow (plasma concentration 0.8–1.2mmol/L in the management of hypomania or mania in bipolar affective disorder; 0.4–1.0mmol/L for prophylaxis: note that blood should not be collected into a lithium heparin tube). Toxicity in therapeutic use can be caused by changes in fluid or electrolyte balance (particularly owing to reduction in fluid intake or increased fluid loss from diarrhoea or vomiting). Diuretic therapy or non-steroidal anti-inflammatory drugs may also cause toxicity by reducing lithium excretion.

Clinical features

Symptoms of toxicity include confusion, agitation, drowsiness, tremor, hyper-reflexia, hypertonia, ataxia, vomiting, convulsions and, rarely, electrocardiographic changes, diabetes insipidus and acute kidney injury. In acute poisoning, serum concentrations of >5mmol/L may be associated with minimal symptoms and the elimination half-life is relatively rapid. The development of marked neurological symptoms is an indication for active elimination. Deaths from lithium poisoning are rare, but neurological impairment may be permanent.

Management

Lithium is not adsorbed by activated charcoal but is readily excreted by the kidneys and a high urine output should be ensured. Saline diuresis enhances lithium excretion but urine alkalization does not.

In a symptomatic patient with high serum lithium concentrations after an acute overdose, haemodialysis should be considered. Although efficiently removed by haemodialysis, lithium has a large volume of distribution leading to a 'rebound' rise in plasma concentrations and repeated dialyses may be necessary. Peritoneal dialysis is much less effective.

Cyanide

Cyanide can be rapidly fatal. It may be inhaled as hydrogen cyanide (either pure, as an industrial gas or as a product of combustion in cases of smoke inhalation) or enter the body by ingestion of cyanide salts or intestinal hydrolysis of cyanogenic glycosides (e.g. following massive ingestion of stone fruit kernels or apple pips) or by cutaneous absorption of cyanide salts in industrial situations.

Cyanide acts as a chemical asphyxiant, rapidly blocking cellular oxygen utilization so that cerebral function and circulation are rapidly impaired with the development of a metabolic acidosis. Early signs include hyperventilation and tachycardia, but coma, cyanosis and convulsions soon supervene. Rapid diagnosis and intervention are essential. A high inspired oxygen content (or hyperbaric oxygen, if available) is an effective treatment, though its mode of action is unclear, perhaps being due to simple displacement of cyanide. When the diagnosis is certain, dicobalt edetate can be given intravenously over 1 min, repeated as necessary, and is an effective antidote. Although relatively non-toxic when administered to a patient poisoned with cyanide, this antidote can produce severe anaphylactoid reactions with laryngeal oedema and convulsions if given to a patient who is not poisoned by cyanide. The safest course of action is not to give the antidote unless the patient's level of consciousness is deteriorating. Another group of antidotes (amyl nitrite and sodium nitrite) act by producing methaemoglobin, each molecule of which can bind four cyanide ions. Sodium thiosulphate acts to neutralize cyanide by donating a sulphur group to produce sodium thiocyanate, in a reaction that is catalysed by rhodanese.

Subacute or chronic cyanide toxicity can also occur during prolonged nitroprusside therapy. The main clinical feature is a lactic acidosis – if none is present then cyanide toxicity can be ruled out. Cyanide measurement is not usually necessary: a rapid improvement should occur after administration of sodium thiosulphate intravenously. Other cyanide antidotes are not indicated.

Carbon monoxide

Toxicity

Carbon monoxide is a colourless, odourless gas produced by combustion of carbon-containing compounds. It has a high affinity for haemoglobin and cytochrome enzymes, and is highly toxic because it acts as a chemical asphyxiant. It accounts for around 50 deaths each year in the UK, which may be suicidal from motor vehicle exhaust fumes, or accidental, mainly from release of products of combustion (of gas, solid or liquid fuels) in the home or exposure to fire smoke.

As little as 0.1% carbon monoxide in the inspired air can be fatal over a period of several hours, while 1% can be fatal in minutes. Toxicity is due mainly to combination of carbon monoxide with haemoglobin to form carboxyhaemoglobin, but is also due to interference with the cellular uptake of oxygen as a result of its combining with cytochrome enzymes. Carboxyhaemoglobin in the blood has a half-life of about 4h if the patient is breathing air. The half-life is markedly reduced (to 1h) if the patient is breathing 100% oxygen and is still further reduced (to 20 min) if the patient is breathing oxygen in a hyperbaric chamber at 2.5 atmospheres, but the effectiveness of hyperbaric oxygen in diminishing the toxicity of carbon monoxide is hotly debated.

Clinical features

The symptoms of exposure are non-specific: lethargy, nausea, headache, drowsiness, hyperventilation, leading to vomiting, collapse, coma and convulsions. Elderly people may present with stroke or exacerbation of coronary heart disease precipitated by reduced oxygen-carrying capacity of the blood. Non-traumatic rhabdomyolysis may occur. If the source of exposure is not apparent, the diagnosis may also not be apparent. Once diagnosed or suspected, evidence should be sought, for example a malfunctioning flue from a fire or heating appliance, or motor exhaust fumes. A rare cause is exposure to methylene chloride, which is metabolized to carbon monoxide by hepatic smooth endoplasmic reticulum.

Specific physical signs are minimal; the 'cherry-red' colour of carboxyhaemoglobin is usually only noted at post-mortem. Diagnosis of exposure should be made by measuring carboxyhaemoglobin on a whole blood sample. Correlation of the percentage of carboxyhaemoglobin with clinical effects is poor and is complicated by the disappearance of carbon monoxide from the blood following exposure, while the clinical effects may remain for longer. However, normal values in non-smokers are <1% and in smokers <5%. Carbon monoxide is produced during the catabolism of tetrapyrroles and severe haemolysis in haemolytic anaemia can, rarely, give a carboxyhaemoglobin as high as 8%.

Management is by removal from exposure, resuscitation as necessary and immediate administration of a high inspired oxygen concentration. Blood should be taken at the earliest possible moment for carboxyhaemoglobin estimation. The role of hyperbaric oxygen therapy in carbon monoxide poisoning is controversial but should be considered in life-threatening poisoning, if the treatment is available.

Methaemoglobinaemia

Causes

The more important causes of life-threatening methaemoglobinaemia, likely to present with acute symptoms, are:

- aniline
- sodium or potassium nitrite
- amyl or butyl nitrite
- sodium or potassium nitrate
- sodium or potassium chlorate.

Nitrites are more potent methaemoglobin formers than nitrates, but nitrate can be converted into nitrite by intestinal bacteria. Inhaled nitrites (amyl and butyl nitrites) produce little methaemoglobin unless the liquid is swallowed, when severe toxicity may occur. Many drugs, including sulphonamides, dapsone and local anaesthetics, can increase methaemoglobin production but are unlikely to produce concentrations exceeding 30%. It should also be noted that the cause may be iatrogenic, for example sodium nitrite given for cyanide poisoning.

Symptoms

At low concentrations, the patient may be deeply cyanosed but otherwise asymptomatic and require no treatment. At high concentrations, the patient may be dyspnoeic on exertion and have postural hypotension. At severely toxic concentrations, the patient becomes flaccid and comatose. Cardiac arrhythmias and convulsions may occur and may progress to cardiorespiratory arrest. Methaemoglobinaemia should be suspected if the skin has a blue or greyish, cyanosed appearance: the blood may be a dark or chocolate-brown colour. This colour change occurs with methaemoglobin concentrations of 15–20%, but clinical symptoms only appear at values >20–30%, while consciousness is likely to be lost at >50%. Death is common at >70%.

Management

In addition to supportive measures, which should include 100% oxygen, methaemoglobinaemia may be reversed by the administration of intravenous methylthionium chloride (methylene blue). It should only be given to symptomatic patients. When the cause is chlorate poisoning, methylene blue is unlikely to reverse the methaemoglobinaemia, although ascorbic acid can be given. In extreme cases, exchange transfusion can be used, though the transfused blood may also become affected and prolong the methaemoglobinaemia. Hyperbaric oxygen, if available, may allow sufficient oxygen to be transported in solution in the plasma to maintain life.

Plant and fungal toxins

Most plants are non-toxic and most childhood ingestions of plant material do not lead to toxicity. However, many plants contain chemical agents that are potentially poisonous when accidentally ingested by children or taken as food by adults; in addition, suicidal or homicidal ingestion may occur. Two examples have already been given in this chapter: *Thevetia* and oleander contain cardiac glycosides, and the seeds of a number of varieties contain cyanogenic glycosides, which may cause cyanide poisoning if sufficient seeds or kernels are ingested. Other potentially serious plant poisons are included in Table 40.6.

Acute fungal poisoning most commonly arises from eating toxic species in mistake for edible species. Many mushrooms can cause gastrointestinal symptoms shortly after ingestion, but most of these are not associated with serious poisoning; a rule of thumb is that mushroom poisonings with symptoms starting <6h after ingestion are unlikely to be due to highly toxic species. A few species, especially *Coprinus atramentarius*, can produce an Antabuse®-like reaction if ingested with alcohol, because they contain a chemical that inhibits aldehyde dehydrogenase.

The most important group of poisonous mushrooms includes those which contain cyclopeptides known as amanitins (*Amanita phalloides*, *A. verna*, *A. virosa* and some *Galerina* and *Lepiota* species). After an initial period of severe diarrhoea, beginning 6–12h after ingestion, the patient may develop fulminant hepatic failure: a single mushroom can cause death and the mortality rate from ingestion is 20%. Another important and potentially fatally poisonous mushroom species is *Gyromitra esculenta*, which contains gyromitrin. If this chemical is not previously removed by evaporation or boiling, severe toxicity may result from the metabolic conversion of gyromitrin to monomethylhydrazine, which is a competitive inhibitor of pyridoxal phosphate. Symptoms start suddenly 6–12h after ingestion and consist of headache, vomiting, diarrhoea and convulsions. Liver damage may also occur. The mushroom species *Cortinarius* contain the toxin orellanine that causes acute kidney injury, which may require renal replacement therapy, after an initial latent, symptomless, phase of several days.

TABLE 40.6 Plants that cause potentially serious poisoning

Plant	Toxic principle	Possibly fatal amount (in an adult)
Ackee (unripe fruit)	Hypoglycin	One fruit
Apple or pear seeds (<i>Malus</i> , <i>Pyrus</i> spp.)	Amygdalin (cyanogenic glycoside)	100 seeds
Castor oil plant (<i>Ricinus communis</i>)	Ricin	Two beans
Death cap (<i>Amanita phalloides</i>)	Amanitin, phalloidin (cyclopeptides)	One mushroom
<i>Galerina</i> spp. mushrooms	Amanitin-type cyclopeptide	One mushroom
<i>Gyromitra</i> spp. mushrooms	Monomethylhydrazine	One mushroom
Holly (<i>Ilex aquifolium</i>)	Ilicin	30 berries
Jequirity (<i>Abrus precatorius</i>)	Abrin	One bean
Oleander (<i>Nerium oleander</i>)	Oleandrin (cardiac glycoside)	One leaf
Stone fruit kernels (<i>Prunus</i> spp.)	Amygdalin (cyanogenic glycoside)	30 kernels
Hemlock water dropwort (<i>Oenanthe crocata</i>)	Oenanthe toxin	Several leaves or one root
Yew (<i>Taxus baccata</i>)	Taxine A and B	50 needles

CONCLUSION

This chapter outlines the causes, mechanisms and management of the more important types of human poisoning. Poisons – drugs, chemicals and plant and animal toxins – can disrupt the physiological and biochemical functions of the body in a remarkable variety of ways. Many individual toxins produce a characteristic clinical and biochemical pattern of harm ('toxidrome'), which sometimes provides the key to the diagnosis. Management involves supportive care, decontamination and, in some cases, the use of specific antidotes. The clinical biochemistry laboratory may become involved in the identification and quantification of poisons and also in the monitoring of biochemical responses following poisoning; close communication between clinicians and biochemists is necessary for the efficient diagnosis and management of many types of poisoning.

ACKNOWLEDGEMENT

I would like to acknowledge the contribution of the late John A. Henry, who wrote the chapter for previous editions of this book.

CONCLUSION 820

INTRODUCTION

Tumours may exert metabolic effects on the host via a wide range of mechanisms. Some of the metabolic derangements related to tumours are directly related to a hormone or other substance that the tumour secretes. Such hormone secretion can be appropriate to the cell line from which the tumour originates or may be inappropriate or 'ectopic'. In the last decade, molecular genetic techniques have helped characterize tumours and explain how neoplastic tissues can secrete hormones that are not typically associated with them. Metabolic derangements can also arise non-specifically, in the absence of hormone secretion or immunological phenomena, for example owing to tumour burden compromising host metabolism or the effects on the host of rapid cell turnover. Autoimmune reactions evoked by tumour antigens may also give rise to systemic effects and are increasingly being implicated in the causation of various tumour-related or paraneoplastic syndromes. The recognition and characterization of the antibodies to shared tumour and host antigens that play a prominent role in paraneoplastic syndromes have advanced their use in both diagnosis and treatment.

Scientific advances have rapidly opened up new possibilities for the management of tumours, even in their advanced stages, where formerly only observation and palliation was possible. Clinical biochemistry has a key role in both diagnosis and monitoring treatment.

NEUROENDOCRINE TUMOURS

Neuroendocrine cells can be identified by their production of a neurotransmitter, neuromodulator or neuropeptide hormone. Neuroendocrine tumours (NETs) are distinguished by their ability to secrete

peptides causing characteristic endocrine syndromes. The gastroenteropancreatic system has diffuse neuroendocrine components and NETs most commonly arise from these tissues, more than 50% being carcinoid tumours.

Carcinoid tumours

Carcinoids are NETs that arise from enterochromaffin cells, principally in the intestine (~80% in the ileum), the main bronchi and, rarely, other tissues including the ovaries, thymus, pancreas and thyroid. Carcinoid tumours all show a similar pattern of neuroendocrine expression and may contain or secrete amines, peptides or prostaglandins. The carcinoid syndrome is the clinical result of systemic release of these substances, particularly serotonin.

Clinical presentation

The incidence of carcinoid tumours found at post-mortem has been estimated to be as high as 1 in 150, whereas carcinoid syndrome only occurs in approximately 1 in every 50 000 individuals, indicating that most tumours appear to be non-secretory. The products of primary intestinal carcinoids are metabolized in the liver prior to release into the systemic circulation: the development of carcinoid syndrome in patients with a gastrointestinal tumour therefore indicates the presence of hepatic metastases. Carcinoid tumours at bronchial (~10% of the total) and other sites secrete products directly into the systemic circulation and can be associated with carcinoid syndrome without the presence of metastases. The main clinical features of carcinoid syndrome are flushing and diarrhoea (Box 41.1). The diarrhoea tends to be secretory in type and weight loss is common. Patients who flush repeatedly may, in time, develop a cyanotic telangiectatic appearance, which persists. Wheezing may occur, caused by transient

BOX 41.1 Clinical features of carcinoid syndrome

- Flushing 70% (usually without sweating)
- Diarrhoea 50%
- Intermittent abdominal pain 40%
- Valvular heart disease (~20% at presentation)
- Palpitations
- Wheezing
- Facial telangiectasis
- Pellagra-like skin lesions

bronchoconstriction, which is most commonly associated with bronchial carcinoids. Hypertension is not typically a feature of carcinoid syndrome: hypotension is more common. Carcinoid syndrome is also associated with fibrosis; the bowel, retroperitoneum (and hence ureters), lungs and heart can all be affected. Fibrosis is thought not to be linked directly to serotonin but to mitogenic growth factors that drive fibroblast proliferation. Tryptophan is a precursor of both serotonin and nicotinic acid. Thus, in carcinoid syndrome, excess production of serotonin may lead to nicotinamide deficiency, manifesting as pellagra with dermatitis of sun-exposed areas. Carcinoid crisis has been described in certain circumstances including induction of anaesthesia, liver biopsy and following combination chemotherapy. It is manifest as extreme flushing, explosive diarrhoea, labile blood pressure and cardiac rhythm irregularities, including asystole.

Metabolism of serotonin

The rate limiting step in the biosynthesis of serotonin is the hydroxylation, by tryptophan hydroxylase, of tryptophan to 5-hydroxytryptophan (5HTP); this is subsequently decarboxylated to yield 5-hydroxytryptamine (serotonin, 5HT) (see Fig. 41.1). 5-Hydroxytryptamine is stored in neurosecretory granules or secreted into the bloodstream. After secretion, some is taken up into platelets. Oxidative deamination, catalysed by monoamine oxidase and aldehyde dehydrogenase, inactivates 5HT to 5-hydroxyindoleacetic acid (5HIAA), which is excreted in the urine.

The normal excretion of 5-HIAA is <math><50\ \mu\text{mol}/24\text{h}</math>. In patients with typical carcinoids, 99% of metabolized 5HT and 5HTP are excreted as 5HIAA. Urinary 5HIAA excretion is typically in the range 150–1500 $\mu\text{mol}/24\text{h}</math>, generally exceeds 500 $\mu\text{mol}/24\text{h}</math> and occasionally is as high as 3000 $\mu\text{mol}/24\text{h}</math>. Carcinoid tumours of the colon and rectum do not contain the hydroxylase or decarboxylase enzymes and so do not form 5HTP or 5HT. A small number of patients have ‘atypical’ tumours. These patients excrete large amounts of 5HTP and 5HT in their urine. It is believed that these tumours, usually bronchial, are deficient in dopa decarboxylase and cannot convert 5HTP to 5HT so that the former is secreted into the bloodstream. Some of the 5HTP is converted to 5HT and subsequently to 5HIAA in extrarenal sites; some is decarboxylated in the kidneys and excreted into the urine as 5HT, and some escapes decarboxylation and is excreted directly into the urine. Thus, patients with atypical carcinoid tumours have$$$

FIGURE 41.1 ■ Pathway of synthesis and metabolism of 5-hydroxytryptamine.

a marked increase in 5HTP and 5HT excretion and only a moderate increase in 5HIAA excretion.

Even in those patients whose tumours produce predominantly 5HTP, urinary 5HIAA constitutes 50–60% of total urinary 5-hydroxyindoles and increased values are found in almost all patients.

Laboratory investigation

The most sensitive indicator of the turnover of serotonin and its metabolites is measurement of 5HIAA in a 24h urine sample. A number of dietary substances can interfere in the measurement of 5HIAA and should be avoided for three days prior to and during the collection of the urine sample (see Box 41.2). The test is not completely specific and a negative result is to be expected in patients with non-secretory tumours and those of the hindgut that do not produce 5HT.

Chromogranin A (CgA) is a 48 kDa protein distributed in dense core granules of neuroendocrine cells, the highest plasma concentrations being found in patients with carcinoid tumours. It has been reported to have a sensitivity of 75–85% and a specificity of 84–95% in the diagnosis of carcinoid syndrome. It is not dependent upon

BOX 41.2 Substances that can interfere with the measurement of 5-hydroxyindole acetic acid

Serotonin-rich foods

- Bananas, aubergine, plums, pineapples, kiwi fruit, walnuts, hickory nuts, pecans, avocados

Artefactual increase in 5-HIAA

- Guafanesin (glycerol guaiacolate) contained in some cough medicines, paracetamol, fluorouracil, methysergide, naproxen, caffeine

Artefactual decrease in 5-HIAA

- Salicylates, L-DOPA, methyl dopa, aspirin, phenothiazines, adrenocorticotrophic hormone

serotonin secretion and is therefore particularly useful in patients with non-secretory or atypical carcinoids and as its concentration reflects tumour burden, it can be used as a marker for assessing response to treatment. False positive results can be seen in hepatic and renal failure, atrophic gastritis, proton pump inhibitor therapy, and inflammatory bowel disease. Prostatic cancers, which may contain a significant neuroendocrine component, myeloma, exercise, trauma and hypertension may also increase CgA concentrations.

Diagnostic imaging

In isolated carcinoid tumours, where surgical excision is a management option, anatomical localization may be useful. Conventional imaging modalities include computed tomography (CT), magnetic resonance imaging (MRI) and positron emission spectroscopy (PET). A more specific option is the use of somatostatin receptor scintigraphy, e.g. using ^{111}In -DTPA-pentetreotide (OctreoscanTM), which binds to somatostatin receptors on the tumour.

Treatment

Circumscribed tumours may be removable by surgical resection. For patients with significant hepatic metastatic disease, radiofrequency ablation or hepatic embolization, alone or in combination with intra-arterial chemotherapy (chemoembolization), while not curative, may provide significant palliation. Somatostatin analogues have been used effectively in the management of the symptoms of carcinoid syndrome.

MULTIPLE ENDOCRINE NEOPLASIA

Multiple endocrine neoplasia (MEN) syndromes are disorders characterized by pathological hyperfunction of two or more endocrine organs. They have been classified into two distinct disorders: MEN type 1 (MEN1) and MEN type 2 (MEN2) with MEN2 further subdivided into three main variants (see Box 41.3).

Two distinct genetic defects contribute to tumorigenesis in MEN syndromes: in MEN1, inactivation (loss of function) of a tumour suppressor gene is thought

BOX 41.3 Multiple endocrine neoplasia syndromes

to be responsible, while MEN2 is caused by overactivation (gain of function or overexpression) of a proto-oncogene. A tumour suppressor gene restrains cell proliferation and tumours are stimulated by inactivating mutations or deletions in such a gene, which render the gene product either absent or nonfunctional. In contrast, a proto-oncogene (the normal unmutated version of an oncogene) can be converted to an oncogene, which can cause cell proliferations or deregulated cell growth when overexpressed.

Multiple endocrine neoplasia type 1

Multiple endocrine neoplasia type 1 (MEN1) typically becomes manifest after the first decade of life, with most men and women developing symptoms in the fourth and third decades, respectively. Typically, MEN1 tumours appear two decades earlier than isolated endocrine tumours.

Parathyroid disease

Primary hyperparathyroidism (HPT) is the most frequent endocrinopathy in MEN1 and is the most common reason for the disease to come to the attention of physicians. It occurs in 90% of affected individuals between 20 and 25 years of age, rising to nearly 100% by the age of 50 years. However, MEN1 itself is rare and accounts for only 2–4% of patients with HPT. There is no sex difference in MEN1 prevalence compared with a ratio of 3:1 females:males in sporadic hyperparathyroidism. Hyperparathyroidism is often found during the second decade of life during screening of immediate family members of an index patient with proven MEN1. The

pathological features are those of diffuse or asymmetrical hyperplasia, with all four glands being involved (although perhaps not all to the same degree) or with multiple adenomas. The investigation and management of HPT is discussed in Chapter 6.

Gastroenteropancreatic neuroendocrine tumours

Gastroenteropancreatic (GEP) neuroendocrine tumours are the second most common tumours in MEN1, with some 60% of patients being affected. They usually present between the second and fifth decades, unless diagnosed earlier by screening. Approximately half of the tumours are gastrinomas. The Zollinger–Ellison syndrome (ZES) is severe, intractable, multiple and recurrent peptic ulcer disease caused by a gastrin secreting tumour, which can be located in the duodenum or pancreas. The majority of gastrinomas associated with MEN1 are in the duodenum, where they are often small (<0.5 cm in diameter) and multiple. Since gastrin secreting cells are not normally found in the duodenum or pancreas, gastrinomas in these sites should be regarded as ectopic and potentially malignant, irrespective of their histological grade. The clinical syndrome does not differ from that seen with non-MEN1 gastrinomas. The extreme hypersecretion of gastric acid may be associated with inactivation of pancreatic lipase, resulting in fat malabsorption and steatorrhoea. Hyperparathyroidism in MEN1 can exacerbate hypergastrinaemia. The diagnosis can be made by demonstrating increased gastric acid secretion with simultaneously elevated plasma gastrin concentrations. Secretin infusion (2 U/kg) may cause augmented gastrin production in those patients whose basal values are equivocal. Excellent treatments are now available for the medical management of peptic ulcer disease using histamine H₂ receptor antagonists or proton pump inhibitors.

Other GEP NETs include insulinomas, vasoactive intestinal peptide secreting tumours (VIPomas) and glucagonomas. Their clinical features are discussed further in Chapter 12.

Chromogranin A is useful, particularly as a marker of midgut tumours, in the investigation of GEP NETs. Cocaine- and amphetamine-regulated transcript (CART), is a 116 amino acid peptide widely distributed in nervous and endocrine tissues and its physiological roles may include regulation of feeding and response to psychological stress. It is produced by various islet cell tumours and is of particular use as a marker in the investigation of NETs of pancreatic origin. Measurement of a screening panel of gut hormones may also be useful.

Pituitary tumours

The true prevalence of anterior pituitary tumours in MEN1 is unclear. Between 30% and 50% of patients with MEN1 develop anterior pituitary tumours. Whilst some are non-functional, approximately 60% secrete prolactin, 25% secrete growth hormone and 5% secrete ACTH. Occasionally, excess secretion of GH and cortisol

in MEN1 is the result of ectopic secretion of GHRH and ACTH, respectively, e.g. by a pancreatic islet or carcinoid tumour. It is important to identify such patients in order to ensure appropriate therapy.

The investigation and management of pituitary tumours in patients with MEN1 is similar to that for other pituitary tumours and is discussed in detail in Chapter 18.

Foregut carcinoid tumours

Carcinoid tumours occur more frequently with MEN1 than in the general population; some 10% of MEN1 patients are affected. In contrast to sporadic carcinoid tumours, which are predominantly derived from the midgut and hindgut, MEN1 carcinoid tumours are usually derived primarily from the foregut. Foregut carcinoids rarely secrete serotonin, peptide hormones or calcitonin and are usually considered as clinically non-functional.

Adrenal tumours

Adrenal cortical lesions are common in MEN1: 20–40% of patients are affected, mostly with bilateral tumours. However, the majority are non-functional, clinically silent and rarely require treatment. Cushing and Conn syndromes are rare in MEN1.

Tumourigenesis in MEN1

MEN1 is the result of an inactivating mutation in the *MEN-1* gene, a tumour suppressor gene located on chromosome 11q13. It consists of 10 exons and encodes a 610-amino acid nuclear protein termed menin. Menin interacts with diverse groups of transcription factors and coregulators, including JunD, suggesting a role in gene transcription, DNA replication and cell cycle control. Genetic mapping studies indicate somatic loss of heterozygosity in accord with the ‘two hit’ hypothesis. The first hit is a genetic mutation rendering the subject heterozygous for the *MEN-1* mutant gene and predisposed to tumour development. A somatic inactivation of the unaffected allele then occurs (second hit) leading to the development of MEN1-associated tumours.

Diagnosis of MEN1

Occasionally, MEN1 may occur without a recognized family history. Some may be patients whose parents died before developing any manifestations of MEN1: a few may have MEN1 caused by two somatic mutations as described above. Sometimes it is difficult to make the distinction between sporadic tumours and MEN1, but an earlier onset and tumour multiplicity in the same organ increase the likelihood of MEN1. The dominant mode of inheritance, the occurrence of asymptomatic gene carriers and the risk of developing malignant disease make it essential to establish carrier status in all relatives whenever the diagnosis of MEN1 has been made in one family member.

Genetic screening. The identification of the *MEN-1* gene (locus 11q13) has opened the possibility of genetic testing. However, over 1300 distinct germline mutations have been identified and there is a lack of genotype–phenotype correlation. Thus, genetic testing can be time consuming, arduous and expensive and a definitive result does not negate the requirement for further biochemical screening of carriers. However, for those found not to be carrying the mutant gene, there is no further need for surveillance or family screening.

Biochemical screening. Biochemical screening continues to play an important role in carrier ascertainment whenever genetic testing is not possible or has failed to detect germline mutations (see below) and is important for tumour surveillance in those known to have the affected gene.

The MEN1 syndrome rarely develops before the age of five or after the age of 70, and so screening should be performed every three years after the age of five until the age of 70 and at longer intervals thereafter. Over 95% of affected individuals will have been identified by the fourth decade. The measurement of serum calcium is a simple, cheap and reliable screening test; additional biochemical investigations include measurement of serum prolactin, gastrin (fasting) and CgA. Screening of patients with apparently sporadic pancreatic endocrine tumours for evidence of MEN1 is probably justified, especially in those with gastrinomas or insulinomas.

Surveillance of MEN1 patients and carriers

Once mutant *MEN1* gene carriers have been identified by biochemical or genetic testing, they should be monitored rigorously to detect the development of new tumours or tumour recurrence. The age-related penetrance is virtually zero below the age of five years, rising to >50% by 20 years, and >95% by 40 years. Surveillance should include a regular history and examination focused on the clinical features of MEN1-associated tumours in combination with biochemical tests and imaging (Table 41.1). Although periodic screening for endocrine tumour expression in MEN1 appears to reduce morbidity and mortality as a result of early tumour recognition, this has not been proven.

Multiple endocrine neoplasia type 2

Multiple endocrine neoplasia type 2 (MEN2) involves two or more of medullary thyroid carcinoma (MTC), pheochromocytoma and parathyroid tumours (see Box 41.3). Medullary thyroid cancer is a universal feature of MEN2 and is often the first tumour to present. MEN2A is the most common subtype, accounting for 80–90%. Patients with MEN2B, in addition to endocrine abnormalities, have a characteristic marfanoid habitus often with scoliosis and pes cavus. The presence of mucosal neuromas is characteristic (see Fig. 41.2). Some kindred appear to have a third form of MEN2, isolated familial MTC, but care should be taken that other features of MEN2 are not overlooked.

Germline activating mutations of the *RET* (rearranged during transfection) proto-oncogene, which is located on chromosome 10 (10q.11.2), have been identified in all three types of MEN2.

Diagnosis. RET germline mutation testing now forms the basis for carrier identification in MEN2 families. Medullary thyroid carcinomas secrete calcitonin, measurement of which serves as a useful tumour marker to assist in assessment of the response to therapy and for the detection of persistent or recurrent disease. Plasma carcinoembryonic antigen (CEA) concentration may be raised in medullary thyroid cancer and prove a useful additional tumour marker.

Before the establishment of DNA analysis for family screening for MEN2, measurement of calcitonin was often performed for this purpose, either on a

FIGURE 41.2 ■ Typical features of a patient with MEN2B. (Photograph courtesy of Professor A G McGregor)

TABLE 41.1 Surveillance for multiple endocrine neoplasia type 1

Procedure	Condition screened for	Frequency	Age initiated (years)
Glucose (fasting) and insulin	Pancreatic NETs	Yearly	5
Insulin-like growth factor 1	Pituitary tumour	Yearly	5
Prolactin	Pituitary tumour	Yearly	5
Calcium and PTH	Parathyroid tumour	Yearly	8
Chromogranin A, CART	Pancreatic NETs	Yearly	<10
Gastrin	Pancreatic NETs	Yearly	20
Brain MRI	Pituitary tumour	Every 3–5 years (or guided by biochemistry results)	5
Abdominal CT/MRI	Pancreatic NETs	Every 3–5 years (or guided by biochemistry results)	20

NETs, neuroendocrine tumours; PTH, parathyroid hormone; CART, cocaine and amphetamine-related transcript; CT, computed tomography; MRI, magnetic resonance imaging.

basal sample or in response to stimulation with pentagastrin or calcium. Every effort should be made to identify gene carriers among the relatives of patients known to have MEN2 in order to offer prophylactic thyroidectomy against MTC. Strong genotype–phenotype correlation exists in MEN2, which can guide the timing of surgery and the screening protocol for optimal detection of parathyroid tumours and pheochromocytomas.

Imaging. Ultrasonography of the thyroid may be useful. However, when invasion to surrounding structures or distant metastases are suspected, other imaging modalities such as MRI or CT scanning are necessary. ^{99m}Tc-technetium-sestamibi scan is a more sensitive technique for the localization of metastases within the neck and chest. Scintigraphic imaging using ¹²³I- or ¹³¹I-anti-CEA monoclonal antibodies is a promising development for the detection of occult disease and in selecting candidates for repeat neck exploration.

Treatment. If a mutation is found, surgical removal of the thyroid is recommended to prevent tumour development. Postoperatively, patients should be treated with suppressive doses of L-thyroxine. Since calcitonin gene expression is activated in inflamed or septic tissue, calcitonin concentration may remain elevated for 3–6 months after thyroid surgery. It is therefore prudent to delay calcitonin measurement for three months after thyroidectomy. Early and prophylactic total thyroidectomy has probably lowered the mortality from MTC to <5%, well below the cancer-associated mortality in MEN1. RET tyrosine kinase inhibitor drugs are currently being developed and may have a role in the treatment of MEN2-related malignancies in the future. Follow-up of MTC is by measurement of calcitonin and CEA.

Surveillance. Genotype–phenotype correlation in MEN2 may be useful in guiding strategies for surveillance. However, a suggested scheme is that after the age of eight years PTH and calcium should be measured for detection of parathyroid tumours and for detection of pheochromocytoma plasma free metanephrines and/or urinary fractionated metanephrines should be measured, with imaging using MRI or CT every 3–5 years or if biochemistry is abnormal. Patients with familial MTC require only periodic monitoring with imaging if biochemistry is abnormal.

Other familial syndromes associated with multiple endocrine neoplasia

Patients presenting with an endocrine tumour should have a full family history taken, looking for evidence of an inherited syndrome. Single, unilateral and late onset tumours are more likely to be sporadic. In contrast, a familial cause is more likely in a patient who presents early, particularly if there is a family history or if there are multiple tumours or associated cutaneous features.

A further type of MEN (MEN4) has been described caused by mutations in cyclin-dependent kinase inhibitor genes. The exact phenotype is, as yet, poorly defined but includes parathyroid, and sometimes pituitary, tumours and other endocrine features.

Pheochromocytoma is predominately a sporadic disorder. However, in 25% of patients, pheochromocytoma may be familial or associated with a number of autosomal dominant hereditary syndromes. Examples of such syndromes are neurofibromatosis type 1 (NF1), von Hippel–Lindau syndrome and paraganglioma syndrome 1, 3 and 4. The cardinal features of NF1 are neurofibromas and dermal café-au-lait skin pigmentation. Other features include skeletal manifestations, vascular stenoses and a variety of endocrine tumours including pheochromocytoma, somatostatin-producing carcinoid tumours and medullary thyroid cancer. The causative gene encodes a GTP-activating protein, neurofibromin. Von Hippel–Lindau syndrome is a multisystem cancer syndrome associated with retinal and cerebral haemangioblastomas, renal cysts and renal cell carcinomas, pheochromocytomas and islet cell tumours.

Paragangliomas (PGL) are tumours derived from the sympathetic and parasympathetic nervous system. About half are familial. The sympathetic-associated PGL arise from the adrenal medulla or from the sympathetic ganglia. They are generally functional and secrete excess catecholamines. Hereditary PGL are characterized by the development of highly vascularized, slowly growing non-chromaffin tumours arising in the parasympathetic ganglia. Parasympathetic-derived PGL usually develop in the head and neck, most commonly at the bifurcation of the carotid artery, and are usually non-functional. Intraabdominal and thoracic catecholamine-secreting PGL are currently being referred to as pheochromocytomas.

Paragangliomas syndromes have been genetically characterized as PGL 1, 3 and 4 and are caused by mutations in the succinate dehydrogenase (*SDH*) subunit D, C and B genes, respectively (*SDHD*, *SDHC* and *SDHB*); the fourth subunit coded by the *SDHA* gene is not associated with hereditary PGL.

METABOLIC CHANGES IN MALIGNANCY

Introduction

Metabolic changes may herald the clinical onset of malignant disease and are often the cause of considerable morbidity and mortality in patients with cancer. During the rapid growth phase of a neoplasm, the nutritional and metabolic state of the host may become modified in favour of the neoplasm. The tumour-related metabolic changes may be a direct consequence of the presence of the tumour, or be secondary to secretory products of the tumour. These may either be normal secretory products of the cells of origin or substances not normally produced by them. Such metabolic alterations may, on occasions, be useful in the diagnosis and management of malignancy, that is, they act as

tumour markers (see Chapter 42). In this section, some of the metabolic consequences of malignant disease are reviewed.

Paraneoplastic syndromes

A paraneoplastic syndrome is one that is attributable to a neoplasm, not as a direct result of local or metastatic presence of the tumour cells, but owing to substances secreted from them or autoantibodies produced against them. Such disorders may broadly be divided into neurological, humoral and other paraneoplastic syndromes.

Neurological paraneoplastic syndromes

Various neurological paraneoplastic syndromes exist. Some have a classic presentation, e.g. Lambert–Eaton, syndrome, which resembles myasthenia gravis and is associated with small cell carcinoma of the bronchus. Some paraneoplastic syndromes appear to have an autoimmune basis; thus Lambert–Eaton syndrome is associated with the presence of anti-voltage gated calcium channel (VGCC antibodies). The majority of neurological paraneoplastic syndromes are thought to have an autoimmune basis, with an immune response being directed against antigens expressed by the tumour. The resulting antibodies then cross react with components of the nervous system. These antibodies can be detected in blood. In a patient with a neurological presentation, the presence of certain well characterized onconeural antibodies (anti-Ho, Yo, Ma2, CRMP-5, amphiphysin and Ri) enables the diagnosis of a paraneoplastic syndrome to be made whether or not a neoplasm has been detected. Neurological paraneoplastic syndromes and associated tumours and antibodies are discussed further in Chapter 36.

Humoral paraneoplastic syndromes

Humoral paraneoplastic syndromes arise from the secretion of substances from a tissue that does not normally produce them. The term ‘ectopic hormone production’ is used to refer to hormones secreted from sites that are not their physiological origin, in amounts sufficient to cause clinical effects. The ectopic secretion of such hormones tends not to be subject to the usual mechanisms of endocrine regulation and characteristic responses to dynamic function testing may be useful in diagnosis. The hormone itself may sometimes circulate in a molecular form distinct from that secreted from the eutopic source. Treatment of the tumour leads to resolution of the endocrine effects, but these reappear if the tumour recurs, accompanied by a demonstrable concentration of the hormone in serum. Some tumours are particularly associated with such ectopic hormone production, e.g. small cell lung cancer. Various theories have been developed in an attempt to explain the phenomenon of ectopic hormone production by tumours. One theory suggests that some fundamental change occurs at the genomic level that allows novel gene expression for that tissue. Thus, neoplastic change would cause certain genes to be switched on and others to be

switched off. Another theory suggests that the neoplastic cell is derived from a stem cell that was capable of expressing the gene at an early developmental stage but is later suppressed, and that following neoplastic transformation, the cell undergoes dedifferentiation and regains some of its developmental properties. It has also been proposed that some widely expressed genes that are transcribed but not translated under normal conditions may, due to neoplastic transformation, be amplified and translated due to the action of different promoters.

Adrenocorticotropin

Ectopic secretion of adrenocorticotropin (ACTH) can occur with a variety of tumours, but is particularly associated with small cell carcinoma of the bronchus. Its clinical features and diagnosis are discussed in Chapter 18. The most common cause of ectopic ACTH production is the expression of the proopiomelanocortin (POMC) gene by tumour tissue. The *POMC* gene encodes for the 31-kDa precursor of ACTH, β -endorphin and melanocyte stimulating hormone. The principal source of POMC-derived peptides in the body is the pituitary gland; however, POMC immunoreactivity and POMC mRNA can be found in almost all tissues. The mRNA species produced in non-pituitary tissue is shorter than that expressed in pituitary tissue, which is thought to be due to the action of different promoters. One theory is that many tumours express the *POMC* gene, but what determines whether the tumour becomes an ectopic ACTH-secreting tumour is the switching of activity to the more conventional pituitary promoter. Excessive ACTH secretion can also be the result of ectopic secretion of corticotrophin-releasing hormone.

Vasopressin

The synthesis of vasopressin, resulting in the paraneoplastic syndrome of inappropriate anti-diuresis is particularly associated with small bronchial carcinoma, although can occur with other tumours (see Table 41.2). It may present acutely with severe symptomatic, hyponatraemia. This condition is discussed further in Chapter 4. Vaptans, agents which antagonize the action of vasopressin via blockade of the vasopressin receptor, have been used in management.

PTH-related peptide

Hypercalcaemia complicating malignancy is common. Mechanisms include prostaglandin-mediated bone resorption, osteoclast activating factors, e.g. tumour necrosis factors, and the action of PTH-related peptide (PTHrP), a protein with N-terminal amino acid homology with PTH. PTH-related peptide is not detected by most modern PTH assays which measure ‘intact’ PTH, hence the finding of a low PTH with a low phosphate in a hypercalcaemic patient is suggestive of hypercalcaemia secondary to PTHrP. Hypercalcaemia as a feature of malignancy is discussed further in Chapter 6.

TABLE 41.2 Hormones arising from tumours derived from tissue not classically associated with their secretion

Hormones	Associated tumour types
Adrenocorticotrophic hormone, lipotrophin, melanocyte-stimulating hormone, endorphin, enkephalin, other pro-opiomelanocortin fragments	Small cell carcinoma of bronchus Adenocarcinoma of bronchus Bronchial carcinoid tumour Thymic carcinoid tumour Medullary thyroid carcinoma Islet cell carcinoma of pancreas Pheochromocytoma Gut, prostate, neurogenic and parotid tumours
Atrial natriuretic peptide Arginine vasopressin	Small cell carcinoma of bronchus Small cell carcinoma of bronchus Pancreatic carcinoma Breast carcinoma Thymic tumour
Calcitonin (clinically silent)	Small cell carcinoma of bronchus Bronchial carcinoid tumour
Calcitonin gene-related peptide Corticotrophin releasing hormone Erythropoietin	Small cell carcinoma of bronchus Bronchial carcinoid tumour Small cell carcinoma of bronchus Uterine fibroma Cerebellar haemangioblastoma Pheochromocytoma Ovarian tumour
Gastrin releasing peptide	Small cell carcinoma of bronchus Medullary thyroid carcinoma
Glucagon	Non- β islet cell tumour Anaplastic lung carcinoma Renal adenocarcinoma
Growth hormone	Bronchial carcinoma Gastric carcinoma
Growth hormone releasing hormone	Pancreatic islet cell tumour Pheochromocytoma
Human chorionic gonadotrophin	Renal and bladder carcinomas Breast carcinoma Prostatic carcinoma Melanoma Gynaecological carcinomas Head and neck carcinomas Lymphoma
Human placental lactogen Insulin-like growth factor 2 Neurotensin	Lung and testicular tumours Mesodermal and mesenchymal tumours Pancreatic endocrine tumours Carcinoid tumour
Parathyroid hormone-related peptide	Squamous cell carcinoma of head and neck, oesophagus cervix, bronchus Breast and ovarian carcinomas Carcinoma of pancreas Renal and bladder carcinomas Multiple myeloma Histiocytic lymphoma
Prolactin	Anaplastic lung carcinoma Small cell carcinoma of bronchus Renal adenocarcinoma
Renin	Renal adenocarcinoma Adenocarcinoma of pancreas Small cell carcinoma of bronchus Adenocarcinoma of lung Ovarian carcinoma
Somatostatin	Adrenocortical carcinoma Small cell carcinoma of bronchus Duodenal somatostatinoma Extra-adrenal paraganglionoma Pheochromocytoma Medullary thyroid carcinoma
Vasoactive intestinal polypeptide	Bronchial carcinoid tumour Ganglioneuroblastoma Pheochromocytoma Non- β islet cell tumour Small cell carcinoma of bronchus

Tumour-induced osteomalacia

Tumour-induced osteomalacia (TIO) is a paraneoplastic syndrome resulting from the secretion of fibroblast growth factor 23 (FGF-23) by mesenchymal tumours. There may be a relatively long history of musculoskeletal symptoms such as bone pain and muscle weakness and, in children, rickets and growth failure may be observed. Classic biochemical features are normal plasma calcium and PTH concentrations and hypophosphataemia with renal phosphate wasting. Plasma 1,25-dihydroxyvitamin D concentration is low and FGF-23 elevated. The only effective treatment for TIO is resection of the tumour. Medical management is with phosphate supplements and calcitriol.

Other paraneoplastic syndromes and features of malignant disease

Haematological sequelae. Anaemia is the most common haematological abnormality encountered in malignant disease. It may have various causes with differing laboratory findings (Table 41.3). Clinical and laboratory features are discussed further in Chapter 27; examples include anaemia of chronic disease, and folate deficiency resulting from altered metabolism or requirements due to the presence of the tumour. Autoimmune haemolytic anaemia can occur, most commonly in patients with B cell lymphoproliferative disorder, and is thought to be caused by an immune response evoked to antigens common to both the tumour cells and red blood cells. In contrast to idiopathic autoimmune haemolytic anaemia, response to corticosteroid therapy is uncommon. Pure red cell aplasia has been described mainly with thymomas, but also in association with adenocarcinomas, squamous cell carcinomas, anaplastic tumours and, rarely, with lymphoproliferative diseases. The mechanism is thought to be a T cell-mediated phenomenon. Microangiopathic haemolytic anaemia is a serious complication of certain malignancies and occurs when red cells are damaged by passage through blood vessels that have been distorted by either tumour or fibrin deposits. The blood film is characterized by the presence of schistocytes and polychromasia and there is biochemical evidence of haemolysis (increased plasma LDH activity,

reduced haptoglobin concentration and haemosiderinuria). In contrast, some tumours, particularly of the kidneys, may be associated with erythrocytosis: this is thought to be the result of prostaglandin-mediated erythropoietin activity.

Hyperuricaemia. In certain patients with malignancy, predominantly those with leukaemia and lymphoma in whom there is a rapid turnover of cells, or massive cell lysis caused by cytotoxic agents (tumour lysis syndrome), hyperuricaemia can occur. Radiotherapy can produce a similar clinical scenario. Other features of the tumour lysis syndrome include hyperkalaemia, hyperphosphataemia and hypocalcaemia.

The increased filtration of urate and the increasing acidity and concentration of the tubular fluid leads to precipitation and renal obstruction. Adequate hydration is important prior to combination chemotherapy in those at risk and it is standard practice to administer allopurinol, a xanthine oxidase inhibitor, to reduce urate formation. Rasburicase (recombinant urate oxidase) catalyses the conversion of urate to allantoin, which is five to ten times more soluble than urate, and is helpful in reducing plasma urate in severely affected patients. Rasburicase should be avoided in patients with glucose 6-phosphate dehydrogenase deficiency as one of the major by-products of the enzymatic reaction is hydrogen peroxide, which may precipitate haemolysis. Preservation of samples at 4°C, or stabilization with perchloric acid, has been recommended prior to analysis of urate in patients receiving rasburicase, as degradation of uric acid can continue in collection tubes, resulting in a spuriously low urate concentration.

A number of other characteristic paraneoplastic syndromes exist. These include immune-mediated renal disease, thrombosis associated with antiphospholipid antibodies and finger clubbing and hypertrophic pulmonary osteoarthropathy attributed to the action of platelet-derived growth factor.

Cancer cachexia

Weight loss is common in cancer patients and in many, is the presenting feature. Cancer cachexia is a hypercatabolic state characterized by loss of body weight associated

TABLE 41.3 Haematological indices of anaemia in malignant disease

Cause	Hb	Mean cell volume	Mean cell Hb	Mean cell Hb conc.	Reticulocytes	Film	Marrow
Iron deficiency	↓	↓	↓	↓	Normal/↑	Hypochromic microcytic	Reduced iron stores
Folate and/or vitamin B ₁₂ deficiency	↓	↑	↑	Normal	Normal/↑	Macrocytic	Megaloblastic

Marrow infiltration	↓	Normal/↑	Normal/↑	Normal/↑	Normal/↓	Normocytic ± malignant cells	Leukoerythroblastic

Hb, haemoglobin.

with a reduction in adipose tissue and muscle mass and loss of appetite. Weight loss can cause severe morbidity and decrease in quality of life and may be associated with an adverse prognosis and increased susceptibility to side-effects during treatment of the malignancy itself. The aetiology of the weight loss is complex: it appears to involve a combination of increased catabolism and decreased anabolism. The physical presence of the tumour may also contribute to weight loss, e.g. by causing obstruction in the gastrointestinal tract.

The regulation of appetite involves both central and peripheral mechanisms, which are integrated in the hypothalamus. There is no evidence that hypothalamic dysfunction per se is responsible for the cachexia of malignant disease. However, it has been suggested that malignant tissue causes anorexia by the secretion of biologically active molecules that depress feeding by interfering with central control mechanisms, e.g. serotonin from carcinoid tumours and bombesin from small cell bronchial cancers. Cytokines, particularly TNF α and IL-6, are thought to be important in the loss of appetite. They arise from tumour cells and as part of the host immune response; they are able to cross the blood-brain barrier and interact with mechanisms affecting appetite. Iatrogenic factors related to the treatment of cancer can also contribute to weight loss. Chemotherapy often causes nausea and vomiting, and radiotherapy can have short-term effects on the gut

(e.g. mucositis) and cause long-term complications, e.g. enteritis that lead to malabsorption.

Changes in metabolism

Although reduced energy intake is common to both starvation and cancer cachexia, there are marked differences between the metabolic changes seen in the two states (see Table 41.4).

Many patients with cancer are mildly hypermetabolic with a resting energy expenditure greater than normal. However, only a fraction of the increased metabolic rate can be accounted for by the tumour tissue itself. Suggested mechanisms for cancer cachexia are shown in Figure 41.3.

TABLE 41.4 Metabolic changes in cancer cachexia and starvation

	Starvation	Cachexia
Acute phase response	No	Yes
Appetite	Increased	Decreased
Metabolic rate	Decreased	Increased
Skeletal muscle mass	Maintained	Decreased
Adipose tissue	Decreased	Decreased
Liver size	Decreased	Increased

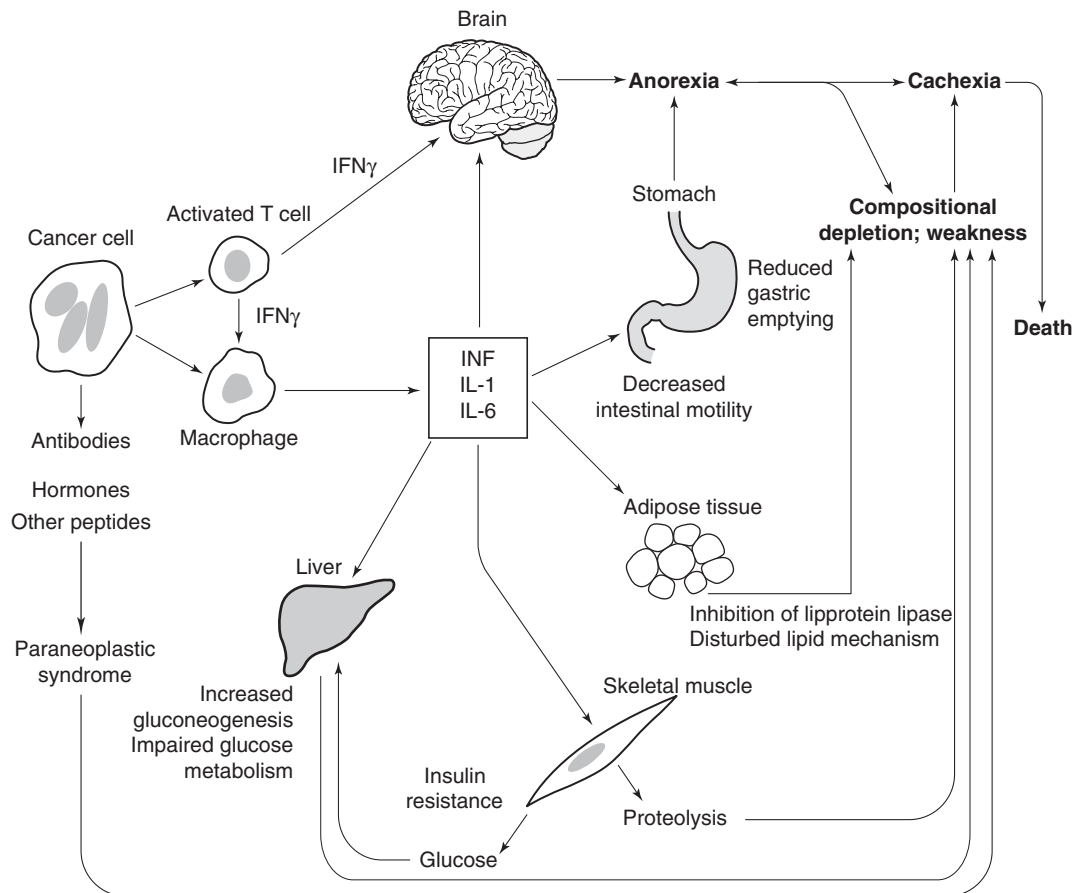

FIGURE 41.3 ■ Possible mechanisms of cancer cachexia.

Many tumours produce energy via anaerobic glycolysis, which results in a net loss of ATP, there is partial uncoupling of oxidative phosphorylation and futile cycles may be activated leading to further energy wastage, e.g. nonesterified fatty acids released from adipose tissue are immediately re-esterified. Free fatty acids are oxidized, even when other energy sources are available, and there is increased protein turnover.

Marked derangements of carbohydrate metabolism are a feature of malignancy. They include abnormal glucose tolerance and hyperglycaemia, hypoglycaemia, lactic acidosis, increased glucose turnover and increased glucose transport into tumour cells. Tumour cells have an increased rate of glucose transport, which may be related to an increase in the number of membrane bound glucose transporters. The main energy source for many tumour cells is anaerobic metabolism of glucose, which results in the production of lactic acid. The lactic acid is then reconverted to glucose in the liver via the Cori cycle. This process also consumes energy, since glycolysis produces only two moles of ATP per mole of glucose, whereas gluconeogenesis consumes six moles of ATP. However, decreased hepatic capacity to utilize lactic acid may lead to its accumulation (lactic acidosis).

Glucose intolerance is a common feature of malignancy, affecting some 60% of cancer patients. Occasionally, frank hyperglycaemia is present. There is insulin resistance (at least with respect to effects on carbohydrate metabolism), although insulin receptor binding appears normal. Fasting insulin concentrations are also normal or slightly decreased but there is a decreased response to both endogenous and exogenous insulin. The picture is further complicated by other factors that may be present in cancer patients, i.e. starvation and malnutrition, sepsis, bed rest, dietary effects and drugs.

Abnormal lipid metabolism is a feature of some malignancies. Some tumours utilize lipids in preference to glucose as a major energy source, with mobilization of free fatty acids from the body's fat stores and a consequent rise in their plasma concentration. Malignant cells may show abnormal lipid composition, particularly with respect to the cholesterol and phospholipid contents of their cell membranes and may synthesize unusual lipids. For example, hepatocellular carcinomas may produce 2-methylolate. Loss of fat mass is facilitated by a tumour-produced lipid mobilizing factor. This appears to be a proteoglycan similar in structure to zinc α_2 -glycoprotein, which acts to sensitize adipose tissue to lipolytic stimuli by increasing production of cyclic AMP within adipocytes.

Patients with malignancy often have a wasting syndrome, where both adipose tissue and lean tissue are lost. The muscle wasting is due to increased protein catabolism as well as decreased synthesis. Proteolysis in cachexia is brought about via increased activity of a number of proteolytic pathways. The major mechanism for proteolysis in cancer cachexia is the ATP ubiquitin-dependent proteolytic pathway initiated in response to cytokines such as TNF α . Lysosomal cathepsins and the calcium/calpain pathway are also involved in proteolysis.

Treatment

Although giving nutrition support to patients with cancer cachexia would seem logical, there is little evidence that provision of energy to patients, via either enteral or parenteral routes, results in weight gain or significant improvement in outcome. Pharmacological management of cachexia has included use of appetite stimulants and drugs intended to counteract catabolism or stimulate anabolism. Corticosteroids have been used to stimulate appetite. Their effect is short lived and is not usually accompanied by weight gain. The progesterone analogue megestrol acetate has been shown to be more effective as an appetite stimulant. Various anabolic agents have been tried in cachexia. Growth hormone has proven efficacy in animal models but its use in clinical settings is associated with increased mortality, possibly owing to diversion of amino acids and energy to skeletal muscle away from the acute phase response. Examples of the use of drugs intended to treat cancer cachexia by modification of the immune response, include thalidomide and pentoxifylline, which both inhibit production of TNF α , and eicosapentaenoic acid, found in fish oil, which can reduce lipolysis produced by lipid mobilizing factor. None of these has been shown to be consistently effective.

ENDOCRINE SEQUELAE OF TUMOURS AND THEIR TREATMENT

With the development of successful therapies for specific malignancies, populations of treated patients are surviving for near-normal life spans. Long-term sequelae are becoming more evident as these survivors are being followed-up (Table 41.5). This section focuses on effects on somatic growth and reproductive capacity.

Effects on somatic growth

Somatic growth may be profoundly suppressed in a child affected with, for example, acute lymphoblastic leukaemia. This effect may be mediated by therapy aimed at destroying the malignant cells, including cranial irradiation with subsequent hypopituitarism, direct radiotherapy to bony structures that determine final height, for example the spine, or the administration of pharmacological doses of glucocorticoids and intensive chemotherapy.

The hypothalamus is more susceptible to radiation damage than the pituitary. Growth hormone secretion appears to be particularly vulnerable to the effects of radiation, and, while doses of 18–50 Gy may lead to decreased growth hormone secretion alone, higher doses (>60 Gy) can cause panhypopituitarism through damage to both the hypothalamus and pituitary. Effects of chemotherapy and glucocorticoids can have significant effects on skeletal development, affecting both final height and bone mineral density. The effects of chemotherapeutic agents on chondrocytes, the extracellular matrix and osteocytes are wide ranging, but evidence for direct effects on chondrocytes' proliferation and

TABLE 41.5 Endocrine sequelae of treatment of malignant disease

Organ affected	Endocrine sequelae
Hypothalamo-pituitary	
Combination chemotherapy: cyclophosphamide, vinca alkaloids, melphalan, cisplatin	Syndrome of inappropriate antidiuresis (SIADH)
Radiation therapy	Panhypopituitarism
Glucocorticoids (pharmacological doses)	Suppression of hypothalamo-pituitary-adrenal axis
	Suppression of growth hormone secretion
	Sick euthyroid syndrome
GnRH analogues	Hypogonadotrophic hypogonadism
Somatostatin	Suppression of growth hormone secretion
Antiemetics (dopaminergic antagonists)	Hyperprolactinaemia
Thyroid	
Systemic illness	Sick euthyroid syndrome
Radiation therapy	Hypothyroidism
Bleomycin, vinblastine, cisplatin (BVP)	Retarded thyroid hormone clearance
Glucocorticoids (pharmacological doses)	Sick euthyroid syndrome
Pancreas	
Combination chemotherapy: vincristine, L-asparaginase, streptozotocin, cyclophosphamide, mitomycin C, 5-fluorouracil	Reduced insulin secretion
Adrenals	
5-Fluorouracil, enzyme inhibitors	Decreased steroidogenesis and hypoadrenalism
Gonads	
Chemotherapy	
Definite: L-phenylalanine mustard, busulphan, cyclophosphamide	Reduced spermatogenesis and suppressed Leydig cell function in the male
Probable: methotrexate, 5-fluorouracil, 6-mercaptopurine	Suppression of ovarian cyclicity and ovarian steroidogenesis in the female
Radiation therapy	Hypergonadotrophic hypogonadism (primary ovarian or testicular failure)
GnRH analogues	Hypogonadotrophic hypogonadism

ossification is limited; however, disruption of growth plate activity will result in skeletal growth disturbance. Chemotherapy seems to enhance the growth-suppressing effects of radiotherapy when they are given in combination, possibly by enhancing the effects of radiation on the hypothalamo-pituitary axis. It has been hypothesized that chemotherapy effects may relate to suppression of IGF1 synthesis in the liver and/or its effects on growth plates.

For growth hormone to effect growth optimally, normal rhythms of secretion must be maintained. This will only occur if there is normal hypothalamo-pituitary function. The secretion of growth hormone may be affected directly as a result of radiation-induced damage to the hypothalamus or pituitary, or secondarily, for example, by depression, which can accompany any severe illness and is associated with impaired growth hormone secretion. Thyroid hormone and glucocorticoids are necessary for the efficient biological activity of growth hormone; the secretion of either may be decreased following radiotherapy to the hypothalamo-pituitary unit and lead indirectly to impairment of growth. Pharmacological doses of glucocorticoids suppress growth hormone secretion. Additionally, they cause a degree of functional hypogonadism (hypogonadotrophic hypogonadism). If gonadal steroidogenesis is suppressed, the pubertal growth spurt will not occur and final height will be compromised. Glucocorticoids and gonadal steroids ultimately bring about long bone epiphyseal fusion. Their pharmacological use may hasten this fusion and so prevent the attainment of the

genetic potential for final height. Low-dose cranial irradiation can also result in early puberty with long bone fusion before attainment of final height.

Strategies to promote growth in these patients can be divided into two groups: either the use of growth hormone replacement in growth hormone deficient individuals, or the use of GnRH analogues to delay puberty in those in whom it is occurring early. Earlier and more aggressive use of growth hormone in those who are growth hormone deficient has resulted in improvements in final height, with safety data suggesting that this does not lead to an increased risk of tumour recurrence. Caution should be exercised, however, as longer term follow-up data are not yet available to determine whether there is an increase in secondary neoplasms. The use of GnRH analogues in combination with growth hormone therapy is more controversial: only some of the few studies suggest an improvement in final height.

Reproductive consequences of therapy

Disease itself, or radiotherapy or chemotherapy directed against populations of actively dividing cells, may influence reproductive potential. This effect may be mediated by a direct action on the germ cell population or be an indirect effect mediated by suppression of hypothalamic GnRH or pituitary gonadotrophin secretion. Specific guidelines are available that may help to predict doses of radiotherapy that may be tolerated, or drug combinations that are less likely to cause depletion of the germ cell pool. Thus, a chemotherapeutic regimen of adriamycin,

bleomycin, vinblastine and dacarbazine (ABVD) is less likely to cause infertility than the alternative regimen of nitrogen mustard, oncovin, procarbazine and prednisone (MOPP) in the treatment of Hodgkin disease, a fact that may influence the choice in a young patient who is anxious to subsequently have a family. As the germ cell pool is greater in younger than older women, the risk of ovarian failure as a result of treatment increases with age. Use of GnRH analogues to suppress oocyte maturation via the hypothalamo–pituitary axis and to make the germinal epithelium quiescent (a premenarche state) has shown some success in protecting ovarian function against chemotherapy in human and animal studies. Other strategies that may be used include oophoropexy (an operation to relocate the ovaries anatomically so that they are shielded from the radiotherapy field) or sperm banking prior to therapy. Freezing ovarian tissue pre-chemotherapy with transplant post-chemotherapy has been shown to be successful at restoring function, including fertility, although this process carries with it the potential risk of the re-introduction of tumour cells.

Radiotherapy can affect the uterus, with a decrease in its volume and changes in its musculature and vascular supply. Embryos or oocytes can be frozen prior to therapy, but success rates for subsequent viable pregnancy are limited by the freeze–thaw process. Furthermore, the time factor involved in stimulating a population of oocytes for retrieval prior to commencement of therapy often militates against this, and ovarian stimulation itself has the potential to increase tumour growth in oestrogen-sensitive tumours.

Some tumours, such as prostatic or breast cancers, are actively stimulated by a particular endocrine milieu. Thus, androgens stimulate the growth of prostatic cancer, while oestrogens may encourage the growth of breast cancer. Direct modulation of the endocrine axis may, in itself, constitute therapy for these particular malignancies. Thus growth of prostatic cancer may be suppressed by orchidectomy or by suppression of the hypothalamo–pituitary–testicular axis by a depot injection of a GnRH analogue. This seeming paradox may be explained by the fact that chronic stimulation with GnRH is associated with downregulation of pituitary receptors and inhibition of gonadotrophin release. Alternatively, the

target organ effect of androgens may be blocked by the administration of an anti-androgen such as cyproterone acetate or flutamide. In women, oestrogen effects may be opposed by the administration of an anti-oestrogen, such as tamoxifen, or the use of an aromatase inhibitor such as 4-hydroxyandrostenedione, which blocks the penultimate step in oestrogen biosynthesis.

These patients have specific concerns not just about their reproductive capacity, but also about the likelihood of transmission of the malignancy to their offspring or the risk of damage to their germ cells, making fetal malformation more likely than in the normal population. With the exception of the heritable syndromes, there is no evidence of an increased likelihood of malignancy or an increased risk of fetal malformation in progeny of treated patients at the present time.

CONCLUSION

Tumours can have profound metabolic effects, even when very small. These can be due to the physical presence of the tumour, to the products of its secretion (whether expected on the basis of its tissue of origin or not) or to the body's response to the presence of the tumour. Metabolic derangements can also occur as a side-effect of treatment, whether this be surgical or with radiotherapy or chemotherapy.

SUMMARY 842

INTRODUCTION

Tumour markers are substances (often proteins, enzymes or hormones) that are present in body fluids or tissues and whose measurement provides information about the presence, progression or remission of tumours. They may be tumour-derived (produced within the tumour by malignant or stromal cells) or tumour-associated (produced by non-malignant cells as a metabolic consequence of tumour presence). Some are tumour-specific (produced by cancerous but not normal tissue), while others are present in normal tissue but are produced at higher concentrations in body fluids or malignant tissue from cancer patients. A few are organ-specific but many are produced by a variety of different cancers.

Histopathological identification of tumour markers expressed at the tumour cell surface and detectable in biopsy specimens can provide both diagnostic and prognostic information, with genetic tests becoming increasingly important in predicting which patients are most likely to respond to costly new therapies. Secreted tumour markers, present in blood or other body fluids, are measured quantitatively, often by immunoassay. While knowledge of circulating marker concentrations may assist in diagnosis and prognosis, their most important clinical use is in monitoring the success of treatment.

This chapter focuses primarily on the properties and clinical applications of the tumour marker tests that usually fall within the remit of clinical biochemistry laboratories (Tables 42.1 and 42.2), with the aim of enabling

readers to provide advice about which tumour marker tests are most likely to be helpful, to recognize which results require immediate action, and to develop a high-quality interpretative tumour marker service. Before considering these aspects, however, it is useful to review some recent developments relevant to the introduction of tumour markers into routine clinical practice. Abbreviations used in the chapter for the names of individual tumour markers are explained in Tables 42.1 and 42.2.

Evaluation of the clinical utility of tumour markers

Although hundreds of potential tumour markers have been investigated, with more than 200 000 papers describing them, the number that contribute significantly to the management of cancer patients is remarkably small, as is evident in Tables 42.1 and 42.2. Historically, over-enthusiastic reporting of small, poorly designed studies of new markers has led to disillusionment when the results have not been confirmed in larger studies or in other centres. Together with the difficulties inherent in comparing different studies reported in non-standard form, this has made objective assessment of the utility of many tumour markers very difficult and has meant that the recommendations made by expert panels about their clinical use tend to be conservative.

The three critical factors that should be considered when evaluating a tumour marker are its clinical utility,

TABLE 42.1 Characteristics of commonly requested tumour markers

Tumour marker	Biochemical properties	Molecular weight	Main clinical applications	Limitations of use
Alkaline phosphatase	Phosphohydrolase	Variable	Raised activities associated with the presence of liver and or bone metastases	Raised in pregnancy and in children, and in non-malignant liver and bone disease
α -Fetoprotein (AFP)	Glycoprotein, 4% carbohydrate; considerable homology with albumin	~70 kDa	Diagnosis and monitoring of hepatocellular carcinoma, hepatoblastoma and germ cell tumours Prognosis of germ cell tumours	Raised in pregnancy and neonates, and in benign liver disease, gastric and other gastrointestinal (GI) tract tumours, e.g. oesophageal and pancreatic
Cancer antigen 125 (CA125)	Mucin identified by monoclonal antibodies OC125 and M11 Developed from serous cystadenocarcinoma cell line OVCA 433	~200 kD	Monitoring ovarian carcinoma Determination of the risk of malignancy index (RMI) for ovarian carcinoma	Raised in patients with pleural effusions, ascites or free fluid in the pelvis, and congestive cardiac failure Also raised in benign renal and liver disease, and in other adenocarcinomas Mildly raised during menstruation and in the first two trimesters of pregnancy Variably raised in endometriosis. May be increased by peritoneal trauma, e.g. postoperatively
Carcino-embryonic antigen (CEA)	Family of glycoproteins, 45–60% carbohydrate	~180 kD	Monitoring colorectal adenocarcinomas	Absent or low concentrations in poorly-differentiated tumours, poor sensitivity for malignancy in early disease, slightly raised in benign renal, liver, lung and GI disease Also raised in other malignancies, including breast, gastric, lung, mesothelioma, oesophageal and pancreatic Smokers may have higher concentrations than non-smokers Contamination with saliva may markedly increase concentrations
Human chorionic gonadotrophin (hCG)	Glycoprotein hormone consisting of two non-covalently bound subunits (α and β); α -subunit similar to LH, FSH, TSH; β -subunit considerable homology with LH	~36 kD	Diagnosis, prognosis and monitoring of germ cell tumours and gestational trophoblastic neoplasia	Raised in pregnancy and in other tumours, e.g. lung Use of cannabis can transiently elevate serum concentrations in patients with germ cell tumours
Lactate dehydrogenase (LDH)	Enzyme of the glycolytic pathway	Variable	Diagnosis, prognosis and monitoring of germ cell tumours To monitor a wide range of malignancies, including haematological	Elevated in cardiac and benign liver disease and some anaemias of non-malignant cause
Paraproteins	Monoclonal immunoglobulins	Variable	See Chapter 30	
Prolactin	Pituitary hormone.	~22 kD but high molecular forms also exist	See Chapter 18	
Prostate-specific antigen (PSA)	Glycoprotein; member of the kallikrein family with serine protease activity Circulates as free enzyme or complexed to α_1 -antichymotrypsin (measurable) or α_2 -macroglobulin (not detected by most immunoassays)	~30 kD (free enzyme)	Diagnosis, risk assessment and monitoring of prostatic carcinoma Lower concentrations of free PSA relative to complexed PSA (i.e. free: total ratio) found in prostatic cancer as compared with benign prostatic hypertrophy	Essentially organ-specific but elevated in both benign and malignant prostatic disease, serum concentrations increase with age Transiently elevated in urinary tract infections, prostatitis, acute retention and following catheterization or other manipulation of the prostate (e.g. prostatic biopsy, transurethral resection of the prostate) Specimens for free PSA should be analysed within 4 h of sampling or stored frozen until assayed

TABLE 42.2 Characteristics of less readily available tumour markers

Tumour marker	Biochemical properties	Molecular weight	Main clinical applications	Limitations of use
Calcitonin Cancer antigen 15-3 (CA15-3), BR 27.29	32 amino acid peptide Mucin (MUC-1 glycoprotein peptide) identified by monoclonal antibodies	~3.5 kD >250 kD	See Chapter 19 Monitoring breast cancer	Raised in benign liver, breast and ovarian disease and in other malignancies, e.g. lung, colon, ovary
Cancer antigen 19-9 (CA19-9)	Glycolipid carrying the Lewis blood group determinant	~1000 kD	Monitoring pancreatic carcinoma following curative resection	Not detected in subjects negative for the Lewis blood group determinant Raised in obstructive jaundice, cholestasis, cirrhosis, hepatitis, pancreatitis and non-malignant GI disease Contamination with saliva may markedly increase concentrations
Catecholamines Chromogranin A	Biogenic amines Member of the granin family of acid secretory glycoproteins	~0.2 D ~49 kD	See Chapter 38 Monitoring neuroendocrine tumours	Raised in renal, liver and cardiac failure
CYFRA 21-1	Fragments of cytokeratin 19	~30 kD	Monitoring lung carcinoma	Contamination with saliva may markedly increase concentrations
Gut hormones, e.g. vasoactive intestinal peptide (VIP), pancreatic polypeptide (PP), somatostatin, gastrin	Small peptide hormones	Variable	See Chapter 12	
Human epidermal growth factor receptor-2 (HER-2 or c-erb2)	Transmembrane glycoprotein encoded from <i>HER-2/neu</i> oncogene	185 kDa	Predicting response to trastuzumab (Herceptin®)	
Human epididymis protein 4 (HE4)	Product of the <i>WFDC2 (HE4)</i> gene that is over-expressed in patients with ovarian carcinoma	~25 kD	Monitoring ovarian cancer. Potentially an aid in diagnosis as part of the risk of malignancy algorithm (ROMA) Under evaluation	Higher concentrations in postmenopausal women
Inhibin A (α - β_A) Inhibin B (α - β_B)	Heterodimeric glycoproteins composed of an α - and a β -subunit. There are several forms of the β -subunit	32 kDa	Monitoring of ovarian granulosa cell tumours and testicular Sertoli and Leydig tumours	
β_2 -Microglobulin	Component polypeptide chain of the HLA antigen complex	~11 kD	See Chapter 30	
Neuron specific enolase (NSE)	Dimer of the enzyme enolase	~87 kD	Monitoring small cell lung carcinoma, neuroblastoma and neuroendocrine tumours	Haemolysis must be avoided Specimens should be separated within 1 h
Oestrogen receptor (ER)	Nuclear transcription factor	~5 kD	Predicting response to endocrine therapy in breast cancer Part of the histological assessment of tissue specimens	
Prostate cancer gene 3 protein (PCA3)	Protein product of <i>PCA3</i> gene in urine of prostate cancer patients	~86 kD	Potentially an aid to diagnosis of prostate cancer particularly in biopsy-negative men Under evaluation	
Placental alkaline phosphatase (PLAP)	Heat-stable isoenzyme of alkaline phosphatase	~86 kD	Monitoring of germ cell tumours (seminomas)	Raised in smokers

(Continued)

TABLE 42.2 Characteristics of less readily available tumour markers (Continued)

Tumour marker	Biochemical properties	Molecular weight	Main clinical applications	Limitations of use
Progesterone receptor	Nuclear transcription factor	A form: ~4 kD B form: ~120 kD	Predicting response to endocrine therapy in breast cancer Part of the histological assessment of tissue specimens	
Squamous cell carcinoma antigen (SCC)	Glycoprotein sub-fraction of tumour antigen T4	48 kD	Monitoring squamous cell carcinomas	Contamination with saliva or skin may markedly increase concentrations
S-100	Polypeptide homodimer		Melanoma	
Thyroglobulin (Tg)	Glycoprotein dimer of two identical subunits	670 kDa	Monitoring differentiated thyroid cancer	Raised in benign thyroid disease Potential assay interference from autoantibodies
Tissue polypeptide antigen (TPA)	Fragments of cytokeratin 8, 18 and 19	~22 kD	Monitoring bladder and lung carcinoma	Contamination with saliva may markedly increase concentrations

TABLE 42.3 Examples of applications of tumour marker measurements at different stages of diagnosis and treatment

Application	Examples
Assessment of risk	PSA: used with or without digital rectal examination to assess risk of prostate cancer and determine the need for biopsy
Screening	HCG: screening of women who have had a previous molar pregnancy and who are at high risk of developing choriocarcinoma
Differential diagnosis	CA125: together with menopausal status and ultrasound findings, contributes to calculation of the risk of malignancy index in the differential diagnosis of women with pelvic masses
Prognosis: prediction of relapse or progression: in primary disease	CEA: measurement at three-monthly intervals following curative surgery in patients to assess need for further treatment
in metastatic disease	Thyroglobulin: following ablation of the thyroid, increasing serum concentrations suggest an alternative site of production
Prognosis: prediction of response to therapy: in primary disease	Oestrogen and progesterone receptors: their presence or absence in breast cancer tissue determines whether endocrine therapy is likely to be effective
in metastatic disease	AFP, hCG and LDH: in patients with germ cell tumours, concentrations of these markers are used to assess prognosis
Monitoring course of disease	
To detect relapse in patient with no evidence of disease post-therapy	AFP, hCG and LDH used in the follow-up of patients treated for germ cell tumours
To follow detectable disease	CA125 used to monitor ovarian cancer patients

the magnitude of the benefit of its use and its reliability. Tumour marker measurement can provide information at multiple stages of diagnosis and treatment (Table 42.3) but, until appropriate studies have been performed, it can be difficult to know how best to use a tumour marker in particular circumstances. Having identified a specific use (i.e. utility), the clinical value (i.e. magnitude) of using the tumour marker for that application needs to be assessed, by evaluating the difference in outcome between marker-positive patients and marker-negative patients, ideally in a randomized controlled trial designed for the purpose. Clinical precision and accuracy (i.e. reliability) then need to be established, since the marker will only be useful if results are reproducible. In this context, it is important to note that, although it is necessary to demonstrate a statistically significant difference in tumour

marker concentrations between patient groups to show that a marker may have potential utility, this is not in itself sufficient evidence that a marker is of clinical benefit (i.e. that it should be used), but merely suggests that the differences observed are not likely to occur by chance. It is also essential to ensure that biochemical analysis of the marker is reliable and reproducible, that assays are standardized and that their analytical and clinical performance is tested objectively in appropriately designed and well-conducted studies.

The Tumour Marker Utility Grading System (TMUGS), developed some years ago, provides a useful framework for such evaluation and it is encouraging that the recommendations made therein have been implemented for some analytes, e.g. by improvements in the standardization of immunohistochemical assays for HER-2 and in

the analytical accuracy and equimolarity of serum assays for PSA. The TMUGS also describes levels of evidence for grading the clinical utility of tumour markers, an approach that has been adopted by the US National Academy of Clinical Biochemistry (NACB), which has developed Laboratory Medicine Practice Guidelines for the use of tumour markers in the clinic. Other initiatives include development of Reporting Recommendations for Tumor Marker Prognostic Studies (REMARK), which provide guidance about study design, pre-planned hypotheses, patient and specimen characteristics, assay methods and statistical analysis methods and complement the broader statements on Consolidated Standards of Reporting Trials (CONSORT) and Standards for Reporting of Diagnostic Accuracy (STARD). These should help to encourage improved design and publication of tumour marker studies in the future.

Tumour marker requests and the responsibilities of the clinical laboratory

Reasons for requesting tumour markers

Knowledge of tumour marker results can contribute useful clinical information relating to different aspects of patient management (Table 42.3). For use in screening and diagnosis, the 'perfect' tumour marker would be absent in all healthy subjects (100% specificity), would be raised in all patients with a single tumour type (100% sensitivity) and its serum concentration would accurately reflect tumour size. Unfortunately, the 'perfect' marker does not exist and the extent to which currently available markers meet this ideal is very variable. Consequently, the predictive value of a positive or negative result also varies and is highly dependent on the population considered (see Chapter 2 for detailed discussion).

There is increasing interest in improving the specificity of some markers (e.g. AFP, CA125 and PSA) by using serial measurements to assess the rate of change in the concentration of the marker with time in individual patients. Such measurements may contribute to diagnosis, but in practice, are more likely to aid post-treatment monitoring, which is the most established clinical role for tumour markers. Whether such monitoring improves patient outcome depends on the availability of further treatment options, should increases in marker concentrations indicate progressive disease. If potentially curative treatment is available, as for example is frequently the case for patients with recurrent germ cell tumours, it is essential to identify patients with rising tumour marker concentrations promptly; failure to do so may constitute a critical clinical error. However, if alternative therapy is not available, knowledge of progressive disease before it is clinically evident may not benefit the patient and can have adverse psychological consequences, in which case it may be advisable to discontinue tumour marker monitoring. Serial monitoring is also desirable for patients with cancers that are unlikely to progress and for which treatment is not necessary or can be delayed: active surveillance (sometimes called 'watchful waiting') programmes, including serial PSA measurements, are appropriate for some men with indolent prostate cancers.

Choice of tumour marker test

In practice, the clinical biochemistry laboratory receives three types of tumour marker requests: those for patients with diagnosed malignancy who have already been referred to specialist centres; those for patients being investigated for suspected malignancy in secondary care, and those for patients presenting to their general practitioners. Requests in the first group are the most likely to be appropriate and are usually made to clarify the patient's diagnosis or to monitor response to treatment and/or detect recurrence.

Non-specialist users, whether in hospital or general practice, should be encouraged to consider carefully whether knowledge of a tumour marker result is likely to be helpful before requesting it. Requests such as 'tumour marker screen' or '?malignancy', particularly from emergency departments and other receiving units, should be actively discouraged. Since it is not usually practicable for requests to be scrutinized prior to analysis, laboratories should provide comprehensive advice about appropriate choice of tumour markers, as well as reminders of their limitations. Most tumour markers do not have sufficient sensitivity or specificity, particularly for early stage disease, to be regarded as diagnostic tests, although they may contribute to diagnosis. Importantly, whatever the malignancy or tumour marker, a result within the reference interval never excludes malignancy or progressive disease.

Requestors should be aware that the converse is also true. Raised tumour marker concentrations do not necessarily indicate malignancy, as they may be increased in a number of benign conditions. Increased concentrations may be associated with more than one tumour type, since, with few exceptions, tumour markers are not organ-specific. Clinical biochemists themselves should also think carefully before requesting any additional testing which may lead to a diagnosis of malignancy and before doing so should seek the agreement of the doctor managing the patient. General advice that can be readily disseminated to non-specialist users has recently been prepared by Pathology Harmony UK.

Pre-analytical requirements

Although the timing of blood sampling is not usually critical, a pre-treatment specimen is helpful when interpreting subsequent results. Specimens should always be taken before any investigative procedure, since some of these may cause transient releases of tumour markers into the circulation (e.g. increases of PSA following insertion of a urinary catheter or prostatic biopsy, of CA125 following abdominal surgery, and of CEA following colonoscopy). Possible conditions, which can transiently affect tumour marker concentrations (e.g. marked increases of PSA in men with active urinary tract infections or of CA19.9 in patients with cholestasis) should be excluded. Failure to recognize that misleadingly high results can be obtained if sampling times are inappropriate may cause undue distress to the patient, as well as decreasing confidence in laboratory testing. Some additional examples are listed in Tables 42.1 and 42.2.

TABLE 42.4 International standards (IS), reference preparations (IRP) and reference reagents (IRR) for tumour markers

Tumour marker	Code	Year established	Description
International standards and reference preparations			
AFP	IS 72/225	1972	Crude cord serum (50%): mass units
CA125	No International Standards yet available		
CA15-3			
CA19-9			
CEA	IRP 73/601	1973	CEA purified from liver metastases of primary colorectal cancer: arbitrary units
hCG	IS 07/634	2007	Highly purified urinary hCG: arbitrary units and molar units
hCG α	IS 75/569	1975	Arbitrary units
hCG β	IS 75/551	1975	Arbitrary units
International reference reagents			
hCG	IRR 99/688	2001	Highly purified: molar units
hCGn	IRR 99/642	2001	Nicked form of hCG: molar units
hCG α	IRR 99/720	2001	Highly purified urinary hCG α , dissociated from hCG: molar units
hCG β	IRR 99/650	2001	Highly purified, free from intact dimer: molar units
hCG β n	IRR 99/692	2001	Partially degraded hCG β : molar units
hCG β cf	IRR 99/708	2001	Molar units
PSA	IRR 96/670	2001	90:10 ratio of bound to free PSA: mass units
fPSA	IRR 96/668	2001	Purified free PSA: mass units
Thyroglobulin	CRM 457	1996	Purified thyroglobulin: mass units

Most currently available immunoassays are calibrated against the relevant standards where they exist. The lack of international standards for the CA antigens is a major hindrance to improved between-method comparability. hCG α , hCG α -subunit; hCG β , hCG β -subunit; hCGn, nicked hCG; hCG β n, nicked hCG β -subunit; hCG β cf, hCG β -core fragment. International Standards and Reference Reagents are available from the National Institute for Biological Standards and Control, Potters Bar, Herts, UK: http://www.nibsc.ac.uk/catalog/standards/preps/sub_endo.html

Analytical requirements

Manufacturers' instructions should always be followed when performing tumour marker measurements, with carefully defined internal quality control (IQC) and external quality assessment (EQA) procedures in place to monitor performance. Internal quality control and EQA specimens should closely resemble patient sera and be of clinically relevant concentrations, including those near important decision limits. Regular assessment of reproducibility and stability of results with time is particularly important for all tumour markers, as these are often monitored over long periods. Ensuring good reproducibility at low concentrations is critical where treatment may be instituted solely on the basis of a relatively small increase in tumour marker concentration, as is the case for AFP and hCG in germ cell tumours and for PSA following prostatectomy for prostate cancer.

Major international efforts are being directed towards improved comparability of tumour marker methods by encouraging accurate calibration against the relevant international standards where these exist (Table 42.4), by producing reference reagents to enable improved characterization of assays, by organizing collaborative workshops to identify the most clinically appropriate antibody specificities and by encouraging use of equimolar assays where relevant (e.g. PSA assays that recognize free and complexed PSA equally well). Nevertheless, the molecular heterogeneity of most tumour markers (as illustrated by the number of hCG-related molecules in Table 42.4) means that results obtained with different methods are not interchangeable. Clinical biochemists should be aware of the characteristics of the methods used in their own laboratory. They should also be familiar with the vulnerability of their methods to potential interferences such as the high-dose hook effect, specimen carry-over and interference from heterophilic or human anti-mouse antibodies (Box 42.1).

BOX 42.1 Potential causes of misleading results that are particularly relevant to tumour markers

High-dose hook effect

- Possible tumour marker concentrations range over several orders of magnitude. Protocols permitting identification of high-dose 'hooking' are essential to avoid reporting misleadingly low results, particularly in patients for whom markers are being measured for the first time. (Hook effects can be minimized by using solid-phase antibodies of higher binding capacity, by assaying specimens at two dilutions, or by using sequential assays that include a wash step.)

Specimen carry-over

- Potentially a problem whenever very high concentration specimens are assayed, so should occasionally be checked

Interference from heterophilic or human anti-mouse antibodies (HAMA)

- Falsely high or low results may be obtained for patient specimens containing anti-immunoglobulin G (IgG) antibodies capable of reacting with antibodies used in the assay. Presence of HAMA, frequently induced in cancer patients who have undergone treatment with mouse monoclonal antibodies for imaging or therapeutic purposes, may also give erroneous results. Such interference can be detected by re-assaying the specimen after treatment with a blocking agent (which is commercially available immobilized on tubes), by adding further non-immune mouse serum to the reaction mixture, or by re-assaying the specimen by a different method. An example of such interference is given in Table 42.8.

Reporting of tumour marker results

Cumulative and/or graphical reporting of serial results can identify trends in marker concentrations, which are generally more informative than single values, and may alert the laboratory to unexpected results (e.g. sudden changes) that require further investigation. Recording brief clinical information (e.g. 'postoperative'), preferably both in the laboratory computer and on any printed reports, can be helpful both in identifying results that are out-of-accord and when interpreting results.

In view of method-related differences in tumour marker results, it is recommended that the method used is stated on the clinical report. If there has been an intervening method change, it is highly desirable that the laboratory also indicates whether this is likely to have affected interpretation of the trend in results. Reference intervals specific to the method used should be provided, although for serial monitoring, the patient's own baseline provides the most important reference point for future results. Laboratory and clinical staff should engage in active dialogue about appropriate clinical decision points (e.g. when using PSA measurements to select patients for biopsy) and should know how these limits were derived. Laboratories can increase the value of their reports by adding short interpretative comments relating to the analytical results and preferably individually tailored to the requestor (e.g. omitting these for specialist users). Tumour marker half-lives, which are defined as the time to 50% reduction of circulating tumour marker concentrations following complete removal of tumour tissue, provide an important measure of the efficacy of therapy, particularly for germ cell tumours, and it may be helpful for the laboratory to calculate these for AFP and hCG (see p. 833 for further information). Providing advice about whether a change in marker concentration is likely to be significant or not is also helpful and should take into account both biological and analytical variation. A confirmed increase of 30%, or two serial increases of 20–25%, are often considered to be of clinical significance. Recommendations about the need for confirmatory specimens and the desirable frequency of tumour marker measurements are also helpful.

The clinical biochemist should identify urgent results that may be required for immediate patient management and ensure that these reach the relevant clinician promptly, telephoning results when appropriate. Results in this category include those which can be used to diagnose advanced disease in critically ill but treatable patients (e.g. AFP in hepatoblastoma; hCG in choriocarcinoma; AFP and hCG in non-seminomatous germ cell tumours; PSA in men with advanced prostate cancer that may respond to endocrine therapy). Provision of a proactive and high-quality tumour marker service helps to encourage good communication between laboratory and clinical staff, and is likely to facilitate both appropriate use of tumour marker tests and early identification of any results that are not in accord with the clinical picture. An example of a laboratory report meeting many of these requirements is shown in [Figure 42.1](#).

TUMOUR MARKERS IN THE MANAGEMENT OF SPECIFIC CANCERS

Regularly updated national guidelines on the management of the majority of tumours are now widely

available, often provided electronically on the world-wide web. Regional cancer networks are also a valuable source of information and have often developed modified versions of national guidelines tailored for local use. The optimal use of tumour markers for assessment of prognosis, monitoring treatment and detecting recurrent disease has been studied in most detail for choriocarcinoma and germ cell tumours, relatively rare diseases for which tumour marker measurements are mandatory for clinical management. Measurements of serum tumour markers also contribute significantly to the management of some of the more common malignancies (e.g. ovarian, colorectal and prostate), while they are less widely used in others (e.g. bladder, breast and lung). In the following sections, the extent to which tumour markers currently contribute to the clinical management of a number of important malignancies is briefly reviewed.

Bladder cancer

The most common symptom of bladder cancer is intermittent haematuria, which is present in 80–85% of patients. The majority of bladder cancers are transitional cell carcinomas but adenocarcinomas, squamous cell carcinomas and sarcomas also occur. In some patients, urine cytology is positive for tumour cells, but the diagnosis is usually established by cystoscopic evaluation.

Urine cytology is very effective in detecting high-grade bladder cancers but will miss the majority of papillary urothelial neoplasms of low malignant potential. Commercially available assays for two tumour markers present in urine have been approved by the United States Food and Drug Administration (FDA) for the detection of recurrent bladder cancer. The BTA (bladder tumour associated antigen) -Trak™ and -Stat™ tests detect complement factor H and related proteins, which are involved in the regulation of the alternative pathway of complement activation to prevent complement-mediated damage to healthy cells. A point of care version of this test is also available. The nuclear matrix protein 22 (NMP22™) test is a quantitative measure of the nuclear mitotic apparatus protein, a component of the nuclear matrix which is over-expressed in bladder cancer. Both these tests are more sensitive than cytology in detecting low grade bladder cancers but are less specific, and their high false positive rates limit their clinical application. Better specificity has been achieved with a fluorescence in situ hybridization assay (UroVysion™), which detects bladder cancer-associated aneuploidy of selected chromosomes and which has been approved by the FDA for screening patients for recurrent bladder cancer.

Breast cancer

Breast cancer is by far the most common cancer affecting women worldwide with approximately one million new cases diagnosed each year. The main presenting features in women with symptomatic breast cancer include a lump in the breast, nipple change or discharge and skin contour changes.

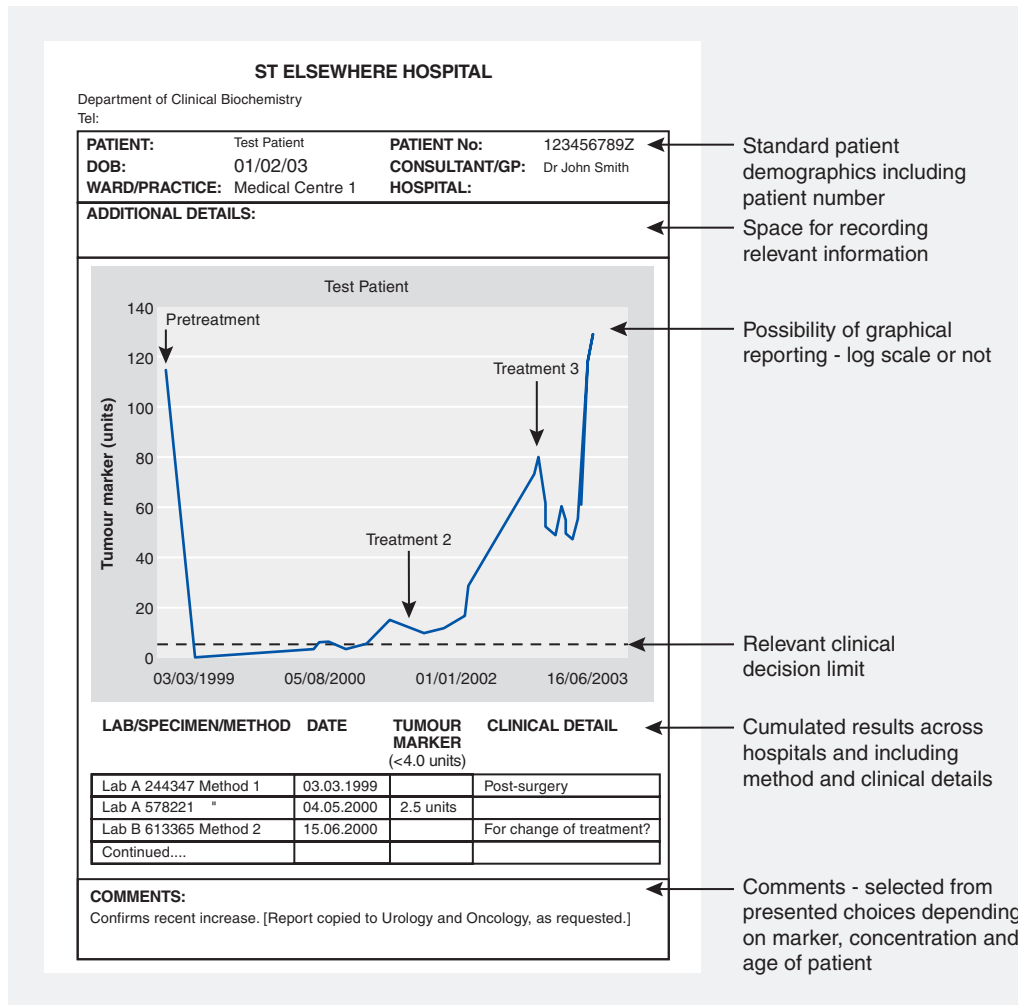

FIGURE 42.1 ■ Possible template for a clinical laboratory report for tumour markers that fulfil current reporting recommendations.

Screening and diagnosis

Currently available blood-based biomarkers are of no value in the early diagnosis of symptomatic or asymptomatic breast cancer, the latter being addressed by national screening programmes using mammography. Individuals who are at increased risk of breast cancer because they are carriers of the *BRCA1*, *BRCA2* or *TP53* genetic mutations and those with a strong family history of breast cancer (e.g. close relatives diagnosed with breast cancer at a young age) may be eligible for screening with magnetic resonance imaging (MRI), as is recommended in the UK by the National Institute for Health and Care Excellence (NICE). Definitive diagnosis requires biopsy and histopathology.

Prognosis

Measurement of oestrogen-binding receptors (ER) and progesterone-binding receptors (PR) in tumour biopsy tissue obtained at diagnosis is mandatory in order to determine the likely response to endocrine therapy of both early and advanced (metastatic) breast cancer. Early ligand-binding and enzyme-linked immunosorbent assay methods

for measuring ER and PR have been superseded by immunohistochemical assessment, which can be performed on paraffin-fixed tissue sections of the smaller tumours now detected by screening. Immunohistochemical or fluorescence in-situ hybridization tissue measurement of HER-2 (or its gene), a glycoprotein that controls cell growth and is amplified in ~30% of early-stage breast cancers, is now essential in all newly diagnosed patients with breast cancer. Patients with tumours that do not produce HER-2 are not likely to benefit from treatment with trastuzumab (Herceptin®), a humanized monoclonal antibody against HER-2, either administered on its own or in addition to other chemotherapy treatment. An assay is available for the measurement of the soluble shed form of HER-2 in serum and has potential value, both for prognosis and for monitoring trastuzumab therapy in patients with advanced breast cancer. However, the serum assay is not widely used.

Monitoring

CA15-3, a high molecular weight mucin, and similar MUC-1 based glycoprotein markers (e.g. BR27-29) may be used to monitor response to treatment, rising serum concentrations providing early indication of progression

in some patients. Their routine use is not currently recommended, since there is as yet no evidence that therapeutic intervention prior to radiological or clinical detection of recurrent tumour is beneficial. However, in individual patients, measurement of CA15-3 may help to determine whether bone symptoms are due to benign or malignant disease, as high concentrations are frequently associated with metastatic disease. CA15-3 may also be useful in monitoring response to therapy in advanced disease if there are no other indicators of response and if rising concentrations would be an indication to stop all but palliative treatment. As with other tumour markers, the low sensitivity of CA15-3 means that results within the reference interval do not exclude active disease or progression.

Cervical cancer

Worldwide, cervical cancer is the major cause of death from gynaecological cancer, with reported incidence rates in developing countries much higher than those in developed countries. Since cervical cancer progresses slowly from pre-invasive cervical intraepithelial neoplasia to invasive cancer, screening asymptomatic women with regular smears provides an effective means of early detection. The addition of human papilloma virus (HPV) testing appears to improve the effectiveness of screening as certain types of HPV are involved in the development of cervical cancer.

Women who have not been screened may present with symptoms of abnormal vaginal bleeding and, in advanced cases, pelvic pain and pressure symptoms relating to the bowel or bladder. Treatment of early stage disease usually requires radical hysterectomy and pelvic lymphadenectomy, with adjuvant radiation therapy if disease has spread to the lymph nodes. Surgery and concomitant chemoradiation or neoadjuvant chemotherapy followed by radical surgery are options for bulky disease. Measurement of plasma CEA and CA125 may have clinical utility in patients with cervical adenocarcinomas, which constitute 10–15% of all cervical cancers. The majority of cervical cancer patients (~85%), however, have squamous cell cervical carcinomas, for which the potentially most useful serum tumour marker is squamous cell carcinoma antigen (SCC), a serine protease inhibitor.

Screening and diagnosis

The low sensitivity and specificity of SCC, particularly for early stage disease, preclude its use in screening or diagnosis, which requires immunohistological evidence. Although 60% of patients with cervical cancer will have elevated concentrations of SCC at diagnosis, raised values are also found in other squamous cell carcinomas (e.g. lung, oesophagus and head and neck) as well as in benign diseases (e.g. psoriasis, eczema, sarcoidosis).

Prognosis

Some studies suggest that a raised concentration of SCC is an independent risk factor for poor survival but other studies contradict this. It has also been suggested

that pre-treatment SCC concentrations may be helpful in stratifying patients at greater risk of recurrence and therefore requiring more intensive therapy, but formal trials will be necessary to confirm this.

Monitoring

Various studies have confirmed that SCC shows a strong correlation with the clinical course of cervical cancer, with a lead time of up to 14 months in detecting progression prior to the onset of clinical symptoms, but whether earlier detection improves treatment outcome is not known. As only 10% of patients with recurrent disease can be cured and most patients with recurrent disease have clinical symptoms, until treatment options improve it is unlikely that SCC measurement will be widely adopted.

Choriocarcinoma

See Gestational trophoblastic neoplasia, below.

Colorectal cancer

Worldwide, colorectal cancer (CRC) is the third most common cancer, with more cases in the developed world than in Africa and Asia. Its incidence increases as populations adopt a western style diet. The risk of recurrence and subsequent death from CRC is closely related to the stage of the disease at the time of the primary operation. Although the treatment of colon and rectal cancer differ, they can be considered together in terms of tumour marker measurement.

Screening

Individuals at high risk of developing CRC (e.g. those with hereditary non-polyposis colon cancer (HNPCC, Lynch syndrome), familial adenomatous polyposis (FAP) or a strong family history of CRC (e.g. first degree relative with CRC diagnosed before age 45) should be referred to a clinical genetics unit for risk assessment and endoscopic screening. Mismatch repair gene mutations (e.g. *MLH1*, *MSH2*) predispose individuals to additional tumours, including those of the endometrium, ovary, genitourinary tract, small bowel and biliary tract. Individuals with FAP are at increased risk of developing duodenal tumours and thyroid tumours.

Early detection of CRC using faecal occult blood testing (FOBT) has been shown to reduce mortality in several randomized controlled trials. A number of countries now provide screening programmes for defined age groups (often >60 years old in the general population and at younger ages in high-risk groups) based on FOBT. Such screening is undertaken biannually in the UK, currently using a guaiac test, which detects the pseudoperoxidase activity of either intact or free haemoglobin. The test has many limitations, including relatively low clinical sensitivity and specificity for CRC; lack of specificity for human haemoglobin; vulnerability to interference from some foodstuffs and medications and difficulties associated with automating it. Screening using guaiac-based methods is therefore gradually being

replaced by faecal immunochemical tests, which detect the globin component of haemoglobin, can be used quantitatively with an adjustable cut-off concentration and are generally superior. All FOBTs lack specificity, and positive screens must be followed-up with colonoscopy. Markers based on DNA detection are potentially more specific than FOBT and may ultimately replace them, provided a clinically cost-effective panel of markers can be identified. At present, however, the cost and technical difficulties associated with these assays preclude their adoption.

Diagnosis

Although CEA is the most frequently used marker for CRC, depending on the cut-off point chosen, serum CEA will be raised in only 30–50% of CRC patients at the time of diagnosis. Its specificity is also low, since CEA concentrations can be raised in benign liver and kidney disease as well as in other malignancies (e.g. breast, gastric, lung, mesothelioma, oesophageal and pancreatic cancers), and may also be raised in smokers. Therefore, CEA cannot be used in isolation to diagnose even advanced CRC. However, raised concentrations can aid in diagnosis in certain clinical circumstances (e.g. indicating a high probability of malignancy in a frail elderly patient who cannot undergo invasive investigations) and confirmed markedly raised concentrations (serum CEA >40 µg/L) are suggestive of metastatic disease.

Prognosis and staging

The strongest predictor of recurrence of CRC is the histopathological stage of disease, as assessed using the Dukes staging system or one of its modified versions (Table 42.5), which take into account local tumour invasion, involvement of regional lymph nodes and presence of distant metastases. The five-year survival for patients with Dukes Stage A disease is >90% but that for those with Stage D disease is <10%.

TABLE 42.5 Pathological staging systems used for colorectal cancer

Extent of spread of malignancy	Pathological stage	
	Dukes	UICC/AJCC
Tumour found in the innermost lining of the colon only (carcinoma in situ)	–	0
Tumour beginning to spread but confined to the inner lining of the colon or rectum	A	I
Tumour extending more deeply into and/or through the colon or rectum, possibly invading nearby tissue	B	II
Invasion of tumour to regional lymph nodes	C	III
Metastasis to distant sites (most frequently lungs and liver)	D	IV

UICC, International Union Against Cancer; AJCC, American Joint Committee on Cancer.

High preoperative CEA concentrations are associated with poorer prognosis, while those within the reference interval are generally associated with better outcomes. An Expert Panel of the American Joint Committee on Cancer has suggested that CEA concentrations should be incorporated in the TNM staging system for CRC, but this proposal has not yet been formally adopted. Supporting this, a College of American Pathologists Expert Panel has ranked preoperative serum CEA as a Category I prognostic marker for CRC. In practice, pathological examination of resected tumour currently determines prognosis and the need for adjuvant therapy but preoperative CEA concentrations may provide additional prognostic information complementing histopathology in newly diagnosed CRC patients. Further information may also be obtained from new prognostic markers, e.g. microsatellite instability and gene expression profiling. Further evaluation of these is required prior to their routine implementation but it is likely that measurement of CEA will continue to be both simpler and cheaper.

Monitoring

Serum CEA is a reliable and validated marker for the surveillance and detection of disease recurrence in CRC. However, it is important to consider whether this would be likely to benefit the individual patient. Monitoring of the disease should be undertaken only if it were likely to lead to clinical action that would either improve the survival or quality of life of the patient, e.g. by early detection of recurrence that is amenable to treatment.

Meta-analyses of a number of trials confirm that intensive follow-up results in 20–30% reduction in all cause mortality, but variation in follow-up strategies and reporting makes it difficult to draw conclusions about the best combination of tests and their timing. Nevertheless, results suggest that inclusion of regular CEA measurements in intensive follow-up regimens is necessary to achieve significant improvement in survival. Intensive follow-up is a cost-effective strategy, with measurement of CEA being one of the least expensive tests performed, estimated to be approximately half the cost of a chest X-ray and less than one-tenth the cost of a colonoscopy in the USA.

A number of expert panels have issued broadly similar recommendations stating that CEA should be measured in patients with Dukes stage B or C CRC who may be eligible for further intervention (e.g. resection of liver metastases or systemic treatment) if their disease recurs. It should be measured at baseline and then every 2–3 months for at least three years after diagnosis and approximately every six months for a further five years. Measurement of CEA following resection of solitary liver metastases provides helpful information, with CEA falling rapidly following successful resection. Unfortunately, while CEA is a relatively sensitive marker for liver metastases, this is not the case for lung metastases.

Increasing CEA concentrations in an asymptomatic patient pose a difficult dilemma. The National Comprehensive Cancer Network (NCCN) recommends that if CEA is increasing in the presence of normal imaging, computed tomography (CT) scans should be repeated every three months until disease is detected or

CEA concentrations stabilize or decrease. Exploratory surgery based solely on an increase in CEA is not recommended by the NCCN; neither is the use of CEA-radiolabelled scintigraphy in patients with negative imaging. It is important to note that low serum CEA results do not necessarily exclude progression and other confirmatory tests (e.g. CT scan, X-ray, colonoscopy or possibly CA19-9 measurement) may be required if this is clinically suspected.

Monitoring of advanced disease

Patients with metastatic CRC are likely to receive a fluoropyrimidine (e.g. fluorouracil) in combination with oxaliplatin and/or irinotecan. Biological treatment with therapeutic antibodies (e.g. bevacizumab, cetuximab and panitumumab) is also increasingly used. While radiology remains the 'gold standard' method for evaluating response, studies have demonstrated good concordance between radiological response and CEA response in >90% of patients being treated for isolated CRC liver metastasis, leading to the conclusion that CEA is as accurate as CT imaging for assessing response to chemotherapy. Caution in interpretation is, however, required, particularly in the first few weeks following chemotherapy, as transient rises in CEA may occur in 10–15% of patients. Interestingly, these increases appear to be associated with a favourable outcome and are thought to be due to necrosis and/or apoptosis caused by the cytotoxic therapy. A confirmed increase during treatment may lead to a change of treatment or withdrawal of ineffective therapy.

Cautions and caveats

It is essential that, whenever possible, CEA concentrations in individual patients are monitored using the same method, since method-related differences in recognition of CEA mean that results may differ sufficiently to influence the interpretation of serial measurements. As for all serum tumour markers, when a change of method is unavoidable, the laboratory should establish a new baseline value for each patient.

An increase of >30% from the previous value of CEA is considered to be significant and should be confirmed by a second sample taken within a month. Smaller increases (e.g. 15–20%) demonstrated over at least three consecutive assays at minimum intervals of two weeks, may also prompt intervention. Patients with symptoms of recurrence require additional investigation such as CT scanning. CEA results within the reference interval do not exclude recurrence. Conversely, increasing CEA concentrations following curative surgery may reflect factors that are not associated with the primary tumour (e.g. lung nodules, liver lesions, ovarian masses and mediastinal lymphadenopathy).

Genetic pre-screening for hereditary non-polyposis colon cancer

Considerable progress has been made in understanding genetic influences on the development of CRC, and genetic testing is likely to become increasingly important.

Pre-screening for HNPCC, which accounts for approximately 3% of all CRC patients and which predisposes to development of other cancers, is currently performed by testing for microsatellite instability (MSI), a surrogate marker for DNA mismatch repair (dMMR) gene dysfunction, which is present in >90% of affected patients. Further testing for mutations in the *BRAF* gene (proto-oncogene B-Raf) may be desirable in some cases, as it may determine sensitivity to specific anti-tumour drugs (see p. 837). Studies have suggested that cancer rates and mortality are both decreased by close surveillance of patients with HNPCC, but there is still much debate about whether routine measurement of MSI/dMMR is desirable in all patients with CRC. Reports also suggest that MSI/dMMR status may have prognostic relevance in CRC, with the presence of MSI or defective MMR activity associated with favourable outcomes.

K-RAS mutation detection

Colorectal cancer patients with specific activating mutations in either codon 12 or 13 of *K-RAS* rarely respond to treatment with anti-epidermal growth factor receptor (EGFR) antibodies, which include cetuximab and panitumumab, both of which bind to the extracellular domain of EGFR. Expert groups have therefore recommended that patients should be tested for *K-RAS* mutations before treatment, to identify individuals unlikely to benefit from these relatively expensive drugs.

Gastric cancer

The second most common gastrointestinal cancer worldwide, gastric cancer, is frequently diagnosed only when it is at an advanced stage. Plasma concentrations of CEA and CA19-9 are raised in 20–50% of patients with advanced disease and AFP in 20–25%, but these markers are increased in <20% of patients with early stage disease. None of these has the sensitivity or specificity required for screening or diagnosis of gastric cancer, although some studies suggest that post-treatment monitoring of patients using serum CEA or CA19-9 may provide early detection of recurrence in a proportion of patients. Further data are required, together with evidence that early detection improves clinical outcome, before monitoring with either can be recommended.

Results of a recent phase III trial suggest that trastuzumab (Herceptin[®]), in combination with chemotherapy, should be implemented as standard treatment for the 15–20% of patients with HER-2-positive advanced gastric cancers. Testing for HER-2 to identify gastric cancer patients who over-express HER-2 is likely to become increasingly important, particularly as there are newer forms of anti-HER-2 therapy (e.g. lapatinib, pertuzumab and trastuzumab-TM1), which may prove more efficacious.

Gastrointestinal stromal tumours (GIST)

Gastrointestinal stromal tumours (GIST) are rare tumours that occur in the stomach, small bowel, large bowel, oesophagus or omentum. At a molecular level,

they are characterized by the presence of KIT protein (also known as CD117 antigen), whose measurement in serum is recommended by a number of expert panels. The mutational status of the *KIT* proto-oncogene is also important in predicting which patients will benefit from imatinib, a tyrosine kinase inhibitor, whose availability has dramatically improved the treatment of patients with GIST.

Germ cell tumours

Germ cell tumours are more common in males than females and can be benign or malignant. Although most frequent in young adults, they can occur at any age. They may be seminomatous germ cell tumours, non-seminomatous germ cell tumours (NSGCT) or combined tumours (tumours with both seminomatous and non-seminomatous elements). Germ cell tumours often originate in the gonads, but they also occur elsewhere, particularly in the mediastinum, retroperitoneum or pineal gland (i.e. along the 'midline'). Testicular germ cell tumours are increasing in incidence and ~1500 new cases are diagnosed each year in the UK. Plasma concentrations of AFP and/or hCG are elevated in 80–85% of men with NSGCT, whereas <25% of those with seminomas have raised hCG and none have raised AFP. Methods used in oncology for the measurement of hCG should recognize both intact hCG and its free β -subunit ('total β hCG' assay) since a significant proportion of hCG in patients with seminomas may be present as the free subunit rather than the intact molecule. Placental alkaline phosphatase (PLAP) is another promising tumour marker in seminoma, but lack of commercially available assays and the significantly increased concentrations of PLAP observed in smokers have thus far limited its application.

Although germ cell tumours are usually aggressive neoplasms, they are highly sensitive to treatment with surgery and, when appropriate, chemotherapy and/or radiotherapy. The anticipated cure rate is >90%, although patients presenting with advanced disease have a lower five-year survival of 50–60%.

There are well-accepted clinical guidelines relating to the management of patients with germ cell tumours, for which measurements of AFP, hCG and LDH are an integral part. In the UK, patients are referred to a regional centre serving a population of two to four million for further assessment and chemotherapy. All patients should be discussed at multidisciplinary team meetings attended by a clinical biochemist. Tumour marker results should be reviewed along with histological immunostaining and radiological results and any inconsistencies noted when treatment decisions are considered.

Screening

The relatively low sensitivity and specificity of AFP, hCG and LDH for germ cell tumours, together with the low prevalence of these cancers in the general population, means that tumour markers cannot be used for screening.

Diagnosis

The possibility of a germ cell tumour should be considered in any patient with a poorly defined epithelial malignancy, particularly young individuals with mid-line masses. Plasma concentrations of AFP and hCG should be measured in any male with a suspicious lump in the testis and in any patient under 50 years of age with a malignancy of unknown origin. Young patients with germ cell tumours and very high serum hCG concentrations may present with thyrotoxicosis as hCG shares structural similarities with TSH. Patients with markedly elevated concentrations of AFP and/or hCG and clinical findings consistent with a germ cell tumour (e.g. testicular lump, lung metastases, abdominal mass) should be discussed urgently with the consultant responsible for managing germ cell tumours at the regional cancer centre. Immediate referral for chemotherapy may be appropriate if surgery is likely to be required later to remove residual tumour.

Distinguishing teratomas from seminomas is essential, as their treatments differ. Production of AFP is associated with yolk sac elements in germ cell tumours and therefore AFP is not found in pure seminomas (which never contain yolk sac elements), while the presence of hCG is associated with syncytiotrophoblast tissue. Differentiated teratoma tissue does not produce either AFP or hCG. Marker measurements can sometimes modify histopathological diagnoses, e.g. raised AFP in a patient diagnosed with pure seminoma suggests that yolk sac elements may have been overlooked or that the AFP is not related to the tumour (e.g. may be of liver origin). Before surgery for a suspected germ cell tumour, measurement of both AFP and hCG is essential to allow the rate of fall of the markers to be monitored post treatment. Some patients with pure seminoma histologically may have a preoperative AFP of 5–30 kU/L (6–36 μ g/L) that remains stable following surgery. Provided that the AFP concentration remains unchanged before and after orchidectomy and is stable when re-checked four weeks after surgery, the AFP may be considered to be 'normal' for that individual and not related to the tumour.

Rarely, if primary or secondary (metastatic) disease of the central nervous system (CNS) is suspected, measurement of hCG in cerebrospinal fluid (CSF) may contribute both to diagnosis and to treatment monitoring. A CSF:serum hCG ratio of >2% is predictive of CNS involvement. In practice, measurement of tumour markers in the CSF has been largely superseded by radiological investigations.

It is important to remember that tumour marker concentrations within reference intervals do not exclude malignancy since up to 25% of NSGCT do not produce AFP or hCG, and only a small proportion of seminomas or dysgerminomas (the female equivalent of seminomas) produce hCG. The possibility of false positive results must also be considered and account should always be taken of clinical and radiological findings. Plasma AFP can be increased in benign liver disease and primary hepatocellular carcinoma as well as in other cancers, including gastric and oesophageal tumours. Similarly, hCG can be increased in other non-germ cell tumours (e.g. bladder, lung) and both AFP and hCG are significantly raised in pregnancy.

Prognosis

Tumour marker measurements contribute significantly to the prognostic assessment of germ cell tumours. Criteria developed by the International Germ Cell Cancer Collaborative Group (IGCCCG) classify patients with metastatic NSGCT as belonging to one of three prognostic groups (Table 42.6). The lowest tumour marker concentration reached post surgery, the primary tumour site, and the sites of metastatic disease all contribute to this prognostic classification.

Whether AFP and hCG measurements made prior to primary surgery are prognostically useful is less clear,

TABLE 42.6 International germ cell cancer collaborative group prognostic classification for metastatic testicular germ cell tumours

Non-seminoma	Seminoma
<p>Good prognosis Testis/retroperitoneal primary No non-pulmonary visceral metastases Good markers – all of: AFP <1000 µg/L hCG <5000 U/L (1000 µg/L) LDH <1.5 × ULN 56% of non-seminomas 5-year progression-free survival 89% 5-year survival 92%</p>	<p>Any primary site No non-pulmonary visceral metastases Normal AFP, any hCG, any LDH 90% of seminomas 5-year progression-free survival 82% 5-year survival 86%</p>
<p>Intermediate prognosis Testis/retroperitoneal primary No non-pulmonary visceral metastases Intermediate markers – any of: AFP ≥1000 and ≤10 000 µg/L hCG ≥5000 U/L and ≤50 000 U/L LDH ≥1.5 × ULN and ≤10 × ULN 28% of non-seminomas 5-year progression-free survival 75% 5-year survival 80%</p>	<p>Any primary site Non-pulmonary visceral metastases Normal AFP, any hCG, any LDH 10% of seminomas 5-year progression-free survival 67% 5-year survival 72%</p>
<p>Poor prognosis Mediastinal primary or Non-pulmonary visceral metastases or Poor markers – any of: AFP >10 000 µg/L hCG >50 000 U/L (10 000 µg/L) LDH >10 × ULN 16% of non-seminomas 5-year progression-free survival 41% 5-year survival 48%</p>	<p>No patients classified as poor prognosis</p>

ULN, upper limit of normal. Note that AFP is expressed in ng/mL rather than kU/L, the units in which many laboratories report AFP results. For most methods, results in ng/mL can be multiplied by 0.83 to obtain kU/L but laboratories should check that this conversion factor is valid for the assay used and ensure that their clinicians are aware of it. Tumour markers refer to plasma concentrations.

since patients with large primary tumours but without metastases may have very high AFP and hCG concentrations that return to normal following surgery.

Monitoring

Tumour markers should be measured before and after surgical excision of germ cell tumours. Ideally, if disease is limited to the testis or ovary, serum AFP and/or hCG should decrease to normal with an apparent half-life of 5–6 days for AFP and 1–2 days for hCG. This is illustrated in Figure 42.2, which shows the decrease in AFP observed in Patient A, a patient with good prognosis following surgical treatment of a malignant teratoma. The apparent half-life ($t_{1/2}$) of the tumour marker can be calculated using the equation:

$$t_{1/2} = \frac{-0.3t}{\log_{10} \frac{[M]_T}{[M]_{T_0}}}$$

where $[M]_T$ and $[M]_{T_0}$ are tumour marker concentrations at time T and T_0 , respectively and t is the difference in days between T and T_0 . As indicated in Figure 42.2, in which AFP concentration is plotted on a logarithmic

Key: ▽ indicates concentration below detection limit of assay

FIGURE 42.2 ■ Serum α-fetoprotein (AFP) concentrations in a patient treated by surgery for malignant teratoma.

scale against time on a linear scale, the apparent $t_{1/2}$ of AFP for Patient A is six days, i.e. at the upper limit of the expected half-life of AFP in normal subjects. This suggests possibly complete tumour removal. If AFP or hCG remains elevated post surgery or if metastatic disease is identified radiologically, further treatment with chemotherapy or radiation is required.

The importance of continued monitoring with tumour markers following surgery is also illustrated in Figure 42.2, where, although the measured AFP became undetectable by day 65, the concentration subsequently increased, first becoming detectable on day 151 (AFP 7 kU/L or 8.4 µg/L). Such findings should be confirmed within two weeks, after which further clinical investigations should be instituted immediately. In the absence of residual tumour or scan evidence, other causes of raised AFP and/or hCG, including the possibility of analytical interference, must be excluded, but provided this is done, Patient A would be a candidate for chemotherapy to combat progressive disease. Patients with very high marker concentrations before chemotherapy are more likely to have undetected micrometastases, as was probably the case for Patient A.

All chemotherapy regimens for germ cell tumours include platinum-based drugs, but the regimen selected will depend both on prognosis and on the results of clinical trials appropriate to that prognostic category. Following chemotherapy, AFP and/or hCG concentrations should decrease linearly when plotted as described above, but their apparent half-lives will usually be somewhat longer, i.e. up to seven days for hCG and ten days for AFP. A somewhat different pattern of AFP results is seen for Patient B (Fig. 42.3), a patient with a metastatic teratoma that did not respond to initial surgery. In some patients, AFP and/or hCG may continue to rise for up to three weeks following the start of chemotherapy, although concentrations usually start to decrease by ten days (as for Patient B). They should then fall linearly with time when

plotted as described above. However, if marker concentrations plateau, as is also illustrated in Figure 42.3 (at about day 130) this is cause for concern, suggesting either that the chemotherapy used is failing to penetrate the target tissue (which may be a large mass) or that the patient has developed drug resistance. A change in chemotherapy may then be implemented or further surgery undertaken if the tumour is considered resectable, as was the case for Patient B. Timing of surgery is important, since the outcome is likely to be most favourable if surgery is performed when the tumour marker concentration is at its nadir (i.e. the lowest concentration that can be achieved with chemotherapy).

It is estimated that with an hCG concentration of only 1 U/L, up to 100 000 tumour cells may persist. Chemotherapy should therefore be continued for some time after AFP and hCG both become undetectable, so that as many tumour cells as possible are eradicated. In some patients, results may be difficult to interpret, since chemotherapy may damage the liver (e.g. causing increased serum AFP concentrations in patients with purely hCG-producing tumours). This is particularly relevant in children.

The availability of serum tumour markers for the majority of NSGCT patients has facilitated clinical trials designed to minimize treatment toxicity for patients with good prognosis disease. By considering the rate of change of tumour marker concentrations it is possible to identify subtle differences in the effects of treatment within days, much more rapidly than the weeks it may take for significant radiological changes to become apparent.

Long-term surveillance

Tumour markers should be measured regularly following treatment, according to defined clinical protocols. Time intervals will depend on prognostic category and treatment. As is clear from Figure 42.2, any analytically significant increases in tumour markers should be reported immediately to the relevant clinical team.

Seminoma patients at low risk of recurrence who have remained well for five years can be discharged from follow-up, as can those with NSGCT who have remained well for ten years. Separate monitoring of cardiovascular risk in these patients may, however, be desirable as there is increasing evidence of an excess of cardiovascular events following chemotherapy with platinum-based drugs.

Gestational trophoblastic neoplasia

Gestational trophoblastic neoplasia (GTN) form a group of several diseases associated with pregnancy, usually involving abnormal growth of cells within the uterus. Rare and once fatal, these now highly curable tumours develop in the trophoblast cells that surround the embryo immediately after conception. Gestational trophoblastic neoplasia may develop after a molar pregnancy, a non-molar pregnancy or a live birth and should be considered in any woman developing acute respiratory or neurological symptoms or persistent abnormal vaginal bleeding after any pregnancy. In the UK, the Royal College of Obstetrics and Gynaecology has developed guidelines for management of GTN (available at: www.rcog.org.uk).

FIGURE 42.3 ■ Serum α -fetoprotein (AFP) concentrations in a patient with metastatic teratoma that was initially unresponsive to surgery.

Since measurement of hCG and related molecules is fundamental to the successful management of these diseases, it is useful briefly to review their characteristics.

Hydatidiform moles

The most common type of GTN is hydatidiform mole (also termed molar 'pregnancy', although a normal baby cannot be produced), which is not cancerous. The moles are villi that have become swollen with fluid and then grow in clusters resembling bunches of grapes. Hydatidiform moles may develop when a sperm fertilizes an 'empty' egg containing no nucleus or DNA ('complete' mole) or when two sperm fertilize a normal egg ('partial' mole). There is no fetal tissue present in complete moles, as all the genetic material comes from the father's sperm. Relatively few patients with partial moles need further treatment after initial surgery and these moles rarely become malignant. Up to 20% of patients with complete moles will need further surgery or chemotherapy; a small percentage develop into choriocarcinoma, a malignant form of GTN.

Invasive moles

Invasive moles develop in about 20% of women who have had a complete mole removed by curettage of the lining of the uterus. Invasive moles penetrate the muscular wall of the uterus (the myometrium) sometimes leading to heavy bleeding. In about 15% of patients, the tumour metastasizes to other sites, most frequently the lungs. The risk of developing invasive mole is increased if more than four months elapse between cessation of periods and treatment, if the uterus has become very large, if the woman is over 39 years old or if she has had a previous GTN.

Choriocarcinoma

Choriocarcinoma is a malignant form of GTN that most often develops from a complete hydatidiform mole but can occur after normal pregnancy or after early fetal loss in pregnancy. Choriocarcinomas are more likely to metastasize to distant organs than invasive moles, but treatment with chemotherapy is highly effective.

Placental site trophoblastic tumours

These are rare forms of GTN that develop where the placenta remains attached to the uterus, often after a normal pregnancy or abortion. They do not usually metastasize but are not sensitive to chemotherapy and must be completely removed surgically.

Screening

All patients in the UK who have had a previous molar pregnancy are automatically registered with the National Hydatidiform Mole Registry. Screening for choriocarcinoma using hCG in this highly selected group of women provides the single best example of a successful screening programme using a tumour marker, since ~8% of these women will develop the disease (i.e. the prevalence in the population studied is high) and early detection

and treatment improves outcome. The logistics are also convenient as hCG, which has approximately 99% sensitivity and specificity for choriocarcinoma, can be measured reliably in urine specimens that are sent by post by the patient to laboratories in specialist referral centres, thereby facilitating early detection of disease and prompt treatment. These laboratories use broad-spectrum hCG methods that are designed to detect hCG and its major isoforms.

Diagnosis

Increasing use of ultrasound in early pregnancy has probably led to earlier diagnosis of molar pregnancy, but measurements of hCG may also contribute as concentrations may be higher than in normal pregnancy.

Prognosis

Prognosis is assessed according to the International Federation of Gynaecology and Oncology staging for GTN, the hCG concentration prior to treatment being one of a number of factors scored. Low risk patients receive different treatment from those classified as high risk.

Monitoring

Women with persistent GTN are treated with appropriate chemotherapy at specialist centres. About 15% of patients with complete moles require chemotherapy and 0.5% after partial moles. Treatment is continued until the hCG concentration has returned to normal and then for a further six weeks. Women should be advised not to attempt to conceive until the hCG concentration has been normal for six months. After any further pregnancy, hCG should again be measured to exclude disease recurrence.

Hepatocellular carcinoma (primary liver cancer)

Hepatocellular carcinoma (HCC) is rare in the developed world but is common in China, South-east Asia and sub-Saharan Africa, and is the fifth most common cause of cancer death worldwide. In most parts of Africa and Asia, infection with hepatitis B virus is a major causative factor, as is ingestion of the fungal toxin, aflatoxin B₁, from contaminated food. The higher incidence observed in Europe during the last decade probably reflects the increased frequency of hepatitis C infection and alcoholic liver cirrhosis, both of which are strongly associated with development of HCC.

Although many potential tissue and serum tumour markers are increased in HCC, AFP is at present the most clinically useful. Normally produced during gestation by the fetal liver and yolk sac, AFP is increased in the maternal circulation during pregnancy and is also markedly elevated in newborns, with concentrations declining over the first year of life. An oncofetal antigen, AFP appears inappropriately in adults with malignancy, most frequently in hepatocellular carcinoma and germ cell cancers, and also in some benign conditions, particularly those associated with liver damage and/or regeneration. Circulating

AFP concentrations range from within the reference interval to as high as 8.3×10^6 kU/L (10×10^6 µg/L), but in the UK, up to 50% of patients with HCC may have normal concentrations of AFP.

Screening of high-risk groups

Screening by six-monthly measurement of serum AFP together with abdominal ultrasound, is now recommended for early detection of HCC in high-risk populations. There is increasing evidence that such screening (when compared with no surveillance) detects HCC of smaller size and enables a greater proportion of patients to be cured, thereby leading to improved long-term survival and cost-savings. In the UK, it is suggested that such screening be restricted to patients with liver cirrhosis secondary to hepatitis B or C or genetic haemochromatosis, and to men with primary biliary cirrhosis (PBC) and alcoholic cirrhosis (if abstinent). (Available data suggest that women with PBC or alcoholic cirrhosis have a lower risk of developing HCC.) Validation of optimal follow-up protocols, when AFP is raised or when suspicious nodules are detected, is now in progress. Sequential measurement of serum AFP provides useful information and is undergoing validation for routine clinical practice. An elevated AFP concentration detected by a single measurement may be transient (e.g. arising from an inflammatory flare of underlying viral hepatitis). Elevated but stable concentrations decrease the likelihood that HCC is the causative agent, while a steadily rising AFP concentration should always be rigorously investigated.

Diagnosis

Plasma concentrations of AFP up to 1245 kU/L (1500 µg/L) may occasionally be associated with benign conditions, with 20–40% of adult patients with hepatitis or liver cirrhosis having AFP >8.3 kU/L (10 µg/L). An AFP result within the reference interval does not exclude a diagnosis of HCC. Rapid increases (a doubling time of <5 days) are suggestive of acute liver damage rather than malignancy. As with screening, a steady rise in AFP is suggestive of HCC, while stable or decreasing results make HCC less likely. Histopathology of appropriate biopsy material is essential for definitive diagnosis of HCC since AFP may be raised in malignancies other than HCC, including germ cell tumours and stomach, biliary tract and pancreatic cancers.

Prognosis

Large multivariate analyses confirm that raised AFP concentrations predict poor prognosis when compared with AFP-negative patients, some studies indicating that patients with larger tumours tend to have higher AFP concentrations. Together with tumour size and extent, AFP appears to be an independent predictor of survival, patients with serum AFP >8300 kU/L (10 000 µg/L) doing less well than those with AFP <166 kU/L (200 µg/L). α-Fetoprotein doubling time may also be an important prognostic factor.

Monitoring

Following complete surgical removal of HCC, AFP concentrations typically decrease with a half-life of 3.5–4 days, incomplete resection being associated with a longer half-life and poorer outcome. α-Fetoprotein concentrations that fail to return to normal suggest incomplete resection or severe liver damage.

Serum AFP measurements can also be used to monitor HCC patients following treatment with chemotherapy or radiotherapy. Decreases in tumour markers may in some cases reflect tumour regression more accurately than CT scans, since interpretation of the latter may be complicated by residual fibrosis and other factors. It is important to note that recurrence is possible even when AFP is stable or within reference limits, presumably from micrometastases too small to produce measurable AFP concentrations in serum, and that recurrent tumour may not secrete AFP even if the original tumour did so.

Lung cancer

Lung cancer is the cancer with both the highest incidence and the highest number of deaths in the world. There are two major histological types: non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC). Non-small cell lung cancer, which accounts for 75–85% of lung cancers, consists of several subtypes, predominantly squamous cell carcinoma, adenocarcinoma and large cell carcinoma. Surgery is the only curative treatment for NSCLC. Small cell lung cancer accounts for 15–25% of lung cancers, often has neuroendocrine elements and is primarily treated with chemotherapy and/or radiotherapy. Small cell lung cancer is an aggressive tumour characterized by a short doubling time and early development of metastatic disease. Many lung cancers are mixed tumours containing both small cell and non-small cell components.

A large number of tumour markers have been tested in lung cancer, different markers being required to identify the response to treatment of the different cell types present. Some of the more promising markers and their associated cell types are listed in Table 42.7.

TABLE 42.7 Tumour markers of potential utility in different types of lung cancer

Tumour marker	Type of cancer	Cell type
Cyfra 21-1	NSCLC	Squamous cell
Carcinoembryonic antigen (CEA)	NSCLC	Adenocarcinoma Large cell
Squamous cell carcinoma antigen (SCC)	NSCLC	Squamous cell
Neuron specific enolase (NSE)	SCLC	Small cell (neuroendocrine)
Progastrin releasing peptide (ProGRP)	SCLC	Small cell (neuroendocrine)

NSCLC, non-small cell lung cancer; SCLC, small cell lung cancer.

Screening

No markers are suitable, either singly or in combination, for screening either in the general population or in specific high-risk groups, such as smokers.

Differential diagnosis

The pattern of elevated serum concentrations of CEA, Cyfra 21-1, NSE, SCC and ProGRP may suggest which histological subtype of lung cancer is present but further work is required before measurement of tumour markers in this situation becomes standard practice. Where inoperable lung cancer is suspected but no histology is available, raised serum NSE and especially ProGRP concentrations are highly suggestive of small cell lung cancer, while raised serum SCC concentration is suggestive of squamous cell cancer.

Prognosis

Studies have suggested that Cyfra 21-1, CEA, NSE and LDH (lactate dehydrogenase) may all provide prognostic information in NSCLC, whereas only NSE and LDH act as prognostic indicators in SCLC.

Monitoring

Although tumour markers can be used in individual lung cancer patients to monitor their response to therapy (using NSE and/or ProGRP for SCLC, and CEA and/or Cyfra 21-1 for NSCLC), in view of the limited range of treatment options currently available, this is controversial. However, serial determinations of the appropriate marker following surgery may help to assess the completeness of tumour removal and provide early indication of recurrence.

In patients receiving systemic treatment, measurements of tumour markers may assist in assessing response to therapy and to document progressive disease, although reliable criteria for 'biochemical progression' have yet to be developed. There is currently no evidence that monitoring with tumour markers improves patient outcome.

Epidermal growth factor receptor and K-RAS mutation analysis

A number of expert panels recommend determining *EGFR* mutation status in patients with advanced NSCLC prior to administration of the tyrosine kinase inhibitors (TKI) gefitinib or erlotinib. Patients lacking the mutation are unlikely to benefit, while 65–70% of those with specific activating mutations in the *EGFR* gene respond to these therapies. Similarly, there is a significant correlation between the presence of *K-RAS* mutations and an absence of response to the TKIs. Combining the tumour mutation status of *K-RAS* with that of *EGFR* can therefore be helpful both in identifying patients with advanced NSCLC who are likely to respond to treatment with TKIs and the likelihood of resistance to specific TKIs.

Melanoma

Melanoma is a malignant tumour of melanocytes (cells that are derived from the neural crest), with a rising incidence worldwide. Most melanomas occur in the skin, but they may also develop at mucosal surfaces or other sites to which neural crest cells migrate. Early stage disease can be cured by surgery but the prognosis associated with metastasis to distant sites is poor.

Immunohistochemical staining with antibodies to S100 is the method of choice for diagnosing malignant melanoma in pathological specimens, but further studies are required to define the role of S100 measurement in serum. Measurement of S100B lacks sensitivity in early disease. Rising concentrations of S100B are specific and sensitive for tumour progression in patients with advanced disease, but measurement is only appropriate if further treatment options are available. Measurement of a tumour-associated glycoprotein antigen (TA90-IC) shows promise as a prognostic indicator and for monitoring patients but requires further evaluation. Lactate dehydrogenase, although a very non-specific marker, can be useful for monitoring patients with melanoma and may have prognostic value in patients with advanced disease.

BRAF mutation analysis

About 40–50% of patients with disseminated disease, but without brain metastases, may respond to treatment with the *BRAF* gene inhibitor vemurafenib, provided they have a V600 mutated *BRAF* gene. *BRAF* gene status therefore needs to be confirmed prior to treatment.

Neonatal and paediatric tumours

Cancer is the second leading cause of death in children <15 years old, but major advances in treatment mean that >70% of children diagnosed with cancer are now cured. Most childhood solid tumours are of mesenchymal or embryonal origin. Tumour markers can contribute significantly to the management of childhood neuroblastomas, malignant hepatic tumours and germ cell tumours. While the general principles of marker use in these cancers are the same as for adult malignancies, some additional points should be noted.

When interpreting AFP, it is important to remember that plasma AFP is markedly raised at birth and then declines steadily to adult concentrations by 6–12 months. α -Fetoprotein is higher in children born prematurely and may remain elevated for longer in children with delayed development. Appropriate gestational and age-related reference intervals therefore need to be used for infants. Serial concentrations are often more useful than isolated results. This is particularly relevant in neonates, in whom acute hepatocellular damage may result in marked increases in AFP concentrations. As with adults, other possible causes of raised AFP need to be considered, including hereditary tyrosinaemia and ataxia telangiectasia. The very high concentrations of tumour markers that may be seen in some childhood cancers mean that particular care must be taken to minimize the risk of the high-dose hook effect (Box 42.1). Since AFP and hCG requests

for young children are relatively infrequent, it would be eminently feasible, and highly desirable, to assay all such samples at more than one dilution.

Germ cell tumours in childhood

As in adults, AFP and hCG are often elevated at the time of diagnosis and their measurement is mandatory. Yolk sac tumours are the most common pure malignant germ cell tumours in children. Seminomas rarely occur in infants or young boys, but dysgerminomas are the most common pure malignant germ cell tumour occurring in the ovary and central nervous system in girls, who may present with precocious puberty.

Hepatoblastoma

Hepatoblastoma and hepatocellular carcinoma (HCC) are the most frequent malignant hepatic tumours of childhood. More than 80% of hepatoblastomas, which are embryonal tumours, are diagnosed in children aged <3 years, with 45% of patients diagnosed during the first year of life. Most patients (98%) have a raised AFP at presentation, often to extremely high concentrations (e.g. 10^6 kU/L or 1.21×10^6 µg/L), which can assist in diagnosis. Thereafter, serum AFP can be used to monitor therapy and follow-up. Children with hepatoblastomas that secrete hCG may develop isosexual precocious puberty. Complete surgical resection is the treatment of choice, with chemotherapy also playing an important role. Overall survival rates are >60%, or >80% if complete resection is achieved.

Hepatoblastomas must be differentiated from HCCs, 50% of which also produce AFP. Positive hepatitis B serology is present in some children with HCC, with other laboratory abnormalities including anaemia and hyperbilirubinaemia. Complete surgical resection is the treatment of choice for HCC. Aggressive chemotherapy has not significantly improved outcome and most children with HCC die within 12 months of diagnosis.

Neuroblastoma

Neuroblastoma is a malignant embryonal tumour that accounts for 8–10% of all childhood cancers, with 80% of cases occurring before the age of four years. The clinical behaviour is varied, some tumours undergoing spontaneous regression and others exhibiting extremely malignant behaviour. Treatment includes surgery, chemotherapy and radiotherapy. Urinary catecholamine metabolites are increased in >90% of patients and are helpful to confirm the diagnosis and monitor progress (see Chapter 38). Significant elevations of serum NSE, LDH and/or ferritin tend to be associated with a poorer outcome.

Ovarian cancer

Ovarian cancer is the fourth most common cause of death from cancer in women in the UK. Early diagnosis is key to successful treatment, but the absence of symptoms in early stage disease means that many ovarian cancers present late. Standard treatment for ovarian cancer is surgical, involving

bilateral oophorectomy and pelvic clearance, usually followed by chemotherapy. New chemotherapeutic agents have significantly improved the five-year survival rate.

About 15% of malignant ovarian tumours are germ cell tumours, for which AFP, hCG and LDH are the markers of choice as previously described, or sex cord stromal tumours, two-thirds of which are granulosa cell tumours. Inhibin is the marker of choice for granulosa cell tumours of the ovary. An inhibin method, which detects all forms of inhibin, including A, B and pro-αC, is required.

However, most malignant ovarian tumours (80–85%) are surface epithelial carcinomas. These occur in five histologically distinct subtypes: serous, mucinous, endometrioid, clear cell and transitional. They exhibit different clinical behaviours, tumorigenesis and pattern of gene expression, which should be taken into account when evaluating the clinical utility of tumour markers in ovarian cancer. The most widely used tumour marker for epithelial ovarian cancer is CA125. Most sensitive in serous adenocarcinomas, it is also used in other histological types of epithelial cancer despite its poorer sensitivity.

Interpretation of CA125 results is particularly challenging, and it is essential to be aware of the many benign conditions in which the marker can be significantly elevated, sometimes transiently (Table 42.1). These conditions include during menstruation and the first two trimesters of pregnancy. Serum CA125 may be raised in any patient with ascites (occasionally to >5000 kU/L) or pleural effusion (usually 200–300 kU/L) and is also raised in patients with a wide variety of tumours, especially adenocarcinomas. Method-related differences in results can also be problematic and some methods are more vulnerable to interference, such as from heterophilic antibodies, as illustrated in Table 42.8.

Screening

In view of the absence of early symptoms, a reliable screening test for ovarian carcinoma would be highly desirable. Variations in results in premenopausal women (including increases during menstruation) mean that

TABLE 42.8 Misleading results for CA125 owing to presumed antibody interference in an automated immunoassay method

Day	CA125 (kU/L)		Treatment
	Method 1	Method 2	
		Undiluted specimen

41	39	420	566
49	–	–	–
76	22	>500	708
104	19	>500	1040
132	21	302	417
160	16	166	267
202	16	274	336
278	16	35	47
			Follow-up

single CA125 measurements lack the sensitivity and specificity essential in a screening setting. However, use of CA125 for screening in postmenopausal women is the subject of several trials. In a large controlled trial (the UK Collaborative Trial of Ovarian Cancer Screening), patients have been randomized into three groups: an unscreened control arm; a group screened annually with CA125, with repeat CA125 and ultrasound follow-up if positive, and a group screened annually with ultrasound, with repeat ultrasound in 6–8 weeks if positive. Until this trial has reported in 2015, screening of the general population cannot be recommended.

There is, as yet, no evidence that using CA125 to screen women at high risk of ovarian cancer (e.g. those with a strong family history) is effective. However, a US National Cancer Institute Panel has recommended annual CA125 determinations, in addition to pelvic and ultrasound examinations, in women with a history of hereditary ovarian cancer, who have an estimated lifetime risk of 40%. Such investigations should always be carried out in specialist units.

Diagnosis

Ultrasound assessment is essential in women with suspected ovarian cancer. This is likely to identify a pelvic mass and may suggest the presence of metastatic disease. If no obvious source is identified, determining whether the pelvic mass is likely to be malignant can be problematic but is important, as it will influence plans for surgery. Prognosis in ovarian cancer correlates strongly with the extent of surgical clearance of malignant tissue.

Cut-off concentrations (e.g. CA125 >95 or >65 kU/L) have been used with some success in postmenopausal women to distinguish between malignant and benign pelvic masses. However, a risk of malignancy index (RMI) scoring system, incorporating CA125, ultrasound findings and menopausal status, is more widely used (Table 42.9). The two scoring systems (RMI 1 and RMI 2) are similar but RMI 2 gives greater weight to ultrasound findings and menopausal status than does RMI 1. A positive predictive value for malignancy of

about 80% is obtained using the RMI 2 scoring system and a cut-off value of 200.

It is clear from Table 42.9 that whichever score is used, the result depends critically on the numerical CA125 value and therefore also on the reliability of the assay, particularly in the range of 10–25 kU/L. If there is a change in method the cut-off value used may need to be reviewed.

In the UK, NICE has published clinical guidelines on the recognition and initial management of ovarian cancer with the aim of increasing awareness of the disease among general practitioners and decreasing the frequency of late diagnosis, which is thought to account for the lower survival rates observed in the UK and Ireland compared with other European countries. The NICE guidelines state that general practitioners should measure serum CA125 concentrations in women presenting with persistent and continuous symptoms (>12 times a month) suggestive of ovarian cancer (e.g. abdominal pain, early satiety and loss of appetite or pelvic pain). If CA125 concentration is ≥ 35 kU/L, an ultrasound scan of the abdomen and pelvis should be arranged to enable calculation of the RMI. Women with an RMI score ≥ 250 should be referred to a specialist multidisciplinary team. Women with CA125 <35 kU/L should be reviewed at six weeks if symptoms persist.

Prognosis

During primary treatment, CA125 concentrations both before and after surgery may be of prognostic significance. Patients with a preoperative CA125 concentration >65 kU/L have a poorer five-year survival than patients with lower CA125 concentrations. A concentration of <250 kU/L before chemotherapy, a fall of CA125 of greater than seven-fold during the first month of chemotherapy, an apparent CA125 half-life of <20 days during chemotherapy and a CA125 concentration of <35 kU/L before the third course of chemotherapy are all thought to indicate a good prognosis.

Detection of residual disease

Measurement of serum CA125 following surgery is only relevant in the small number of patients with disease limited to the ovary (Stage I) who would not automatically receive further treatment. It is essential that these patients have CA125 measurements at least once a week initially so that the rate of fall can be checked. The apparent half-life of CA125 in patients with no residual disease is five days.

Monitoring

Serum CA125 concentrations correlate well with the response to treatment in ~90% of patients. A rising or stable CA125 at the beginning of the second or third course of chemotherapy, together with an apparently poor clinical response, may be used as an indication either to change the treatment or to institute appropriate palliative therapy. While an increased CA125 concentration (>35 kU/L) at the end of treatment is always associated

TABLE 42.9 The risk of malignancy index (RMI) scoring system for ovarian cancer

Feature	RMI 1 score	RMI 2 score
Ultrasound features:		
multilocular cyst solid areas	0=no abnormalities 1=one abnormality 3=two or more abnormalities	0=no abnormalities
bilateral lesions		1=one abnormality
ascites		4=two or more abnormalities
intra-abdominal metastases		
Premenopausal status	1	1
Postmenopausal status	3	4
Plasma CA125 (kU/L) concentration	Pre-treatment value	Pre-treatment value

RMI score = (ultrasound score) × (menopausal score) × (CA125 concentration in kU/L).

with disease, the reverse is not true, as a low CA125 concentration does not exclude active disease.

Long-term surveillance

A confirmed rise in CA125 to more than twice the upper reference limit accurately predicts relapse with a sensitivity of 86% and a positive predictive value of 95%. Whether early treatment for relapse in patients who are asymptomatic improves outcome, is still unclear. Results of a Medical Research Council and European Organisation for Research and Treatment of Cancer randomized control trial (MRC OV05 and EORTC 55955) addressing this question suggests that instituting early chemotherapy based on a rising CA125 does not improve either survival or quality of life, and that it is appropriate to delay treatment until signs and symptoms of recurrence develop. Whether this would also be the case with the improved treatment regimens now available is not clear. However, the recommendation from the trial investigators is that it is appropriate to offer women with ovarian cancer two informed choices for follow-up, i.e. no routine CA125 measurements but rapid access to CA125 testing if there are symptoms or signs of relapse, or, alternatively, regular CA125 measurements.

Pancreatic cancer

In pancreatic ductal adenocarcinomas (i.e. non-endocrine tumours of pancreas), CA19-9 is the only tumour marker for which there is sufficient evidence to support its clinical use. It can be used as an adjunct to diagnosis in association with appropriate imaging but it is not suitable for screening even in high-risk populations. Measurements can provide independent prognostic information with regard to resectability and survival but should only be used in conjunction with other clinical information. The American Society of Clinical Oncology recommends serial measurements of CA19-9 every 1–3 months for pancreatic cancer patients with locally advanced or metastatic disease who are receiving active therapy. Increases in serial CA19-9 measurements suggest progressive disease, but confirmation by other means should be sought. It is important to note that there are significant method-related differences in CA19-9 results and particular care should be taken if changing methods. Many non-malignant conditions, including any that cause cholestasis, can cause elevated plasma concentrations of CA19-9 (see Table 42.2).

Prostate cancer

Prostate cancer is one of the most common malignancies in men, autopsy data indicating the presence of histologically apparent cancer in the prostates of ~42% of men aged >50 years who have died from other causes. Recent increases in the apparent incidence of prostate cancer almost certainly reflect widespread measurement of serum PSA, elevations of which can identify disease long before it is symptomatic. Since many men have indolent prostatic cancers that pose little threat to their life or health, there is increasing concern that the use of PSA measurements,

which cannot differentiate slow-growing cancers from aggressive cancers that require treatment, is causing over-diagnosis and over-treatment of some men. A further difficulty is that, while PSA is essentially organ-specific, it is not cancer-specific, and men with non-malignant conditions, such as benign prostatic hypertrophy, may also have raised PSA concentrations. This lack of specificity complicates the interpretation of results, as well as having major implications for use of PSA in screening. Many uncertainties also remain concerning optimal treatment of early stage disease, even when clinically localized to the prostate.

Screening and diagnosis

Screening men for prostate cancer using PSA is controversial, as is evident from the disparate recommendations, both for and against screening, that have been made by different professional organizations. Consensus is unlikely to be achieved until publication of the final conclusions of a number of major national and international prospective screening trials using PSA (with or without digital rectal examination). Results from the European Randomized Study of Screening for Prostate Cancer, which involved 182 160 men age 50–74 years at entry, showed that, at 11 years of follow-up, PSA-based screening significantly reduced mortality from prostate cancer but did not affect all-cause mortality. To prevent one death from prostate cancer at 11 years of follow-up, 1055 men would need to be invited for screening and 37 cancers would need to be detected. In contrast, after 13 years of follow-up, results from the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial in the USA showed no evidence of a mortality benefit for organized annual screening as compared with opportunistic screening. Various explanations for these apparently contradictory results have been put forward.

However, whatever the final outcome of the ongoing trials, men will continue to request *ad hoc* screening for prostate cancer, whether or not an official programme is established. There is therefore general agreement that men should be informed of the benefits and limitations of PSA measurement before deciding whether to have the test performed, particularly if asymptomatic. In the UK, the NHS Cancer Screening Committee's Prostate Cancer Risk Management Programme provides helpful information about the test (Informed Choice Programme, see Further reading).

Early detection is likely to be most effective in younger men (in their 50s and 60s) who are at high risk of developing prostate cancer, African American men and men with a family history of prostate cancer. It is unlikely to benefit men with a life expectancy of less than ten years. Men with a strong family history (e.g. a first-degree relative diagnosed before the age of 60) may have a 3–4-fold higher than average risk of developing prostate cancer and should be carefully investigated.

Considerable effort has been made to improve the specificity of PSA assays, for example by considering the ratio of free to total PSA (the proportion of circulating free PSA is higher in benign disease), by assessing the rate of doubling of PSA (doubling time is more rapid in

malignant than benign disease) or by implementing age-related reference intervals (PSA may increase with age as the size of the prostate gland increases). Promising data are also emerging regarding proPSA, a proenzyme molecular form of free PSA, and a few truncated proPSA isoforms, but these tests are still under evaluation and are not widely used.

While each of these measures improves the differentiation of benign and malignant prostatic disease, whatever PSA decision limit is selected and however the marker is used, a significant number of men with benign prostatic disease will still be recommended for biopsy on the basis of a high PSA result. Conversely, a significant number of men with malignancy but with PSA below the decision point will be missed. It is estimated that up to 20% of men with a clinically significant prostate cancer will have a normal serum PSA concentration, and as many as two in every three men with an elevated PSA do not have prostate cancer detectable at biopsy. Nevertheless, PSA is currently the best routinely available serum tumour marker for screening or diagnosis of prostate cancer. It has been suggested that screening might be made more effective by starting screening earlier and referring patients with screen-detected cancers for treatment at specialist centres, and be made less harmful by avoiding screening in older men and promoting active surveillance with well-organized follow-up programmes for those with disease that is of low risk of progression.

Management

Once a diagnosis of prostatic cancer has been confirmed by finding malignant cells in a biopsy specimen, the treatment selected depends on whether disease is confined to the prostate gland or has spread to other organs. Using predictive tables combining the pre-treatment PSA concentration with information on clinical stage and the immunohistochemical Gleason score (which provides a measure of the degree of differentiation in biopsy tissue and ranges from 2 in well-differentiated tumours to 10 in completely anaplastic cancers), a reasonable prediction of the stage of localized prostate cancer can be made. For example, patients with a Gleason score of ≤ 6 and a PSA of $<10 \mu\text{g/L}$ are unlikely to have bone metastases.

Such information can then be used to select the most appropriate treatment option. If the disease has not spread beyond the prostatic capsule, possibilities include radical prostatectomy (complete removal of the prostate), brachytherapy (insertion of radioactive needles to ablate the prostate) and external beam irradiation. Active monitoring, i.e. regular clinical assessment together with measurement of PSA, is as appropriate as active intervention in some patients with localized tumours. The benefit of treatment is not yet proven, except in men with localized disease who are candidates for radical prostatectomy. In these men, the absolute reduction in the risk of death after ten years is small, but the reduction in the risks of metastasis and local tumour progression is substantial.

Following radical treatment, PSA should decrease to undetectable concentrations, with measurable concentrations providing evidence of residual disease. However, undetectable PSA concentrations do not necessarily

indicate cure. Similarly, while rising PSA concentrations following radical treatment provide biochemical indication of recurrent disease, clinical symptoms may never occur or may appear many years later. The use of ultrasensitive PSA methods with low detection limits (usually $<0.005 \mu\text{g/L}$), which permit very early identification of rising PSA concentrations, therefore remains controversial and is probably most appropriate within the context of clinical trials.

Treatment options for patients with prostatic cancer that has spread beyond the prostate (most frequently to local lymph nodes and bone) include endocrine therapy (usually by androgen blockade as prostate cancer is hormone-sensitive), radiotherapy and chemotherapy. Men with serum PSA $>100 \mu\text{g/L}$ and clinical, biochemical or radiological evidence of metastatic disease may, in some cases, be treated without histopathological confirmation of the diagnosis, while in other patients, active monitoring may be appropriate.

A major clinical application of PSA is in evaluating the efficacy of therapy, sustained increases providing evidence of disease progression, usually earlier than other diagnostic procedures. An increase in PSA should always be confirmed, and intraindividual variation in PSA of up to 20–30% taken into account before any increase is considered to be clinically significant. The doubling time of PSA can give some indication of the likely time to clinical progression. A stable PSA concentration does not necessarily exclude progression if clinically suspected. In patients with advanced, androgen-independent prostate cancer, measurement of alkaline phosphatase may be helpful to detect bone involvement. As knowledge of increasing PSA concentrations may have adverse psychological consequences, it may be desirable to stop measuring PSA in some patients, particularly if effective alternative therapy is not available.

Analytical and reporting requirements

Rigorous adherence to the quality control measures described at the beginning of this chapter is essential. The NHS Prostate Risk Management Programme formally requires that PSA assays used in the Informed Choice programme be accurately calibrated in terms of the International Standard for PSA (Table 42.4) and that they recognize free and complexed PSA equivalently (i.e. are equimolar). Screening programmes place particularly high demands on analytical performance, since relatively minor differences in performance have a major influence on outcome, i.e. whether or not a prostatic biopsy is advised. Even when PSA assays are accurately calibrated and equimolar, results for individual patients obtained using different methods are not necessarily interchangeable. It is therefore strongly recommended that laboratory reports for PSA state both the name of the assay used and the appropriate clinical decision limits.

Testicular cancer

More than 90% of testicular tumours in adults are germ cell tumours: these are discussed above. Leydig and Sertoli cell tumours, which are rare, develop in the supportive

hormone-producing tissue of the testicles (the stroma). These tumours represent 4% of adult testicular tumours and 20% of childhood tumours. Tumours of the Leydig cells (which normally produce androgens) do not usually spread beyond the testicle and can be cured by surgical removal. Those that do spread are resistant to chemotherapy or radiation. Tumours of the Sertoli cells (which normally support sperm-producing cells) are similar to Leydig cell tumours and are also difficult to treat if they spread beyond the testes. Inhibin is the marker of choice for Sertoli and Leydig cell tumours and the same analytical issues apply as for granulosa cell tumours of the ovary.

Thyroid cancer

Thyroid cancer is a relatively rare tumour, accounting for approximately 2% of cancers in all age groups and 4% of cancers in those <20 years old. There are four major types: papillary, follicular and anaplastic thyroid cancer and medullary carcinoma of the thyroid (MCT). Calcitonin is an excellent marker for MCT, which can be associated with multiple endocrine neoplasia (see Chapter 41). Papillary and follicular cancers are differentiated epithelial thyroid cancers and can be monitored using thyroglobulin, a large glycoprotein synthesized by the follicular cells and stored in the colloid space. Thyroglobulin is present in benign and malignant thyroid tissue.

Screening, diagnosis and prognosis

Serum thyroglobulin measurement has no role in the screening for, or diagnosis of, thyroid cancer and is of no value as a prognostic indicator. However, immunohistochemical detection of thyroglobulin can be useful in identifying the thyroid as the site of primary tumour in individuals presenting with metastatic disease from an unknown primary.

Monitoring

Thyroglobulin has an important role in monitoring patients with follicular or papillary thyroid carcinoma after treatment with surgery and/or radioiodine. Since thyroid stimulating hormone (TSH) stimulates thyroid follicular cells to produce thyroglobulin, serum thyroglobulin concentrations will be higher in patients with a raised TSH if there is remaining thyroid tissue or in the presence of recurrent tumour. TSH should therefore always be measured at the same time as thyroglobulin.

Detectable concentrations of thyroglobulin may be appropriate in patients treated by surgery alone, provided they are stable, but not in patients who have been treated with radioiodine to ensure total ablation of any remaining thyroid tissue. In these patients, serum thyroglobulin concentrations should decrease to <2 µg/L following ablation. In an individual with suppressed TSH, a rising thyroglobulin suggests recurrent tumour.

Historically, the difference in thyroglobulin values on and off thyroxine replacement was used to assess the presence of residual or recurrent tumour. This can now be done more effectively by measuring plasma thyroglobulin

concentration after administering recombinant TSH (rhTSH).

Analytical and reporting requirements

It is important to be aware of several potential pitfalls in thyroglobulin measurement. As for other tumour markers, it is highly desirable that specimens for thyroglobulin measurement should be taken prior to any invasive procedure. A common cause of very high serum thyroglobulin results is inappropriate specimen collection following fine needle aspiration biopsy of the thyroid.

Analytically, radioimmunoassay (RIA) and immunometric methods for thyroglobulin are particularly vulnerable to interference from anti-thyroglobulin auto-antibodies (TgAb), which may be present in some patient sera. Results obtained may be falsely low or falsely high, with immunometric methods being particularly prone to giving falsely low thyroglobulin results. Thyroglobulin antibodies should be measured in the same sample as thyroglobulin, using a sensitive immunoassay method. The presence of antibodies usually invalidates the thyroglobulin result. Comparison of results with RIA results available from specialist laboratories is informative. When interference is present, RIA results may be more reliable. It is important to note that interference may be absent even in the presence of antibodies or conversely present in their absence. Appropriate cautions should be added to patient reports.

Cancers of unknown primary

Cancers of unknown primary origin account for ~3% of all new cancer diagnoses and generally have a poor outlook, with median survival of less than a year. Although it is not clear to what extent tumour marker measurements may influence the clinical management of cancers of unknown primary, for a few patients the benefit may be considerable, enabling identification of appropriate treatment. Diagnoses for which this is most likely to be the case, together with the tumour marker measurements of relevance, are gestational trophoblastic neoplasia (hCG), germ cell tumours of the testis or ovary (hCG and AFP) and prostate cancer (PSA). These are potentially curable malignancies, which, once diagnosed, can rapidly respond to appropriate treatment. The NICE guidelines for metastatic malignant disease of unknown primary origin recommend measurement of serum AFP and hCG (particularly in the presence of midline nodal disease), PSA in men, CA125 in women with peritoneal malignancy or ascites, and a myeloma screen when there are isolated or multiple lytic bone lesions.

SUMMARY

Measurements of tumour markers already make an important contribution to the management of cancer patients. Maximizing their clinical usefulness and cost-effectiveness provides an excellent opportunity for close liaison between laboratory and clinical staff. Tumour

BOX 42.2 Key points for using tumour markers in the clinic

- A negative result for a serum tumour marker, either prior to diagnosis or following treatment, does not exclude active disease.
- A pre-treatment result is essential and provides the baseline against which subsequent results can be assessed.
- Serial results are nearly always more useful than single isolated results and frequency of marker measurement should follow guidelines where these exist.
- If decisions about proceeding to surgery or chemotherapy depend on a single tumour marker result, the result should be confirmed.
- Results that are not in accord with the clinical picture should be investigated and if necessary re-checked by another method.
- Tumour markers are seldom tissue-specific and therapy may result in a transient increase in the serum concentration because of release of tumour marker from normal tissue.
- Tumour markers should always be interpreted in the context of all available information, including clinical findings, imaging investigations and other blood tests. The possible influence of other factors (e.g. abnormal renal or liver function) should be carefully considered.

marker requests should be made only when the results are likely to be of benefit; pre-analytical and analytical requirements should be met and those using tumour markers clinically should be familiar with the key points summarized in Box 42.2.

It is likely that over the next decade, new analytical techniques such as proteomic profiling and novel genetic tests will lead to the development of more targeted tumour markers. Their introduction into routine practice will provide new challenges, which clinical biochemists are well positioned to meet.

CONCLUSION 871

INTRODUCTION

If we distinguish the actual combination of genes possessed by an individual, that is the genotype, from the observable activity of those genes, the phenotype, then study of inherited disease in clinical biochemistry laboratories has traditionally been concerned exclusively with analysis of phenotypes. The last two decades have witnessed a dramatic change in this situation: molecular biological techniques are now a much more common part of the repertoire of clinical biochemistry laboratories. Initially, the identification of genes responsible for inherited diseases involved heroic efforts, requiring expensive, complex and extremely time-consuming procedures plus a few strokes of luck. Once a gene has been identified, however, modern analytical techniques make detection of mutations more straightforward than before.

Although each nucleated human cell contains about two metres of deoxyribonucleic acid (DNA) (around 3 billion bases), it is the fundamental simplicity of DNA – its building blocks comprise just four nucleotides – that favours its automated analysis. With a few exceptions, every cell in the body of an individual contains a complete copy of their DNA (or genome). For this reason, genetic analysis can be carried out on almost any nucleated cell type (such as lymphocytes or buccal mucosal cells) that can conveniently be collected. The application of DNA analysis now extends well beyond diagnosis of the classic inherited diseases to include, for example, the diagnosis and prognosis of cancer.

This chapter provides a general background to clinical laboratory applications of molecular genetic analysis. The emphasis is on diagnostic techniques with the potential for automation, utilizing polymerase chain reactions (PCRs), since classic techniques such as Southern blot analysis are not widely used in hospital biochemistry laboratories, but tend to be restricted to specialist molecular genetics departments. As far as possible, only a very basic knowledge of molecular biology has been assumed, but several excellent introductions to the topic are available (see Further reading) and a glossary is provided on page 872.

GENES AND GENE EXPRESSION

What is a gene?

A common working definition is that a gene is a sequence of nucleotide bases in DNA that codes for a single polypeptide, but the complexity of genomic organization is such that it is probably unwise to adhere rigidly to any one definition of the gene. Towards the end of the 19th century, it was already accepted that linear groups of ‘invisible self-propagating vital units’ were present in chromosomes. Mendel’s discovery (1865) that inheritance is particulate was rediscovered and publicized at the beginning of the 20th century, and the term gene was introduced to describe Mendel’s ‘particulate elements’ in 1909. By 1911, a specific gene (for colour blindness) had

already been assigned to a particular chromosome (the X chromosome). With the work of Garrod, who first presented his studies on alkaptonuria in 1902, the association of specific diseases with inherited Mendelian traits became established.

Certain stains produce clearly defined bands on chromosomes, so the location of genes is described according to the number of the chromosome on which they are found, whether they are on the long (q) or short (p) arm, and the band number. For example, the location of the α_1 -antitrypsin gene is described as 14q31–32.3, meaning that it is found on the long arm of chromosome 14 in the region of bands 31–32.3. The locations of some of the genes that have been mapped to the X chromosome are shown in Figure 43.1.

After the double helical structure of DNA had been discovered in 1953, the rather abstract concept of a gene became more tangibly associated with a physical structure. Nucleic acids consist of two complementary polymers of nucleotides. Each nucleotide consists of a purine or pyrimidine base, linked to a phosphorylated pentose. In DNA, the pentose is deoxyribose and the bases are adenine (A), guanine (G), cytosine (C) and thymine (T). In ribonucleic acid (RNA), the pentose is ribose and the pyrimidine uracil (U) replaces thymine. Protein coding sequences (exons) are interrupted by non-coding sequences (introns), which are variable in number (up to 50 in collagen genes, for example) and size (up to several thousand base pairs). As a consequence, although the knowledge that three bases code for an amino acid allows us to predict that the coding sequence for an average protein of 400 amino acids will be 1200 nucleotides, the complete gene could be an order of magnitude larger. The boundaries between exons and introns are critically dependent on the GT-AG rule: that is, introns almost invariably begin with GT (or GU in RNA) and end with AG. The structure of a hypothetical gene is shown in Figure 43.2. The promoter region of DNA, which precedes the coding region ('upstream' from the 5' end of the gene, that is, in the opposite direction to transcription) is intimately involved in permitting and regulating expression. Some genes code for RNA (e.g. ribosomal and transfer RNA) that is not translated into protein, and modifications in the process of intron removal can result in one sequence of DNA participating in synthesis of different proteins, so that certain genes can be considered to overlap.

The Human Genome Project

The Human Genome Project (HGP) represents an outstanding piece of multinational cooperation to map the entire human DNA sequence. The project, started in 1990, had several aims, the first of which was to determine the entire base pair sequence. The sequence of 3 billion base pairs was announced in draft form in 2000 and the complete sequence in 2003. It was thought initially that the human genome would consist of approximately 100 000 different coding genes. As the HGP neared completion, it emerged that the actual number would be closer to 30 000.

FIGURE 43.1 ■ The mapping of genes to specific sites on the X chromosome. The regions in the X chromosome where the genes associated with Duchenne and Becker muscular dystrophy (the dystrophin gene at p21.2), Lesch-Nyhan disease (the hypoxanthine-guanine phosphoribosyl transferase or HGPRT gene at q26.1-q26.2), fragile X syndrome (the FRAXA gene at q27.3) and glucose 6-phosphate dehydrogenase (the G6PD gene at q28) deficiency are located are shown.

The 'Encode' project

Protein coding sequences and introns account for about 20% of DNA. The function of the remainder is being elucidated but in 2012, the initial findings of the 'Encode' project, which had been examining what had previously been called 'junk' DNA, were published. It appears that the remaining 80% does have a function within the genome, with much of the non-protein coding DNA appearing to code for RNA transcripts that may have other regulatory functions alongside those of gene enhancers and promoters.

FIGURE 43.2 ■ The structure of a hypothetical gene. Coding sequences (exons) are shown in black, introns and non-coding regions are shaded and regulatory regions are in dark shading. Bases in exon sequences are shown in upper case, while bases in intron sequences are shown in lower case, illustrating the GT-AGT rule for starts and ends of introns.

That the number of genes is much lower than expected appears to be because many genes can perform multiple functions, and it now appears that these functions may be regulated by the remainder of the genome. These discoveries have implications for the investigation and diagnosis of genetic disease, and issues concerned with gene expression will have a growing role in clinical genetics.

Gene expression

The differentiated properties of each cell are determined by the pattern of genes in the cell that are active or dormant. In any one cell, only a small percentage of genes are likely to be actively engaged in directing synthesis of RNA at any one time. Many of these are ‘housekeeping’ genes, which are expressed in virtually all cell types. Much remains to be learned concerning the factors that determine whether or not a gene is expressed, but regulation of gene expression is clearly determined by proteins that interact with DNA.

In higher (eukaryotic) organisms, DNA is found within the nucleus and the mitochondria, although the mitochondria have a very small percentage of the total DNA within the cell and a very small number of genes. Nuclear DNA is complexed with basic proteins (histones) to form chromatin. At regular intervals, DNA is wrapped around complexes of eight histones to form nucleosomes. The copying of DNA into RNA (transcription) is performed by RNA polymerase, which initiates transcription by interacting with the promoter region of a gene. Gene expression is inhibited if nucleosomes cover a promoter region and many factors that regulate transcription probably do so by competing with histones for binding to the promoter region. Within each promoter region, there are several elements that bind specific proteins capable of interacting with RNA polymerase and associated proteins. One of the key proteins in this group binds to the so-called ‘TATA box’ element (actually a TATAAAA or related sequence), which is found in most eukaryotic promoters and is usually located around 30 base pairs (bp) upstream from the transcription start site. Other conserved sequences, such as CAAT, also bind transcription factors and are found within the promoter region. Another class of regulatory sequence in DNA, the enhancer region, binds regulatory molecules, which include the steroid hormone receptors. Enhancer sequences may be some distance from the gene

that they regulate, but the proteins that bind to them may nevertheless interact with the transcriptional apparatus as a result of looping in the DNA molecule.

The initial RNA transcript (pre-mRNA) is modified in several ways before it leaves the nucleus (Fig. 43.3). First, a ‘cap’ structure (7-methylguanosine) is attached to the 5’ end and a sequence of about 200 adenylic residues (poly A) is added at the 3’ end. The non-coding introns are then removed by a two-step splicing mechanism to form a mature messenger RNA (mRNA). Splicing, which takes place within ‘spliceosomes’ (complexes of RNA and proteins), requires cleavage at the 5’ and 3’ ends of the intron and ligation (joining) of the exons. The specific boundary sequences found at splice junctions (see above) act as signals for splicing. Comparison of large numbers of splice junctions reveals these ‘consensus sequences’ to be of the general form AGgta at the 5’ junction and cagG at the 3’ junction (where bases in the intron sequence are in lower case). Given that pre-mRNA molecules can contain up to 65 exons and an intron may consist of thousands of nucleotides, it is remarkable that the correct sites for splicing can be chosen.

Finally, the process of translation involves the activity of ribosomes, transfer RNA and a variety of other molecules which synthesize a protein using the mRNA code as a template. A group of three nucleotides (a codon) specifies an amino acid and most amino acids are coded for by more than one codon (i.e. the genetic code is degenerate). In principle, each RNA sequence can be decoded in three different reading frames, depending on which triplet is chosen as the first codon. In practice, the reading frame is determined by the site of initiation, which always occurs at an AUG codon (AUG codes for methionine, but the initiating methionine is cleaved from proteins in eukaryotic cells). Translation stops at any one of three stop codons (UAA, UAG or UGA). Any subsequent modification of a protein, such as proteolytic cleavage or addition of carbohydrate, is known as post-translational modification.

Mutation, the source of diversity and disease

The accepted terminology, which referred to the ‘normal’ gene in a population as the ‘wild type’, has changed and the terms ‘normal’ and ‘mutant’ (or ‘variant’ if pathogenicity is unclear or questionable) are now preferred.

FIGURE 43.3 ■ Transcription and mRNA processing. After transcription, processing of precursor mRNA involves capping, whereby GTP is attached to the 5' end of the mRNA precursors via a 5'-5' triphosphate linkage (i.e. in the reverse orientation to all other nucleotides); addition of around 200 adenylate residues to form a poly(A) tail at the 3' end; and splicing, in which introns are excised and exons spliced together. Translation of mRNA into protein is initiated by ribosomes and transfer RNA at the AUG codon and terminated at one of the stop codons (UAG, UAA or UGA).

However, the genetic constitution of populations is in a constant state of flux with new genes appearing as a result of mutation and deleterious genes being removed by natural selection. Mutations can be broadly divided into those that change the genetic code at a specific location (point mutations or single nucleotide polymorphisms, SNPs) and those that result in gain or loss of genetic material (deletions, duplications and insertions). Point mutations can result from incorrect insertion of a base during DNA replication by DNA polymerase or spontaneous decomposition reactions such as depurination and deamination. Mutagenic chemicals that increase this error rate include those that mimic the natural bases or distort the structure of DNA and those that chemically modify DNA. Ultraviolet light also causes point mutations, particularly by formation of pyrimidine dimers. Point mutations in which a purine is replaced by another purine (e.g. A replaced by G) or a pyrimidine is replaced by another pyrimidine are known as transitions, while replacement of a purine by pyrimidine (e.g. G replaced by C) or vice versa is known as a transversion. Gain or loss of genetic material can result from various errors, including chromosomal breakage and unequal crossing over. Insertion of viral sequences into DNA can also disrupt the genetic code and the rate of spontaneous chromosomal breakage can be markedly increased by ionizing radiation. Whenever the number of bases deleted or inserted is not a multiple of three, the reading frame of the mRNA is altered (frameshift mutation) and the RNA sequence subsequent to the mutation becomes nonsense.

Accumulated damage to DNA would rapidly overwhelm the organism, but repair mechanisms recognize and repair damaged DNA so that fewer than 1 in every 1000 accidental base changes results in a stable mutation. It is estimated that stable point mutations are acquired at a rate of about 1 in every 10^9 base pairs during each cell generation. Consequently, an average gene of about 10^3 coding base pairs is likely to acquire a mutation once in every 10^6 cell generations. As might be expected, individuals with inherited defects in the enzymes responsible for DNA repair are markedly more susceptible to the effects of environmental mutagens.

A significant proportion of germline point mutations are thought to be caused by modification of methylated cytosine residues. DNA methylation, restricted in eukaryotic cells to cytosine residues, usually at CpG dinucleotides (CpG denotes C-phosphate-G in a linear sequence, in distinction from a CG base pair) is not present in all such organisms but is thought to play an important role in ensuring stable inheritance of expression patterns when cells divide. Spontaneous deamination of the 5-methylcytosine creates thymidine, and problems can then arise when the normal guanine on the complementary strand becomes an adenine and the mutation cannot be detected by DNA repair mechanisms. Consequently, methylation of cytosine can produce mutation 'hot spots' (i.e. sequences associated with an unusually high frequency of mutations or recombination).

Some mutations may have no effect on the structure of a protein – either because the genetic code is degenerate

and the new sequence codes for the same amino acid, or because some amino acids in a protein can be substituted without producing any significant effect on the function of the protein. However, some apparently 'silent' mutations may have an effect on the protein product, not because of the actual base change involved, but rather through an effect on splicing by activating cryptic splice sites or destroying splice enhancers. Mutations that change the three-dimensional structure of a protein and so alter its function or stability may do so by a variety of mechanisms (Fig. 43.4).

A Missense

 Ile	Asp	Glu	Lys	Gly
Normal: ATC	GAC	GAG	AAA	GGG
Mutant: ATC	GAC	AAG	AAA	GGG
 Ile	Asp	Lys	Lys	Gly

Mutant: AAG	GGG	GGG	CTA	TAA
		Lys	Gly	Gly	Leu	Stop

F Expansion of triplet repeat

Normal: GCG	(CGG) ₅₋₅₄	CTG
Mutant: GCG	(CGG) _{>200}	CTG

FIGURE 43.4 ■ Examples of mutations. (A) G to A transition in the α_1 -antitrypsin gene, a missense mutation resulting in substitution of glutamic acid by lysine at position 342, producing the Z variant associated with α_1 -antitrypsin deficiency. (B) Transversion of C to T in the steroid 21-hydroxylase gene, converting the codon for glutamine to a stop codon, one of the mutations causing congenital adrenal hyperplasia. (C) G to A transition in the 5' splice site of intron 12 in the phenylalanine hydroxylase gene, resulting in deletion of exon 12, the most frequent cause of phenylketonuria in Caucasians. Bases in intron sequences are shown in lower case. (D) Deletion of three bases in the cystic fibrosis transmembrane conductance regulator (CFTR) gene resulting in deletion of phenylalanine at position 508, the most frequent mutation causing cystic fibrosis in Caucasians. (E) Insertion of a G in the hypoxanthine-guanine phosphoribosyl transferase gene, a frameshift mutation that results in the Lesch-Nyhan syndrome. (F) Amplification of a CGG triplet repeat in the FMR-1 gene, which causes the fragile X syndrome.

By convention, the DNA strand that has the same sequence as mRNA (except that it possesses T instead of U) is represented. This strand is known as the coding strand, although it is the 'anticoding' strand that is complementary to mRNA and therefore provides the template for mRNA synthesis.

Some amino acid changes (missense mutations), such as that which produces the Z variant of α_1 -antitrypsin (Fig. 43.4A), can have a profound effect on the processing or function of a protein. Some mutations (nonsense mutations) create or destroy codons for the start or stop signals of translation so that a protein of abnormal length is produced (Fig. 43.4B). Mutations at splice sites (Fig. 43.4C) frequently result in production of abnormal mRNA that is unstable. Deletion of three bases removes the codon for a single amino acid without altering the reading frame, as occurs in the most common mutation causing cystic fibrosis (Fig. 43.4D). Insertion (Fig. 43.4E) or deletion of any number of bases that is not a multiple of three will alter the reading frame so that the message becomes garbled. Amplification of triplet repeat sequences (Fig. 43.4F) has been identified as the basis of several inherited diseases. Occasionally, mutations affect regulatory regions of DNA so that the amount of protein produced is altered. Although mutations are most frequently either neutral or deleterious, rare mutations will alter the function of a protein in such a way that the fitness of an individual is improved, so contributing to evolution. Inheritance of the mutations that have accumulated in our ancestors, whether they be advantageous, neutral or deleterious, is what constitutes our individuality.

An individual inherits two copies of each chromosome (one maternal and one paternal). On each chromosome, the sequences at each site, or locus, are known as alleles. If the two alleles are identical, the individual is said to be homozygous at that locus, while if the alleles are different, the individual is said to be heterozygous for each allele. As will be seen later, genetic disease is usually heterogeneous, so that an individual said to be homozygous for a deleterious gene may be found, when studied at the molecular level, to carry a different mutation in each allele (i.e. is a compound heterozygote). When the prevalence of a mutant allele becomes more common in a population than could be maintained by new mutations alone (generally taken to be when more than 1% of the population carry the allele), there is said to be polymorphism. Many proteins in blood (e.g. haptoglobin) and on cell surfaces (e.g. human leukocyte antigen, HLA) are polymorphic.

The classic inherited diseases result from single gene defects and more than 6000 inherited diseases likely to be associated with defects in single genes have already been identified. Inherited diseases could, in theory, result from mutations in any one of the human genes – the only limitation being that the structure of some gene products is so critical that any mutation will not be compatible with life. Most of the more common diseases that afflict western society, including most cases of diabetes, atherosclerosis and hypertension, are the result of interaction between the environment and polygenic factors (i.e. they are determined by interactions between

several genes). Molecular analysis of the polygenic diseases is considerably more difficult than analysis of single gene defects, but alleles that predispose individuals to development of these diseases are being identified. Both single gene defects and most multifactorial/polygenic diseases arise from mutations in the nuclear DNA but genetic diseases also arise from mutations in mitochondrial DNA and from chromosomal abnormalities. Mitochondrial DNA is extranuclear and shows almost complete maternal inheritance. Chromosomally inherited disorders include the trisomies, where faulty meiosis allows two copies of a chromosome to be present in a gamete, leading to three copies in the embryo. Trisomy of chromosome 21, for example, is responsible for Down syndrome.

If new mutations occur in germ cells, then they may give rise to an inherited disease in the next generation. The effects of mutations on non-germ cells, or somatic cells, will depend both on the gene affected and on the state of differentiation of the cell affected. The ageing process is likely to be one result of accumulated mutations in somatic cells and the central role of mutations for the development of cancer has become clearer during the last few years.

Genesis of an individual: the formation of gametes

An individual's genotype is determined at the time of fertilization, when the chromosomes of the gametes (i.e. the male sperm and female egg) are combined. The formation of gametes (gametogenesis) is particularly relevant to an understanding of the detection of inherited disease because it is at this stage that 'shuffling' of genes occurs.

Normal cell division, or mitosis, involves a simple copying of each chromosome, with one identical copy being passed on to each daughter cell. To avoid a doubling in the number of chromosomes in each generation, gametogenesis involves a reduction (by half) of the chromosome number during two specialized cell divisions known as meiosis. Since the chromosome complement of parent and offspring must be equivalent, the reduction in chromosome number cannot be arbitrary: parental contributions must be equal and equivalent. This requirement can be met because each somatic cell of an individual is diploid, containing corresponding (homologous) pairs of chromosomes, one derived from the mother and the other from the father. Meiosis consists of two cell divisions: in the first, after duplication of DNA, pairing of homologous chromosomes occurs, and to ensure that each gamete receives just one member of each homologous pair, the duplicated paternal chromosome is distributed to one, the duplicated maternal chromosome to the other. The assortment between the two cells appears to be random so that each cell acquires some maternal and some paternal chromosomes. The second cell division is like ordinary mitosis, except that it is not preceded by duplication of chromosomes. As a consequence, the gametes produced are haploid, with half the normal number of chromosomes.

At first sight it might be expected that a chromosome would be transmitted from one generation to the next as an intact unit and that two genes on the same chromosome would always be inherited together. The fact that this is not so is a result of events that occur during the first meiotic division, which have important consequences for genetic analysis. As chromosomes pair prior to the first division, crossovers (or chiasmata) occur by breakage and rejoining between the chromatids of homologous chromosomes resulting in recombination (Fig. 43.5). The recombination fraction is a measure of the genetic, rather than the physical, distance between two genes (or loci). The recombination fraction for two loci can never be more than 0.5 as the resulting chromatids can only ever be recombinant or non-recombinant, no matter how many crossovers have occurred between the loci. In simple terms, linkage of two genes (i.e. a tendency to be inherited together) occurs only when the genetic distance separating them is sufficiently short to make crossover between them unlikely. The association of two genes on separate chromosomes is random but association of genes on the same chromosome is not, as it is known that crossovers do not occur at random. A process known as interference prevents a chiasma forming if one already exists nearby. When genes are associated more frequently than would be predicted by chance, they are said to be in linkage disequilibrium.

In females, gametogenesis is initiated during fetal development and, at birth, the germ cells are in a phase of arrested maturation of the first stage of meiosis, which is not completed until ovulation. The increased risk of chromosomal abnormalities in older mothers may be

FIGURE 43.5 ■ Crossover and linkage. Exchange of alleles as a result of crossover between homologous chromosomes. Linkage between alleles a and b (or A and B) occurs if they are sufficiently close that crossover is unlikely to occur between them.

explained by the fact that completion of meiosis occurs only after ovulation, when the second stage of meiosis (which is similar to ordinary mitotic division) occurs and during which fertilization can take place. This may happen up to 50 years after formation of the germ cells. In males, sperm production continues from the time of sexual maturity into old age and the large number of cell divisions involved is probably the cause for the increased number of new single gene mutations that seem to occur in the children of older men.

Genes in families and populations

Mendel introduced the concepts of dominant 'characters' (or traits), which are transmitted without change, and recessive traits, which become latent after cross-fertilization. In modern terms, an allele coding for a dominant trait can be said to manifest its phenotype in the heterozygous state (i.e. only one copy is required for its effects to be apparent), while an allele for a recessive trait expresses its phenotype only in homozygotes. An individual who is heterozygous for an autosomal recessive condition is described as a carrier. The types of family pedigree associated with autosomal dominant and recessive genes are illustrated in Figure 43.6A and B. Autosomal dominant conditions affect males and females equally, and affected individuals who are heterozygous for the abnormal allele will transmit it to half of their offspring. Autosomal recessive disorders occur

in individuals whose parents are both carriers for the mutant gene. The risk for such patients of having affected children is 25% and the probability of any child they have being a carrier is 50%. Dominant diseases are often associated with genes coding for proteins that have structural, carrier or receptor functions, while genes coding for enzymes are often associated with recessive disorders. The explanation for this is probably that the activity of most enzymes is considerably greater than necessary for normal metabolism, so loss of up to half of the normal activity is of little consequence. Inheritance is somewhat different for alleles on X chromosomes. Dominant X-linked diseases will affect both males and females, but an X-linked recessive disease will be manifest only in males, who have only one X chromosome (Fig. 43.6C). In females, during the very early stages of embryogenesis, one or other X chromosome is inactivated in every cell; consequently, females can be carriers but will usually only suffer from an X-linked recessive disease if they are homozygous. However, sometimes, in some disorders, the inactivation is not random but occurs in such a way that only the normal chromosome is inactivated, with the result that only mutant alleles are expressed in critical tissues ('skewed' X-inactivation) and the individual becomes a manifesting heterozygote. This has been reported in several X-linked recessive disorders including, for example, Duchenne muscular dystrophy.

When both alleles are expressed in a heterozygote, each producing its phenotype independently, inheritance is said to be codominant. This type of inheritance is seen most clearly when phenotypes are determined by immunological or biochemical tests – for example, in testing for blood groups and in restriction fragment length polymorphism (RFLP) analysis and, more recently, in the growing field of pharmacogenetics (see later), where it is possible to distinguish both alleles at each locus.

Of the inherited diseases currently recognized, the overwhelming majority are due to problems in nuclear DNA and are autosomal dominant, autosomal recessive or sex linked. However, it is now known that some diseases are associated with the small amount of DNA that is present in mitochondria. These diseases are maternally inherited, since the mitochondria in the fertilized egg are of maternal origin.

The relative frequency of inherited disease varies markedly between populations: for example, cystic fibrosis and α_1 -antitrypsin deficiency are associated primarily with northern Europeans, while red cell disorders (thalassaemia, sickle cell anaemia and glucose 6-phosphate dehydrogenase deficiency) are found primarily in people of Mediterranean, Oriental or African origin, and Tay-Sachs disease is found primarily in Ashkenazi Jews. In some populations, the prevalence of an inherited disease is due to a 'founder effect', as with variegate porphyria in South Africans, which can be traced to a single couple who emigrated from Holland in the 1680s. Autosomal recessive diseases that are particularly widespread in larger populations are likely to represent a balanced polymorphism in which disadvantage to homozygotes is balanced by an advantage to the larger number of heterozygotes. With some red cell disorders (e.g. HbS, the

FIGURE 43.6 ■ Patterns of inheritance in families. Inheritance of (A) a dominant condition, (B) a recessive condition and (C) an X-linked recessive condition. Squares represent males and circles represent females. Open symbols represent normal individuals, while fully shaded symbols refer to affected individuals and half-shaded symbols represent carriers.

sickle cell trait), the balanced polymorphism is clearly a response to the environment, in this case with heterozygosity conferring resistance to malaria caused by *Plasmodium falciparum*.

In a large population, the relative frequencies of different alleles tend to remain constant and a simple mathematical formula allows calculation of the frequency of different genotypes. If two alleles, A and a, occur at a given locus and their frequencies are p and q , respectively, then:

$$p + q = 1$$

(since one or other allele must be present,
their sum must be 1)

It can be shown that the genotypes AA, Aa and aa have frequencies p^2 , $2pq$ and q^2 , respectively (the Hardy-Weinberg law). Use of this law allows simple calculation of carrier frequencies for autosomal traits. For example, if the homozygote frequency (q^2) for cystic fibrosis is about 1 in 2500, q is $1/50$, p is $1 - q$ or $49/50$ (~ 1) and the heterozygote frequency ($2pq$) is about $1/25$.

The variable expression of genetic disease

Several factors dictate that each genetic disease is associated with symptoms of quite variable nature and severity.

It is often naively assumed that all mutations of a particular gene will have identical consequences for the organism, but this is far from being true. Different mutations in a given gene are quite likely to give rise to different phenotypes, just as a particular phenotype can result from many different mutations in the same gene or even in different genes. Since many different mutations that have deleterious effects on a particular gene are present in most populations, it is not surprising that molecular analysis often reveals that individuals who have been described as homozygous are in fact compound heterozygotes, that is, they are affected by two different deleterious alleles.

Because the haemoglobin gene has been investigated in detail, it provides a good illustration of the complexity of genetic disease. Several hundred abnormal haemoglobins have been identified. The majority have amino acid substitutions resulting from single base changes and the consequences range from complete absence of protein to variant haemoglobins with function indistinguishable from that of normal (see Chapter 29). As study of other genes progresses, similar complex arrays of mutations of every imaginable type and with differing consequences are being discovered. With the introduction of screening for phenylketonuria (PKU), it soon became apparent that the disease is heterogeneous. It has been shown that, in PKU, phenotypic heterogeneity is related to the level of phenylalanine hydroxylase activity expressed in each patient which, in turn, is determined, in classic PKU, by the particular mutations that are present in the two alleles of the phenylalanine hydroxylase (PAH) gene. However, not all cases of neonatal hyperphenylalaninaemia are due to PAH deficiency. Benign hyperphenylalaninaemia arises from a transient liver immaturity and does not lead to the disease. Two rare causes of PKU are

deficiencies in the enzymes dihydropteridine reductase and dihydrobiopterin synthetase, leading to PKU with a severe phenotype. Glucose 6-phosphate dehydrogenase (G6PD) deficiency, which is an X-linked recessive condition estimated to affect as many as 500 million people worldwide, has also proved to be extremely heterogeneous at both the phenotypic and molecular levels. Some variants appear to have no clinical consequences, while at the other extreme, severe defects in G6PD cause hereditary non-spherocytic haemolytic anaemia (see Chapter 27). Intermediate defects are associated with haemolytic anaemia only in the presence of precipitating factors (e.g. infection, ingestion of fava beans or certain drugs). Analysis of the protein had indicated the existence of about 400 variants of G6PD and a similar number of mutations have now been described, but many of these appear not to cause disease. Many of the mutations causing the most severe disease are clustered near the carboxy end of the enzyme in the region of the putative NADP binding site.

A further level of heterogeneity in genetic disease occurs as a result of varying degrees of penetrance and expressivity. Penetrance refers to the degree to which the mutation causes disease. Thus, in some disorders, the presence of the mutant gene is disease-causing in some individuals but not others, demonstrating variable penetrance, whereas in diseases that are fully penetrant, the presence of the mutation will always lead to the disease phenotype. For example, the C282Y (Cys282Tyr) mutation in the *HFE* gene (causing substitution of the cysteine residue at position 282 of the human haemochromatosis protein by tyrosine), causes haemochromatosis in some individuals but results in a completely normal phenotype in others. Expressivity is a slightly different aspect of a gene's effect and refers to the presence of variable phenotypes arising from the same mutation. It can be age-related or determined by the environment (as when drugs such as barbiturates precipitate attacks of acute intermittent porphyria). An example of a disorder demonstrating variable expressivity is Waardenburg syndrome, where the 'full' syndrome includes several phenotypic features (such as different coloured eyes, a white forelock or deafness) but where, within a single affected family, different individuals may have only one feature, which is not always the same one within that family. Variable expressivity and penetrance tend to be features of dominant, rather than recessive, conditions.

Another aspect of inheritance, known as imprinting, may help to explain processes such as variable penetrance and expressivity. Contrary to the assumptions of classic genetics, it now appears that expression of some genes depends on whether they are of maternal or paternal origin. The molecular mechanism of imprinting, which is likely to occur during meiosis, involves DNA methylation, which 'marks' certain genes and ensures that they are preferentially expressed in the next generation. If such a gene is imprinted in the maternal line, it will continue through a woman's daughters but not through her sons, although both may be affected. The converse is true for paternally imprinted genes, which will be transmitted through

sons but not through daughters. Consequently, if an imprinted gene contains a deletion, offspring will not show expression of the gene product even in the presence of a normal gene on the opposite chromosome, as this will be 'switched off'.

Prader–Willi and Angelman syndromes are good examples of disorders arising due to abnormalities in a region carrying imprinted genes (chromosome 15 at 15q12.). Prader–Willi syndrome, features of which include hypotonia and hyperphagia, is produced by deletion of the paternal alleles at 15q12. Angelman syndrome, which is associated with ataxic movements and seizures, is also associated with deletion of 15q12 but, in this case, of the maternal allele. In some cases of Prader–Willi syndrome, rather than deletion of the paternal alleles, loss of the paternal chromosome occurs together with maternal isodisomy (two copies of the same allele from the mother) or heterodisomy (one copy of each maternal allele). There are several possible mechanisms by which two alleles can be inherited from one parent. Trisomies, for instance, usually result in spontaneous abortion, but if one chromosome is then lost there is a one in three chance that resulting cells will have a normal complement of chromosomes but with one pair of chromosomes derived from a single parent. The interesting possibility that a recessive disease can be inherited from one carrier parent then arises. This unusual mode of inheritance has been demonstrated in some patients with cystic fibrosis, but it is not yet clear how frequently it occurs in this or other diseases.

THE TECHNIQUES OF GENETIC ANALYSIS

Detection of specific sequences in DNA

Analysis of DNA is heavily dependent on the availability of techniques to identify specific nucleotide sequences. Fortunately, the function of DNA has resulted in the evolution of proteins capable of recognizing specific DNA sequences and it is inherent in the structure of DNA that one strand should recognize and bind (hybridize) specifically to its complementary strand. Most of the techniques currently used in DNA technology exploit one or other of these properties.

Use of proteins that recognize DNA sequences: restriction endonucleases

Without restriction enzymes, much of the molecular biological analysis carried out in the last 30 years would not have been possible. These enzymes are widespread in bacteria: over 3000 having been recognized so far, of which around 600 are available for commercial/analytical use. Each enzyme is named after the species of bacteria in which it was found (e.g. *EcoRI* from *Escherichia coli*), and in which it probably fulfils a defensive function, cleaving molecules of foreign DNA. The usefulness of these enzymes derives from the fact that they do not cleave DNA at random, but recognize and cut specific nucleotide sequences. The most commonly used restriction enzymes recognize sequences of 4–6 nucleotides that have a two-fold axis of symmetry

and are therefore said to be palindromes (i.e. the sequence reads the same on the complementary strand) (Fig. 43.7A). Digestion of DNA by a particular enzyme provides reproducible fragments whose size will depend on the frequency with which the enzyme recognition site occurs. On average, a 4-bp site occurs every 256bp and a 6-bp site every 4096bp. While some enzymes (e.g. *HaeIII*) cut in such a way that 'blunt ends' are produced, others (e.g. *EcoRI*) cut asymmetrically so that 'sticky ends' are left, which are extremely useful for reannealing fragments to produce recombinant DNA (Fig. 43.7B).

In addition to allowing reproducible cleavage of DNA to a manageable size, restriction enzymes are also valuable tools for analysing molecular diversity and identifying the individuality of DNA sequences. Differences in DNA sequences between individuals may create or destroy sites for restriction enzymes (i.e. there is polymorphism of restriction sites). Thus, the distance between restriction sites will often differ between individuals and between the maternal and paternal strands of DNA. The pattern of restriction sites can therefore provide a 'signature' for each individual strand of DNA. The different populations of DNA fragments produced on digestion by an enzyme are known as restriction fragment length polymorphisms or RFLPs.

Restriction enzymes have more recently acquired a new use in preparing genomic DNA for the various techniques employed in 'next generation' sequencing.

Hybridization: probes and the polymerase chain reaction (PCR)

A probe is a sequence of DNA (or RNA) that has been labelled in order to identify complementary base sequences by molecular hybridization. The two strands of DNA can be dissociated ('denatured' or 'melted') in various ways, such as by heating or addition of alkali. Denaturation for a given fragment of DNA occurs at a specific temperature, and the temperature at which 50% of the duplex is dissociated is known as the T_m . When the temperature is lowered to just below the T_m , hydrogen bonds begin to reform between complementary bases, a process known as annealing or renaturation. If the probe and target DNA are mixed before reannealing is allowed to occur, the probe can be used to 'find' its complementary sequence. The conditions under which reannealing occurs (in particular salt concentration and temperature) determine the degree of stringency of the hybridization.

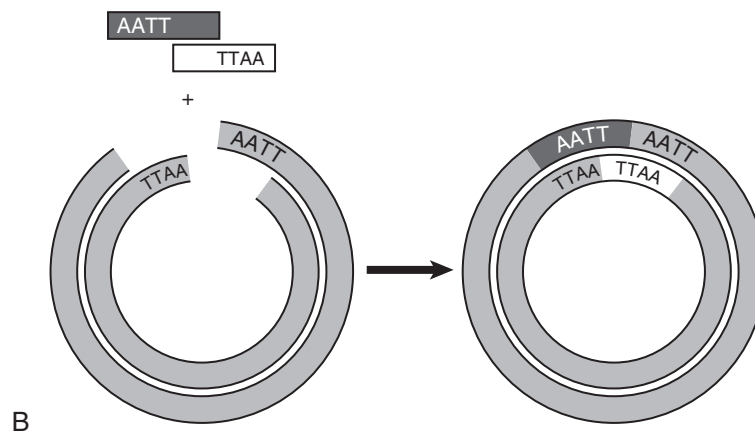

Probes can be used to detect their complementary sequences, traditionally after DNA (or RNA) fragments have been separated by electrophoresis. Digestion of genomic DNA with a restriction enzyme will produce a million or so fragments of different sizes and electrophoresis has the great advantage of allowing simple determination of the size of fragments detected by probes. The now classic technique of Southern blotting involves the transfer of electrophoretically separated bands of DNA to a sheet of nitrocellulose or nylon. Complementary DNA sequences are then detected by hybridization with labelled probes. The technique was originated by Dr (later Professor) E M Southern. Subsequently, the terms Northern and

(B) Cohesive ends produced by restriction enzymes can be used for annealing of DNA sequences, which can then be joined by a ligase to form a recombinant DNA molecule.

Western blotting have been used for processes in which RNA or proteins, respectively, are transferred.

In the past, all DNA analysis required some technique of visualizing the products of the reaction, and with probe hybridization this involves labelling the probe in some way. ³²Phosphorous radioactive labelling, although still in use for blotting protocols, was superseded by the use of fluorescent dyes, particularly for gene sequencing, a system which allowed the development of large, high-throughput, DNA analysers, as well as techniques such as real-time PCR. However, some of the technologies employed in 'next generation' sequencing systems require neither gels nor dyes, as will be discussed later. Some of the newer systems allow for an electrical signal to be generated when hybridization of probe to target

occurs, which may eventually lead to the development of point-of-care systems.

Probes, generally of a few thousand bases, may be sequences cut from genomic DNA or they may have been produced by making complementary DNA (cDNA) to an mRNA species. The latter procedure uses the enzyme reverse transcriptase, which transmits genetic information in the 'reverse' direction, that is, from RNA to DNA. Genomic and cDNA sequences differ, particularly in the absence of intron sequences from the latter. The tolerance of probes for mismatching of base sequences will depend on their size and on the stringency of hybridization. Shorter oligonucleotide probes are often more useful for direct identification of point mutations since

conditions can be chosen such that hybridization occurs only when there is complete complementarity between probe and target. Because hybridization of a relatively smaller proportion of bases in the probe is required, larger genomic or cDNA probes will usually recognize corresponding sequences of DNA from different individuals in a population or even different but related genes.

Cloning, where the sequence of interest was 'grown' in bacteria such as *E. coli* after being inserted into the bacterial genome using bacteriophage viruses, has been largely superseded as a method of producing probes by the ability to create synthetic oligonucleotide sequences, although cloning as a technique is still employed in areas of research.

Without doubt, the commonest use for synthetic oligonucleotides has been as 'primers' in the polymerase chain reaction (PCR). After its introduction in 1985, PCR supplanted many of the more tedious techniques of molecular biology and opened up completely new possibilities. Essentially, a means of cloning DNA without the need for vectors or bacteria, PCR uses the enzyme DNA polymerase to copy DNA. To do this, the enzyme needs two oligonucleotide primers that are complementary to sequences flanking the region of interest in the target DNA, with one on each strand (Fig. 43.8). Computer and web-based programs are available for designing primers (usually 20 or more bases) in order to choose sequences likely to be most suitable for the PCR reaction and to maximize specificity by ensuring that the

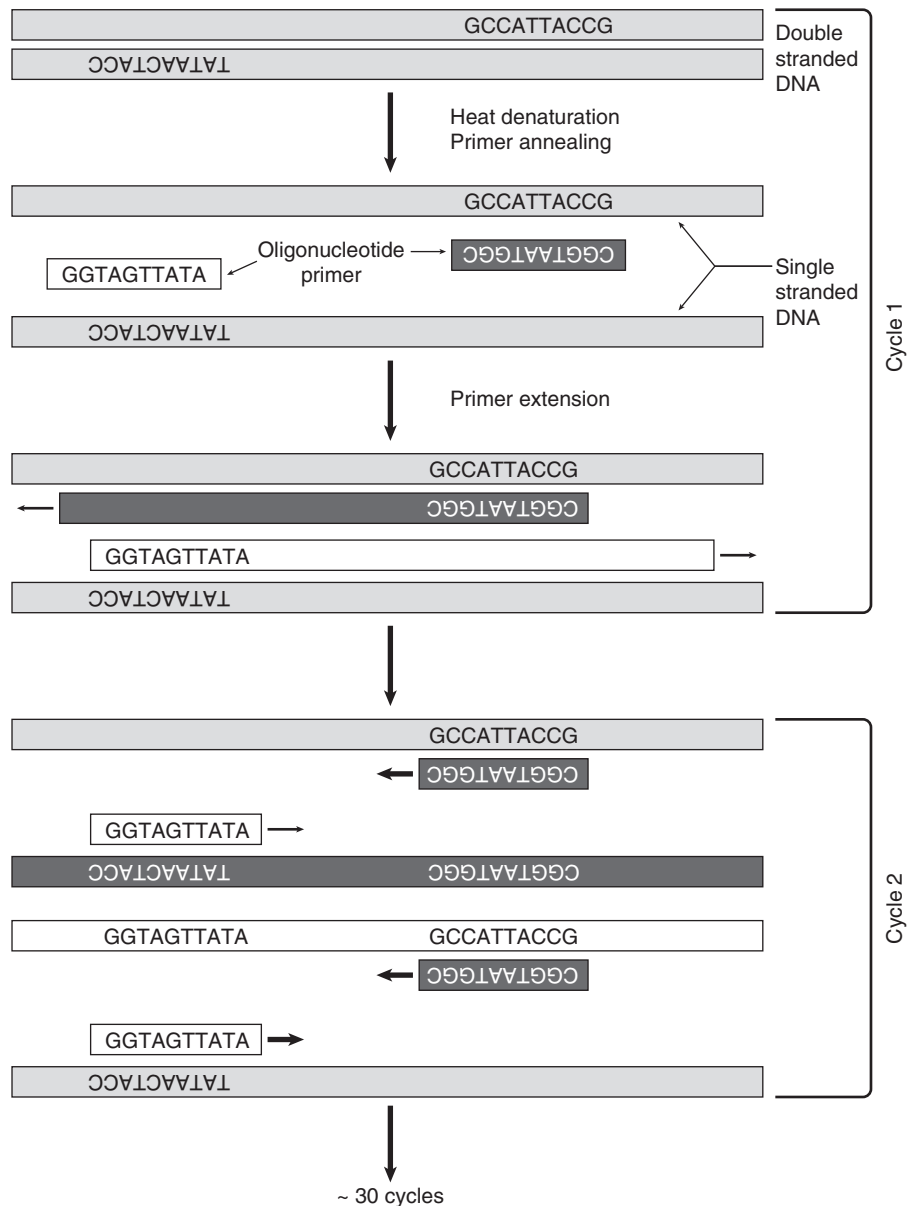

FIGURE 43.8 ■ The polymerase chain reaction. After denaturation of DNA, primers anneal to complementary sequences. During the first cycle, a heat-stable DNA polymerase (usually *Taq*) initiates synthesis of two new strands. After a further denaturation cycle, primers anneal to the newly synthesized DNA as well as the original sequences and four new strands are synthesized (cycle 2). With an exponential increase in the number of DNA strands, after around 30 cycles the sequence will have been amplified about one million times.

complementary sequence is virtually unique in the genome. The target sequence is amplified exponentially by repeated cycles of enzymatic copying. In the first cycle, double-stranded DNA is denatured by heating to between 92°C and 96°C for 5 min, and then cooled to (usually) between 55°C and 60°C, so that the oligonucleotide primers can anneal to their complementary sequences in the target DNA. For optimal specificity, the highest annealing temperature possible is used to minimize extension of primers bound non-specifically. Extension of the primers by DNA polymerase, using added nucleotides and the DNA target as a template, is then allowed to take place. Use of a heat-stable DNA polymerase, which can withstand the heating cycles, avoids the necessity of adding fresh enzyme at each cycle and allows extension to take place at a high temperature (72°C). After heat denaturation, excess primers can then anneal to the newly synthesized DNA as well as the original DNA strands and the process is repeated. In 30 cycles, amplification of over one million-fold can be achieved. Originally, the only enzyme available for PCR was that from *Thermus aquaticus* (*Taq* polymerase), but more have now been identified and developed, making amplification of much longer sections of genomic DNA possible.

Stringent control of conditions, such as the concentrations of magnesium and nucleotides in the reaction mixture, have usually been needed to maintain the specificity of a PCR although conditions that maximize polymerase fidelity may reduce PCR efficiency. Where such manipulation was necessary, it was predominantly dependent on the sequences involved, especially that of the primers. However, the ability to amplify longer sections of DNA means that primers can be 'picked' to suit the conditions required, allowing the use of universal 'master mixes' and thus a greater standardization of PCR assays. PCR is so sensitive that it has been used to amplify the DNA from a single cell and it can be used with samples obtained from materials as diverse as ancient mummies, fossils, hair follicles, preimplantation embryos and fixed pathological specimens. The large quantities of amplified DNA produced by PCR, which can be detected using a variety of visual labels, have eliminated the need for radiolabelling. The extreme sensitivity of the technique is also the source of one of its disadvantages – contamination by extraneous DNA (e.g. from the operator) can create havoc, so that strict precautions must be taken to avoid artefacts.

Non-isotopic fluorescent labels are employed in the widely used technique of real-time PCR. There are several versions of this technique but the basic principle is that a PCR reaction is followed, in real time, by monitoring the signals produced by dye-labelled probes that bind to the accumulating products. Various modifications to the technique allow real-time PCR to be used for quantitation of a target sequence (hence, its other, abbreviated name of qPCR) and determining dosage (the number of copies of a gene in a cell) and gene duplication as well as for mutation detection. Quantitative analysis has become increasingly important as a tool for microbiologists for determining such things as viral load in samples from patients suffering from diseases such as human immunodeficiency virus infection.

Not to be confused with real-time PCR, reverse transcriptase PCR (rtPCR) uses purified RNA as the start point and uses the enzyme reverse transcriptase to produce cDNA, which can then be amplified using conventional PCR and used to examine the protein expressed by the gene of interest. Potentially, this allows investigation of both the effect of any sequence variants in a gene on its protein product, and the possible phenotypic consequences.

Detection of mutations

The search for mutations causing disease involves either the detection of a previously identified, known mutation or the screening of the gene to search for an unknown mutation. In clinical samples, the process will usually begin with the former and proceed to the latter if none of the former is found. There are now a variety of methods available for mutation detection and these can be divided into manual, low-throughput techniques and automated, high-throughput ones. The basic principles of the manual methods often form the basis of the automated ones and it is for this reason that several of the manual techniques are described here as they demonstrate principles of analysis and the properties of DNA that are exploited, however it should be acknowledged that in most large genetics laboratories these have largely been superseded by automated high-throughput systems.

Detecting known mutations

The principles of several manual techniques for detecting known mutations are shown in Fig. 43.9. The allele-specific oligonucleotide (ASO) technique utilizes synthetic oligonucleotide probes (about 19 residues) – one that is complementary to the normal and one to the mutant allele, with the site of mutation in the middle of the complementary region (Fig. 43.9A). Under appropriate conditions of hybridization, the oligonucleotides will bind only when there is complete complementarity. This technique was first used for detection of the β^s allele of the β globin gene that is responsible for sickle cell anaemia. Although ASO testing can be performed directly on genomic DNA, it is more easily carried out after prior amplification of the region of interest using PCR. If a mutation (or the corresponding normal sequence) happens to be a target site for one of the many restriction enzymes, then testing for the presence or absence of a restriction site by restriction endonuclease allele recognition can be used to analyse genotypes (Fig. 43.9B). This technique was also first used for detection of the β^s allele. Again, initial PCR amplification simplifies the procedure.

Another method for identifying point mutations exploits the specificity of the primers used for PCR: the amplification refractory mutation system (ARMS) (Fig. 43.9C), also known as allele-specific amplification, is based on the observation that oligonucleotides that are not exactly complementary to the target DNA sequence frequently do not function as primers in PCR. The method uses two forward primers, one which is complementary to the normal sequence and one which

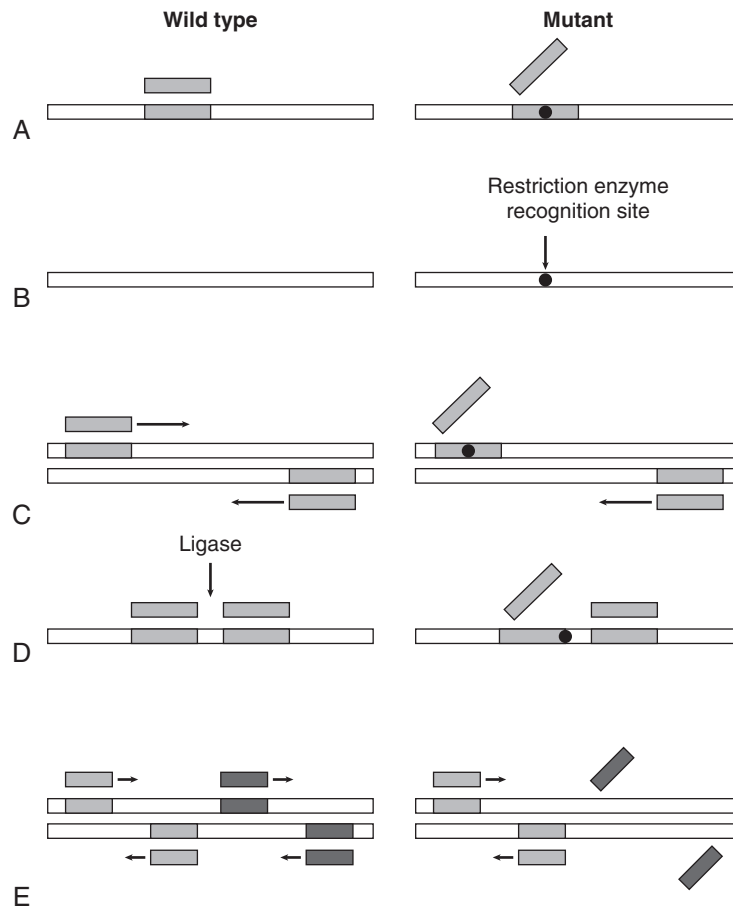

FIGURE 43.9 ■ Some techniques for detecting known mutations. (A) Allele-specific oligonucleotides. A synthetic oligonucleotide complementary to the normal sequence will bind to wild-type, but not mutant, DNA (while an oligonucleotide complementary to the mutated sequence will bind to mutant DNA but not wild-type DNA). (B) Restriction endonuclease allele recognition. A mutation may create a recognition site for a restriction enzyme which is absent in the wild-type sequence. Consequently, digestion with the enzyme would cleave mutant DNA into two fragments, but would have no effect on wild-type DNA (similarly, a mutation may destroy a recognition site for a restriction enzyme so that wild-type DNA is cleaved, but not mutant). (C) Amplification refractory mutation system (ARMS). Primers, one of which spans the site of mutation, are designed for a PCR reaction. Primers complementary to wild-type sequence amplify normal DNA, but not mutant DNA (for confirmation, a second set of primers which are complementary to the mutated sequence is also designed so that a positive reaction is obtained with mutant DNA). (D) Ligase-mediated allele detection. Oligonucleotides flanking the site of mutation are joined by a ligase only if they are complementary to the DNA sequence. One of the oligonucleotides corresponds to a constant region, while the other is complementary to either wild-type or mutant DNA. (E) Multiplex PCR for detection of deletions. Simultaneous PCR reactions for amplification of two or more sequences detect any deletions which remove recognition sites for PCR primers.

is complementary to the mutant sequence, in combination with a common reverse primer. In yet another technique – ligase-mediated allele detection (Fig. 43.9D) – DNA ligase is used to couple two oligonucleotides at the site of a mutation. If one of the pair of nucleotides corresponds to either the normal or the mutant sequence, the ligase will only link the two oligonucleotides if there is a perfect match between the oligonucleotides and the target DNA, which has usually been amplified by PCR.

Because of the heterogeneity of genetic disease, one of the biggest obstacles to the application of DNA analysis is the requirement for simultaneous detection of multiple mutations. Since it is possible to perform several PCR reactions simultaneously ('multiplex PCR', Fig. 43.9E), several of the systems for the detection of mutations can be adapted to identify more than one mutation in a single assay. Alternatively, a reverse ASO method (in which oligonucleotides are immobilized and the test material is

used as a probe) allows simultaneous detection of several alleles. Such a principle underlies one form of the increasingly available 'microarray' or DNA chip, systems of DNA analysis. There are basically two forms of microarray. In the first, target DNA samples are immobilized on the chip and are then interrogated using labelled probes. The technique requires great precision in locating the sample sequences precisely on the chip, which needs to be done using robotic delivery systems. The second form is a reverse hybridization method in which the chip production procedure is highly complex but involves synthesizing thousands of different oligonucleotide sequences in situ on glass or silicon slides; these are the probes. The target DNA is amplified in a reaction that labels it with fluorophore, and allowed to hybridize with the immobilized probes. Bound label is detected using a laser scanner, with perfect sequence matches between sample and probe demonstrating stronger signals,

and the signals analysed using digital imaging software. The second method may be more appropriate to clinical analysis but the complexity of production means that chips tend to be produced by specialist manufacturers. At the moment, the instrumentation, and the chips themselves, remain costly but, as with all advances in molecular analysis, costs are likely to fall as the technology becomes more widespread.

In some inherited diseases, the gene responsible is particularly prone to deletions, copy number changes or duplications. Screening a gene by simultaneous amplification of several regions of DNA by multiplex PCR can be used effectively to screen such genes for deletions. Sequences that are absent or of decreased molecular weight can be detected simply by electrophoretic separation of the amplified sequences, although more precise methods have now been developed, for example multiplex ligation-dependent probe amplification (MLPA) (see Muscular dystrophy, p. 865).

Scanning or screening methods

To detect mutations when the precise site of mutation in a given individual is unknown, mutation screening methods were developed (Fig. 43.10). The sequence to be screened (e.g. one complete exon in a gene) is usually amplified first by PCR. One of several techniques that are capable of detecting the presence of single base differences in the sequence can then be used. In cleavage mismatch detection (Fig. 43.10A), hybridization of mutant and normal DNA strands produces a heteroduplex, and chemical or enzymatic techniques are used to cleave the strands at the site of mismatched base pairs. The size of fragments produced then allows localization of mutations within the sequence. Denaturing gradient gel electrophoresis and temperature gradient gel electrophoresis are methods that take advantage of the sudden decrease in electrophoretic mobility that occurs when a double-stranded molecule of DNA begins to dissociate (Fig. 43.10B). A homoduplex molecule (i.e. a duplex of complementary strands) will begin to dissociate and decrease its mobility at a characteristic point in a gradient of either denaturing agent or temperature. If denatured normal DNA is allowed to re-anneal in the presence of mutant DNA, heteroduplex molecules will form with a mismatch in almost complementary strands, which will begin to denature early so that the electrophoretic profile is altered. The technique of single-stranded conformational polymorphism (SSCP) is based on the fact that sequences of single-stranded DNA fold into specific conformations (Fig. 43.10C), so that normal and mutant DNA sequences can be separated by acrylamide gel electrophoresis. All of these, essentially manual, techniques are still used and remain valid techniques, but with rising workloads and the need for rapid results, they too are being increasingly overtaken by automated methods using large analytical platforms. Conformational sensitive capillary electrophoresis (CSCE) and denaturing high performance liquid chromatography (DHPLC) both utilize the principles of heteroduplex formation, with detection based on the different mobilities produced by conformational changes. Conformational

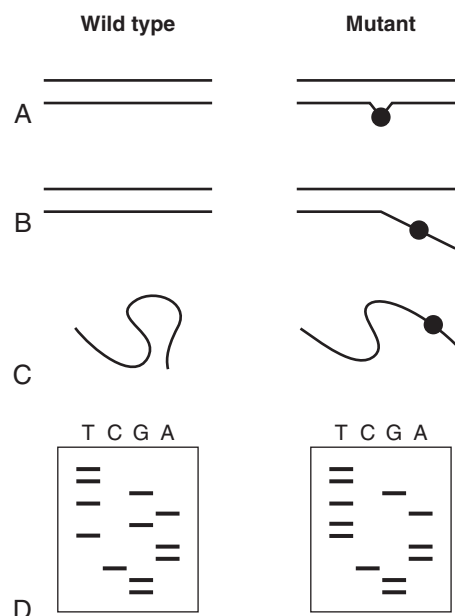

FIGURE 43.10 ■ Detection of unknown mutations. (A) Cleavage mismatch. If a heteroduplex is formed between wild-type and mutant DNA, unpaired bases at mutation sites are susceptible to chemical modification and subsequent cleavage. (B) Denaturing or temperature gradient electrophoresis. As DNA migrates through a gel with a gradient of temperature or denaturant, the rate of migration changes suddenly when the strands begin to separate. The presence of a mutation will alter the point at which this event occurs. (C) Single-strand conformational polymorphism. Molecules of single-stranded DNA form three-dimensional structures determined by their sequence, so that in non-denaturing gels, mobility is determined by sequence as well as length. The presence of a mutation may alter the three-dimensional structure formed and hence mobility. (D) DNA sequencing (dideoxy method of Sanger). Sequencing gels are read starting from the smallest fragment. Thus, the wild-type sequence is GGCAATGATGTT and the mutant sequence is GGCAATTATGTT.

sensitive capillary electrophoresis uses fluorescence detection to screen for the presence of mutations in a DNA sequence, while DHPLC uses altered retention times in an HPLC system.

If one of the above scanning techniques reveals the presence of a mutation, DNA sequencing can then be used to identify, or confirm, the precise mutation. Two techniques for sequencing of DNA were introduced in 1977, one by Sanger and the other by Maxam and Gilbert. Both techniques share the same basic principle in that a series of single-stranded DNA molecules, each one base longer than the last, is generated. These molecules can be separated by electrophoresis to generate a 'ladder' from which the sequence can be read. The dideoxy terminator method of Sanger (Fig. 43.10D) uses DNA polymerase to synthesize a complementary copy of the target DNA starting from a primer annealed close to the region of interest. The enzyme can incorporate dideoxynucleosides, but chain elongation then ceases immediately because these nucleoside analogues lack a 3' hydroxy group. DNA synthesis is carried out in four separate incubation mixtures, each containing the four deoxynucleoside triphosphate substrates (one of which is labelled) in addition to a low concentration of just one

of the four dideoxynucleoside analogues. When incubation is terminated, a population of labelled DNA molecules of varying lengths will have been produced. All molecules will have the same 5' end, but will vary in length to a base-specific 3' end (e.g. all terminating in A if dideoxy ATP was used). Originally, it was necessary to clone a fragment of DNA before sequencing could be carried out, but sequencing now uses PCR products obtained from either genomic DNA or cDNA. The use of radioactive (^{32}P) labelling followed by polyacrylamide electrophoresis (PAGE) gel and autoradiography has been superseded by DNA analysers which use four different dyes for the four different nucleosides, and automated read outs. The availability of these instruments, plus automated software for mutation and variant 'calling', makes sequencing more attractive for detecting mutations, and some laboratories use automated DNA analysers and sequencers as their front-line mutation detection system for some genes.

Tracking of mutant genes

When the gene causing a disease has not been identified, or it is not feasible to identify the precise mutation causing a defect, it may nevertheless be possible to predict, by gene tracking, whether a particular individual is affected provided a closely linked marker is available. Even when a disease gene has been identified and cloned, because the gene screening methods described above are not always 100% sensitive, gene tracking methods may still be useful to identify affected individuals. To be useful, a marker must exhibit a degree of polymorphism so that it is possible to distinguish between alleles associated with normal and mutant genes. Thus for a marker to be informative, an individual who is heterozygous for the disease locus must also be heterozygous for the marker. For genetic analysis, information on phase is also required, that is, it is necessary to determine which allele is linked to (tracks with) the mutation in an individual who is heterozygous. Some of the situations that may occur with a recessive disease are illustrated in Figure 43.11. Family 1 is fully informative and the disease gene is associated with allele a, so that the fetus would be affected only if it were also homozygous for allele a. In family 2, the analysis is informative only for the mother (in whom the mutant gene is linked to allele b), so that there is a 50% probability that the fetus can be predicted to be unaffected and a 50% chance that the fetus will be predicted to be at 50% risk. In family 3, the analysis is completely uninformative, since both parents are homozygous for the marker. In family 4, a marker with greater polymorphism is used, which is entirely informative.

Often a polymorphic marker can be found within the gene of interest, but if a linked marker outside the gene is used, there is an increased possibility of errors being made as a result of crossover. Even with intragenic markers, in large genes such as the dystrophin gene, there is a distinct possibility of crossover occurring between a marker and a mutation site. Similarly, there can be a degree of uncertainty as to whether an affected member of a pedigree has a new disease-causing mutation; again this may be particularly true in cases of

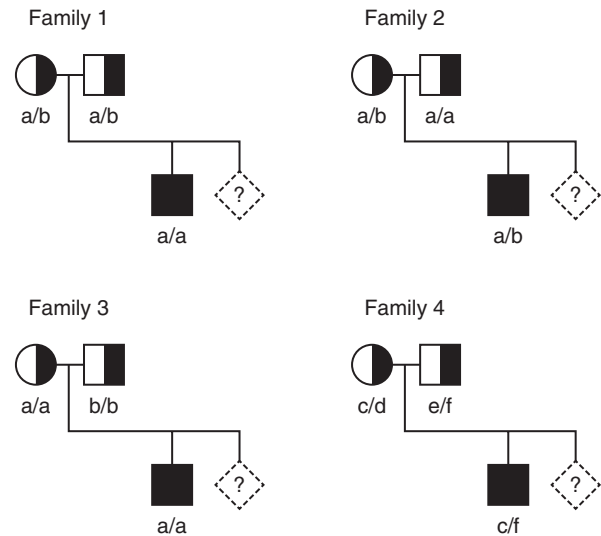

FIGURE 43.11 ■ Linkage analysis for a recessive condition. Linkage of alleles a, b, c, d, e and f is shown in four families. Half-shaded alleles symbols represent heterozygotes for the condition. Fully shaded symbols refer to affected individuals and diamonds refer to a fetus for which diagnosis is requested.

muscular dystrophy. The risk of incorrect diagnosis can be minimized by the use of multiple markers, but diagnosis will nevertheless be based on an estimate of probability. Other disadvantages of linkage studies are the expense, time and need to test other family members, so these techniques are used mainly in specialist laboratories. The developments of 'next generation' sequencing described below are likely to allow great improvements in identifying, and tracking, pathogenic mutations in such diseases and pedigrees.

There are several types of polymorphic marker that are suitable for tracking inheritance of particular alleles within families. Polymorphism at restriction sites (Fig. 43.12A) has been used extensively for linkage analysis, both for identification of the genes causing disease and for genetic analysis in families. Throughout the human genome, about one base in 1000 is polymorphic and around one in six random base changes creates or abolishes a restriction site. The majority of these polymorphisms are of no consequence to the organism, but their detection with restriction enzymes has provided what was, until recently, the most important technique for genetic mapping and linkage studies. Restriction fragment length polymorphisms (RFLPs) can be identified either by digestion of genomic DNA with the enzyme and subsequent use of a probe to identify fragments separated by electrophoresis or by PCR amplification of the region surrounding the restriction site, followed by restriction digestion and direct visualization of fragments after electrophoresis. A limitation of RFLP analysis is that the maximum polymorphism at any one site, can be no more than 50% (i.e. presence or absence of the site), and strategies that use relatively small numbers of SNPs have now been largely superseded.

However, the use of SNPs for gene tracking has now come full circle as a consequence of the Human Genome Project and the production of a dense SNP map of the

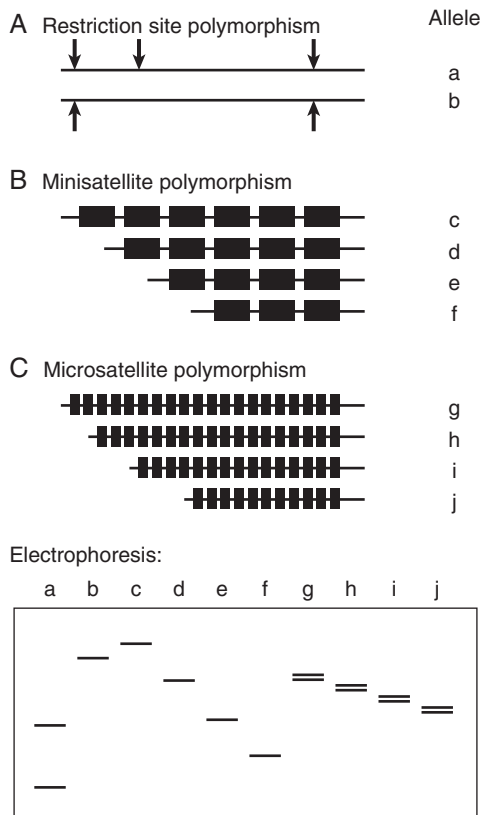

FIGURE 43.12 ■ Polymorphic markers used for linkage studies. (A) Alleles a and b are produced by polymorphism at a restriction site; (B) c, d, e and f, by polymorphism in the number of repeats in a minisatellite; (C) g, h, i and j, by polymorphism in the number of repeats in a microsatellite. Electrophoresis of a produces two small fragments after digestion, while b is not cleaved and remains as one large fragment. Electrophoresis of alleles c–j detects different sizes of mini- and microsatellites, but the latter may be complicated by separation of the two DNA strands (see text).

human genome. This knowledge, combined with the development of high-throughput microarray technology, means that it is possible to obtain SNP chips linked to large SNP databases; the use of large numbers of SNPs makes these chips more informative.

The discovery of hypervariable sequences in DNA consisting of a variable number of tandem repeats (VNTRs), with considerable polymorphism in the number of repeats, has found widespread application. Such sequences consist of short (10–60 base pairs) oligonucleotide sequences ('minisatellites') repeated 20–100 times, so that PCR amplification spanning the region (or excision of the region with a restriction enzyme) produces fragments which vary considerably in size in different individuals (Fig. 43.12B). The high degree of heterozygosity makes these VNTR loci particularly informative and, since they are inherited in a simple Mendelian fashion, they can be used in just the same way as RFLP analysis. Detection of these repeat sequences can be used, for example for determining zygosity in twins.

Similar repetitive sequences, with around 10–60 copies of motifs consisting of 1–4 bases (short tandem repeats or 'microsatellites') have been identified more recently (Fig. 43.12C). Unlike minisatellites, which are frequently

located near the ends of chromosomes, microsatellites are found scattered more evenly. One of the most common microsatellites, the (CA) n repeat (where n is roughly 15–30), occurs on average every 30 000 bases. Polymorphism in the length of these sequences can be detected by PCR amplification and used to track mutant genes in families. Dinucleotide repeats such as AC may separate into two bands on electrophoresis because the AC strand migrates faster than TG. Because fainter bands, which are probably generated during amplification, may also be apparent, there are advantages to using microsatellites with tri- and tetranucleotide repeats that are less susceptible to these problems, though the latter occur considerably less frequently in the genome.

Using a multilocus probe capable of hybridizing under low-stringency conditions to VNTR sites at several chromosomal sites, digestion with restriction enzymes gives a characteristic profile for each individual. The technique of 'DNA fingerprinting' has found most widespread use in forensic studies (e.g. the identification or elimination of crime suspects using samples of blood or semen) and in proving or disproving family relationships in civil cases (e.g. confirmation of maternity or paternity).

Analysis of these repeat sequences can now be performed quite straightforwardly by determining fragment length using capillary electrophoresis, a technique with greater accuracy than traditional gel based electrophoresis.

Next generation sequencing

One of the challenges in clinical genetics is the search for pathogenic mutations, where several genes may be implicated in a disease, or a group of disorders, for example, the peripheral neuropathies, and the clinical phenotype does not necessarily point to any one gene as the prime suspect, or where a large pedigree needs to be searched for potential disease causing mutations where one has not yet been identified in any individual of that pedigree. Traditional methods would involve testing one gene, or gene locus, after another. It would, however, potentially be more useful to screen all of the likely candidates, from all the members of a pedigree on a single sequencing run. The new high throughput technologies collectively called 'next generation' (or 'massively parallel' or 'deep') sequencing may well be the answer to this diagnostic problem. Several different platforms have been developed, with different sequencing technologies, but all the systems employ roughly the same essential steps.

- Step 1. Genomic DNA is fragmented using restriction enzymes.
- Step 2. The fragments are enriched for the regions of interest.
- Step 3. All the fragments are sequenced in parallel.
- Step 4. The results are aligned with a reference sequence to search for any variants (which at this stage may number in the thousands).
- Step 5. The bioinformatics step, comparing these variants to a polymorphism or SNP database (which may take the number down to the hundreds).
- Step 6. Variant calling, to determine if the variants detected are likely to be pathogenic or not.

Another common feature of these new platforms is that none of them use traditional Sanger type sequencing using dNTPs. Some of the techniques include:

- pyrosequencing, which uses luciferase to generate light when each of the individual nucleotides is added to the new DNA, with the reactions happening inside water droplets suspended in oil (emulsion PCR)
- use of reversible dye-terminators. Each molecule of DNA is amplified as a clone and fluorescently labelled nucleotides allow identification of each nucleotide as it is added before the dyes are removed prior to the next addition
- sequencing by ligation, whereby dye labelled oligonucleotides of known sequence are annealed and ligated to clones of amplified DNA immobilized on beads or glass slides
- ion-semiconductor sequencing, where the terminal incorporation of nucleotides uses traditional sequencing chemistry but detection of the incorporated nucleotides is achieved using a supersensitive ion sensor, essentially a form of pH meter, which detects the hydrogen ions released when each base is added, each cycle (taking only seconds) uses a different nucleotide but runs of the same nucleotide in the sequence will all be incorporated in the same cycle, giving a proportionally higher signal.

Even in the few years since the last edition of this book, both run (or 'read') times and cost per read have come down considerably, as has the size of the instruments, with recent ones very definitely being bench top, so why is it that these new techniques cannot automatically replace all the others currently in use? Over time, they may well do so, but at the moment the ability to sequence a whole genome or exome is not necessary for the detection of common pathogenic mutations in well characterized disorders, which tend to benefit from a targeted approach.

THE APPLICATIONS OF DNA ANALYSIS

The clinical application of DNA analysis has grown enormously since the first edition of this book, demonstrated by the increase, in both number and size, of molecular and clinical genetics departments in our hospitals.

Diagnosis of index cases

The very nature of inherited disease, with its implications for the families of affected individuals, means that most molecular testing now takes place in specialized genetics laboratories. These laboratories work closely with clinical geneticists and genetic counsellors. Consequently, any clinical biochemistry laboratory undertaking molecular testing must be aware of the consequences of a positive diagnosis. However, diagnosis of inherited metabolic diseases (e.g. amino acid and organic acid disorders) has, for many years, been undertaken in biochemistry laboratories, and the initial diagnosis of an inherited disease is still usually based on clinical history, physical signs and non-genetic laboratory tests. Confirmation of the diagnosis

can then often be obtained by a specific enzyme assay or protein study, but such assays frequently require the use of cell cultures, with their accompanying problems. Consequently, in an increasing number of diseases, DNA testing is now used for the diagnosis of index cases. These are often diseases in which (a) partial or complete gene deletions, which are relatively easy to detect, are frequent (as in muscular dystrophy) or (b) the defective protein has not yet been characterized or where it is difficult to devise methods for direct analysis of the protein (as with cystic fibrosis). One other potential advantage of DNA tests for diagnosis of index cases is that mutant genes are usually present in all nucleated cells, so that in diseases in which expression of the gene is limited to organs such as liver or kidney, biopsy can be avoided.

In the use of DNA analysis for diagnosis in index cases, it is important that accurate and reliable data exist on the relationship between genotype and phenotype.

Prenatal diagnosis

Analysis of fetal DNA, often with a view to selective termination of an affected pregnancy, can be used to determine the presence of severe or potentially fatal genetic disease. Such testing is most likely to be carried out when the parents have previously had an affected child, when they have been identified as carriers, or when one of them is affected by a dominant condition.

Although fetal blood samples can be used to detect many inherited diseases – particularly those that affect proteins in red blood cells or plasma proteins – DNA analysis can be carried out without taking tissue samples from the fetus. In the earliest prenatal diagnoses of genetic disorders, amniotic fluid cells obtained by amniocentesis at 16–18 weeks of gestation were used. However, it is now more common to use chorionic villus sampling (CVS), carried out at 8–10 weeks (see Chapter 22). Potential problems with prenatal diagnosis are contamination with maternal DNA and – especially where linkage studies are being carried out – uncertainty concerning paternity. Analysis of mini- or microsatellites can help avoid both of these problems. Where the diagnosis relates to an X-linked recessive disorder, if the fetus is shown to be female, either by cytogenetic analysis or a specific molecular test for identifying the Y chromosome, no further CVS testing may be necessary, as the fetus will, at most, be a carrier and this can be determined once the child is born.

Use of PCR makes testing of individual cells possible, so that it is possible to test fertilized embryos and implant only those known to be unaffected by a particular disease. This procedure has been carried out successfully with parents who are both heterozygotes for cystic fibrosis. The implications of this procedure are considerable, not least because many parents find selective abortion an unacceptable means of avoiding affected children. The use of such techniques for in vitro fertilization (IVF) is controlled, in the UK, by law, and is overseen by the Human Fertilisation and Embryology Authority.

A recent advance has been the ability to detect cell-free, fetal DNA in the blood of the mother, bringing with

it the possibility of testing the fetus for inherited disease without the need for invasive testing. Such testing does come with risks, mainly relating to avoiding contamination with the mother's own DNA. However, where the fetus is male, looking for markers carried on the Y chromosome only overcomes this problem. The use of DNA methylation ratios to separate fetal from maternal DNA has also been described. The use of fetal DNA in this way is very much in its early stages and is currently used primarily for determining fetal gender but is also being looked at as an alternative, and early, method of screening for Down syndrome.

Screening

The word 'screening' is used in various ways in medicine, and in the section on detection of mutations above, it was used in the context of examining a whole gene to find disease-causing mutations in patients with a clinical diagnosis of a genetic disease. In this section, the term is used in the context of testing healthy or presymptomatic individuals for molecular evidence of disease.

Screening of individuals

Screening can be 'targeted' in that individuals from families with strong family histories of a disease (high risk) are included and it may involve presymptomatic or carrier (heterozygote) testing. Such screening is often applied to determining the risks of developing a particular form of cancer, for example as in breast cancer screening. For women with several close relatives with the disease, there is a targeted screening programme based on DNA analysis. Although familial breast cancer represents a small percentage of cases of the disease, screening high-risk individuals is effective and involves examining the entire *BRCA1*, *BRCA2* and *TP53* genes.

Population screening

Population screening involves making available to all, on an equitable basis, testing for certain diseases or conditions. Examples of such programmes include antenatal screening for Down syndrome and those for cervical and breast cancer screening in women (not the same as the targeted testing described above). Currently, there are no such programmes that use DNA analysis in a primary testing strategy, although proposals have been made to use detection of fetal DNA in maternal serum for screening for Down syndrome, as mentioned above.

The criteria that must be satisfied for a successful screening programme are the same, regardless of whether traditional chemical analysis or DNA techniques are used (or, indeed, imaging or cytological testing) and have changed little in recent decades. All screening programmes are fraught with ethical and organizational problems, but none of these is peculiar to the analytical technique employed. The importance of education and the provision of counselling services for the success of a screening programme have been repeatedly emphasized, but the obtaining of informed consent, the reliability of methods (i.e. numbers of false positives and false

negatives), prevalence of disease in the population and the existence of a clearly recognized advantage to pre-symptomatic diagnosis (e.g. the possibility of avoiding precipitating factors in the environment) must be considered. In the UK, such screening has, since 1996, been overseen by the National Screening Committee, which also advises the government on the relevant issues.

Newborn screening to detect affected individuals with phenylketonuria and congenital hypothyroidism has been widely performed for some years using conventional biochemical tests on dried blood spots obtained by heel prick in the first two weeks of life. This scheme has now been extended to include testing for cystic fibrosis (see later section) haemoglobinopathies and medium chain acyl-CoA dehydrogenase deficiency (MCADD). While DNA diagnostic tests can also be carried out on blood spots, the programme still uses biochemical tests as the 'frontline' screening test. DNA testing can be used to follow-up positive screening results but currently is still employed mainly to identify the mutation(s) present in the child, rather than confirmation of the diagnosis.

At the present time, there are no plans to use DNA testing for primary screening of newborn infants. There are several reasons why this is not appropriate yet. In many genetic diseases, there can be large numbers of disease-causing mutations that produce the same biochemical (or haematological) effects. Similarly, not all mutations and variations in a gene will be pathogenic. Also, some mutations show variable penetrance or expressivity, so that whole gene screening, for example by sequencing, might create problems by identifying infants who have gene mutations but who will not necessarily develop the disease being screened for. Currently, it is still more efficient to screen by testing for the gene products. However, as DNA arrays and microchips become more accessible and cost-effective, molecular screening may become more widespread, providing there are accurate data on the genotype/phenotype correlations.

Pharmacogenetics

An area of laboratory testing in which biochemistry laboratories may find themselves involved is that of pharmacogenetics. Pharmacogenetics is concerned with identifying genetic variations that affect an individual's response to drugs. Initially, the term was used in respect of variations in drug metabolizing enzymes, but it has now been expanded to include polymorphisms in drug receptor, drug transporter and ion channel genes. Pharmacogenomics, on the other hand, refers to the (generally commercial) application of genomic technology in drug development and therapy. The two terms are often used interchangeably and there is some difference of opinion as to whether or not this is an acceptable practice. However, even though the differences may appear to be semantic, in general, pharmacogenomic studies in drug discovery regimes mainly aim to identify suitable drug targets and are concerned with multiple genes and phenotypes, whereas pharmacogenetics aims to identify variants in individual genes with the aim of 'personalizing' drug dosage and thus reducing adverse drug reactions. These are responsible for high levels of therapeutic

morbidity and mortality worldwide every year, with an associated cost to the health services of millions of dollars each year. Biochemical methods of identifying poor metabolizers (see below) are often cumbersome and demanding, using metabolic ratios that measure the relative concentrations of parent drug and metabolites in blood and urine.

The term 'pharmacogenetics', coined by Vogel in 1959, was originally brought to prominence by Kalow in descriptions of the variation in response to the muscle relaxant suxamethonium seen in patients with serum cholinesterase (butyrylcholinesterase) deficiency. Another of the earlier described pharmacogenetic effects was that observed with the enzyme N-acetyltransferase 2 (NAT2), where patients treated with the antituberculosis drug isoniazid were found to show variation in the rate at which they metabolized the drug: they were either slow, intermediate or rapid acetylators. The largest group of drug metabolizing enzymes is the cytochrome P450 (CYP P450) 'superfamily', which accounts for the metabolism of well in excess of 100 commonly used prescription and over-the-counter drugs. Of the large number of CYP P450 enzymes, six account for close to 90% of the drugs metabolized by this family. Of these, CYP3A4/5 account for around 50% but the most extensively characterized is CYP2D6, debrisoquine hydroxylase, accounting for 30%. It is the metabolizing enzyme for a large number and wide variety of drugs including antipsychotic, antiarrhythmic and antihypertensive drugs. Many drug metabolizing enzymes are now known to be highly polymorphic and many of them also demonstrate codominant inheritance, such that heterozygotes for normal and certain variant alleles show intermediate phenotypes. Poor metabolizers can be affected in a variety of ways, depending on whether it is the parent drug or its metabolite that is the pharmacologically active moiety. Thus, poor metabolizers may suffer the adverse effects of overdosing on a standard drug dose if the parent drug is active, or a poor therapeutic response if the metabolite is active. In the case of CYP2D6, more than 75 polymorphisms have been identified so far, and the prevalence of poor metabolizers and the frequency of different causative alleles vary significantly in different geographic and ethnic groups. Thus, in Caucasians, poor metabolizer status is found in 5–10% of individuals and is caused in nearly 90% of those cases by one of just three variant alleles, *CYP2D6*3*, *CYP2D6*4* and *CYP2D6*5*. (By convention, the commonest, or normal, allele of a gene is denoted as *1.) 'Extensive metabolizer' is the name given to individuals with an expected or normal response to a drug, and while these are mainly *1 homozygotes, some of the other alleles, such as the *2, also produce an extensive metabolizer phenotype. Intermediate metabolizers are thought to represent heterozygotes with extensive and poor metabolizer alleles.

The molecular variation responsible for the different alleles includes not only simple changes such as SNPs, small deletions and insertions but also whole gene deletions and duplications. The phenotypic effect of these differences can be on the concentration of enzyme produced or on its function, depending on the location of the polymorphism in the translated gene product. In the

case of CYP2D6, a duplication of the *2 allele leads to an ultra-rapid metabolizer phenotype.

Other clinically important drug metabolizing enzymes include thiopurine S-methyltransferase (TPMT) and uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1). Thiopurine S-methyltransferase is involved in the metabolism of the immunosuppressant azathioprine and the antileukaemia drug 6-mercaptopurine; biochemical testing for TPMT phenotype has been available for some time but the role of genotyping has yet to be firmly established. Variants of UGT1A1 are responsible for Gilbert syndrome (unconjugated hyperbilirubinaemia) and Crigler–Najjar disease but the enzyme is also involved in the metabolism of the anticancer drug, irinotecan, and prospective genotyping may be useful in the future for avoiding some of the side-effects that can occur during treatment with this drug.

With the identification of the genes and sequences for an increasing number of drug metabolizing enzymes, analysis using the new techniques for rapid, high-throughput DNA testing should allow early identification of many of the variants, thus allowing altered drug dosage prior to, or shortly after, therapy commences, and so avoiding dangerous and costly adverse drug reactions.

Inherited diseases – some examples

Single gene disorders

The diseases most often thought of as 'genetic' tend to be those that arise from mutations in a single gene. Some disorders may arise from mutations in any one of a collection of genes related to a particular metabolic pathway, i.e. they may have monogenic causes but are not necessarily single gene diseases.

α_1 -Antitrypsin deficiency

The function of α_1 -antitrypsin (α_1 AT) is to inhibit neutrophil elastase and other proteases. The rate of association between α_1 AT and elastase is rapid, but after cleavage at the reactive site (methionine at position 358) of α_1 AT by the elastase, the molecule undergoes a radical change in structure that prevents dissociation of the elastase, thus inactivating it. The gene coding for α_1 AT (the protease inhibitor or PI gene) spans 12200 bases and is transcribed into a protein with a single chain of 394 amino acids.

α_1 -antitrypsin displays considerable polymorphism, with around 75 alleles having been detected so far. The variants are inherited in an autosomal codominant fashion, so that both alleles are expressed independently and can be detected in serum. Many of the variants, which are identified by letters of the alphabet depending on their electrophoretic mobility, function normally. The Z variant is of greatest clinical significance. In northern Europeans, around 5.3% of the population are carriers (i.e. are MZ heterozygotes) and about 1 in 2000 live births are ZZ homozygotes. Although deficiency can usually be detected by quantitation of serum α_1 AT, phenotyping by isoelectric focusing is more informative and reliable.

Secretion of α_1 AT, which is synthesized in the liver, is markedly reduced in ZZ homozygotes because the

mutant protein forms insoluble polymers, which accumulate in the endoplasmic reticulum of hepatocytes. The Z variant results from a point mutation converting a lysine residue in normal (M) protein to a glutamic acid one at position 342, which is at the base of the reactive centre loop. Juvenile cirrhosis occurs in 3–10% of ZZ homozygotes as a result of damage caused by the intracellular aggregates, though a much higher percentage are affected if a sibling has liver disease. The reasons for the incomplete penetrance of this condition are not known: intrauterine infection, gut-derived proteases, autoimmunity, fever and subclinical hepatitis have been suggested as possible exacerbating factors. Additional genetic factors, possibly in chaperone proteins responsible for directing misfolded protein to the secretory pathway, or other proteins involved in α_1 AT clearance have also been suggested.

Although other protease inhibitors are present in the lungs, α_1 AT contributes over 90% of the inhibitory activity capable of blocking neutrophil elastase. In the absence of α_1 AT, neutrophil elastase rapidly degrades tissue matrix components in the lung so that individuals with a markedly reduced plasma concentration of α_1 AT are prone to develop emphysema. As a result of reduced hepatic secretion of α_1 AT, the plasma concentration of this protein is reduced to about 15% of normal in ZZ individuals. Not all of these individuals are affected by disease, but 60–70% of ZZ homozygotes who smoke cigarettes develop pulmonary emphysema in the third or fourth decade of life. Smoking compromises the defences of the lung further because free radicals in cigarette smoke oxidize methionine at the reactive site of α_1 AT, drastically lowering its ability to inhibit neutrophil elastase.

Of the other mutations affecting the α_1 AT gene, the S mutation (changing the glutamic acid at position 264 to valine) is more common than Z, with an allele frequency of 2–4% in northern Europeans, but the consequences are less serious. Although some degradation of the S variant occurs in the liver and the serum α_1 AT concentration is reduced, S homozygotes are not considered to be at increased risk of liver or lung disease, although inheritance of the S allele with an allele causing severe deficiency (such as Z) confers a mild risk of emphysema. A number of other rare mutations (including the 'null' mutation) are associated with a decrease in plasma α_1 AT activity to a level that confers a risk of emphysema, and some others are characterized by accumulation of mutant protein in hepatocytes.

DNA-based techniques for identification of mutations in the PI gene complement phenotypic studies. Prenatal diagnosis is possible in juvenile cirrhosis families, where the causative mutation can be detected in the index case. DNA sequencing is the gold standard for detecting small deletions and point mutations, and this is readily available owing to the relatively small size of the gene. Various SNP detection techniques have also been developed for common mutations (e.g. Z and S), which have the potential to be used in screening programmes. While screening for this condition has been advocated, it has not been taken up widely owing to concerns regarding the variable penetrance of the condition, and the limited efficacy of interventions such as advice on smoking cessation.

Cystic fibrosis

Cystic fibrosis is inherited in an autosomal recessive manner. The homozygous condition is associated with defective exocrine secretion and consequent malabsorption with chronic obstructive pulmonary disease. The disease has a prevalence of about 1 in 2500 live births in northern Europe and a carrier frequency of 1 in 25, though it is much less common in other populations. For many years, laboratory diagnosis relied on the demonstration of raised chloride (and, optionally, sodium) concentrations in sweat. About 77% of affected individuals can be identified using the sweat test at two years of age and about 95% at 12 years. The test is far from ideal, because it is technically difficult to perform; not all patients with compatible clinical features have a raised sweat chloride and some individuals with a raised sweat chloride have no clinical features of cystic fibrosis. In one report, up to 40% of patients referred to cystic fibrosis centres had been wrongly diagnosed because of false positive or false negative sweat tests. Serum immunoreactive trypsin concentrations tend to be higher in affected newborns, forming the basis of a UK screening programme that can detect at least 95% of cases.

The gene affected in cystic fibrosis was mapped to 7q31 using linkage analysis. The gene itself was cloned in 1989 and named the cystic fibrosis transmembrane conductance regulator (CFTR). It has a size of approximately 250 kb with 27 exons and the CFTR protein is 1480 amino acids with a molecular weight of 168 kDa. The primary role of the CFTR protein is to form a chloride channel that reduces intracellular chloride. It appears to consist of two transmembrane domains, two ATP binding regions or nucleotide binding folds, and a regulatory domain. Phosphorylation of the regulatory domain by protein kinase A results in the opening of the chloride channel.

Over 1500 pathogenic mutations have been identified in the CFTR gene, although the great majority of them are extremely rare. The mutations include frameshift, nonsense, missense and splice site mutations and deletions. However, the commonest, and the first to be identified, is a 3-bp deletion in exon 10 of the CFTR gene that results in the loss of a phenylalanine codon at position 508. This mutation, Phe508del (Phe being the three letter code for phenylalanine and 'del' represents a deletion) represents around 70% of cases of cystic fibrosis. The frequency of this mutation in different populations varies markedly, however, and in Europe its frequency increases along a South East to North West gradient.

Detection of several cystic fibrosis mutations by multiplex PCR can be performed simultaneously using an ARMS assay (Fig. 43.13). In this assay, the common Phe508del mutation is detected together with 28 or 32 other mutations, depending on the kit manufacturer (e.g. the mutation causing substitution of Gly-551 by aspartic acid (Gly551Asp), another that converts Gly-542 to a stop codon (Gly542X) and a splice site mutation substituting T for G immediately after the last nucleotide in exon 4 (621+1G>T)), but chosen to be appropriate for the local population. This strategy will, for most

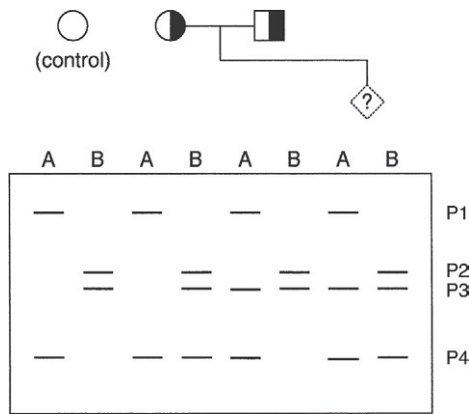

FIGURE 43.13 ■ Simultaneous detection of the common mutations in the cystic fibrosis gene by ARMS analysis. Bands P1, P2, P3 and P4 represent the product amplified using primers complementary to the sequences spanning the 621+1G>T, G551D, G542X and F508del mutation sites, respectively. Two reactions are carried out on DNA from each individual. In A lanes, P1 and P4 primers are complementary to the normal sequence, while P2 and P3 are complementary to the mutant sequences. In B lanes, P1 and P4 primers are complementary to mutant sequences while P2 and P3 primers are complementary to normal sequence. Thus, the mother is a carrier for the F508del mutation and the father is a carrier for the G542X mutation. The fetus has inherited both deleterious mutations (i.e. is a compound heterozygote). Adapted from Ferrie R M, Schwartz M J, Robertson N H et al. 1992 Development, multiplexing, and application of ARMS tests for common mutations in the CFTR gene. *American Journal of Human Genetics* 51: 251–262, with permission.

populations, identify the mutation responsible in more than 80% of cases. If the front-line test fails to reveal the mutation, additional mutations of progressively lower frequency are tested for and, ultimately, a full gene sequence may be the only way to identify a rare or new mutation.

Muscular dystrophy

Duchenne muscular dystrophy, one of the most common X-linked diseases (prevalence about 1 in 3000 live male births), results from mutations in the dystrophin gene and is characterized by progressive proximal muscle weakness in early childhood. Rarely, females can be affected, usually as a result of X-autosome translocations or skewed X inactivation. Symptoms are also apparent in 2–3% of female carriers ('manifesting carriers') caused by a non-random X inactivation. The diagnosis of this condition is often beyond doubt clinically, but confirmation is usually required because of its gravity. Plasma creatine kinase activity is markedly raised (often to 50–100 times normal), providing a useful confirmatory test. Becker muscular dystrophy, a less severe condition with onset in late childhood (affecting about 1 in 30000 newborn males), is an allelic disorder, that is, it also results from mutations in the dystrophin gene.

The dystrophin gene was discovered in 1986 and turned out to be an unusually large gene, currently the largest known gene in man, spread over around 2.5 million bases. The size of the gene may be one of the reasons why it is particularly prone to new mutations: it has been calculated that a third of all cases of

Becker muscular dystrophy arise from new mutations. Although at least 99% of the dystrophin gene is accounted for by introns, there are nevertheless 79 exons coding for a mRNA of 14000 bases. The dystrophin protein has a molecular weight of about 400000 kDa and it is expressed primarily in muscle cells. Dystrophin is normally localized to the inner surface of muscle cell sarcolemma and it is tightly linked with an oligomeric complex of glycoproteins that provides a linkage between the cytoskeleton and the extracellular matrix. When muscle biopsies of patients have been examined, it has been found that dystrophin is undetectable in patients with Duchenne muscular dystrophy, and present, altered in size or quantity, in patients with Becker muscular dystrophy.

In many patients (about 60%), the mutations causing disease are deletions or, less commonly (5%), duplications of exons. The remaining 30–35% are point mutations. Although the situation is undoubtedly more complex, in many cases it appears that Duchenne muscular dystrophy results from mutations that cause frameshifts, while the mutations causing Becker muscular dystrophy tend to be in-frame. Molecular diagnosis of muscular dystrophy has advanced considerably with the invention of PCR and its subsequent developments. Initially, diagnosis relied on RFLP linkage and cDNA probe analysis by Southern blotting. This technique was cumbersome and not always successful in identifying the disease mutation. An early use of PCR to detect deletions is shown in Figure 43.14, where ten pairs of primers were used to scan the whole dystrophin cDNA, allowing identification of some 65% of affected individuals. This was followed by the use of multiplex PCR, where deletions were detected by the failure of deleted exons to amplify in the reaction. Multiplex PCR has now been superseded as a front-line test by a technique called multiplex ligation-dependent probe amplification (MLPA). This technique involves the amplification of specifically hybridized

FIGURE 43.14 ■ PCR analysis to detect deletions in the dystrophin gene. Using PCR amplification to amplify the cDNA spanning exons 43–51, the mother is shown to be a heterozygote for the normal allele (band of 1227 bp) and a mutant allele (band of 670 bp) with a deletion of exons 45–48. The father is homozygous for the normal allele but the son expresses only the mutant allele. His sister, like their mother, is a heterozygote. Adapted from Roberts R G, Bentley D R, Barby TF et al. 1990 Direct diagnosis of carriers of Duchenne and Becker muscular dystrophy by amplification of lymphocyte RNA. *Lancet* 336: 1523–1526, with permission.

probes and enables the rapid identification of a deletion or duplication of any of the 79 exons in the dystrophin gene. It is particularly effective in determining the carrier status of females and has been used to identify the defect in families who appeared to be normal by earlier techniques. A series of characteristic 'printouts' is shown in Figure 43.15. It is also possible to detect point mismatch. In families in which the defect in one allele is not due to deletion, either multiplex PCR or RFLP analysis can be used for prenatal diagnosis. Multiplex PCR can also be carried out on dried blood spots for neonatal screening. However, in the absence of any effective treatment, this will not benefit the child being screened. Any advantage conferred by the opportunity for counseling to avoid further affected children must be balanced against the effect on the parents of having to explain to their son that he has a fatal illness, and, indeed, the effect of this knowledge on the child himself.

Huntington disease

In Huntington disease, progressive chorea (irregular involuntary movements) and dementia lead to death on average 17 years after the onset of symptoms. The condition is autosomal dominant with a prevalence in the UK of 3–7 per 100 000. The trait shows complete penetrance, but age-dependent expressivity: only 10% of affected individuals have symptoms by 30 years, but this proportion reaches 95% by 70 years. Thus, most individuals who are at risk reach the age at which they may wish to have children without knowing whether or not they will develop the disease.

As a result of exhaustive research by several groups, the genetic defect causing Huntington disease was first located on chromosome 4; the gene (named *IT15*) has since

been pinpointed to 4p16. Inheritance of many disorders, including fragile X syndrome, myotonic dystrophy and spino-bulbar-muscular atrophy (Kennedy disease), is linked to a mechanism in which increasing expansion of triplet repeats eventually leads to disease. Huntington disease is caused by this type of mutation, with expansion of a CAG repeat in exon 1. The variable age of onset and severity of the disease correlates with the extent to which the CAG repeat has been expanded. Normal alleles contain up to 26 repeats, are stable and not associated with disease, while disease genes contain more than 39 repeats. Those with 27–35 repeats have the potential either to decrease or to expand and thus become disease alleles: they are 'mutable'. Alleles with 36–38 repeats show reduced penetrance with some heterozygotes never developing symptoms. Disease-associated alleles containing more than 39 repeats are prone to large increases in repeats from one generation to the next, which results in a phenomenon called anticipation, where symptoms develop at a younger age.

Before the identification of the mutation, presymptomatic diagnosis using RFLP analysis and linkage studies was performed with a probability that depended on the number and informativeness of family members who could be tested. Not only did this technique leave a degree of uncertainty over the diagnosis, but diagnosis of one individual might depend on analysis of samples from other members of the family who did not wish to be tested. This technique is now used only rarely and the diagnosis is now made using PCR analysis to measure directly the size of the CAG repeat region.

The ability to identify patients with Huntington disease many years before symptoms become apparent raises some of the ethical problems of DNA testing in

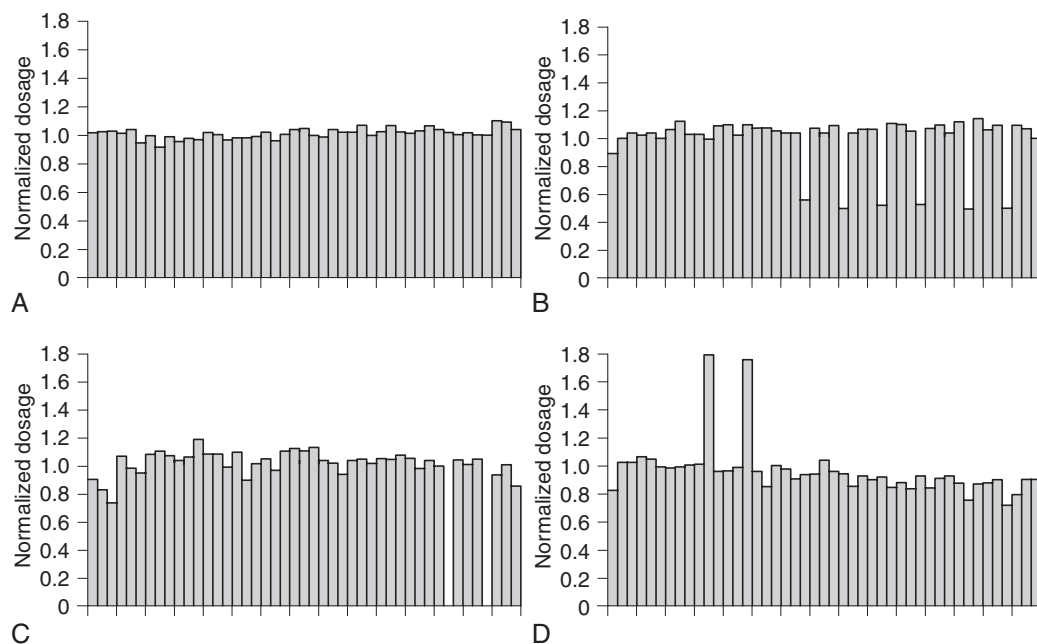

FIGURE 43.15 ■ Results of MLPA analysis of the dystrophin gene showing normalized ratios of the hybridization signal: (A) is from a normal individual; (B) shows deleted exons in a female carrier; (C) shows deleted exons in an affected male and (D) shows duplicated exons in an affected male. In (B) (C) and (D) the affected exons are contiguous in the gene but not in the readout. Courtesy of the Bristol Genetics Laboratory, North Bristol NHS Trust.

their most acute form. Potential psychological problems for individuals without symptoms knowing that they have a fatal disease must be considered and appropriate counselling provided. The risk of stigmatization, with difficulties in employment and obtaining insurance, makes absolute confidentiality of results crucial. The fact that the disease is transmitted in a dominant fashion also raises issues where members of one generation wish to be tested but those of another do not, as a positive result in a child almost certainly implies a positive result in the parent (depending on the repeat number). Consequently, in the UK at least, predictive testing is only undertaken using a robust protocol involving close working between clinical genetics and laboratory genetics teams.

Multifactorial and polygenic disease

While much progress has been made in understanding single gene disorders, and developing techniques for their diagnosis, such diseases are still rare in most populations. The current challenge lies in understanding those common diseases that have a polygenic or a multifactorial basis. Where a disease or disorder arises from mutations in a small number of genes, each of which contributes, it can be said to be polygenic. Diseases where the role of genetic factors is combined with environmental triggers can be thought of as multifactorial. However, in reality, conditions such as diabetes and essential hypertension, which affect millions of people worldwide, can be both and remain the focus of a lot of current investigation.

Atherosclerosis

Atherosclerosis is one such multifactorial disease and the recognition of a correlation between plasma cholesterol concentration and coronary artery disease has provided the background for genetic studies of several candidate genes. (A search for atherosclerosis on the Online Mendelian Inheritance in Man (OMIM) website gives more than 200 'hits'.) Environmental factors such as diet are clearly important for determining plasma cholesterol concentrations, but it has been estimated that at least 50% of the population variance of cholesterol concentration has a genetic basis, with only a small group being monogenic (requiring no, or virtually no, environmental triggers for their expression). Transport of lipids between tissues is a complex process involving formation, modification and clearance of lipoprotein particles (see Chapter 37). The plasma concentration of one of these particles, low density lipoprotein (LDL), is positively correlated with the risk of atherosclerosis. LDL particles consist predominantly of cholesteryl esters and an apolipoprotein (apoB), and their removal from plasma depends on binding of apoB to a specific cell surface receptor (the LDL receptor). Abnormalities in both the apoB and the LDL receptor genes have been shown to affect clearance of LDL, both resulting in elevated plasma cholesterol concentrations with greater elevations caused by abnormalities of the LDL receptor than of apoB.

Familial hypercholesterolaemia

Familial hypercholesterolaemia (FH) is a dominant disorder affecting about 1 in 500 individuals and which accounts for around 5% of individuals with clinically evident atherosclerosis. In the UK, the most recent guidance from the National Institute for Care and Excellence (NICE), Clinical Guideline 71, and the subsequent Diagnostics Guidance published in 2011, recommends that a diagnosis of FH should be made based on the Simon Broome criteria, which include DNA-based as well as clinical/biochemistry criteria, and that those with a clinical diagnosis should be offered a DNA test. Of the mutations associated with FH approximately 93% are in the LDL receptor gene (*LDLR*). It is, however, a heterogeneous condition and mutations in the genes for apoB, proprotein convertase subtilisin/kexin type 9 (*PCSK9*) and LDL receptor-associated protein (*LDLRAP*) are now known also to cause it (see Chapter 37).

The LDL receptor gene is located on chromosome 19, spans 45 kilobases and codes for a protein of 839 amino acids. More than 400 mutations, many of which are deletions, have been identified. These mutations can be divided into five main classes:

1. 'null' alleles that produce no protein
2. mutations that block transport of the newly synthesized receptor from the endoplasmic reticulum to the Golgi apparatus
3. mutations that prevent the binding of LDL at the cell membrane
4. mutations producing receptors that can bind but cannot internalize LDL
5. mutations producing receptors that cannot release LDL following internalization and so are not recycled back to the cell surface – receptors must be freshly synthesized.

The apoB gene (*APOB*) is located at chromosome 2p24 and codes for a protein of 4536 amino acids. Apolipoprotein B-100, the full-size protein that is found in LDL, is produced by the liver while a smaller protein, apo B-48, is produced in the intestine by a unique tissue-specific process that introduces a stop codon into the mRNA. Familial defective apoB-100 is a dominant disorder, with a frequency of around 1 in 800 in the general population. Unlike deficiency in the LDL receptor, it is a much more homogeneous condition. Most cases result from one mutation, a SNP affecting codon 3500, which decreases the affinity of apo B-100 for the LDL receptor. Mutations in *APOB* account for around 1.5% of FH cases.

The third gene for which the NICE Diagnostics Guidance now also recommends testing is *PCSK9*, which encodes proprotein convertase subtilisin/kexin type 9. This protein is involved in degradation of the LDL receptor. A gain of function mutation of *PCSK9* results in a reduction in the number of LDL receptors at the cell surface, thus reducing LDL uptake into cells and leading to increased circulating cholesterol. There remains some uncertainty as to the percentage of cases attributable to *PCSK9* mutations.

FH, arising from mutations in the three genes described above is inherited in autosomal dominant fashion

but a very small percentage (<1%) show an autosomal recessive mode of inheritance. Mutations in the *LDLRAP* gene (previously referred to as the autosomal recessive hypercholesterolaemia gene, *ARH*) are one of the causes of this rarer form of LH. Patients with ARH have a normal LDL receptor but the receptor associated protein, encoded by *LDLRAP*, fails to mediate internalization of the receptor in the usual way.

Apolipoprotein E genotypes

Apolipoprotein E (apo E) mediates clearance of two other classes of lipoprotein particle (chylomicron remnants and intermediate density lipoprotein, IDL) by binding to the remnant receptor (IDL can also bind to the LDL receptor). There are three common apoE isoforms, E2, E3 and E4, characterized by different electrophoretic mobilities, with frequencies of 10, 30 and 60% respectively. The E4 variant is associated with increased cholesterol concentrations in comparison with those associated with E3, while E2 is associated with lower concentrations. Familial dysbetalipoproteinaemia (remnant, or type III, hyperlipidaemia) is associated with the E2/E2 phenotype, but although almost all individuals with the condition are E2 homozygotes, the genotype shows poor penetrance so that most E2 homozygotes do not manifest the disorder, and other factors in addition to the E2 allele are clearly involved in expression of disease.

It has been estimated that about 7% of the variance in plasma cholesterol LDL concentrations found in populations can be accounted for by recognized mutations in the apo B, LDL receptor and apo E genes. Other candidate genes that may eventually prove to be involved in the complex process of atherosclerosis include those involved in cholesterol absorption, intracellular cholesterol metabolism, haemostasis and fibrinolysis. Angiotensin-converting-enzyme (ACE) regulates the concentrations of factors (angiotensin II and bradykinin) that are involved in modulation of vascular tone and proliferation of smooth muscle cells, and some recent results suggest that a polymorphism in this candidate gene is a risk factor for atherosclerosis. Two polymorphic forms of ACE have been described called the I (insertion) and D (deleted) forms, arising from the presence or absence of a 287bp sequence in the gene. Individuals homozygous for the D form have been shown to be at increased risk of atherosclerosis, particularly those considered to be at low risk from other criteria.

Cancer genetics

Cancer can be considered to be a genetic disease. This is because it arises either from somatic mutations in cells that then become cancerous or from inherited germline mutations that lead to a predisposition to the disease, although cancers arising from a single gene defect account for fewer than 5% of cases. The genetic component is often triggered by environmental or behavioural factors (such as cigarette smoking, which increases the risk of developing lung cancer) and it is now clear that cancer is the end-point of an accumulation of somatic and germline

mutations, most notably in proto-oncogenes and tumour suppressor genes.

Oncogenes and suppressor genes

The oncogenes were first identified as genes in retroviruses capable of producing tumours in birds and rodents. The first of these genes was identified in 1973, when a single gene (*src*) of the Rous sarcoma virus was shown to be capable of producing sarcomas in chickens. Later, it was shown that precursors to oncogenes, the proto-oncogenes or cellular oncogenes, were present in normal cells and that viral oncogenes were copies of these normal genes that had become incorporated into the retroviral genome. These viral oncogenes are able to transform infected cells once activated in some way.

Although it is now known that viruses do not cause most of the common cancers in humans and most of the oncogenes detected in this way (including *src*) are not of prime importance in human cancer, work with viral oncogenes made possible the rapid advances in understanding of human tumours that are now taking place. The isolation of human oncogenes was facilitated by the development of transfection techniques, in which DNA isolated from tumours can be tested for ability to transform cultured cells to a cancerous phenotype. Mechanisms for activation of proto-oncogenes include:

- chromosomal translocations so that the oncogene comes under the influence of regulatory elements from other genes
- amplification of a region of DNA including the oncogene
- point mutations that confer constitutive activity on the gene product.

Because the activation of only one allele is sufficient for transforming activity, oncogene mutations are generally dominant.

More than 50 cellular oncogenes have now been identified; the proteins they code for are mostly involved at some stage in the cascade of events associated with stimulation of cell division by growth factors. Thus, the *sis* protein is a mutated form of the platelet derived growth factor (PDGF); *erbB* codes for a truncated form of the epidermal growth factor (EGF) receptor; *erbA* codes for a mutant form of the thyroid hormone receptor; *ras* (a GTP-binding protein related to the hormone receptor G proteins) is a transducer of growth factor responses, and the *jun* and *fos* oncogenes mediate growth factor-induced gene expression. Oncogenes such as *mos* have been linked to factors that control the cell cycle.

In normal cells, the growth-promoting effects of proto-oncogenes are thought to be balanced by growth-constraining suppressor genes (tumour suppressor genes). Early evidence for the existence of such genes came from experiments in which fusion of tumour cells with normal cells resulted in hybrids with properties of normal cells. These experiments were interpreted as evidence for a tumour-suppressing gene in normal cells whose activity had been lost in tumour cells. Retinoblastoma, a rare form of eye tumour occurring in children, was later shown to result from loss of both copies of a gene (*RB*) located in

the q14 band of chromosome 13. In familial retinoblastoma (around 40% of cases), a defect in one *RB* allele is inherited, so that tumours arise in cells in which the remaining (normal) allele is lost. In the remaining 60% of cases (sporadic cases), both alleles in the tumour founder cell have undergone somatic mutation. This is the two-hit hypothesis of Knudson, who proposed that the disease followed two-hit kinetics but that, in familial cases, the first 'hit' is inherited, that is, is a germline mutation, and the second is somatic.

Most cancers do not follow the retinoblastoma paradigm in such a straightforward manner, but one that does is neurofibromatosis type 1, associated with tumours derived from the embryonic neural crest and caused by a defect in the *NF-1* gene located in the 17q11.2 chromosomal region. As with retinoblastoma, predisposition can be inherited from an affected parent as a germline mutation and tumour formation is initiated in cells that lose the activity of the remaining normal allele. The effects of suppressor gene mutations are usually only apparent when both alleles are inactivated, so that most of these genes behave in a recessive manner.

The majority of tumours that lack a functional suppressor gene (such as *NF-1* or *RB*) are found to have two identical mutant alleles. Elimination of the normal alleles is thought to occur in these cases by mechanisms such as chromosomal non-disjunction or gene conversion, which replace the normal allele with a copy of the mutant allele at high frequency (10^{-3} – 10^{-4} per cell generation). By looking for evidence of this process, suppressor genes have been identified through demonstrating 'loss of heterozygosity' at specific chromosomal sites. Anonymous, highly polymorphic, DNA markers that identify heterozygous sites in normal tissue were used to demonstrate reduction to homozygosity in tumours, indicating loss of one or more alleles (Fig. 43.16), although this approach is not without pitfalls. However, the development of DNA arrays has been useful in demonstrating the possible location of tumour suppressor genes specific for different tumour types against the general background of non-specific ones. One pitfall is that simple loss of heterozygosity is not the only molecular abnormality in tumours; many demonstrate multiple structural abnormalities and some of the observed losses may be due to deficient DNA repair mechanisms or to chromosomal instability rather than the selective loss of a tumour suppressor gene. One likely mechanism for inactivation of tumour suppressor genes involves methylation of specific CpG dinucleotides in tumour suppressor gene promoters. In some cases, methylation may be an alternative to point mutation, whereas in others it appears to be the only mechanism for loss of function.

One of the most studied tumour suppressor genes is *TP53* (which encodes the transcription factor p53), the loss of which is a major contributor to genomic instability and is possibly the commonest single genetic change seen in cancer. The function of p53 appears to be related to apoptosis (programmed cell death) so that – unlike normal cells – any cell with a defective p53 protein is more likely to proliferate despite the acquisition of mutations. Defects in this gene, which is located at 17p12, can be from mutation or deletion, and p53 can be eliminated by inhibitive action of other gene products such as that of *MDM2*.

FIGURE 43.16 ■ Loss of heterozygosity in tumours. Electrophoretic separation of digested total genomic DNA and detection of an allele on chromosome 5 with a single-locus probe in normal tissue (N) and tumour (T) of two patients with colorectal tumours. In both cases, the probe detects the alleles on DNA fragments of different size in normal tissue, demonstrating heterozygosity. Loss of heterozygosity in tumour tissue is demonstrated by disappearance of one allele. Adapted from Solomon E, Voss R, Hall V et al. 1987 Chromosome 5 allele loss in human colorectal carcinomas. *Nature* 328: 616–619, with permission.

Inherited mutations of *TP53* are found in Li–Fraumeni syndrome, a dominantly inherited condition in which sufferers demonstrate multiple primary tumours, and are also implicated in some familial breast and colon cancers.

Another mechanism whereby suppressor genes function is illustrated by the 'deleted in colonic carcinoma' (*DCC*) gene, identified initially by loss of heterozygosity in the long arm of chromosome 18, which occurs in over 70% of colonic carcinomas. Sequencing of this gene showed that it encodes a 190 kDa protein with properties that suggest that it might be a transmembrane molecule that binds cells to the extracellular matrix or basement membranes.

The protein encoded by *RB* (pRB) has been shown to form a complex with the oncoproteins produced by the adenovirus SV40 and the human papillomavirus, suggesting that the ability of these viruses to form tumours results from their ability to inactivate *RB*. During the cell cycle, pRB switches from hyperphosphorylated to relatively unphosphorylated forms, so that pRB is likely to be involved in regulating the cell cycle.

In solid tumours, full malignancy requires acquisition of the ability to metastasize. The processes involved include changes in adhesion molecules, proteases and angiogenic factors. Little is known about the genetic changes that activate these processes, but it may be a side-effect of the overall genomic disarray seen in the cells of advanced tumours.

It has been recognized for many years that tumour cells become increasingly genetically unstable, accumulating mutations more rapidly as the tumours grow. Genetic changes, which may be acquired or inherited, can play

a critical role in tumour progression by influencing mutation rates rather than growth regulation. Genes with this type of function are well illustrated by xeroderma pigmentosum, a rare autosomal recessive disease caused by defects in nucleotide excision DNA repair. Sufferers are extremely sensitive to ultraviolet light so that skin exposed to sunlight develops large numbers of freckles, which often progress to skin cancer as the damage caused by the sun cannot be repaired.

The early emphasis of research on genetic changes in cancer has been on understanding the mechanisms by which oncogenes and suppressor gene abnormalities can bring about transformation of a normal cell. The knowledge obtained thus far is now leading to progress in pre-symptomatic detection of tumours, and of identification of high-risk individuals, as well as in their diagnosis and treatment. This is demonstrated by the breast cancer screening programme for women at high risk of developing the familial form of disease. Sequence screening of the entire *BRCA1* and *BRCA2* genes in high-risk individuals (around 5% of cases) has close to 100% sensitivity, thus allowing prophylactic mastectomy when individuals are shown to have inherited the abnormal gene but, significantly, permitting reassurance for those women who have not. Testing regimens for other forms of cancer, for example bladder cancer, are being developed based on the fact that tumours shed cells. Sensitive PCR techniques can amplify the DNA of tumour cells shed into urine, blood and faeces, which can then be examined for SNPs (possibly using high-density arrays), loss of heterozygosity and microsatellite instability in characteristic tumour suppressor and oncogenes. Although not in routine use, such systems, as well as being useful for early detection of tumours, are likely to be valuable for monitoring possible disease recurrence.

The focus of clinical cancer genetics is now not only development of screening programmes capable of detecting tumours at earlier stages, but on the determination of whether or not the tumours are malignant, and how responsive they are likely to be to treatment. Studies on colorectal tumours have shown that formation of malignant tumours requires mutations in at least four or five genes, but that fewer changes are present in benign tumours. Work on glioblastoma tumours has shown that the degree of methylation in the O⁶-methylguanine DNA methyltransferase (MGMT) gene can predict response to chemotherapy. O⁶-methylguanine DNA methyltransferase is a DNA repair enzyme that removes toxic alkyl groups from the O⁶ position of guanine. Epigenetic silencing of MGMT by promoter CpG methylation has been associated with longer overall survival in patients with glioblastoma who, in addition to radiotherapy, received alkylating chemotherapy with an alkylating agent such as temozolomide. High levels of MGMT activity in cancer cells create a resistant phenotype by reducing the efficacy of alkylating chemotherapy.

Multiple endocrine neoplasia (MEN)

Not all 'cancers' or neoplasms are malignant, and some have both benign and malignant forms, a fact demonstrated by the MEN group of disorders (see Chapter 41).

As the name suggests, these disorders are characterized by tumours of endocrine glands; they are familial and much is now known about their genetics. MEN1, characterized by tumours of the pituitary, parathyroids and pancreas, is inherited in a dominant fashion with a high penetrance. The gene involved is located on chromosome 11, at 11q13, and codes for the protein menin. The exact function of the protein remains unknown but at the time of writing is thought likely to be a tumour suppressor gene, as the majority of mutations found in MEN1 patients appear to result in loss of function. Pathogenesis follows Knudson's 'two-hit' hypothesis as described above, whereby tumour development occurs in individuals who have inherited the first 'hit' as a germline mutation in the *MEN1* gene when a somatic mutation occurs in a relevant endocrine cell. MEN1 is notable in that many different mutations have been described as contributing to the condition.

MEN2 also demonstrates autosomal dominant inheritance and consists of three sub-groups, all of which have medullary carcinoma of the thyroid in common. In the case of MEN2, the gene responsible is the *RET* proto-oncogene on chromosome 10, which codes for a receptor tyrosine kinase. However, unlike in MEN1, the germline *RET* mutations of MEN2 result in gain of function effects and the site of the mutation appears to be critical in determining the site of the tumour. There are also fewer loci within the gene where the small number of activating mutations are likely to be found, of great value in the molecular diagnosis of MEN2 and in contrast to the very many in the menin gene leading to MEN1.

GENE THERAPY

Gene therapy can be characterized in several ways, but essentially, it is the use of introduced genetic material to correct disease, either to replace a defective gene product or to correct an abnormal gene. It should not be confused with the treatment of genetic disease, which currently still uses conventional therapies. Ethically, correction of genetic defects by insertion of genes into somatic cells is akin to organ transplantation. However, germline gene therapy, where introduced genes could be transmitted to future generations, is universally agreed to be unethical for use in humans, although the production of transgenic animals by introduction of genes into fertilized eggs is widely used for studying gene function and regulation. Consequently, many countries have regulatory bodies to oversee gene therapy programmes, which concentrate on somatic cell gene therapy. Such programmes target the cells, organs or tissue affected by the disease or disorder under investigation. The first replacement of a defective gene in a human (to correct immune deficiency resulting from adenosine deaminase deficiency) took place in 1990, with limited success in that while none of the ten patients in the trial was cured, no adverse effects were reported. Since that first trial, gene therapy has had a difficult history, but the picture has improved since the last edition of this book, with nearly 2000 clinical trials approved in the last five years. As the field is once again changing rapidly, this section is intended to provide an outline of the issues and principles involved.

To be a suitable candidate for potential gene therapy, it is an essential prerequisite that the gene involved has been cloned and sequenced, together with all the appropriate promoter and regulatory elements. The next step requires a mechanism for introduction of the therapeutic DNA into suitable target cells, and the affected tissue or organ must be identified and accessible. The introduction of the DNA into the target needs a vector, which may be viral (such as retroviruses or adenoviruses) or non-viral (such as liposomes) and can be *ex vivo*, where the patient's own cells are cultured with the vector and then reintroduced, or *in vivo*, where the transformed vector is delivered directly to the affected tissue or organ. *Ex vivo* techniques are generally to be preferred as the cells can be checked before they are returned to ensure that the desired change has been achieved.

With retrovirus vectors, the viral genome is integrated into the DNA of infected cells after reverse transcription of viral RNA into DNA. Disadvantages in the use of retroviruses are, first, the relatively small amount of DNA that can be introduced (less than ~7 kb), and second, that they are unable to infect non-dividing cells, which limits their use as very few cell types are continually dividing. Adenoviruses avoid these problems, since they can carry much larger segments of DNA and are also able to infect non-dividing cells, but they do have the problem of potentially being immunogenic. Indeed, a crucial part of the development of a gene therapy strategy is that the vector should produce no harmful effects. One potential danger of gene therapy using a viral vector is the initiation of cancer if the inserted gene disrupts the function of a cellular oncogene or suppressor gene. This is called insertional mutagenesis and such an effect was seen in trials for treating the immunodeficiency disorder X-linked severe combined immunodeficiency (XL-SCID), using *ex vivo* enrichment of patients' lymphocytes with a retroviral gene vector. This trial was initially seen as a great success, with 9 of the 11 patients being cured, but two of them later developed leukaemia owing to an insertional activation of the oncogene *LMO2*. This adverse outcome led to the suspension of gene therapy trials using pools of lymphocytes. Such a problem occurs mainly with the use of retroviruses and can be avoided by using adenoviruses, but they do have the problem of immunogenicity, and are known to contain genes of their own that can be involved in the process of malignant transformation and thus may also induce malignancy but by a different mechanism. It has not been possible, thus far, to determine precisely where in the host genome the introduced gene will insert: the process is random. In the case of the XL-SCID trial, only a small number of insertions were in a position to activate the oncogene but they produced clones that outgrew the other, beneficial, clones. Consequently, until, or unless, it is possible to direct the insertion site, or avoid damaging insertions, protocols using random insertion of vectors are unlikely to be approved.

A further problem is that the introduced normal gene must be capable of expressing its normal product in sufficient amounts to be effective in correcting the host disorder. Surprisingly, it has been found that functional genes can be transfected to skeletal muscle by direct injection, but this approach does not appear to be successful

for other tissues. This approach has had some success in treating haemophilia where adeno-associated virus expressing factor VIII was injected intramuscularly. The encouraging results of this strategy are thought to be because only a small increase in the amount of factor VIII has a major clinical benefit.

Non-viral methods of gene therapy include the use of 'naked' DNA, that is, the direct injection of DNA into target cells, and the use of liposomes, aqueous vesicles with an outer lipid bilayer, as vectors for the foreign DNA. Non-viral methods have the advantage of being non-immunogenic and so of being safer. The use of directly injected DNA is likely to be of use mainly where a small amount of product will have a significant benefit, as in the example above of factor VIII. Liposomes have the advantage of being able to carry larger quantities of DNA, but the expression of the introduced gene is short lived, meaning that repeated treatment is necessary. A potentially useful development of liposome-mediated transfer has been in the use of DNA-protein complexes designed to target cell surface receptors. The use of an appropriate protein, recognized by the cell receptor, leads to internalization to intracellular vesicles of the complex. This allows transport to lysosomes where the complex is degraded and, once the gene has escaped from the lysosome, it can be expressed.

Stem cells in gene therapy

Correction of defects in haemopoietic cells is of particular interest because stem cells in bone marrow are relatively accessible and diseases that can be corrected by bone marrow transplantation are obvious candidates for gene therapy, bearing in mind the difficulties associated with random insertion vectors described above. This is most likely to be feasible in the correction of enzyme deficiencies such as Lesch-Nyhan and Gaucher diseases, where effective therapy could be achieved with relatively low levels of gene expression.

Early stem cell work looked at the use of embryonic cells. However, such work raised ethical concerns and more recent studies have looked at inducing pluripotency in somatic cells (called iPS cells), such as fibroblasts, by introducing genes known to be involved in maintaining pluripotency. A hope for these iPS cells is that they could be used in autologous therapy in patients with genetic disease once the gene defect had been corrected in the iPS cells *in vitro*. A major target for gene therapy has been cystic fibrosis. In this disorder, some of the most damaging effects result from a lack of the gene protein in the lungs, and studies have indicated that restoration of as little as 5–10% of normal gene expression would be enough to produce a beneficial clinical response. An adenovirus, tropic for respiratory epithelium, was successfully exploited as a vector to insert these genes while other trials used liposomes or adeno-associated virus. However, although gene transfer was demonstrated, there were concerns about the safety of using adenoviruses that might cause an immune reaction and in both types of trial the gene expression was too short-lived. If stem cells, such as iPS cells, could be used, this could avoid some of the need for repeat administration and thus reduce the risks of an immune reaction.

Early trials using stem cells as gene therapy in this way, to correct some rare forms of inherited eye disorders, have shown some success and hold promise for the future of these techniques.

Gene therapy in cancer

A major aim of gene therapy has been the treatment of cancer, with more than 60% of approved trials targeting this area. Projects are looking at various stages of the process, including the supplementation of tumour suppressor genes and the prevention of activated oncogene expression, but also at areas such as the manipulation of tumour cells to promote apoptosis or to render them vulnerable to the host's immune system by increasing their antigenicity. Such trials demonstrate the diverse potential of gene therapy.

So, while the work carried out in the field of gene therapy has mushroomed in the last decade, there are still many problems to be overcome before its use in clinical medicine becomes frequent or widespread. However, the knowledge gained in the process has been enormous and it may take only one significant breakthrough to produce a major leap forward.

CONCLUSION

Clinical molecular genetics has advanced tremendously in recent years, a fact demonstrated by the almost exponential rise in the establishment of genetics laboratories in hospitals in developed countries. Its perceived importance in the future of healthcare in the UK was demonstrated by the publication, in 2003, of a Department of Health White Paper, *Our Inheritance, Our Future*, which resulted in large injections of money into NHS genetics laboratories to fund investment in new technology and staffing and was followed by a review document in 2011.

The advances of the past ten years have perhaps not been in the direction that might have been predicted at the start but some of the most startling have been in technology. Surprisingly, some techniques, such as DNA chips and microarrays, have been slower to transfer to routine clinical use than might have been expected, almost certainly because the cost of the analytical platforms and consumables did not fall as quickly as hoped. However, other technologies such as CSE and real-time PCR have become routine and the speed with which next generation sequencing is being applied to clinical genetics is remarkable. Consequently, predictions of high-throughput, faster turnaround analysis have become a reality – and technological development is still enabling scientific discovery.

Gene therapy is beginning once again to live up to its early promise with more successes being reported and safer solutions coming forward. Conversely, pharmacogenetics has grown much more slowly than predicted, despite evidence that shows that predictive genotyping can prevent adverse drug reactions, the reasons for this remain unclear, but unexpected complexity of the issues may play a part.

The emphasis in the coming years is likely to be 'more and faster'; that is, increasing laboratory capacity for molecular analysis and improving turnaround times. In terms of innovation, areas such as direct analysis of cell-free DNA in plasma may well begin to make an appearance in the laboratory.

The role of molecular biology in polygenic and multifactorial diseases is receiving a lot of attention, especially as these are the conditions (diabetes, hypertension, heart disease) that affect a large proportion of the population. Linked to this is the growing area of epigenetics, an area that examines heritable characters that are not due to changes in the DNA sequence. One mechanism for such inheritance is methylation.

Other areas that are finding their way into the clinical laboratory now are expression analysis and proteomics. At its simplest, expression analysis (sometimes called 'transcriptomics') examines the products of genes by creating cDNA from a gene's mRNA (usually by reverse transcriptase PCR – rtPCR) and cloning it into vectors from which the protein product can then be expressed and studied. Expression screening employs microarray technology to examine heterogeneous mixtures, usually of mRNA or cDNA, often to compare expression in different tissues. An area worthy of a book in its own right, proteomics takes expression analysis one step further, in that it is concerned with the analysis of complex mixtures of proteins, that is, with the expressed mRNAs that are actually translated. Not all mRNAs are translated into protein products and some undergo post-translational changes. Proteomics allows identification of changes in the relative abundance of expressed proteins as well as of their structure and function using mass spectroscopy techniques, in particular matrix-assisted laser desorption-time of flight mass spectrometry (MALDI-TOF MS). The technique is expected to be particularly valuable not only in the study of cancer (e.g. bladder cancer), but also, it is hoped, in its diagnosis and treatment.

Clinical molecular biology has made huge advances in recent years but there are still many more to be made.

ACKNOWLEDGEMENTS

The author wishes to acknowledge the invaluable help of the staff of the Bristol Genetics Laboratory, North Bristol NHS Trust and of David Halsall, Department of Clinical Biochemistry, Addenbrooke's Hospital, Cambridge in the preparation of the earlier edition of this chapter. The chapter is based, with permission, on that written by Dr Michael Norman, Department of Medicine, University of Bristol, for the first edition of this book.

GLOSSARY

- Allele** alternative forms of a gene at the same locus
Balanced polymorphism a polymorphism that is stable in a population
Carrier an individual who is heterozygote for a recessive gene

cDNA DNA that is complementary to a mRNA molecule

Clone a cell line derived from a single cell, or gene sequences propagated by recombinant DNA techniques

Codominant pertaining to two alleles which are both expressed in a heterozygote

Compound heterozygote an individual with two different mutant alleles at the same locus

Crossover (or recombination) exchange of information between homologous chromosomes during meiosis

Diploid chromosome complement with two copies of each chromosome (as in normal human cells where the diploid number is 46)

Dominant an allele that manifests its phenotypic effect in heterozygotes

Downstream sequences further in the direction of expression (5' → 3')

Enhancer a regulatory DNA sequence that can function to stimulate transcription of a gene irrespective of its position and orientation relative to that gene

Epigenetic heritable traits (e.g. those caused by gene methylation) that are not dependent on DNA sequence changes

Exome all the exons in a genome

Exon any segment of an interrupted gene that is present in the mature mRNA

Expressivity variability in the severity of a genetic trait

Frameshift mutation mutation resulting from insertion or deletion of bases (but not a multiple of three) that alters the reading frame of an mRNA

Gamete haploid cell generated by meiosis (sperm or egg)

Genome the complete ensemble of genetic information of an individual

Germ cell gametes or their precursors

Haploid cell a cell containing only one copy of each chromosome

Haplotype a group of closely linked alleles that are inherited as a single unit

Heterozygote an individual with different alleles (usually one normal and one mutant) at a given locus on homologous chromosomes

Homozygote an individual having the same allele at a given locus on homologous chromosomes

Hot spot site with a high frequency of mutation or recombination

Imprinting differences in the expression of genes depending on parental origin

Intron any segment of an interrupted gene that is transcribed but removed during formation of mature mRNA

Linkage two or more loci on a single chromosome that are sufficiently close that they do not segregate independently in offspring

Linkage disequilibrium association of two loci more frequently than predicted by chance

Locus unique location on a chromosome of a gene or particular DNA sequence

Loss of heterozygosity (LOH) homozygosity (in a tumour or somatic cell) when the constitutional state is heterozygous

Meiosis a series of two modified mitoses generating haploid gametes from a diploid cell

Messenger RNA (mRNA) sequence of RNA transcribed from a gene which, after processing, codes for a protein

Microsatellite polymorphic sequences due to a variable number of tandem repeats of a di-, tri- or tetranucleotide sequence

Minisatellite polymorphic sequences due to a variable number of tandem repeats of a short sequence of ten or more nucleotides

Mitosis process of division in somatic cells

Multiplex PCR simultaneous PCR reactions performed using more than one pair of primers in the same reaction mix

Mutation a heritable change in the genetic material

Northern blot a technique for transferring RNA to a filter for subsequent detection

Oncogene a gene involved in cell development capable of causing transformation to a tumour cell

Polymerase chain reaction (PCR) a technique for amplifying a specific sequence of DNA

Penetrance the frequency with which a particular genotype is expressed

Phenotype the observable characteristics of an individual

Point mutation changes in the sequence of DNA involving single base pairs

Polygenic a trait influenced by the cumulative effects of several genes at different loci

Polymorphism the occurrence of two or more alleles at a given locus at significant frequencies in the population

Positional cloning cloning of a gene after determining its chromosomal position by linkage analysis without knowing its function.

Probe a labelled fragment of DNA used to identify complementary sequences by hybridization

Promoter region of DNA to which RNA polymerase binds before initiating transcription

Recessive an allele that produces a phenotypic effect only when present in the homozygous state

Restriction enzyme an enzyme that cleaves DNA at specific sequences

Retrovirus an RNA virus that utilizes reverse transcriptase to insert itself into the DNA of a host cell

Restriction fragment length polymorphism (RFLP) polymorphism in the size of fragments produced by digesting DNA with a restriction enzyme

Somatic cell all cells of the body except gametes

Southern blot the technique of transferring fragments of DNA after electrophoresis to a filter

Trait any phenotypically detectable character or property

Transcription production of mRNA from the DNA template

Transfection incorporation of foreign DNA into a cell

Transformation conversion of cells to a state of unrestrained growth, resembling tumour cells

Transgenic animal animal into which a foreign gene has been incorporated

Translation conversion of the mature mRNA message into a protein

Tumour suppressor gene a gene that is growth constraining and whose inactivation can lead to unrestrained growth of a cell

Upstream sequences located in the opposite direction to transcription (3' → 5')

Vector any plasmid, phage etc. into which foreign DNA can be inserted for cloning

Variable number of tandem repeats (VNTR) minisatellite and microsatellite sequences with polymorphism in the number of repeats

Western blot transfer of proteins to a filter after electrophoresis

Wild type the allele which is most frequent in natural populations; now referred to as 'normal type'.

Further reading

In a subject that changes as rapidly as this one, any bibliography is likely to become outdated very quickly and so this one is short with respect to texts, listing only those likely to form a valuable 'core' for the subject. Readers are directed to the internet, where the most up-to-date information is to be found: several appropriate starting points are listed. Regular review of appropriate journals, many of which are available online, is also recommended, especially for technological applications.

Background

Strachen T, Read PR. *Human molecular genetics*. 4th ed. London: Garland Science; 2011.

Essential text covering the principles of molecular genetics; well referenced.
Turnpenny P, Ellard S. *Emery's elements of medical genetics*. 14th ed. London: Elsevier; 2012.

Highly readable text for clinical aspects, covering cytogenetic as well as molecular genetic disease with a useful chapter on ethical issues.
Young ID. *Medical genetics*. Oxford: Oxford University Press; 2005.

Although slightly older now, this is another very readable introductory text that uses landmark publications and case histories to illustrate the issues effectively.

Internet resources

The British Society for Human Genetics. <http://www.bshg.org.uk>.

An excellent place to start: it is a searchable site and has extensive links to other major websites as well as to useful online genetics journals.

OMIM database, linked through the NCBI website (PubMed). <http://www.ncbi.nlm.nih.gov/omim>.

For information on Mendelian disorders, the OMIM site contains highly referenced entries for most disorders and genes. The NCBI website is also the starting point for links to other databases, e.g. on protein structure, as well as being the best starting point for literature searching.

Journals

Clinical Chemistry. The Journal of the American Association of Clinical Chemistry (AACC).

Now subtitled as an International Journal of Molecular Diagnostics and Laboratory Medicine, this is an excellent source of up-to-date information on emerging molecular techniques and their applications, which also tend to be of particular relevance to clinical biochemists.

Nature Genetics.

The dedicated genetics journal in the 'Nature' family of scientific journals.

Forensic biochemistry

INTRODUCTION

Forensic biochemistry can be defined as the application of biochemical assays in the service of the courts. Examples include DNA analysis for human identification and methods for the detection of trace evidence, such as the Kastle–Mayer (phenolphthalein/hydrogen peroxide) and luminol reactions used to detect the presence of blood. This chapter, however, focuses on laboratory measurements rather than methods. Many of these are standard laboratory procedures, while others are specific to forensic work.

The range of forensic situations that the clinical biochemistry laboratory may be asked to help with is wide and, as in all such work, the results of tests can usually be properly interpreted only when considered together with all the available evidence. Post-mortem biochemistry has a role in investigating the cause of death in some apparently natural deaths, including both diabetic and alcoholic ketoacidosis, deaths that may have involved a prolonged stress response such as hypothermia, as well as in the diagnosis of disease processes such as early myocardial infarction, which may be difficult to diagnose by physical examination. There is clearly considerable overlap between clinical and forensic toxicology, in that some endogenous substances can be used as poisons (e.g. sodium chloride, potassium chloride and insulin) and in some instances, suspicion of poisoning may be aroused by abnormal biochemical results (see [Table 44.1](#)).

Forensic biochemistry has an important role in the investigation of deaths and serious injuries occurring in hospital. Assault committed within hospital may involve poisoning, and can range from murder (intent to kill), through manslaughter (culpable homicide) and attempted murder, to malicious poisoning (usually of a child or an elderly relative). Iatrogenic poisoning may range from

relatively minor drug administration errors, to catastrophes such as asphyxia caused by an anaesthetic error. The results of an analysis, or residual or unused samples, or even apparatus used in giving the drug, may be required by officers acting on behalf of the courts. Therefore, in all cases, careful specimen labelling and handling, reporting and laboratory record-keeping is important. The standard of completion of request forms and sample labelling is still very poor in some hospitals. This can cause many problems if samples are required by the police or coroner. Knowledge of the limitations of the analytical methods used is also important – an enzymatic ethanol assay is not as selective as headspace gas chromatography, for example.

One practical problem is that samples may be collected, assays performed and results reported before the need for forensic investigation has become apparent. Another problem is that all that may be available are specimens collected after death (see [Box 44.1](#)), although in general it is information on an analyte's concentration prior to, or at the time of death that is required. In this case, the likelihood of agonal or post-mortem change, and indeed, sample contamination during collection, must be taken into account when interpreting results. An associated problem is that there are often no reference ranges for fluids such as vitreous humour, pericardial fluid, or synovial fluid since such samples are, for practical purposes, rarely available during life, except from laboratory animals. Method validation is also compromised by this same lack of reference material. Furthermore, the time needed for analyte equilibration between plasma and, for example, vitreous humour during life remains unknown.

Of course the laboratory, too, can be the subject of forensic investigation if laboratory error of whatever nature comes under scrutiny of the courts (see [Box 44.2](#)). Examples here include the use of inappropriate analyses,

TABLE 44.1 Some laboratory investigations commonly requested on blood samples that may arouse suspicion of poisoning

Investigation	Possible cause of increase	Possible cause of decrease
Sodium	MDMA ^a (malignant hyperthermia), sodium salts	Diuretics, water intoxication (acute and chronic), MDMA (very rare)
Potassium	Digoxin, potassium salts	Diuretics, laxatives (both chronic), insulin, salbutamol, sulfonylureas, theophylline
Glucose	Salicylates, theophylline	Ethanol (especially children), insulin, salicylates, sulfonylureas, valproate
Calcium	–	Ethylene glycol, fluorides, magnesium salts
Chloride	Bromide or organobromines (actually interference in method)	–
Lactate	Ethylene glycol (artefact on some blood gas analyzers)	–
Magnesium	Magnesium salts	–
International normalized ratio (INR, prothrombin time)	Anticoagulant rodenticides (warfarin, brodifacoum), paracetamol (early marker of hepatic damage)	–
Anion gap ($[(\text{Na}^+) + (\text{K}^+)] - [(\text{HCO}_3^-) + (\text{Cl}^-)]$)	Ethanol, ethylene glycol, iron salts, isoniazid, methanol, metformin, paraldehyde, salicylates, toluene (chronic)	–
Osmolar gap ^b	Acetone, ethanol, ethylene glycol, methanol, 2-propanol, hypertonic i.v. solutions (e.g. mannitol)	–

^aMethylenedioxymetamphetamine.

^bMeasured osmolality (freezing point depression) – calculated osmolality. Calculated osmolality = $2([\text{Na}^+] + [\text{K}^+]) + \text{urea} + \text{glucose}$ (all mmol/L).

delayed analyses, sample mix-ups and errors in reporting, including the use of inappropriate units. In all cases, it is best to write out units in full, for example ‘milligrams per litre’, rather than using symbols, when producing reports for the courts. The laboratory should provide clear guidance as to the significance of a result, especially when different units may be used. Patients have died when a paracetamol result reported in mg/L has been assumed to be in mmol/L. Mass units (SI) should be used for drugs except for lithium, thyroxine and methotrexate, where molar units should be employed. For metals/trace elements and for alcohol (ethanol), either molar or mass units may be employed. However, for forensic purposes, including the regulations governing occupational lead exposure, mass units are often the rule and the laboratory should remember this when providing interpretation of results. For clinical purposes, ethanol is often reported as mass units per litre (mg/L), but for forensic purposes, at least in the UK, ethanol is still reported as mg/100 mL (mg%).

SAMPLES AND SAMPLING

Information recorded on the sample container at the time the sample is collected should include the names (first and family or last name) and date of birth, patient or post-mortem number and the date and time of collection. This information, together with details of the collection site in post-mortem work, and the sample type (including a note of any preservative), and any other appropriate information, should be recorded on an accompanying assay request form (see Box 44.3). The date and time of receipt of all specimens by the laboratory should be recorded and a unique identifying number assigned in each

BOX 44.1 Thanatochemistry

Post-mortem biochemistry is sometimes termed ‘thanatochemistry’ (from the Greek, *Thanatos*, the personification of death in Greek mythology).

BOX 44.2 Red or dead?

A 64-year-old male with a long history of medical problems, including type 2 diabetes, was admitted to hospital at approximately 17:00 with a 2-day history of diarrhoea. A blood sample was requested on admission for electrolytes and assessment of renal function. However, phlebotomy was difficult; blood was obtained at the sixth attempt (22:12). The results were sodium 128 mmol/L, potassium 8.2 mmol/L, urea 36.8 mmol/L and creatinine 596 μmol/L. The results were known in the laboratory at 23:40, but were not reported because the sample was haemolysed. Instead, the laboratory asked for an urgent repeat sample.

In the event, no attempt was made to obtain a second specimen urgently in view of the difficulty in obtaining the first sample. The patient was found collapsed at about 01:10 the next day. Resuscitation was unsuccessful. The high urea and creatinine indicated that the patient had been in renal failure for some hours before he died and, if the urea and creatinine results had been reported together with the potassium, this would have alerted the clinician to the possibility of a potentially fatal hyperkalaemia and placed the likelihood of haemolysis contributing to the raised potassium in proper clinical context.

In retrospect, it was agreed that appropriate action to lower the plasma potassium should have been taken. Insulin, nebulized salbutamol and/or haemodialysis (depending on the clinical condition of the patient and the facilities available) would have been the treatments of choice.

BOX 44.3 Information that should accompany a request for forensic biochemistry or toxicology

- Name, address and telephone number of clinician/pathologist and/or coroner's officer, and address to which the report and invoice are to be sent. A post-mortem (reference) number may also be appropriate
- Circumstances of incident (including copy of sudden death report if available)
- Past medical history, including current or recent prescription medication, and details of whether the patient suffered from any serious potentially infectious disease such as hepatitis or tuberculosis
- Information on the likely cause, and estimated time, of ingestion and/or death and the nature and quantity of any substance(s) implicated
- If the patient has been treated in hospital, a summary of the relevant hospital notes should be supplied, including details of emergency treatment and drugs given both therapeutically and incidentally during investigative procedures
- Note of occupation/hobbies
- A copy of any preliminary pathology report, if available

case. Any residual specimen should be kept securely at -20°C or below until investigation of the incident has been concluded.

In forensic work, it is important to be able to guarantee the identity and integrity of the specimen from when it was collected through to the reporting of the results, although this ideal is often not attained in normal clinical laboratory practice. 'Chain of custody' is a term used to refer to the process used to maintain and document the history of the specimen (see Box 44.4). Procedures for appropriate storage of samples that may be required for forensic analysis and for authorizing and documenting the release of such samples on request of a coroner, for example, must also be in place. Ideally, samples should be protected during transport by the use of tamper-evident seals and should be submitted in person to the laboratory by the coroner's officer or other investigating personnel. If storage is to be at -5 to -70°C , basic precautions to preserve sample integrity, including labelling, must be undertaken (glass tubes will break if over-full when frozen). The requirements of the UK Human Tissue Act, or

BOX 44.4 Chain of custody documents

- Name of the individual collecting the specimen
- Name of each person or entity subsequently having custody of the specimen, and details of how it has been stored
- Date and time the specimen was collected or transferred
- Specimen or post-mortem number
- Name and date of birth of the subject or deceased
- Brief description of the specimen
- Record of the condition of tamper-evident seals

other relevant legislation on the retention and storage of pathological samples, must be met.

POISONING WITH ENDOGENOUS AGENTS

Many analytes of toxicological interest (and their metabolites) also occur naturally in the body and hence, reference ranges, 'cut-offs' or other means of delineating an exogenous source for the compound(s) of interest must be adopted. Examples include acetone, carbon monoxide (measured as % carboxyhaemoglobin) ethanol, γ -hydroxybutyrate (GHB), insulin, iron, potassium, sodium and testosterone.

Testosterone continues to be abused by athletes and this remains the most common adverse finding declared by World Anti-Doping Agency accredited laboratories; the practice is usually detected by the demonstration of an elevated testosterone:epitestosterone ratio and by procedures to ensure that such a finding is not 'natural' for a particular athlete. Numerous other endogenous agents have been used in an attempt to enhance performance or to mask use of other agents in sport but further discussion of this topic is beyond the scope of this chapter.

γ -Hydroxybutyrate

γ -Hydroxybutyrate (GHB), and its precursors γ -butyrolactone (GBL) and 1,4-butanediol, are used to improve athletic performance, as intoxicants and sometimes in assault such as drug-facilitated sexual assault (which includes rape). As with alcohol, voluntary ingestion always has to be considered (Box 44.5). γ -Hydroxybutyrate exposure may also arise from unexpected sources (Box 44.6). The substance is practically odourless and tasteless and has a short plasma half-life (20 min or so), making covert administration hard to detect. Quantitation is needed as GHB is an endogenous compound. A urine cut-off of 10 mg/L is recommended in attempting to differentiate endogenous GHB excretion from deliberate GHB/GBL administration. Unusually, the urine cut-off seems more reliable than a measure of plasma GHB, but by ~ 12 h after GHB ingestion, the concentration in urine is usually <10 mg/L. For post-mortem blood, the cut-off is

BOX 44.5 Covert GHB administration?

A man and a woman met at a party. They spent the evening together and took a taxi to the woman's house around midnight. She had no further recollection of events until she awoke and thought that she had had sexual activity. She reported the suspected incident to police and provided blood and urine samples (fluoride preserved) about 20 h after the incident. Cannabinoids and GHB (30 mg/L) were present in urine. No GHB was detected in either blood (limit of detection 5 mg/L) or drinks containers (glasses etc.) at her home.

The man was arrested and charged with rape on the day the incident was reported. A bottle of 'Lucozade' in his possession contained about 20% (w/v) GHB. However, although he was found guilty of rape, the woman later admitted to prior voluntary GHB ingestion.

BOX 44.6 Girl nearly killed by 'GHB' toy

A girl of 7 years nearly died after eating some toy beads. She suffered severe poisoning. The beads were coated with 1,4-butanediol, a GHB precursor. The girl said she ate the beads thinking they were sweets: they tasted of marzipan. Six children in Australia and NZ and two in the USA needed hospital treatment after swallowing them. The beads, made in China, could be arranged into designs and fused together when sprayed with water. Half a million Bindeez toys were recalled in the UK/Eire in November 2007.

generally taken as 50 mg/L because of the likelihood of post-mortem GHB production.

Insulin

Endogenous insulin is co-secreted with C-peptide. In theory, therefore, in suspected administration of exogenous insulin, which lacks C-peptide, the ratio of the two analytes could be useful as an indicator of the source of the insulin. However, commercially available immunoassays have highly variable responses to different types of insulin making the insulin:C-peptide ratio extremely difficult to interpret. An insulin-degrading enzyme (IDE) is widely distributed in tissues including erythrocytes, hence use of haemolysed samples, including post-mortem samples, is likely to give false results. Use of different anticoagulants to preserve samples is also associated with differences in plasma insulin results. The presence of hepatic or renal insufficiency, or of endogenous anti-insulin or anti-proinsulin antibodies (analogous to the analytical problems with digoxin assay if anti-digoxin Fab antibody fragments have been given) may be further possible sources of error (see also Chapter 17).

Plasma C-peptide is stable for only ~2–3 weeks at -20°C and for up to 6 months at -80°C , whereas plasma insulin is more stable (~5 h at room temperature, ~1 week at 4°C and several months at -20°C). On the other hand, C-peptide is not degraded by IDE. Anti-insulin antibodies bind proinsulin via its insulin moiety and greatly retard its clearance from the circulation. Because of cross-reaction with proinsulin in some C-peptide immunoassays, proinsulin bound to anti-(pro)insulin antibodies can interfere.

Murder or suicide by insulin is difficult to diagnose and to prove (see Box 44.7). Immunohistochemical demonstration or measurement of elevated insulin concentration in tissue around an injection site compared with a control site can help support the diagnosis. Unlike most purely immunological methods, liquid chromatography-tandem mass spectrometry (LC-MS/MS) may allow differentiation of human insulin from its synthetic derivatives. Besides its use in doping control, the method has been applied to post-mortem material related to an insulin poisoning case.

Magnesium

Poisoning with magnesium is rare, and usually follows intravenous administration. Confusion over units is not uncommon (see Box 44.8). Clinical features of

BOX 44.7 The Grantham disaster

February to April 1991: three children died suddenly on Ward 4 at Grantham and Kesteven Hospital. A further baby died at home soon after discharge. Nine other patients collapsed unexpectedly, some more than once. All but one were transferred urgently to the paediatric ITU. Clinical and post-mortem investigations were inconclusive. One patient had three hypoglycaemic attacks on Ward 4, and insulin poisoning was suspected.

On 12 April, a very high insulin/low C-peptide result was reported on a blood sample collected on 28 March. On 30 April, police were called to investigate continuing emergencies (which included a further death). In November 1991, enrolled nurse Beverly Allitt, 26, was charged with four murders, nine attempted murders and nine counts of causing grievous bodily harm. She was also charged with the attempted murder of two adult patients when she had worked on their ward before moving to the children's ward. Potassium and lidocaine were implicated in some of the Ward 4 assaults.

In 1993, she was convicted of four murders, three attempted murders and on six counts of causing grievous bodily harm. She was found not guilty with respect to the charges concerning the adult patients. As in all criminal poisoning cases, much of the evidence was circumstantial. Allitt's history suggested factitious disorder (Münchhausen syndrome).

BOX 44.8 Was it poisoning?

A 57-year-old male presented to hospital complaining of chest pain and dizziness. He was sweaty and light-headed (heart rate reported as 230/min). Ventricular tachycardia was diagnosed, and three unsuccessful attempts were made at electrical cardioversion. His condition deteriorated.

Cardiology advice at this stage was to give 8 mmol magnesium ion by slow i.v. bolus followed by further magnesium by infusion. In the event, an i.v. bolus of 8 g magnesium sulphate (32 mmol magnesium ion) was administered, whereupon the patient complained of feeling flushed and unwell. He was visibly hot and sweaty, and suffered cardiac arrest. After 13 cycles of cardiopulmonary resuscitation and administration of calcium chloride to reverse possible magnesium toxicity, he was pronounced dead some 2 h after presentation.

Whole blood magnesium was 1.50 mmol/L in a sample obtained on admission and was 2.67–3.54 mmol/L in three samples obtained after the administration of magnesium sulphate, but before death. These latter results provided evidence to support the report of accidental magnesium overdose, but the blood magnesium concentrations are similar to those obtained in patients given magnesium to control convulsions.

At post-mortem the next day, femoral whole blood magnesium was 10.0 mmol/L and vitreous humour magnesium (each eye separately) was 0.46 and 1.42 mmol/L. In court, it was suggested that:

1. the post-mortem blood magnesium result was likely to have been affected by post-mortem change
2. the average of the vitreous humour results (0.94 mmol/L) was compatible with the ante-mortem post-overdose results, given that vitreous humour magnesium probably reflects plasma magnesium
3. although the temporal relationship between magnesium administration and the fatal event might suggest a causal relationship, there was no toxicological or cardiological evidence of fatal magnesium poisoning.

Verdict: death by natural causes.

magnesium overdose may include drowsiness, unconsciousness, loss of muscle tone and respiratory and cardiac arrest. Plasma magnesium in healthy adults ranges from 0.7 to 1.3 mmol/L. Features of toxicity are reported at plasma magnesium concentrations of 3.5–5.0 mmol/L, and cardiorespiratory arrest may occur at concentrations of >8.5 mmol/L. During life, magnesium is distributed within cells (approximate cell:plasma distribution ratio 4:1), hence whole blood concentrations are somewhat higher than plasma concentrations. Doses of magnesium sulphate of up to 4 g (16 mmol magnesium ion) are sometimes given for control of convulsions.

Sodium

Hypernatraemia from sodium chloride (common salt) poisoning must be distinguished from hypernatraemia owing to dehydration from fluid loss or, very rarely, low fluid intake. This is especially important because sodium chloride poisoning may be the result of deliberate administration of large amounts of salt by a third party – salt is hardly ever encountered in self-poisoning episodes nowadays, although there were many deaths, especially in children, when saline emetics were used in an attempt to induce vomiting.

When a patient presents with hypernatraemia, diabetes insipidus and renal disease have to be excluded before salt poisoning can be diagnosed. Hypernatraemia caused by disease processes may be associated with obvious polyuria and polydipsia. Negative water balance can occur easily. This reduces solute excretion and induces hypernatraemic dehydration. Finally, there are rare individuals who develop hypodipsic hypernatraemia (see p. 44). A water deprivation test may be required if this disorder is suspected in life.

Common criteria used to diagnose salt (sodium chloride) poisoning focus on hypernatraemia, with high urinary concentrations of sodium and chloride. However, high urinary concentrations of sodium alone cannot distinguish salt poisoning from dehydration. The medical and legal implications of the two conditions are fundamentally different, so reliable ways to distinguish between them are needed. Be this as it may, both salt poisoning and dehydration (caused by neglect) may lead to criminal or civil action. Fractional excretions (the proportions of sodium and water filtered at the glomerulus that subsequently reach the urine), calculated from the sodium and creatinine concentrations of paired plasma and associated ('spot') urine samples, can distinguish the two situations (see Box 44.9). The values should be >2% in an individual who has been poisoned with salt and is volume replete and <1% when dehydrated but with viable renal tubules. Note that the units of measurement used must be the same for plasma and urine (plasma creatinine is usually reported in $\mu\text{mol/L}$, while urine creatinine is often reported in mmol/L).

POST-MORTEM BIOCHEMISTRY

Gradients that are maintained by active processes during life, such as that between intra- and extracellular potassium begin to break down soon after the occurrence of

BOX 44.9 Derivation of the fractional excretion of sodium (FE_{Na}) and water ($\text{FE}_{\text{H}_2\text{O}}$)

Fractional excretion of water, $\text{FE}_{\text{H}_2\text{O}}$

- The $\text{FE}_{\text{H}_2\text{O}}$ is the volume of electrolyte-free water that appears as urine compared with the amount filtered
- Thus, $\text{FE}_{\text{H}_2\text{O}} = V / \text{GFR}$
- Since $\text{GFR} = U_{\text{Cr}} \times V / P_{\text{Cr}}$
- $\text{FE}_{\text{H}_2\text{O}} = V \times P_{\text{Cr}} / U_{\text{Cr}} \times V$
- Simplifying, $\text{FE}_{\text{H}_2\text{O}} = P_{\text{Cr}} / U_{\text{Cr}}$ (then multiply by 100 to express as a percentage)

Fractional excretion of sodium, FE_{Na}

- The FE_{Na} is the amount of sodium lost in the urine compared to the amount filtered
- Thus, $\text{FE}_{\text{Na}} = \text{urinary sodium excretion} / \text{filtered sodium}$
- The urinary sodium excretion = $U_{\text{Na}} \times V$
- And the filtered sodium = $P_{\text{Na}} \times \text{GFR}$
- Since $\text{GFR} = U_{\text{Cr}} \times V / P_{\text{Cr}}$
- The filtered sodium = $P_{\text{Na}} \times U_{\text{Cr}} \times V / P_{\text{Cr}}$
- Therefore, $\text{FE}_{\text{Na}} = U_{\text{Na}} \times V \times P_{\text{Cr}} / P_{\text{Na}} \times U_{\text{Cr}} \times V$
- Simplifying, $\text{FE}_{\text{Na}} = U_{\text{Na}} / P_{\text{Na}} \times P_{\text{Cr}} / U_{\text{Cr}}$ (then multiply by 100 to express as a percentage)

P, plasma concentration; U, urine concentration; Cr, creatinine; GFR, glomerular filtration rate; V, urine flow rate.

BOX 44.10 Diabetic or alcoholic ketoacidosis?

A 56-year-old female had a history of chronic alcohol abuse and diabetes mellitus requiring insulin, probably secondary to an episode of alcohol-induced pancreatitis. Her husband found her collapsed one evening. This was a regular occurrence. He measured her capillary glucose concentration, and found it to be 1.5 mmol/L. He gave her an injection of 1 mg glucagon. She woke up, and so he went to bed. He awoke the following morning to find her dead in bed.

A blood sample was obtained post-mortem. The only notable finding was a raised β -hydroxybutyrate concentration (11.36 mmol/L). No ethanol was detected. It was not possible to measure glucose because of the condition of the sample.

At the inquest, it was thought that an individual who had abused alcohol chronically was unlikely to have a significant hepatic glycogen store, hence it was felt unlikely that a standard dose of glucagon would have led to excessive release of glucose. Thus, it was thought more likely that the ketoacidosis was due to the consequences of chronic alcohol abuse rather than to diabetic ketoacidosis.

hypoxic or anoxic damage, hence the possibility of both terminal and post-mortem change has to be evaluated when interpreting results. Most deaths that become the subject of post-mortem investigation occur outside hospital and it may be some days before the body is found and samples collected for analysis. Therefore, blood samples are invariably haemolysed to a greater or lesser degree and the likelihood of other changes, such as loss of labile analytes (e.g. glucose and insulin), is high (see Box 44.10). It should be remembered that most clinical

reference values are established for plasma or serum, and not haemolysed whole blood.

Vitreous humour

Vitreous humour is preferred to blood for most post-mortem biochemistry (Table 44.2), since it is thought to be far less susceptible to autolytic change, is less likely to be subject to post-mortem contamination by diffusion of drugs or other poisons that may be present at high concentration in the thorax or abdomen at death, and lies within the relatively protected environment of the eye socket. After death, however, potassium quickly leaks from the retina and hence vitreous potassium is not a reliable indicator of ante-mortem plasma potassium and is of minimal value in the diagnosis of exogenous potassium administration. The possibility of concurrent vitreous disease confounding the results must also be remembered.

When collecting vitreous humour, ideally both eyes should be sampled independently and the results reported separately. Potassium concentrations may differ by up to 2.3 mmol/L between the two eyes (in samples from non-putrefied bodies). Specimen contamination with retinal cells is a recognized source of falsely raised vitreous potassium concentrations. Hence, aspiration must be gentle

to avoid contamination with retinal fragments as far as possible. Differences may also be due to inappropriate sample handling. Vitreous humour is viscous, hence may require treatment such as centrifugation, heating, dilution or addition of hyaluronidase, to facilitate accurate pipetting. A vitreous potassium concentration >15 mmol/L suggests gross post-mortem decomposition.

Vitreous sodium and chloride concentrations may fall after death, at rates of up to 1 mmol/L per hour, whereas potassium increases at a rate of 0.14–0.19 mmol/L per hour. If the potassium concentration is <15 mmol/L, then the sodium and chloride concentrations are thought likely to reflect the situation at death. Urea and creatinine are relatively stable in post-mortem specimens. If vitreous sodium, chloride and urea are >155, >115 and >10 mmol/L, respectively, this may indicate ante-mortem dehydration. If the urea concentration is >20 mmol/L and creatinine >200 µmol/L with sodium and chloride concentrations within the normally accepted range, this indicates that uraemia was present before death.

A number of biochemical tests have been advocated for particular purposes, but remain little used (see Table 44.3). Attempts to employ the rate of rise of vitreous humour potassium concentration, in order to calculate the time of death, have largely been abandoned because of the

TABLE 44.2 Post-mortem biochemistry interpretation

Analyte	Matrix	Acceptable post-mortem range	Interpretation of raised concentration
Glucose	Vitreous humour	After death, vitreous humour glucose falls rapidly, therefore any detectable glucose requires investigation	(Drug induced) hyperglycaemia, diabetic ketoacidosis, stress response (interpret in conjunction with lactate)
β-Hydroxy-butyrate	Blood, vitreous humour	0.1–1.0 mmol/L	Fasting, prolonged alcohol abuse, diabetic ketoacidosis, stress response (e.g. hypothermia)
HbA _{1c}	Blood	27–67 mmol/mol	Poor long-term (2–8 weeks) blood glucose control
Creatinine	Vitreous humour	<100 µmol/L	Poor renal function; high protein intake; large muscle mass; heat shock
Lactate	Vitreous humour	<10 mmol/L	Interpret in conjunction with glucose
Sodium	Vitreous humour	135–145 mmol/L	Salt poisoning; dehydration (interpret in conjunction with creatinine and urea)
Chloride	Vitreous humour	95–105 mmol/L	Salt poisoning; dehydration (interpret in conjunction with creatinine and urea)
Urea	Vitreous humour	<10 mmol/L	Poor renal function; upper GI haemorrhage
Tryptase	Blood	<100 µmol/L	Anaphylactic shock

TABLE 44.3 Post-mortem biochemistry: some little used/unvalidated tests

Analyte	Matrix	Suggested role in diagnosis of:
Adrenaline:noradrenaline ratio	Urine	Hypothermia
Chymase	Blood	Anaphylactic shock
Chromogranin A	Serum, cerebrospinal fluid	Hypothermia
C-reactive protein (CRP)	EDTA blood, liver	Recent infection, trauma, burns, ketoacidosis, necrosis. Diagnosis of sepsis if measured soon after death
Fructosamine	Vitreous humour	Diabetic ketoacidosis
Hypoxanthine	Vitreous humour	Time of death
Lactate	Vitreous humour	If very high, may indicate lactic acidaemia (but may be formed perimortem)
Thyroglobulin, free tri-iodothyronine (fT ₃)	Blood	Neck trauma (e.g. strangulation)
Troponin	Pericardial fluid	Myocardial damage present prior to microscopic changes

inherent uncertainty of this method, even when vitreous humour hypoxanthine is also analysed, with the aim of increasing the accuracy of the procedure. Use of synovial fluid, as an alternative to vitreous humour, for potassium measurement for time-of-death estimation, has also been advocated. It has been claimed that regression analysis of vitreous humour hypoxanthine, potassium and urea concentrations can give a reliable time-of-death estimate, taking into account the cause of death. There are reports of immunochemical detection of glucagon in pancreatic cells and of calcitonin in thyroid C-cells being used to indicate time of death, but these methods are experimental at best. Serial monitoring of C-reactive protein (CRP), procalcitonin, interleukin-6, interleukin-1 β , soluble interleukin-2 receptor or lipopolysaccharide binding protein in the hours after death, has been suggested as an aid to the diagnosis of sepsis, but has not been widely adopted.

The measurement of markers of heart muscle damage (e.g. myoglobin, creatine kinase, troponin) as an adjunct to searching for evidence of microscopic changes in samples of myocardium post-mortem, has been investigated with the aim of improving the diagnosis of ante-mortem ischaemic damage. However, the only post-mortem fluid with which there has been some success in this approach, has been pericardial fluid; concurrent post-mortem changes limiting the value of fluids such as blood. Unfortunately, as microscopy has always been viewed as the definitive method for the diagnosis of ante-mortem heart damage, the use of biochemical markers in cases where death has occurred prior to microscopic changes becoming apparent has not been fully investigated. Hence, the interpretation of results remains problematic.

SPECIFIC DIAGNOSTIC PROBLEMS

Anaphylaxis/anaphylactoid reactions

Many drugs may precipitate anaphylaxis or anaphylactoid reactions. Mast-cell tryptase is an indicator of anaphylactic shock. Measurement of blood chymase has also been suggested in this context. Although a raised serum or plasma tryptase activity can supply important supporting evidence in the diagnosis of anaphylaxis, it cannot be used as the sole criterion for the post-mortem diagnosis of anaphylaxis as a cause of death, since there is overlap with results from people who die from causes other than anaphylaxis.

Diabetes

Blood and vitreous humour glucose concentrations generally fall rapidly after death and are thus an unreliable guide to ante-mortem glucose concentration. However, since glucose undergoes anaerobic glycolysis to lactate, some investigators have suggested that measuring the sum of vitreous humour glucose and lactate may give a better estimation of the glucose concentration at the time of death. A potentially complicating factor is that lactate may increase perimortem. Moreover, some drugs that are themselves unstable in biological systems, for example

ethanol and insulin, may cause fatal hypoglycaemia, hence compounding the difficulties that may be encountered in establishing a cause of death.

An elevated post-mortem blood HbA_{1c} concentration might indicate poor glucose control during life. This suggestion may be supported by an elevated vitreous humour glucose concentration. In patients with type 1 diabetes, the presence of ketones (principally acetone and its metabolite 2-propanol, but also acetoacetate) may indicate the presence of diabetic ketosis prior to death, especially if considered together with the blood β -hydroxybutyrate (BHB) concentration. Schemes to aid interpretation of vitreous glucose concentrations, similar to that in [Figure 44.1](#), are often cited, but even these may not give clear guidance as to the likely situation perimortem in some cases.

Measurement of ketones in blood or vitreous humour is recommended in unexplained deaths in chronic alcoholic as well as diabetic patients. Prolonged poor nutrition and use of alcohol (common in chronic alcoholics) promote the accumulation of ketones (acetone, butanone) and BHB, and often, elevated ketone concentrations (acetone >20 mg/L) are the only notable post-mortem finding. A practical scheme for investigating such deaths is given in [Figure 44.2](#).

Drowning

Haemodilution is likely in victims of fresh-water drowning, but not in those drowned in salt water. Thus, concentrations of ethanol, drugs or other analytes measured in the blood of victims of fresh-water drowning may be misleadingly low. Conversely, haemoconcentration is likely if a cadaver has been dehydrated, for example by heat or by mummification. In all such cases, measurement of blood haemoglobin may give an estimate of the magnitude of haemodilution/concentration, if it has not been degraded by heat or by prolonged storage.

It has been suggested that haemodilution in fresh-water drowning produces a lower chloride concentration in left heart blood as compared with right heart blood, while in salt water drowning, haemoconcentration and chloride ion absorption is said to produce the opposite result. High concentrations of magnesium in left heart blood compared with right heart blood may reflect magnesium absorption from salt water. Trace element analysis has been proposed as an aid to discriminate fresh-water drowning from salt-water drowning, but seems to offer poor discriminatory power and other (non-biochemical) investigations, notably looking for species of diatoms, are more helpful in such cases.

Hypothermia/hyperthermia

Cold may be a significant factor in a death, but there are no specific biochemical markers that can be used to confirm a diagnosis of fatal hypothermia. Indications of ante-mortem cold stress include high urinary adrenaline and noradrenaline concentrations and Wischnewsky spots (small gastric mucosal bleeds). An increased adrenaline:noradrenaline ratio may be a better indicator of ante-mortem hypothermia than the separate

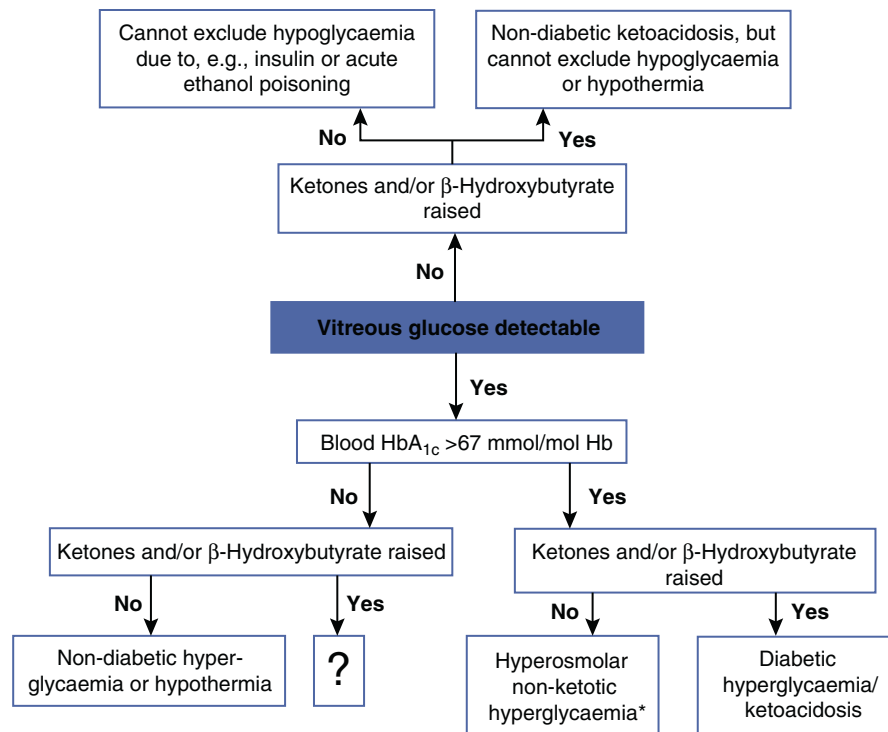

FIGURE 44.1 ■ Aid to the interpretation of post-mortem vitreous humour glucose and blood β -hydroxybutyrate concentrations. *Requires confirmation from vitreous humour sodium and urea/creatinine.

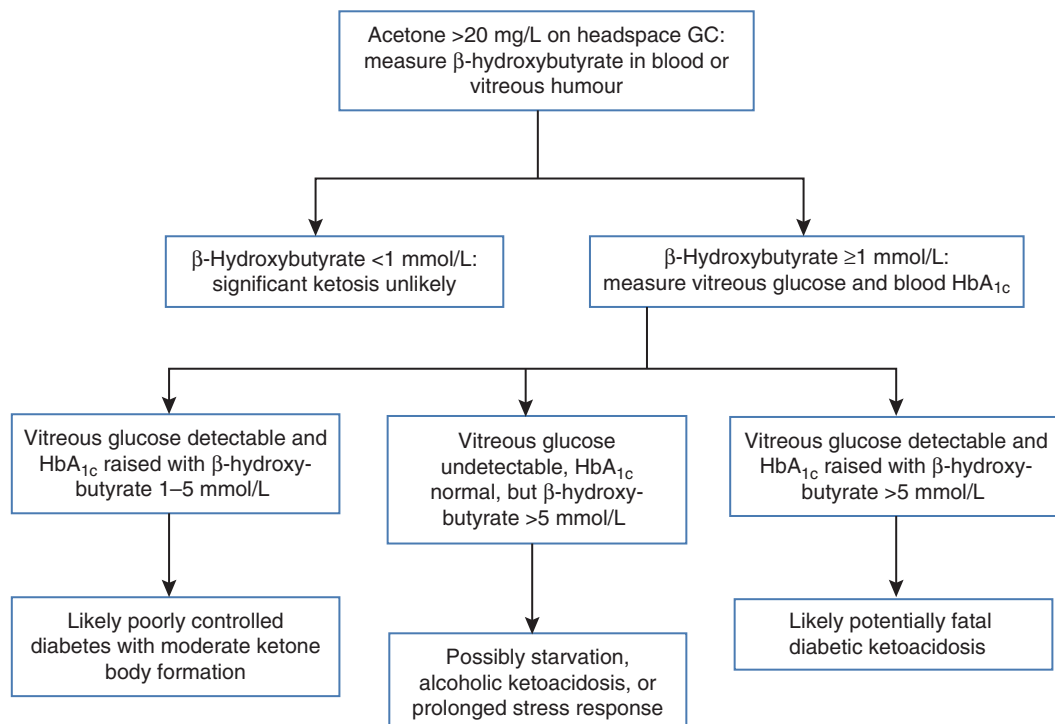

FIGURE 44.2 ■ Suggested scheme for investigation of unexpected deaths in patients in whom diabetes or alcoholism is a possibility.

catecholamine results. Ketone and glucose concentrations may also be elevated, and in persistent hypothermia, there may be electrolyte disturbances and metabolic acidosis. A role for measurement of chromogranin A has been postulated.

Fatal hyperthermia (heat stroke) often involves multiple organ dysfunction, including skeletal muscle damage without marked inflammatory responses. It has been suggested that isolated elevation of serum creatinine may help in diagnosis.

Inflammation

Blood CRP concentration peaks within 6 h of a stimulus and CRP is stable in post-mortem samples. Liver is said to be a good alternative specimen if blood is not available. Interpretation of results can be difficult, however, as there are many causes of a raised blood CRP in addition to inflammation (see Table 44.3).

Sudden death

Sudden unexpected death in infancy (SUDI, also known as sudden infant death syndrome (SIDS), Table 44.4), may be an acute manifestation of an inborn error of metabolism, particularly a fat oxidation defect, and therefore these should be excluded. Sudden arrhythmic death syndrome (also known as sudden adult death syndrome (SADS)) is thought likely often to have a cardiac origin

TABLE 44.4 Some biological samples required when investigating sudden unexpected death in infancy (SUDI)

Sample (volume)	Handling	Test
Blood (serum) (1–2 mL)	Centrifuge, store serum at –20°C	Toxicology
Urine (20 mL if possible)	Store at –20°C	Toxicology and specialized tests for inherited metabolic diseases
Blood from Guthrie card	Ensure circle is filled. Do not put in plastic bag	Tests for inherited metabolic diseases
Skin biopsy	After discussion with paediatrician and laboratory	Tests for inherited metabolic disease, e.g. fibroblast enzyme activity
Muscle biopsy	After discussion with paediatrician and laboratory	If history suggests mitochondrial disorder

Further details: Royal College of Pathologists and Royal College of Paediatrics and Child Health (2004).

such as a fatal arrhythmia, but a full toxicological analysis is required to exclude recent use of not only illicit drugs (such as cocaine and other stimulants), but also therapeutic drugs (e.g. tricyclic antidepressants and antipsychotics) that may increase the risk of a fatal cardiac arrhythmia.

 sources 519t, 521
 status, laboratory determination 523–524
 structure 521, 523f
- Vitamin B₁₂ deficiency 217, 219, 501, 521
 causes 523
 features 686
 encephalopathy 686
 peripheral neuropathy 693
 spinal cord degeneration 688–689
 laboratory investigation 523–524
 in malignant disease 816t
 serum folate concentration 521
 treatment 693. *See also* Pernicious anaemia
- Vitamin C 189
 deficiency 189, 198
 dietary sources 189
 excess intake 189
 function 189
 laboratory-based assessment 198
- Vitamin D 96–98
 actions 97–98
 circulating metabolites 97, 97t
 function 703t
 laboratory-based assessment 197, 621
 measurement of metabolites 97t, 98
 receptor 97–98
 synthesis and metabolism 96–97, 97f
 synthetic analogues 98
 hyperparathyroidism treatment 627
 toxicity 103, 197, 627
- Vitamin D₂ 96
 Vitamin D₃ 96
 Vitamin D deficiency 197, 615, 617
 haemolysis in neonates 529
 in nephrotic syndrome 159–160
 osteomalacia 620–621
 in primary hyperparathyroidism 628–629
 treatment 109
 responses 622. *See also* Vitamin D
 supplementation
- Vitamin D-dependent rickets (VDDR) 621
 treatment 622
- Vitamin D supplementation 98
 in hyperparathyroidism 628–629
 in nephrotic syndrome 159–160
 in osteopenia of prematurity 492
 in osteoporosis 617
 in phosphopenic osteomalacia 623
- Vitamin E 185–186
 atherogenesis and 743
 deficiency 185, 197, 689, 694
 ataxia with 185, 699–700
 function 703t
 laboratory-based assessment 197
 structure 185f
 supplementation 185
- Vitamin K 186–187
 antagonists 186f
 deficiency 186–187, 197
 dietary 186
 function 186, 703t
 laboratory-based assessment 197
 neonatal administration 186–187
 structure 186f
 toxicity 187
- Vitreous humour, post-mortem biochemistry
 879–880, 879t
- Vitronectin 607, 607t
 Volatile substance abuse 792t, 803
 von Gierke disease 277
 von Hippel–Lindau syndrome 813
- W**
- Waardenburg syndrome 851
 Waist circumference 194
 Waldenström macroglobulinaemia 591t, 595,
 595t, 693
 'Washout' phenomenon 91
 Wasting syndrome, cancer patients 818
 Water 27
 balance
 in chronic kidney disease 147
 in hyperthyroidism 389
 in hypothyroidism 395
 body content 27, 28t
 pre-term *vs.* term infants 487, 487f
 compulsive drinking 41, 681
 deficiency
 with thirst 44
 without thirst 44–46, 45f
 deficit calculation in hypernatraemia 62
 fractional excretion of 878, 878b
 intake control 31–32
 intoxication, estimation of sodium required
 62
 intracellular fluid and 30–32
 metabolism, disorders 39–51
 hypernatraemia. *See* Hypernatraemia
 hyponatraemia. *See* Hyponatraemia
 polyuria. *See* Polyuria
 renal output, control 30–31
 restriction, hyponatraemia management
 51
 retention
 ascites 259–260
 in nephrotic syndrome 159
 Water channels (aquaporins) 27, 30, 129
 Water deprivation test 42, 63, 357, 372
 interpretation 42, 63, 372
 protocol 42, 63, 63t, 372
 Water drinking
 compulsive 41, 681. *See also* Thirst
 Water load test 64, 64t
 interpretation 64
 Water-soluble vitamins 187–190, 192. *See also specific vitamins*
- Watery diarrhoea–hypokalaemia achlorhydria (WDHA) syndrome 53–54
 Weaning, inherited metabolic disease
 presentation 464
 Wegener granulomatosis 639t
 Weight, assessment of nutritional status
 193–194, 193t

- Weight gain
 growth hormone deficiency 203. *See also*
 Obesity
- Weight loss 193, 205
 amenorrhoea and 369, 440
 in anorexia nervosa 207
 in cancer patients. *See* Cancer cachexia
 dietary approaches 205
 in hyperthyroidism 388
 pharmacological approaches 205
 physical exercise 205
 surgical approaches. *See* Bariatric surgery
- Wermer syndrome. *See* Multiple endocrine
 neoplasia (MEN), type 1
- Wernicke–Korsakoff syndrome 187, 686
- Western blot, definition 873
- Whipple's triad 227, 334
- White blood cells (WBCs) 515, 562–566, 564*f*
 in cerebrospinal fluid 661, 662
 count 498, 498*t*, 562, 563*t*, 602
 differential 498–499, 499*f*, 563*t*
 low 504
 raised 503–504
 function 503
 morphology 503–504, 504*f*, 564*f*
 abnormal 502*f*, 504, 505*f*
 in redistribution hyperkalaemia 58
 in redistribution hypokalaemia 52
 stress and 407
 urinary casts 131. *See also specific types*
- Wild type, definition 873
- Williams syndrome 491
- Wilson disease 191, 266–268, 496, 698–699
 diagnosis 243, 254*t*, 255, 266–267, 267*t*
 long-term management 267
- Wolff–Chaikoff effect 376
- Wolffian ducts 413, 451
- Wolfram syndrome 39–40
- Wolman disease 717
- World Health Organization (WHO),
 diagnostic criteria for diabetes
 mellitus 282, 283*b*, 283*t*, 284*b*
- X**
- Xanthine oxidase 639–640, 640*f*
 deficiency 177–178
- Xanthine stones 177–178
- Xanthinuria 177–178
- Xanthochromia 661, 667
- Xanthomata 723*t*
 in acquired hyperlipidaemia 729
 eruptive, in chylomicronaemia syndrome
 725, 725*f*
 in remnant hyperlipoproteinaemia 726, 726*f*
 tendon, in familial hypercholesterolaemia
 726, 726*f*, 727*f*
- X chromosome, gene mapping 845, 845*f*
- Xeroderma pigmentosum 868–869
