ANIMAL MODELS OF ATHEROGENESIS

Diet-Induced Nonmurine Models Historically, relatively large animals, such as nonhuman primates, swine, and rabbits, have been predominantly used for arteriosclerosis-related research. Rats and dogs are not good models because they do not develop spontaneous lesions and require heavy modifications of diet to produce a vascular lesion. In recent years, however, some transgenic rat models have been produced that develop lesions resembling human atherosclerosis.[12,13]

Rabbits are useful because they are highly responsive to cholesterol manipulation and develop lesions in a fairly short time.[14] The lesions, however, are much more fatty and macrophage-rich (i.e., more inflammatory) than human lesions and plasma cholesterol levels are extraordinarily high.[15] The Watanabe heritable hyperlipidemic rabbits (WHHL) are genetic variants that mimic familial hypercholesterolemia.[16] This strain of rabbit was produced by inbreeding from a mutant discovered in 1973. The rabbits consistently showed spontaneous development of aortic arteriosclerosis over 5 months of age. The existence of rabbit strains with congenital abnormalities in lipid metabolism has contributed to the feasibility of creating particularly informative transgenic rabbits.

The guinea pig provides valuable models for studying early arteriosclerosis development.[17] Guinea pigs carry the majority of their plasma cholesterol in low-density lipoprotein (LDL), and present other striking similarities to humans in terms of cholesterol and lipoprotein metabolism making them a unique animal model. Many of the mechanisms by which guinea pigs regulate cholesterol and lipoprotein metabolism as a response to diet or drug treatment are analogous to those reported in clinical human studies.

Nonhuman primates including chimpanzees and various monkeys fed a high-cholesterol diet develop a form of atherosclerosis that is very similar to that of humans. However, the cost of nonhuman primates is prohibitive and many of these species are protected. Therefore, arteriosclerosis research in primates is today generally confined to the study of complex issues such as the effects of psychological stress.[10]

The domestic pig is one of the most useful currently available large animal models of arteriosclerosis. Over time, pigs develop atherosclerosis even on a normal porcine diet.[18] When fed a high-cholesterol diet, they develop elevated plasma cholesterol levels and atherosclerotic lesions that are similar to those seen in humans. However, the maintenance of pigs can be expensive and they require special facilities and handling.

Miniature pigs (e.g., Yucatan miniswine) have been used in several studies to gain insight into early-stage arteriosclerotic disease. One study concluded that early pathological changes (i.e., increased intima-media thickness and foam cell accumulation) induced by a high fat cholesterol diet precede decreases in endothelium-dependent relaxation (endothelial dysfunction) in femoral arteries.[19] This model may be an important tool to evaluate the effectiveness of interventions in modifying or blocking the development of diet-induced vascular disease and the role of the vascular endothelium in these processes. Yucatan minipigs have been used to study material property alterations in femoral and carotid arteries with atheroma induced by endothelial denudation and a high cholesterol diet.[20,21] The data demonstrated a striking difference between the two arteries. While lesion progression resulted in stiffening vascular wall elastic modulus in carotid arteries, the elastic modulus in the femoral arteries decreased first with early stages of atheroma development and increased as lesions progressed.

The use of pig models of atherosclerosis initially revealed that monocyte infiltration was one of the primary cellular events in the atherogenic process.[22] Studies in monkeys and rabbits were pivotal in defining the cellular events in the initiation and development of atherosclerotic lesions.[23,24]

Murine Models In recent years there has been an explosion in the number of *in vivo* studies that is largely attributable to the use of murine models to study atherogenic mechanisms.[25] Mice are highly resistant to atherosclerosis. The only exception is the C57BL/6 strain. A special diet (30% fat, 5% cholesterol, 2% cholic acid) led to arteriosclerosis in C57BL/6 mice, but the lesions differed from the human condition in their histological nature and location. Additionally, this diet was toxic and resulted in weight loss and respiratory infections. Paigen *et al.* modified the diet (15% fat, 1.25% cholesterol, 0.5% cholic acid), but the

lesions were very small (range of 200–1000 μm^2) in the aortic root and usually did not develop beyond the early foam-cell, fatty streak stage.[26]

It is now possible to add exogenous transgenes into mice as well as many other species. However, uniquely in mice, it is also possible to knock out or replace endogenous genes, which is one of the main advantages of working with the mouse.[25] Knockout murine models can be used to identify arteriosclerosis susceptibility modifying genes, the role of various cell types in atherogenesis, and environmental factors affecting atherogenesis and to assess therapies that block atherogenesis or lesion progression.[25]

Although genetic modifications render mice susceptible to atherogenesis, lipid-enriched diets are indispensable to induce or accelerate the rate of development of atherosclerotic lesions. It appears that the induction of persistent hypercholesterolemia to levels >300 mg/dl is required for the development of experimental atherosclerosis in the mouse where dietary cholesterol is the major proatherogenic component.[27]

Apolipoprotein E-Deficient Mice Apolipoprotein E (apoE) is a glycoprotein that is a structural component of all lipoprotein particles other than low-density lipoprotein (LDL). One of its most important functions is to serve as a high-affinity ligand for the apoB- and apoE-LDL receptor and for the chylomicron-remnant receptor, thereby allowing the specific uptake of apoE-containing particles by the liver.[28]

In 1992, apoE-deficient mice were generated by selectively inactivating the apoE gene.[29] The apoE-knockout mice exhibited increased total plasma cholesterol levels, which were five times those of normal littermates. Mice naturally have high levels of high-density lipoprotein (HDL) and low levels of LDL, in contrast to humans who have high LDL and low HDL. The mice lack the cholesteryl ester transferase enzyme that converts HDL to very low-density lipoprotein (VLDL) to LDL. The sequential events involved in the formation of atherosclerotic lesions in apoE-deficient mice are strikingly similar to those in humans. Initial fatty streak lesions rapidly progress to advanced lesions with a necrotic core surrounded by proliferating SMC and varying amounts of extracellular matrix. These lesions have well-formed fibrous caps. It is not uncommon for the inflammatory lesion to erode deep into the medial wall of the aorta, sometimes resulting in the formation of aortic aneurysms.

When apoE-deficient mice are fed a "Western type" diet (21% fat, 0.15% cholesterol, no cholic acid),[30] they exhibit over a 3-fold elevation in plasma cholesterol (to 2000 mg/dl), while wild-type mice show a 2-fold elevation. On this diet, formation of atherosclerotic lesions is greatly accelerated and lesion size is increased. Lesions in the apoE-deficient mouse, as in humans, tend to develop at vascular branch points and progress from a foam cell stage to a fibroproliferative stage with well-defined fibrous caps and necrotic lipid cores.

ApoE-deficient mice are considered to be one of the most relevant models for arteriosclerosis since they are hypercholesterolemic and develop spontaneous arterial lesions.[31] The apoE-deficient mouse contains the entire spectrum of lesions observed during atherogenesis and was the first mouse model to develop lesions similar to those in humans.

In 1995, Kashyap *et al.* described the successful correction of apoE deficiency in apoE-deficient mice by using an approach involving systemic delivery of recombinant adenoviral vectors expressing human apoE to the liver. Thus the single genetic change causing the absence of apoE and severe hypercholesterolemia is sufficient to convert the mouse from a species that is highly resistant to atherosclerosis to one that is highly susceptible.[32]

Low-Density Lipoprotein Receptor-Deficient Mice Gene targeting in embryonic stem cells has recently been used to create LDL receptor-knockout mice, a model of familial hypercholesterolemia.[33] The lipoprotein abnormality in these mice is more modest than that in the apoE-deficient mice, featuring increases in LDL and VLDL with plasma cholesterol of about 250 mg/dl on a normal chow diet without developing arteriosclerosis. However, after being fed the Paigen diet, their plasma cholesterol level soars to 1500 mg/dl and large arteriosclerotic lesions form.[34] The less toxic Western type diet also leads to the development of large lesions in these mice with a plasma cholesterol level of 400 mg/dl.

Other Murine Models Overexpression of human apoA-I in apoE-deficient mice increased HDL cholesterol levels 2-fold and substantially decreased fatty streaks and advanced fibroproliferative lesion formation.[35,36] All but 3–5% of apoE-deficient mice had detectable fatty streaks by 4 months of age, and had lesions that were highly organized and that occluded on an average 25% of the aortic lumen by 8 months of age. In contrast, more than 50% of apoE-deficient mice that overexpressed human apoA-I had no lesions by 4 months of age and by 8 months of age the lesions that occurred occluded on average only 5% of the aortic lumen. These data suggest that overexpression of apoA-I can diminish lesion size and slow the initiation of fatty streak formation.

A human apoB transgenic murine model has also been created. These mice have mildly increased LDL and total cholesterol levels with a lipoprotein profile showing a distinct LDL peak, which differs from the wild-type mice that have only a distinct HDL peak.[37,38] This model also shows a strong diet responsiveness; while a normal chow diet is not atherogenic, arteriosclerotic lesions develop upon feeding the Paigen and/or the Western diet.

ApoE/LDL receptor (LDLR) double knockout mice have recently been created.[34] These animals develop severe hyperlipidemia and arteriosclerosis[39] and have been reported to develop more marked arteriosclerotic lesions with accelerated progression than the apoE-deficient mice even when fed a regular chow diet.[40] Thus, the double knockout model is suitable for studying antiarteriosclerotic compounds without having to feed the animals an atherogenic diet.

More recently, Veniant *et al.* successfully elevated blood cholesterol levels in chow-fed apoE-deficient and LDLR-deficient mice by making both mouse models homozygous for the apolipoprotein B-100 allele.[41] That change resulted in alleviating the hypercholesterolemia in the setting of apoE deficiency, but worsening it in the setting of LDLR deficiency. Furthermore, the LDLR-deficient apoB100/100 mice developed extensive arteriosclerosis even on a normal chow diet.

Conclusions In summary, the apoE-deficient mice are the most widely used experimental model of atherosclerosis because they spontaneously produce lesions that simulate complex human atherosclerotic lesions.[42] It is generally believed that apoE-deficient animals, even when maintained on regular chow, exhibit more severe or complex lesions than do LDLR-deficient mice fed a Western type diet despite higher plasma cholesterol levels. The

apoE-deficient mouse model, however, is not an ideal model for most forms of human arteriosclerosis, which often involve an elevation in LDL. In that regard, the LDLR-deficient mouse coupled with apoB-editing deficiency (double knockout mice) seems to be more promising as an LDL model that develops arteriosclerosis on a low-fat diet.[41]

Transgenic Rabbit Models By filling the gap between the laboratory mouse and larger domesticated mammals, transgenic rabbits expressing human genes have become a relatively large mammalian model to explore the pathophysiological processes of arteriosclerosis. To date, a wide variety of human transgenes [e.g., apo(a), apoA-I, apoB-100, apoE-2, and apoE-3] have been expressed in rabbits. These models have helped to elucidate the metabolic roles of selected proteins in atherogenesis.

Elevated plasma levels of lipoprotein(a) [Lp(a)] constitute an independent risk factor for coronary heart disease, stroke, and restenosis.[43] However, apo(a), a unique component of Lp(a), is naturally present exclusively in Old World monkeys, humans, and hedgehogs. Therefore, there are no convenient experimental animal models for studying Lp(a). Using the apo(a) transgenic rabbit model, no arteriosclerotic lesions were found on a regular chow diet, suggesting that lower plasma apo(a) is not atherogenic.[44] When transgenic rabbits were fed a 0.3% cholesterol diet for 16 weeks they exhibited more extensive atherosclerotic lesions than nontransgenic rabbits, although cholesterol levels were similarly elevated. Compared to the lesions in nontransgenic control animals, the areas of atherosclerotic lesions in the transgenic rabbits were increased in the aorta as well as the iliac, carotid, and coronary arteries.

Transgenic Rabbits versus Transgenic Mice Rabbit strains have even more diverse genetic backgrounds than inbred and outbred mouse strains. On the one hand, this might be advantageous for studying complex disease models such as arteriosclerosis, but it is obviously a disadvantage for defining the effects of gain or loss of target gene function.

Rabbits like humans are LDL mammals and have features of lipoprotein metabolism that differ from mice that are HDL mammals. Therefore, the two species show different phenotypes even when the same gene is introduced. For instance, overexpression of apoE in mice caused inhibition of atherosclerosis,[45] but led to increased plasma LDL and spontaneous arteriosclerosis in transgenic rabbits.[46]

ANIMAL MODELS OF PLAQUE VULNERABILITY Prevention of heart attack and stroke depends on the detection of vulnerable plaques and the development of plaque-stabilizing therapies.[47] Vulnerable plaque is one of the toughest cases in animal model design. Plaque rupture is a complication of an already complex atherosclerotic process, and precise mechanisms of this complication remain hypothetical.[48] The current paradigm of plaque rupture may be described as a combination of four overlapping components: mechanical, thrombogenic, inflammatory, and lipid.[4]

Plaque rupture occurs as a result of interactions between external and internal mechanical triggers and vulnerable (i.e., weak) regions of the plaque when forces acting on the plaque exceed its tensile strength. Disruption of the protective fibrous cap allows the thrombogenic (lipid/necrotic) core to come into contact with the blood coagulation system, which leads to the formation of thrombus. Plaques with a thin fibrous cap and large core are considered vulnerable. Hence, the cap thickness, core size, and cap/core ratio are the most basic established "vulnerability endpoints."

Models of Plaque Rupture and Plaque-Associated Thrombosis

Spontaneous Plaque Rupture/Thrombosis Spontaneous hemorrhage and rupture were observed in the coronary arteries of 39- to 54-month-old pigs with inherited hyper-LDL cholesterolemia bearing mutant alleles for apolipoprotein B.[49]

In apoE-deficient mice aged 42–54 weeks, a high frequency (up to 75%) of intraplaque hemorrhage and fibrotic conversion of necrotic zones was found with the loss of the fibrous cap in the innominate (brachiocephalic) artery.[42] Surprisingly, intraplaque hemorrhages were not associated with mural thrombosis. These lesions had been previously overlooked because the majority of studies concentrated on the aortic root and the aortic arch. These observations indicate that the character of atherosclerotic lesions is site dependent.

In another study, 37- to 59-week-old apoE-deficient mice fed the Western type diet died spontaneously. Necropsy revealed luminal thrombi associated with ruptured plaques in the brachiocephalic artery.[50] Recently, these observations were further extended. Of 98 mice, 51 had acutely ruptured plaque in the same locations. The major finding was a significant increase in the number of buried caps in ruptured versus intact lesions, probably indicating previous ruptures in the same plaque.[51]

Induced Plaque Rupture/Thrombosis The use of direct mechanical injury to induce plaque rupture and thrombosis ignores the complexity of clinically relevant trigger mechanisms. Platelet and fibrin-rich thrombi have been induced in association with atherosclerotic plaques in apoE-deficient mice after squeezing the aorta between forceps.[52] Similarly, accelerated atherosclerotic lesions were developed in rabbits by combining balloon injury and hypercholesterolemia, and subsequently mechanically disrupted by inflation of an angioplasty balloon in the arterial lumen.[53] In another labor-intensive rabbit model, arteriosclerotic plaque could be ruptured at will after an inflatable balloon was embedded into the plaque.[54] This model could also be used for induction of thrombi associated with plaque rupture where the pressure needed to inflate the plaque-covered balloon is an indicator of the overall mechanical strength of the plaque.

A more recent study described a pharmacological model of plaque rupture in which plaque was first made vulnerable and then challenged by a systemic stressor.[55] First, accelerated arteriosclerosis was initiated in apoE-deficient mice by placement of a perivascular collar. The resulting plaques were transfected with the p53 gene, which led to an increase in cap cell apoptosis, and in return resulted in a marked decrease in the cellular and extracellular content of the cap. Whereas spontaneous plaque rupture was rare, it was found in 40% of cases after treatment with the vasopressor compound phenylephrine.

Myocardial Infarction-Prone Rabbit Model Originally, the Watanabe heritable hyperlipidemic (WHHL) rabbit was established as a model of human familial hypercholesteremia due to an LDL receptor deficiency.[16] Based on the WHHL rabbit strain, a special rabbit model was developed, designated as WHHL-MI, in which myocardial infarction (MI) occurred spontaneously.[56] This model possesses several types of coronary plaques that are possibly correlated to sudden cardiac events. Although many of the coronary plaques in WHHL-MI rabbits appeared histologically to be rupture prone in nature, no occlusive thrombus was detected

in any rabbits, suggesting that some additional stimuli play a definitive role in causing disruption of the rupture-prone plaques and thrombosis. The most common feature of WHHL-MI rabbits is plaques that occlude most of the arterial lumen due to macrophage accumulation, suggesting that they are responsible for sudden cardiac events. This model could be useful for studying the mechanisms of plaque rupture and thrombogenesis if plaque rupture/thrombosis could be induced by additional triggering factors.

Mouse Models Simulating Plaque Vulnerability The currently used mouse models are plaque-centric and do not take into consideration the processes that lead to occlusive thrombus formation after plaque rupture. The current modeling of vulnerable plaques emphasizes the acute nature of plaque rupture. In reality, several layers of spontaneous plaque fissures are frequently observed in coronary arteries and aortas indicating a series of disruptions of the protective cap in which only the last one becomes a clinical event.[48] Even more disturbingly, emerging clinical data suggest that coronary thrombi can arise without plaque rupture and without signs of severe local inflammation.[57]

Any model is based upon a limited set of assumptions and therefore by default has its own limitations. A model often exaggerates only one feature of a complex process to make analysis more convenient and more accurate.[48]

Researchers have largely focused on mouse models for the study of arteriosclerosis because of their obvious advantages (e.g., easy handling, extensive knowledge of mouse physiology, large amount of available genetic information). The mouse models, however, have fundamental limitations.[10] Mice have a lipid physiology that is radically different from that in humans (HDL vs. LDL dominance) and therefore they do not develop arteriosclerosis without genetic manipulation. Furthermore, mice weigh about 25–30 g, some 3000 times less than the average human. Because mouse cells are about the same size as human cells, a section of coronary artery in the mouse contains about 3000 times fewer cells than an equivalent section of human coronary artery. Consequently, the endothelial layer in mice lies directly on the internal elastic lamina and the media consist of only a few layers of SMC. In contrast to humans, arteriosclerotic lesions in the mouse coronary artery often extend beyond the elastic lamina. Also, it is difficult in mice to make a distinction between plaque erosion, as defined by endothelial denudation, and complete rupture of the fibrous cap.[58] Although classic eccentric atheromas with a single fibrous cap exist in lesion-prone murine models, multiple necrotic core areas with or without separate fibrous caps are the norm.[31,59,60] Disruption of these lesions may not mimic plaque rupture in humans, placing a fundamental limit on the applicability of mouse models for the investigation of rupture mechanisms.[58]

In addition to the difficulties arising from the differences between mouse and human biology, problems also occur when two different genetic models of a particular illness are used to investigate the effect of a third genetic manipulation. Another major problem with the genetically manipulated mouse strains is the genetic heterogeneity between the strains used to generate transgenic and knockout mice. This may lead to a situation in which animals containing the same genetic manipulation exhibit profoundly different phenotypes when present on diverse genetic backgrounds.[10] The ideal features of an animal model of plaque rupture are summarized in Table 40–2.

Table 40–2
Ideal features of an animal model of plaque rupture[10]

1. The atherosclerotic process in the animal model should be histologically identical to that in humans
2. The atherosclerotic plaque in the animal model should show the same vulnerability to rupture as its human counterpart
3. The events leading to vulnerability and rupture (i.e., cap/core ratio, cellular composition, collagen production, and breakdown) should as far as possible be identical to those in humans
4. Plaque rupture in the animal model should occur without the need for manipulations such as cuffing of the artery or insertion of balloon catheters
5. Plaque rupture should at least in some cases be accompanied by the formation of platelet-rich fibrin thrombi
6. Response to treatment in the animal model should have the potential for duplication in humans
7. The species should be available for research, easy and economical to maintain, and plaque rupture should occur under reproducible conditions within a reasonable time frame

CONCLUSIONS Arteriosclerosis in humans is a multifactorial condition that develops over many years and modeling it in animals is a notoriously tricky business.[10] Reproducing the events leading up to occlusive thrombosis, the event that actually kills and disables humans, is even more challenging. Existing animal models are useful for studying certain features of arteriosclerosis in regard to the function of specific genes. However, because of the complexity of the processes involved in plaque rupture and thrombosis, it is not certain whether a good model of these complications will ever be developed.

RESTENOSIS

BACKGROUND Restenosis in the form of accelerated arteriosclerosis and intimal hyperplasia constitutes the greatest threat to prolonged vessel patency following treatment of vascular occlusive diseases by percutaneous endovascular revascularization procedures. Although such procedures can achieve high initial success rates (>95%), a significant proportion of the treated vessels (20–50%) develops restenosis within 3–6 months.[61–64]

Animal models have been used successfully to study specific aspects of the early phase of the restenotic process (e.g., smooth muscle cell proliferation). Ideally, restenosis research should be performed on arteries with advanced arteriosclerotic disease. However, animal models with complex arteriosclerotic obstructive plaques are difficult to produce and require expensive, lengthy experiments. Complex lesions similar to those clinically significant in humans have been produced experimentally only in hyperlipemic pigs[49] and in nonhuman primates.[65]

Although arteriosclerosis progresses over a lifetime in humans, experimental settings try to reproduce atherosclerotic lesions in weeks or months based on diet modifications, and then following vascular injury the restenosis process is studied over a period of weeks or months. Furthermore, there are significant interspecies differences relevant to vascular disease. While elastic arteries (aorta and its primary branches) from various species have been reported to demonstrate remarkable structural similarity, muscular arteries (coronary and femoral arteries) exhibit major differences between species with respect to their thickness, medial

elastin content, and intimal cellularity.[66] In addition, the type, duration, and number of successive injuries as well as the associated forces (e.g., shear stress) cause a proportional injury-related vascular response in various species, which is measured by an intima-to-media area ratio or luminal cross-sectional area narrowing by neointima. However, the relationships vary among species; the injury-neointimal thickness regression slope is steep in pigs, intermediate in baboons and rabbits, and almost flat in dogs.[67–69]

VASCULAR INJURY TECHNIQUES Localized arterial endothelial and mural injuries are primarily used for studying restenosis (morphology, mechanisms, and therapeutic strategies). Vascular injury accelerates lesion development and can be produced in animal models using a variety of methods including dietary manipulation. Some of the nondietary methods for inducing vascular injury include the Baumgartner balloon catheter technique,[70] nylon and wire loop techniques,[71,72] air desiccation,[73] chemical irrigation,[74] thermal drying,[75] and irradiation.[76] As the names imply, mechanical devices (balloon catheters or wire loops) or agents (chemical, electrical, thermal, or radiation) are used to create site-specific injury in the arterial tree, and lesions develop shortly thereafter. Restenosis can be studied on either normal or previously injured arteries. In the latter model, the animal may be placed on a high fat/high cholesterol (HFHC) diet after focal injury to enhance lesion formation.

The most commonly employed vascular injury technique is focal balloon catheter injury. This technique involves inflating a Fogarty balloon at the desired site within the artery and then withdrawing the dilated balloon along a specific length of the vessel to create adequate shear stress on the wall to produce a significant injury. Nondietary methods such as this can be used either alone or in combination with an HFHC diet.

The decision to use a particular method or a combined approach to induce vascular injury depends on the type of lesion that is required, which in turn depends on the purpose of the study. When combinations of techniques of disease induction are utilized, lesions develop at an accelerated pace and with greater similarity to the human prototype.[77] Such manipulations also allow greater control over the type of lesion that can be created. The utilization of combined techniques has been more successful in creating a range of morphological lesions of desired severity.[77–84] For instance, a combination of an atherogenic HFHC diet and balloon-mediated endothelial injury in Yucatan microswine produces consistent high-grade arterial stenoses, and this model has been proposed for the study of cardiovascular interventional techniques.[78]

The creation of fatty streaks and plaques with minimal luminal narrowing may be sufficient for assessing the cellular and molecular roles in the histopathogenesis of restenosis,[82] whereas a lesion of intermediate magnitude with moderate narrowing of the luminal diameter is needed for pharmacological therapy research.[83] The investigation of endovascular recanalization devices requires consistent high-grade stenoses.[84] Injury of the media is critical to the formation of such lesions and an integrated approach to their creation may be useful.[85]

ANIMAL MODELS Arterial injury models simulating vascular injury in humans resulting from revascularization procedures are created in animals with the aim of determining morphology, pathogenesis, and preventive as well as therapeutic strategies. However, there is no single ideal model. The rat, rabbit, swine, and nonhuman primate have all been used as models of restenosis, with the last two affording the best approximation to humans. The rat carotid artery balloon injury model developed in the 1960s has been well characterized. However, the rat as well as the rabbit are small animals and do not serve all the demands of restenosis models. In this regard, the larger size of the Flemish Giant rabbit (6–7 kg) offers an advantage over the common New Zealand white rabbit (3–4 kg), and this strain of rabbits has been used to study the effects of percutaneous transluminal angioplasty (PTA) on the arterial wall.[86] As for testing coronary stent designs, the rabbit iliac artery offers a reliable model.[87,88]

Studying restenosis following stent placement in peripheral vessels requires large animal models such as the sheep, dog, and pig.[89–91] These models allow evaluation of postplacement healing, short- and mid-term stent patency, as well as mechanical integrity of the stent.[92] They also allow determination of the mechanical factors dictated by the stent design that may play a significant role in the development of intimal hyperplasia.

In large animal models, arterial size allows easy targeting of the selected vessel (e.g., coronary arteries), and this is one reason the porcine coronary artery model has become a common model for coronary restenosis studies.[93,94] In addition, the neointima that forms in this model is identical to human restenotic neointima, and the amount of neointimal thickening is directly proportional to the degree of injury. Therefore, this model permits the creation of an injury-response regression relationship that can be used to quantitate the response to potential therapeutic strategies.[95]

Previously, research activities related to restenosis following balloon angioplasty focused on intimal hyperplasia and the smooth muscle cell as crucial players in its pathogenesis. Dissenting opinions, however, have emerged. The main reason for this has been that despite favorable results with numerous pharmacological strategies in many animal models, clinical trials in humans did not match the experimental success.[96] This discrepancy led to a rethinking of the pathogenesis of restenosis, and arterial wall remodeling is now being considered as a major contributor to the underlying mechanisms of restenosis.[97]

Endovascular procedures in humans are carried out on atherosclerotic arteries with large plaques, whereas in the majority of animal experiments, procedures are used to create injury in the normal disease-free vascular wall. Therefore, factors contributing to the development of restenosis may be different in animal models, which would explain the lack of success of therapeutic strategies in humans.

Angioplasty Until recently, PTA has been the most commonly used revascularization procedure in clinical practice. PTA alleviates luminal stenosis by affecting plaque fractures and remodeling with overstretching of the disease-free portion of the arterial wall.[98,99] Acute restenosis is often the result of wall spasm, *in situ* thrombosis, and/or elastic recoil.

Constrictive vascular remodeling, which is defined as a loss of vessel area within the external elastic lamina, is the major determinant of chronic restenosis in humans after balloon angioplasty. Excessive neointimal formation, including proliferation of smooth muscle cells and synthesis of the extracellular matrix, has traditionally been considered the major cause of restenosis. However, a third process, the formation of neoadventitia, has been suggested to play an active role in both vascular remodeling[100] and neointimal formation.[101,102] It was hypothesized that neoadventitia could act in a way similar to scar contraction leading to "strangulation" of the vessel.[100] It was also shown that adventitial fibroblasts

migrate toward the lumen and take on a myofibroblastic phenotype to form the neointima.[101–103]

A recent porcine model has provided more accurate insight into the pathophysiology of constrictive vascular remodeling.[97] After 30% overdilation of the porcine coronary arteries, loss of lumen, constrictive remodeling, and formation of neointima occurred between days 7 and 28. These processes were preceded by the formation of neoadventitia and adventitial neovascularization occurring during the first 4 days after angioplasty. Neointimal formation began just after day 7; therefore, the constrictive remodeling coincided with the formation of neointima rather than the formation of neoadventitia. At late follow-up, loss of lumen was found to be correlated with remodeling, not neointimal formation. However, the neointimal area was not correlated with either late loss of lumen or vascular remodeling. These results indicate that qualitative rather than quantitative changes within the vessel wall neointima, media, and adventitia may play an important role in late luminal narrowing.

In conclusion, the time course of events after PTA is as follows: (1) platelet adhesion/aggregation and *in situ* thrombosis occur minutes after a type II/III arterial injury,[63,104] (2) formation of neoadventitia including adventitial neovascularization occurs within 4 days, and (3) late loss of lumen consisting of constrictive remodeling and formation of neointima occurs between 7 and 28 days.[97] Late loss of lumen is more dependent on vascular remodeling than on the formation of neointima. The time course of remodeling, however, coincides with the growth of neointima rather than with changes in the adventitia, indicating that constrictive vascular remodeling might depend on the formation of neointima. Thus, the present knowledge of restenosis after balloon angioplasty indicates that in humans and pigs late loss of lumen after balloon angioplasty is caused more by constrictive remodeling than by neointimal formation.

Stenting and Drug-Eluting Stents PTA has been replaced by arterial stenting as the most common revascularization procedure in certain instances. This is especially true for the coronary artery and the majority of the peripheral vascular territories where primary stenting has become the treatment of choice.

Compared to percutaneous transluminal coronary angioplasty (PTCA), the introduction of intracoronary stents reduced the 3- to 6-month restenosis rate to 20–30%.[105] To further reduce the "in-stent" restenosis rate, drug-eluting stents (DESs) have recently been introduced into clinical practice for coronary artery application. This change in clinical practice was made possible by extensive preclinical studies that required relevant changes in the animal models used to evaluate restenosis after stenting.

The pathological responses to balloon dilatation (PTA) and stenting differ. Regional constrictive remodeling predominates after balloon angioplasty, whereas after stent implantation, restenosis is due solely to neointima thickening. Early studies in the porcine coronary injury model suggested that the deeper the arterial injury, the greater the neointimal thickening.[106] This proportionality in the pig model resulted in the development of stent designs that reduce arterial injury. Early balloon expandable stents caused substantial injury when they were overexpanded, whereas the currently used self-expanding slotted tubular stent designs produce less injury.

Overstretch injury to pig coronary arteries holds important lessons for neointimal response to injury. Simple overstretch without stent implantation causes medial fracture and laceration with frequent dissections.[107] A typical balloon/artery ratio is 1.2/1 or 1.3/1, which creates enough injury for acceptable neointimal thickening without the risk of large dissections. Larger balloon/artery ratios yield the likelihood of severe dissection with resulting thrombosis and occlusion. When stents are implanted, dissections are usually controlled except at the stent margins. However, stent/artery ratios of >1.3/1 often result in chronic vessel injury dominated by a high degree of inflammation. This inflammation is undesirable because drug elution cannot overcome such severe injury, making assessment of stent/drug efficacy impossible. Therefore, for preclinical DES testing a stent/artery ratio of 1.1/1 is usually employed so as to produce only a minimal to mild degree of neointima formation, which in turn makes it possible to determine the efficacy of the drug used for coating the stent.

The porcine coronary model suggests a temporal comparability for healing after stenting that can be predicted for human application. Stent healing occurs approximately six times faster in pigs compared to humans.[107] This proven time relationship has established standardized times for porcine studies (1, 3, 6, and 12 months). Times points after 1 month are used principally to evaluate safety issues only because few changes occur in the pig model beyond this time with the exception of the slow healing process.

Self-expanding stents induce a neointima composed of cells migrating from the media. Conversely, balloon overstretch injury resulting in complete rupture of the media and exposure of the adventitia to blood components can lead to SMC stimulation in addition to activation and proliferation of adventitial fibroblasts followed by their inward migration and participation in the formation of neointima. The different SMC markers characteristic of these two different pathomechanisms of neointimal formation were demonstrated in the established porcine coronary artery model.[108] The lessons learned from animal restenosis models are summarized in Table 40–3.

It is essential to rapidly and effectively screen candidate compounds for DES before large, expensive, and time-consuming preclinical trials take place. Moreover, it is necessary to evaluate

Table 40–3
Lessons learned from animal restenosis models[107]

1. Arterial injuries are major determinants of neointimal thickening; the optimization of stent design should limit arterial injury as much as possible
2. Neointimal formation on drug-eluting stents (DESs) develops the same as on bare-metal stents
3. Although DESs limit neointimal formation, they may also delay or cause incomplete healing to a greater degree than bare-metal stents
4. The porcine coronary and rabbit iliac artery models provide useful information regarding stent thrombosis risk, and thus can be used to measure safety
5. Significant lumen loss in animal models resulting from medial cell death, inflammation, and neointimal thickening should be taken into consideration when initiating clinical trials
6. Efficacy testing in currently used preclinical models (rabbit, porcine) has proven difficult to establish
7. Innovative preclinical model enhancements are required to achieve more rapid turnaround time of the results of experimental interventions

safety-related pathological features of the existing antirestenotic compounds to properly define the therapeutic window of candidate compounds for DES.[109] Therefore, it is important that the animal model used possesses the underlying atherosclerotic lesion. DES may not only affect the formation of in-stent restenosis, but could also affect the formation or progression of the underlying atherosclerotic stented lesions (stabilization vs. destabilization of the stented plaque).

While the porcine coronary stent model appears predictive for stent thrombosis and adverse neointimal formation, this model is simply too expensive and time consuming to be used for screening drugs suitable for DES technology. Furthermore, the lack of arteriosclerosis in this native-vessel model is a major limitation to the proper evaluation of the efficacy and safety of DES strategies.

Well-established genetically modified murine models appear to be helpful for the purpose of accurately screening candidate compounds for use on DES. Pires *et al.* recently described an inventive new model using an established transgenic mouse strain to screen possible drugs for DES.[110] First, a nonconstrictive polyethylene perivascular cuff is surgically placed around the femoral artery of diet-driven hypercholesterolemic apoE*-Leiden transgenic mice, which results in the development of atherosclerotic-like lesions in 2 weeks. Then, the first cuff is replaced by a second drug-eluting cuff constructed from a poly(ε-caprolactone) polymer matrix that is loaded with the drug of interest. This novel mouse model enables cost-effective screening of candidate drugs for DES and the establishment of dose–response relationships with respect to both therapeutic and harmful effects on the vessel wall. The candidate drugs with reasonable potential for DES can subsequently be tested in large animal models. Evaluating DES in the presence of atherosclerosis results in new insights into restenosis and elucidates the effects of DES on atherosclerotic lesions.

CONCLUSIONS Animal models have been used successfully to study specific aspects of the restenotic process. These arterial models are created to simulate the vascular injury seen in humans following revascularization techniques (i.e., balloon angioplasty and stenting) with the aim of determining morphology and pathogenesis as well as preventive and therapeutic strategies. However, none of the described methods for inducing restenosis produces a single ideal model.

ENDOVASCULAR ANEURYSM REPAIR

BACKGROUND Among the animal models that have been created for studying aneurysm formation and repair, abdominal aortic aneurysm (AAA) models have dominated the field. The ideal animal model for AAA should possess all of the features of the human disease. While the manifestations of AAA may vary considerably depending on the stage of the disease, consistent features of the dilated segment are medial degeneration and adventitial inflammation. There are several small animal models (mouse, rat) in which biochemical or genetic perturbations have been used to develop AAAs. The interested reader is referred to detailed articles on the basic mechanical and clinical implications as well as small animal models.[111–114]

In the past decade, the use of stent grafts has become the therapeutic alternative of choice for the endovascular repair of AAAs, while minimally invasive transcatheter embolization techniques have become the treatment of choice for endovascular treatment of intracerebral aneurysms. Recent developments in these two fields of endovascular aneurysm repair have been based on extensive experimental studies using a variety of animal models. An overview of these models follows.

AORTIC ANEURYSM MODELS One of the most exciting developments in interventional imaging guided minimally invasive techniques in recent years is endovascular stent grafts for the endoluminal exclusion of aneurysms. Animal testing of endovascular grafts, and of the techniques employed in their deployment, is an essential step for the successful clinical application of these devices. Such experimental trials require the creation of an aneurysm in an animal model for effective testing. Since 1986, when Balko *et al.*[115] reported the first endoluminal exclusion of an experimentally created AAA in sheep, several large animal aortic aneurysm models have been used for the study of endovascular grafts. These have included models of dissecting, saccular, fusiform, and acutely rupturing aneurysms. The choice of research animal and the choice of aneurysm model to be used for the study of endovascular grafts are two of the most important decisions to be made by an investigator. Animal models can serve as an adequate test for endovascular prostheses only to the extent that they simulate the human condition.

Animals The choice of an experimental animal is especially important because of species differences relative to humans. Appreciable differences in the coagulation and fibrinolytic systems between humans and the experimental animal used to evaluate an endovascular prosthesis could significantly bias the interpretation of test results. Comparative studies have shown that the clotting and fibrinolytic systems of the calf and nonhuman primates are more similar to the human than to those of dogs or pigs.[116] Interspecies differences also exist regarding neointimal formation. Apart from specific situations (subsequently described), all models reported to date have employed normotensive, nonatherosclerotic animals.

In 1993, the Ad Hoc Committee of the Joint Councils of the Society for Vascular Surgery and the International Society for Cardiovascular Surgery, North American chapter, recommended that the canine be used for preclinical testing of arterial grafts in most instances.[117] According to the committee's report, the dog has two characteristics that make it a suitable animal model. One is the lack of significant spontaneous endothelialization of prosthetic surfaces, which is similar to humans. The other is a variable and relatively unpredictable tendency toward hypercoagulability, which presents a challenging test of device thrombogenicity. Other advantages of the dog include large peripheral arteries, ease of handling, and tolerance of prolonged anesthesia. However, the availability of dogs is being restricted by animal-rights activists, and as a result, the cost of using dogs is rising sharply. Furthermore, the dog has an extremely potent fibrinolytic system.[116]

Pigs and sheep also have been used for the study of endovascular grafts, although not as frequently as dogs. The arterial morphology of the pig is most similar to humans; they exhibit a tendency toward hypercoagulability, and their fibrinolytic system is not as active as the canine. When compared with dogs, however, they are not as easy to handle, are less tolerant of anesthesia, and their arteries are smaller, making it difficult to use large introducer systems and prostheses. Sheep, however, are more similar in size to the human and their arteries are large enough to accommodate larger diameter prostheses (18 mm). In addition, their coagulation system is closer to the human than either dogs or pigs. The sheep is an easy animal to manage in the laboratory and to use for testing

of vascular devices. However, sheep can harbor a rickettsial infection (Q fever) that is transmissible to humans.

Experimental Models and Techniques Only a few published reports have dealt with the evaluation of endovascular grafts in animal models of dissecting and acutely rupturing aortic aneurysms. The standard technique for the creation of dissection aortic aneurysms continues to be the Blanton technique.[118] The aorta is surgically exposed, cross-clamped, and a 120° transverse aortotomy incision is performed. An intramural pocket is formed by dissecting a free edge of the vessel caudally, and the outer wall of the free edge is sutured back to the proximal edge of the aortotomy site creating a dissecting aneurysm. Williams *et al.*[119] reported the use of covered stents in a model of acutely rupturing thoracic aortic aneurysm. The model was created by puncturing the aortic wall with a Colapinto needle and then balloon dilating the tract. However, immediate treatment and homologous blood transfusions were needed to prevent rapid exsanguination.

To date, endovascular grafts have been studied primarily for the purpose of intraluminal exclusion of saccular and fusiform aneurysms of the infrarenal abdominal aorta. Since the first published studies in the mid-1980s several experimental AAA models have been used to test the delivery, biocompatibility, and efficacy of endovascular grafts.

Anterior Patch Model The anterior patch AAA model has been one of the most popular animal models for the study of endovascular grafts. Saccular AAAs have been created in dogs, pigs, and sheep using various patch materials including Dacron,[115,120] rectus fascia without[120,121] and with[122] peritoneum, jejunum,[123,124] iliac vein,[125] and double layer peritoneum.[126] The advantage of using autologous tissue as a patch material is that it can progressively enlarge and rupture similar to a human AAA. This has been shown to occur with fascial and jejunal patches. Although iliac vein patches enlarge, they do not rupture because scar tissue forms around the aneurysm. The double layer peritoneum model created in swine has been shown to have the closest behavior to human AAA in regard to gradual expansion and tendency for rupture. Its rupture rates (70% in long and 20% in short aneurysms within 2 weeks) are higher than the rate associated with rectus fascia with peritoneum (11% in 5 months)[122] and with iliac vein (0% in 4 ± 2 months),[125] much lower than that with untreated jejunum (100% within 42 h),[123] and comparable to that with glutaraldehyde-treated jejunum (66% at 11 days).[123]

During the creation of the anterior patch aneurysm model, the aorta is isolated, the animal is heparinized, the aorta is cross-clamped below the renal arteries and above the iliac bifurcation, and collaterals are temporarily controlled with vessel loops or hemoclips that are removed upon the completion of the aortic patch suture. A longitudinal aortotomy is created in the anterior aspect of the aorta and an elliptical-shaped patch is sutured into the incision. No mural thrombus has been reported within fascial or iliac vein patch aneurysms and only trace amounts of thrombus have been found in Dacron patch aneurysms prior to graft implantation. It is unclear whether this is a limitation of these models because the effect that thrombus deposition within an aneurysm has on the early healing of the graft is unknown. Aneurysms formed by a jejunal patch have been found to contain thrombus prior to grafting, but none has been completely thrombosed. Approximately 95% of the aortic collateral arteries associated with anterior patch AAAs have remained patent prior to graft replacement. AAA models without patent lumbar and inferior mesenteric arteries are unrealistic. The absence of collateral branches prevents the study of their role in maintaining patency of the aneurysmal sac after endovascular grafting and the efficacy of any particular device in preventing aneurysm rupture. At 30 and 60 days after graft placement, approximately 80% of the lumbar arteries bridged by the prosthesis have reportedly thrombosed. Collateral flow has remained in some instances in which blood flow into and out of the excluded aneurysmal sac occurred via two separate vessels. Unfortunately, with the anterior patch model, lumbar arteries are usually flush with the endovascular graft and are more likely to thrombose than if they were more separated from the prosthesis, as may be the case in human aneurysms.

An "endoleak" AAA model based on a modified anterior patch technique was created to yield a large aneurysmal sac after stent-graft placement for testing of techniques for its percutaneous occlusion.[127] Infrarenal AAAs were created in dogs by anastomosis of an isolated segment of the inferior vena cava (IVC) to the right side of the abdominal aorta in combination with a large anterior patch from the external jugular vein. During surgery, the aorta and IVC were isolated from the renal arteries to the bifurcation, and both were cross-clamped at these levels. The aorta and IVC were opened along their apposing surfaces, anterior to the origin of the lumbar arteries and veins. The medial aspects of the aorta and IVC were joined over a distance of approximately 3 cm in a side-to-side anastomosis. At least one or two lumbar arteries and one or two lumbar veins were incorporated into the AAA sac formed. The anterior wall of the aorta was then partially resected and replaced with a large vein patch. The patch was sewn to the aorta and to the anterior aspect of the IVC incision to create the anterior aneurysmal pouch. The IVC was then ligated immediately below and above the level of the side-to-side anastomosis, thereby transferring the anastomosed segment of the IVC and its lumbar veins to the aorta. One hour later, the animals underwent percutaneous implantation of polytetrafluoroethylene-covered Z stent endografts with three 3-mm-diameter holes through the fabric. Immediately after endograft placement, all nine animals had artificial type III endoleaks with angiographic filling of lumbar arteries and veins. One aneurysm ruptured at 1 week. Of the remaining eight endografts, six remained patent for 1 week (n = 1), 1 month (n = 1), 2 months (n = 2), 3 months (n = 1), and 6 months (n = 1), and two were occluded at 3 and 6 months, respectively. The aneurysm sac had enlarged by approximately 50% in seven animals during the follow-up period. The model proved to be technically feasible, but was not found to be reliable for chronic evaluation because of rapid progressive thrombosis in most aneurysm sacs and occasional complete thrombosis of the AAA and endograft. The model was later modified by Hiraki *et al.* to eliminate the use of the jugular vein patch and thereby shorten the aortic clamping time to about 30 min.[128]

Mural-Stripping Model Economou *et al.*[129] described a method for creating saccular aortic aneurysms in dogs that involved removal of the adventitia and the outer 60–70% of the media, while leaving the remaining media, internal elastic membrane, and subendothelial layer intact. After dissection of the adventitia, the media was cut through in layers with gentle strokes of the scalpel. By not occluding the aorta during dissection, the pressure within the vessel produced a bulge at the dissected area, which acted as a guide to the depth of cutting necessary. Once the desired depth of the cut was achieved, the media was peeled along

a cleavage plane at the depth of the dissection. An ellipse of media was then cut away. Optimal aneurysm formation occurred when approximately 70% of the media had been excised. A lesser dissection failed to produce an aneurysm, whereas removal of more than 70% of the media resulted in acute rupture of the resultant aneurysm. All aneurysms persisted for up to 13 weeks and no evidence of spontaneous repair was noted microscopically. Moreover, production of hypertension before and after aneurysm creation did not result in larger aneurysms at the time of death. This method was used by Mirich *et al.*[130] to create AAAs in dogs for the evaluation of an aortic stent graft. Although cross-clamping of the aorta and its side branches was not required, surgical stripping of the adventitia and the media was slow, uncertain, and difficult to perform. Furthermore, no definite aneurysm was identified in any dog 2 weeks after surgery and angioplasty was required to achieve mild aortic dilation. The mean aortic diameters after the procedures increased by only an average of 46% (range, 36–58%).

Interposition Graft Model Parodi *et al.*[131] described a fusiform AAA model for the study of endovascular grafts that involved replacement of a portion of infrarenal aorta with a large crimped artificial graft. To date, this model has been created in dogs, pigs, and sheep with interposition grafts to mimic an aneurysm made from crimped woven Dacron,[131–135] biomedical grade elastomeric polyurethane,[133] and segments of glutaraldehyde-treated bovine internal jugular vein.[136]

After isolation of the aorta, the animal is heparinized, the aorta is cross-clamped below the renal arteries and above the bifurcation, and collaterals are ligated and divided. A segment of infrarenal aorta 2–6 cm in length is excised. The artificial aneurysm is anastomosed end to end with the aorta as an interposition graft.

All aneurysms created with an artificial conduit have remained patent prior to endovascular graft placement. A decrease in aneurysmal diameter has been reported, but it has been difficult to determine if this decrease was associated with the formation of mural thrombi or with fibrosis and shrinkage of the graft material. In some studies, nonsignificant mural thrombus formation was noted in the aneurysmal sac by the time of endovascular graft placement. A moderate to severe fibrous reaction was present around the artificial aneurysm in all animals.

All aneurysms created with glutaraldehyde-treated bovine internal jugular vein were immediately pulsatile and remained so until endovascular exclusion.[136] No significant change in maximum aneurysm diameter was reported, although 1 of 12 aneurysms ruptured. High-flow jets at the proximal and distal anastomoses with turbulent flow in the sac itself were noted prior to stent placement. This was due to fibrointimal hyperplasia at the anastomoses. No mural thrombus developed in the sac prior to stent placement, and in all cases the sac wall demonstrated a florid inflammatory reaction with foreign body giant cells.

The interposition graft AAA model is useful for the evaluation of delivery systems and of graft deployment techniques; advantages of this model include an aneurysmal size and configuration that more closely resemble human AAAs. However, it is not appropriate for studying either the role of the biological aneurysmal wall in the healing process around the prosthetic bypass or the effects of the patent aortic side branches. Furthermore, scarring of the prosthetic aortic system occurs, which is an experimental variable not likely to be present in human AAA.

Elastase Model Martin *et al.*[137] reported the creation of AAA in dogs by temporary exposure to the elastolytic action of pancreatic elastase. Segments of the abdominal aorta measuring 3 cm in length were exposed to 0.1% trypsin or 0.1% elastase for a period of 90 min while blood flow was arrested. All animals underwent thyroidectomy and were given an HFHC diet with a large dose of vitamin D. None of the dogs exposed to trypsin developed aneurysms, whereas 50% of the dogs exposed to elastase developed aneurysms of the exposed aortic segment 2 months after the procedure. The elastin content of the aorta in the exposed area averaged 51% of that in the unexposed area. The technique, however, proved to be inconsistent, and when successful resulted in the formation of small aneurysms.

Boudghène *et al.*[138] reported the use of elastase to create an AAA model in dogs for evaluation of endovascular grafting. All infrarenal lumbar arteries, except for one lumbar branch at the caudal end of the aortic segment, were ligated. After heparinization, a 4-cm length of infrarenal aorta was isolated between two clamps. This isolated segment was catheterized via the preserved lumbar artery, which was then tied to the catheter. The blood was removed from the isolated segment and the segment was flushed several times with saline. A solution of porcine type I elastase was then infused at a rate of 60 ml/h for 40 min. The dose of elastase was found to be critical. When low doses of elastase (<2000 U) were used, no aneurysm formation occurred, and when high doses of elastase (>3000 U) were used, the aneurysms ruptured within 24–72 h. All animals treated with 2800 U of elastase developed a 4-cm-long aneurysm of the infrarenal aorta. Aneurysmal diameter was approximately twice the size of the normal aorta and aortic wall thickness decreased by an average of 50%. Parietal thrombus was present in three of eight animals. Histological examination showed intense inflammation around the induced aneurysm. In addition, the elastic laminae were frayed and broken in all sections and had totally disappeared in some areas. These lesions were not uniform throughout the length or circumference of the perfused segment and are similar to acquired aneurysms in patients that result from the progressive degeneration of the arterial wall with diffuse loss of elastic tissue. Ligation of the lumbar arteries is a technical disadvantage in the assessment of their role in maintaining AAA patency after grafting and in the evaluation of the efficacy of the graft in preventing aneurysm rupture.

Transluminally Created Model Hallisey[139] reported the first transluminal creation of a fusiform AAA in dogs. After systemic heparinization, a Palmaz stent was deployed in the infrarenal aorta. The stent and aorta were then dilated to twice the diameter of the normal aorta with an appropriately sized angioplasty balloon. The animals were maintained on oral aspirin daily for the entire 30-day follow-up period. All lumbar arteries remained patent and the AAAs remained unchanged. No gross evidence of rupture or retroperitoneal hematoma was noted in any of the dogs. A less than 1-cm-long nonstented but dilated segment was seen at either end of the aneurysm. The normal mural architecture was present, although hidden by stent compression. Some degeneration of the smooth muscle and replacement by fibrous connective tissue were seen. The luminal surface of the AAA was smooth and there was no significant inflammation around the stent wires, even when they entered the tunica media of the aortic wall.

This AAA model is easily created transluminally without the need for retroperitoneal dissection or major surgery. The aneu-

rysms are short in length, with a normal neck of abdominal aorta above and below. Lumbar arteries and the lumen of the aneurysm remain patent. However, the model lacks true elastin breakdown, inflammatory cell reaction, and arterial wall degradation, all of which are found in human AAAs. The Palmaz stent also prevents any reduction in the size of the aneurysmal sac that might occur after endovascular graft placement.

The model originally described by Hallisey was modified by Schoder *et al.* who created an infrarenal AAA sheep model.[140] First, the aorta was overdilated with a transluminally placed Palmaz stent similar to the Hallisey model. Then an approximately 20% undersized endograft suspended between two stent-graft adapters was used to bridge the aneurysm in such a manner that two pairs of lumbar arteries remained patent within the residual aneurysm sac. The stent-graft adapters were large-vessel occluders consisting of a 20-mm-square stent with four barbs and a small intestinal submucosa (SIS) cover with a 6-mm-long central slit. The specific goal of this modification was to percutaneously create an AAA model that duplicates the anatomic and physiological events associated with endoleaks after endografting.

CEREBRAL ANEURYSM MODELS The selection of an experimental *in vivo* cerebral aneurysm model (CAM) for evaluation of medical devices for repair requires two critical decisions: the first is the selection of the specific animal species and the second is the methodology of CAM creation. For example, device safety is tested in a swine model due to its hypercoagulative and hyperproliferative nature. However, the efficacy of the bioimplant is difficult to assess in pigs since aneurysms in these animals readily thrombose. In contrast, a device successful for aneurysm treatment in humans will more likely be effective following evaluation in canine models because of the dogs' strong fibrolytic profile. High patency rates in canine sidewall CAMs have been demonstrated by angiography in excess of 6 months.[141] Thus, the selection criteria of an experimental *in vivo* CAM are strongly dependent upon the study objective.

Experimental Models and Techniques Numerous experimental *in vivo* CAMs have been reported in the literature, and the methods of creation may be divided into the categories of mechanical vessel wall trauma, chemical injury, enzymatic elastolysis, surgical anastomosis of a venous pouch, and the combination of induced renal hypertension, unilateral carotid ligation, and lathyrism. In the latter model, high hemodynamic stress and the administration of neurotoxic amino acids leading to angiolathyrism create an environment for the eventual formation of aneurysms. This model produced in nonhuman primates is the most representative model of the pathogenesis of human cerebral aneurysms; however, unpredictable aneurysm formation, high cost, and the length of time for aneurysmal dilations make this model unattractive.[142] This model may be reliably produced in rats or mice, but the small size of the vessels makes evaluation of endovascular repair impractical.[143–145] Only enzymatic digestion and surgical venous pouch construction have been shown to reliably produce practical CAMs.

One of the oldest and most frequently reported ways to create a CAM involves an arteriotomy with a vein segment sutured to the margins of the incision.[146] Many variations of this technique have been employed in multiple animal species including the rabbit, canine, swine, and rat. Furthermore, a myriad of configurations of both the venous pouch anastomosis as well as the parent artery have evolved to produce a variety of aneurysm types including fusiform, saccular sidewall, bifurcation, and terminal bifurcation geometries. Stehbens was the first to describe a bifurcation venous pouch CAM made in the rabbit at aortic bifurcation.[147] Strother *et al.* developed a method of constructing a bifurcation CAM by performing an end-to-side anastomosis of the left common carotid artery (CCA) to the right CCA and subsequently suturing a vein segment to the apex of this juncture.[148] One key advantage of the lateral wall configuration of the venous pouch model is the ability to create similar CAMs bilaterally in the same animal allowing for the evaluation of the safety profile of a repair device compared with a control device in the contralateral CCA. However, the lateral wall model does not produce realistic intraaneurysmal flow characteristics, which may be simulated with the more complex bifurcation models.

Although the surgical techniques used to create the bifurcation models allow excellent manipulation of the aneurysm-parent vessel geometry and the ability to create various aneurysm types in many different animal species allowing precise control of the local hemodynamics,[148,149] the venous pouch CAMs are not histologically similar to the human aneurysms that they are intended to represent.[150,151] One striking dissimilarity is the average aneurysmal wall thickness, which was found to be more than four times greater in the venous pouch CAM model compared with human aneurysms.[150] Moreover, the attenuation or absence of the tunica media and the internal elastic lamina at the dome of the human aneurysm is not reproduced in the experimental CAM, which might explain the infrequent rupture of venous pouch CAMs (other than acutely at the suture line of the neck). Within 2 h of creation, the experimental CAM is extensively infiltrated by inflammatory leukocytes. Rapid, spontaneous, and progressive fibromuscular neointimal proliferation occurs shortly after the venous pouch is sutured to the arterial segment and has been shown to continue for as long as 2 years.[152] It has been postulated that the disruption of the endothelium by suturing a venous patch to the margins of an arteriotomy causes the release of platelet-derived growth factor, which leads to fibrotic scarring.[153,154] The presence of fibrotic scarring in the model, which is frequently absent in human aneurysms, could complicate treatment efficacy studies[154] if they are not conducted over sufficient time, since mural thickening occurs over several months.

More recently, a method of experimental CAM construction has been proposed wherein the wall of the aneurysm is arterial and not venous.[153,154,155–158] The fundamental concept of the technique is to create an arterial "stump" in the CCA of the rabbit either by surgical ligation or by the use of an endovascular balloon, and then to incubate within the stump pancreatic elastase for a period between 10 and 45 min. This technique has been employed to create CAMs that resemble human cerebral aneurysms for testing of endovascular treatment modalities.[141,156]

The elastase-induced rabbit CAM has been extensively studied over the past decade, and the results indicate that this model offers certain advantages over the experimental vein pouch CAM. The technique is simple, the model has been shown to remain patent for more than 1 year, and depending on the artery used to construct the CAM, both lateral aneurysms located on the outside aspect of a curved parent vessel and bifurcation-type aneurysms may be induced that mimic the geometry typical of human intracranial aneurysms. Furthermore, the elastase CAM is histologically representative of human cerebral aneurysms, with a similar

wall thickness, attenuation or absence of the internal elastic lamina beyond the neck, the absence of intramural inflammation, and only a moderate presence of cellular elements within the aneurysmal sac.[150] The migration of fibroblasts and cellular elements into the sac of the venous pouch CAM due to the disruption of the basement membrane by the surgical wound is avoided by the elastase technique. Thus, it has been proposed that the elastase-induced CAM shares more common morphological and histological characteristics with human cerebral aneurysms than the vein pouch model.[150] However, control of the angioarchitecture of the elastase CAM is not reliable, as it has been discovered that hemodynamic factors determine the final dimensions of the CAM.[159] Another point to keep in mind is that if this model is created in the CCA, the proximity of the model to the thorax creates vascular motion due to respiration. This motion can potentially affect the evaluation of treatment strategies since it is not present within the intracranial vessels.

CONCLUSIONS In conclusion, judicious selection of an aortic or cerebral aneurysm animal model allows specific scientific hypotheses to be addressed. Therefore, the choice of the animal species and the technique employed to create the aneurysm must be based on the desired characteristics of the model that are compatible with the objectives of the experiment.

41 Transgenic Mouse Models of HIV-1/AIDS and Cardiac Performance

James J. Kohler and William Lewis

ABSTRACT

Cardiomyopathy (CM) associated with HIV/AIDS is important clinically and increasingly may impact the epidemic of AIDS as survival with HIV/AIDS increases due to effective antiretroviral therapies. Animal models offer sophisticated *in vivo* biological systems to recapitulate many direct and indirect effects of HIV-1 infection or the effects of therapeutics on the host. Few small animal models are available to investigate cardiovascular parameters associated with HIV/AIDS or highly active antiretroviral therapy (HAART). Unlike nonhuman primates, murine models of AIDS offer a safe, cost-effective approach to evaluate cardiac structure and function in AIDS CM. Experimentally, the mouse serves as perhaps the foremost laboratory mammal for genetic and immunological research. Several models utilize the well-established approach of transgenesis for general expression or specific, cardiac-targeted expression of viral genes. Gene targeting to generate gain or loss of function mutations in the mouse has yielded remarkable advances in understanding the roles played by specific gene products. This chapter focuses on mechanisms of CM in AIDS through the use of transgenic murine (TG) models as an important biological tool to study the impact of HIV-1, its gene products, and antiretroviral therapy on the pathophysiology of CM.

Key Words: Transgenic mouse, HIV/AIDS, Cardiomyopathy, Antiretrovirals, Mitochondria.

INTRODUCTION

Few small animal models are available to investigate cardiovascular parameters associated with HIV/AIDS. Animal models ideally completely recapitulate HIV-1 infection, its systemic or cardiovascular effects, or the effects of therapeutics. The use of nonhuman primates, for example, offers a model that closely reflects many virological and immunological effects of human HIV-1 but with limited availability, high cost, and intrinsic complexity that make cardiac studies in this model more difficult.[1,2] Murine models of AIDS, on the other hand, offer a safe, cost-effective approach to the evaluation of cardiac structure and function in AIDS cardiomyopathy (CM), particularly if they capture features of the disease and/or its therapy. Therefore, this chapter focuses on mechanisms of CM in AIDS through the use of rodent and transgenic murine (TG) models.

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITOR–HIGHLY ACTIVE ANTIRETROVIRAL THERAPY TOXICITY AND SMALL RODENT MODEL

Nucleoside analog reverse transcriptase inhibitors (NRTI) are a class of antiretrovirals commonly used as part of the combination known as highly active antiretroviral therapy (HAART). Compelling experimental and clinical evidence suggests that combined HAART is a formidable way to combat HIV-1 infection and to treat AIDS.[3,4] Despite the benefits of HAART, adverse effects associated with antiretroviral therapies include clinical symptoms such as myopathy, CM, polyneuropathy, lactic acidosis, steatosis, pancreatitis, and lipodystrophy.[5–9] The central pathogenetic mechanism in these complications is hypothesized to relate to mitochondrial dysfunction with morphologically damaged mitochondria, decreased mitochondrial DNA (mtDNA), and depletion of mitochondrial-encoded enzymes.[6,10,11] Of note, these are all findings in clinical mitochondrial genetic diseases.[12,13]

A supply of nucleotides and balanced nucleotide pools is required for mtDNA replication.[14–27] Even in postmitotic cells, mtDNA replication is continuous.[28] Phosphorylated nucleotides within mitochondria comprise a distinct pool.[28,29] The clinical impact of NRTI therapy on this pool is largely unknown, despite extensive therapeutic use of NRTIs. Some NRTIs exhibit cardiac toxicity, and may be etiologically linked to AIDS CM, the latter of which is a focus of our laboratory studies. Our group has identified deleterious cardiac effects from NRTIs (including zidovudine, fialuridine, stavudine, and others; see Table 41–1), which cause cardiac mitochondrial dysfunction and related effects in other tissues.[10,11,20,30–35]

Because we focus sharply on NRTI toxicity in the heart, an overview of mechanisms of NRTI toxicity is presented here. A number of mechanisms may underlie NRTI mitochondrial toxicity. mtDNA polymerase-gamma (pol-γ), for example, is the eukaryotic mtDNA replication enzyme and is thought to play a key role in NRTI MT.[36] "The DNA pol-γ hypothesis" was proposed over a decade ago.[5] It postulates that inhibition of pol-γ leads to the depletion of mtDNA and thereby causes mitochondrial dysfunction. Specifically, possible mechanisms of mitochondrial toxicity include direct inhibition of mtDNA pol-γ without

Table 41–1
Nucleoside Reverse Transcriptase Inhibitors with mitochondrial toxicity

Zidovudine (AZT)[14,15]
Tenofovir (TDF)[16,17]
Zalcitabine (ddC)[18]
Fialuridine (FIAU)[19–21]
Stavudine (d4T)[22,23]
Lodenosine (FddA)[24]
Adefovir (Adf)[26,27]

NRTI incorporation, chain termination by incorporation of NRTI triphosphate into mtDNA by DNA pol-γ, persistence of incorporated analogs in mtDNA because of inefficient excision by DNA pol-γ and resultant defective template mtDNA, or a combination of these mechanisms.[30]

Additionally, the hypothesis addresses the impact of NRTIs on pools of native nucleotides in mitochondria. With respect to intramitochondrial nucleotide pools, four potential pathways exist from which phosphorylated nucleotides arise within mitochondria. First, phosphorylated nucleotides could be synthesized in the cytosol and taken up by specific transport systems.[37] Second, cytosolic phosphorylated nucleotides could be dephosphorylated and then the corresponding deoxyribonucleoside diphosphates (dNDPs) taken up by the deoxynucleotide transporter (DNC)[38] and converted to triphosphorylated nucleotides intramitochondrially. Third, ribonucleoside diphosphates could be imported by DNC, then reduced within the mitochondrion by mitochondrial ribonucleotide reductase,[39] but evidence to support the latter moiety is sketchy. Last, mitochondria could directly import deoxyribonucleosides using the equilibrative nucleoside transporter (ENT1),[40–43] although evidence is emerging for species-related differences.[44]

USE OF SPECIFIC MARKERS IN GENETICALLY MANIPULATED MOUSE

Experimentally, the mouse serves as perhaps the foremost laboratory mammal for genetic and immunological research.[45,46] Biochemical screening of genetically manipulated mice offers the distinct advantage of a scientifically panoramic, *integrative* view of the general health of the living, genetically manipulated mouse while focusing on a parametric evaluation of cardiovascular dysfunction. The approach offers the advantages of broad screening for a variety of analytes, both murine general health and disease (cardiac)-related screening. Analogous screenings are routinely performed for human patients for the presence of health and disease, and serve as important tools for the presence of cardiovascular diseases, their prognosis, and efficacy of therapy. It follows that use of mouse models to elucidate mechanisms of AIDS CM in humans includes such screening methods and data analysis of markers in mice. These screening tests offer the investigator an opportunity to explore pathophysiological events in the cardiovascular system while maintaining its integrity *in vivo* in a mammalian system. Rapid nonlethal analyses are performed while simultaneous examination of the general well being of the genetically manipulated mouse is monitored. It should be understood that such analyses would likely not fall under routine monitoring procedures and animal care, and specialized breeding, husbandry, and care of the mice are required.

With respect to heart failure studies, one clinically relevant approach is to evaluate the presence of heart failure through the screening of plasma or serum analyses and immunoassay. This approach offers the advantage of defining illness early in the genetically manipulated mouse where sequential blood samples may be obtained. Cytokines, in particular, can be measured. Circulating or locally acting cytokines including endothelin (ET-1) and tumor necrosis factor-α (TNF-α) play key roles in cardiac dysfunction, cardiomyopathy, myocarditis, and other cardiovascular diseases.[47–50] TNF-α, interleukin (IL)-1β, and interferon (IFN)-γ can lead to increased levels of inducible nitric oxide syntheses (iNOS), increased nitric oxide (NO) synthesis, and myocyte death.[51]

Cytokines do not cause myocyte dysfunction or necrosis directly. However, cytokines may alter myocyte function, through the β_1-adrenoceptor-G-protein-adenylyl cyclase axis.[52–54] From *in vitro* studies, long-term treatment of cardiomyocytes with immune cell supernatants containing IL-1 and TNF-α reduced contractility and cyclic adenosine monophosphate (cAMP) accumulation by inhibition of β-adrenergic responsiveness.[55] Furthermore, TNF-α depressant effects on cardiomyocytes have been demonstrated in culture and lead to left ventricle (LV) dysfunction *in vivo*.[56,57]

Plasma ET-1 concentrations are increased in patients with cardiac heart failure (CHF)[58–60] and suggest poor prognosis in patients with New York Heart Association (NYHA) class III or IV CHF. ET receptors are expressed on several cell types in the myocardium, including myocytes, fibroblasts, and endothelial cells. Stimulation with the ET-1 ligand, endothelin, stimulates myocyte hypertrophy[61,62] and impacts the synthesis and degradation of the extracellular matrix.[63]

The progressive nature of cardiac dysfunction encompasses a complex of molecular and cellular events termed "remodeling" that leads to changes in the structure, function, and phenotype of myocardium.[64] These changes include hypertrophy and death of myocytes, regression to a molecular phenotype characterized by the expression of fetal genes and proteins, and alterations in the quantity and composition of the extracellular matrix. NF-κB substantially increases the progression of cardiac remodeling.[65] LV expression of atrial natriuretic factor (ANF), a fetal gene product, is a marker of LV hypertrophy (LVH) and cardiac dysfunction.[66] Thus, ANF serum and/or plasma levels offer affective markers for consideration. ANF is a 28-amino-acid peptide that is normally synthesized in the atria and to a lesser extent in the ventricles and is released into the circulation during atrial distention.[67] In patients with CHF, plasma ANF concentrations rise as atrial pressure increase. Increased secretion of atrial natriuretic peptide in early CHF may attenuate or delay systemic and renal arterial vasoconstriction, venoconstriction with increased cardiac preload, and renal sodium retention. In animals with CHF, administration of antibodies to ANF peptide or antagonists to ANF receptors decreases renal blood flow; increases right atrial pressure, plasma rennin activity, and sodium retention; and worsens diastolic dysfunction by impairing myocardial relaxation.[68]

Plasma ANF and brain natriuretic peptide (BNP) levels increase in patients with heart failure with progression of clinical symptoms.[69,70] Therefore, monitoring plasma BNP may be useful as a noninvasive biomarker for identifying possible cardiac dysfunction. Echocardiography (ECHO) is a noninvasive, highly accurate

and quick assessment of the overall health of the heart through generation of a two-dimensional ultrasound image of the heart, providing a quick assessment of the heart valves and degree of heart muscle contraction. Together with echocardiography, the routine assay of plasma BNP offers important markers to monitor cardiac function in mouse models.

Increased local and circulating concentrations of norepinephrine (NE) may also contribute to myocyte hypertrophy, but are difficult to measure in the mouse. Their action can occur directly through stimulation of α_1- and β-adrenergic receptors or secondarily by activating renin–angiotensin–aldosterone.[71,72] NE's toxicity to myocardial cells is mediated through calcium overload and/or the induction of apoptosis.[48] Blocking β-adrenergic receptors can prevent NE-induced myocyte death. Patients with plasma NE concentrations >800 pg/ml (4.7 nmol/liter) have a 1 year survival rate of less than 40%. Thus, a simple method of screening of plasma NE levels may be effective for identification of CHF in mice, but has not been widely used.

As mentioned, renin–angiotensin–aldosterone system activity is also increased in CHF. Together with plasma NE and ANF, measurement of plasma renin activity provides a prognostic index in patients.[73] If such measurements were possible in microvolume samples, this could prove a useful screen of cardiovascular disease in mice.

TRANSGENIC MURINE STRATEGIES

GENERAL EXPRESSION TGs are well-established, efficient models of living systems that are useful to evaluate viral gene function and pathogenesis in AIDS and other viral illnesses.[74–76] Transgenesis, particularly in the models with HIV, is predicated on the cellular incorporation of viral sequences into genetic material. This technique eliminates possible problems associated with viral administration since the viral sequences are contained within every target cell. The extensive use of TG in cardiovascular research and HIV/AIDS is established.[46,77] The power of transgenesis provides a unique experimental system to dissect complex aspects of AIDS CM.

For the purposes of studying HIV-1 effects in the heart, the challenge has been to develop a TG harboring a defective provirus that results in expression in the heart. An early model developed by Iwakura *et al.*,[78] while expressed primarily in the eye, had no viral mRNA detected in the heart, kidney, liver, or bone marrow. Alternatively, a hemizygous NL4-3Δ *gag/pol* TG mouse, which contains an internal deletion that eliminates most of the gag/pol coding sequence, was developed,[79] which has become an important generalized model of AIDS that can be used to evaluate CM in AIDS. No founder mice carrying the transgene developed disease during their life span. Three founders (Tg22, Tg25, and Tg26) produced progeny that developed renal disease, and one founder (Tg26) developed myopathy/myositis.[80] Variable tissue distribution and level of viral transgene expression occurred among the three lines. Three mRNA species were detected (full-length, single and double spliced messages, respectively) with widespread expression but varied tissue distribution (high levels in skin and muscle, followed by moderate levels in thymus, gastrointestinal tract, kidney, eye, brain and spleen, but low levels in heart). More importantly, NL4-3Δ *gag/pol* TG demonstrate key features of HIV/AIDS including AIDS nephropathy, wasting, and skin diseases that phenotypically resemble clinical counterparts in AIDS. Specific viral protein expression patterns, as determined by immunoblotting, were tissue specific. Altered Rev functions in different tissues may explain the apparent disparate protein expression patterns.

GENE-SPECIFIC EXPRESSION TGs expressing HIV Tat have also been generated.[81,82] In this model, a single gene from HIV (*Tat*) is driven by the viral long terminal repeat (LTR) and by the β-actin promoter. Tat TG mice develop hepatocellular carcinomas, endothelial proliferation, and skin lesions that resemble Kaposi's sarcoma.[83–85] Some Tat TG lines appear to potentiate zidovudine (AZT)-induced toxicity and oxidative damage.[86] Other Tat-TG murine models have demonstrated a molecular mechanism of reduced glutathione levels and induction of B-lymphomas.[87,88]

Another replication-defective HIV-1 TG created by Gilbert Jay is based on a construct with a *gag/pol/env* deletion. Viral mRNA expression occurred in all tissues with a perivascular inflammation as a prominent phenotypic feature.[77] These TGs had minimal cardiac physiological changes, compared to NL4-3Δ *gag/pol* TG, which have striking defects in contractility and relaxation.[33]

Lastly, a series of HIV-1 TG lines was generated by Paul Jolicoeur's group that expresses coding sequences of HIV-1 regulated by the CD4 gene.[89–92] Thus, expression of HIV-1 genes occurs in the same subset of immune cells that is infected by HIV-1 ($CD4^+CD8^+$ immature thymic T cells, circulating $CD4^+CD8^-$ T cells, and $CD4^+$ monocytes/macrophages). Interestingly, these TG mice spontaneously develop severe cardiac inflammatory lesions. Thus, this TG line may constitute an animal model of inflammatory cardiomyopathy, a subset of the clinically relevant heart diseases found in human AIDS.

CARDIAC-SPECIFIC TARGETING OF INDIVIDUAL GENES Targeting transgenic expression exclusively to a specific tissue target is a more focused, organ-relevant approach. Although plausible, a complete infectious HIV-1 genome is technically possible, but problematic. Such a system employing an intact human provirus in rodents would warrant serious concerns for laboratory safety. Mice expressing intact HIV-1 may constitute animal reservoirs for virus and potentially be infectious to humans.[93]

The fundamental approach taken to develop TG CM models is based on the fact that a specific protein relates to cardiac function and dysfunction.[94] Modification of the cardiac protein repertoire in a defined manner through stable transgenesis facilitates expression of engineered proteins in the heart. The most widely used and successful promoter candidate for these purposes is the α-myosin heavy chain promoter (α-MyHC), although it is not the only approach available. This promoter meets the criteria of the key features desired, including a high degree of cardiac specificity, high levels of expression in adult atria and ventricles, the presence of sequences necessary for copy-number dependent and position-independent expression, and homogeneous expression across the cardiac myocyte population. Then, cardiac contractility and structure can be examined exclusively.[94] We have utilized Robbins' approach[95] to achieve cardiac targeted transgenesis. In principle, key features included selection of an ideal promoter for cardiac expression that (1) would elicit a high level of cardiac-specific gene expression at appropriate times of development with a minimum of position-sensitive effects of chromosomal context and (2) would be copy number dependent and (3) position independent.

Table 41–2
HIV-1 viral proteins used in transgenics (in the Lewis laboratory)

Protein	*Function*
Tat	Transactivation[98–101]
Nef	Pleiotropic, can increase or decrease virus[102,103]
Vpr	Helps in virus replication[104,105]
Vpu	Helps in virus release; disrupts gp160–CD4 complexes; expression regulated by Vpr[106]

Applying this TG approach, we targeted selected HIV-1 transgenes to cardiac ventricular myocytes in mice. Targeting single-gene TG with cardiac myocyte-specific expression of individual HIV-1 genes has proven to be a unique and powerful model system to define structural and functional effects of HIV-1 gene products on cardiac performance and myocyte structure. Granted the disadvantages of the single-gene-targeted transgenesis may be that the interaction of multiple viral proteins may be required to induce the observed clinical pathological or physiological (phenotypic) changes. Moreover, isolation of a gene from its genomic context may alter or eliminate critical *cis*-acting control elements required for effective, native gene expression.

Despite some potential limitations of single-gene-targeted transgenesis, we successfully generated several TG lines expressing HIV-1 gene products using this cardiac-targeted approach (see Table 41–2). TG AIDS lines that express HIV-1 *Tat* in ventricular cardiac myocytes with different levels of *Tat* expression were created. Progeny of founders demonstrate exclusive expression of HIV-1 *Tat* mRNA in cardiac myocytes. Hemizygotes demonstrate left ventricle hypertrophy pathologically, and ultrastructural defects in mitochondrial cristae with enlarged, abnormal mitochondria.[96] Six TG lines targeting HIV-1 viral protein R (Vpr) to cardiomyocytes have been developed; each develops congestive heart failure (~8 weeks of age), abnormal cardiomyocyte nuclei, and mitoses.[97] In addition, Vpr TGs have induced four-chamber dilation, defective contraction, and atrial masses. We developed TG lines each expressing HIV-1 *Nef* exclusively targeted in ventricular cardiac myocytes. Phenotypic analysis of mice up to 12 months of age reveals no gross pathological changes in hemizygous *Nef* TG.[98–106]

ORGANELLE-SPECIFIC TARGETING As mentioned above, because our focus in AIDS has been to examine the effects of antiretroviral agents on mtDNA replication, other models of mitochondrial biogenesis may be important tools. A number of other transgenic and knockout mouse models have been examined to delineate the role of specific, related signaling pathways on cardiac performance and CM.[107] Sah *et al.*[108] generated transgenic mice in which constitutively activated RhoA or wild-type (WT) RhoA were expressed in a cardiac-specific manner through the α-MHC promoter to determine the role of Rho family GTPases on cardiac performance. Results demonstrated evidence of heart failure seen in RhoA transgenics, with severe edema, ventricular chamber dilation, increased cardiac fibrosis, atrial enlargement, and decreased fractional shortening. Unlike Rho, Rac1 proved to be more challenging by use of conventional gene targeting approaches as deletion results in embryonic lethality.[109] Instead, genetic manipulation of Rac1 to study the consequences of increased myocardial Rac1 activity was accomplished by cardiac-specific transgenesis with an unusual dichotomy: (1) rapid-onset, high-level postnatal expression that led to lethal dilated CM or (2) slow-onset postnatal expression leading to transient hypertrophy in juvenile mice that resolved with age.[110]

Transgenic mice have also been created to investigate the role of cardiac regulatory proteins, protein kinase C (PKC) and troponin I (cTNI).[111] Pioneering work in the laboratory of Chris Vlahos[112] has shown that PKC is upregulated in the human heart in end-stage failure. To demonstrate causality of PKC in heart failure, transgenic mice have been created in which the PKC isoform is overexpressed in the heart, often in a constitutively active form.[113–116] Collectively, studies with these TG show that chronic PKC overexpression can lead to features of cardiac failure including hypertrophy, reexpression of fetal genes, wall thinning, and left ventricular dysfunction.

Mouse transgenic models also may alter expression of genes involved in cardiac uptake and metabolism of either lipid or carbohydrate.[117] Disruption of the insulin-sensitive GLUT4, for example, by various transgenic techniques results in cardiac hypertrophy.[118,119] Studies by Yang *et al.* utilized TG murine models to investigate the role of myosin-binding protein C and molecular regulation of lipotoxicity in the heart.[120,121] Results from these and many other TG models demonstrate that alterations in cardiac uptake and metabolism may precede both the functional and morphological alterations that accompany diabetic cardiomyopathy and heart failure.

Understanding the critical role of NO signaling in myocardial function has also advanced with targeted overexpression of endothelial NOS (NOS3).[122] In the hearts of three lines of mice carrying the αMHC-NOS3 TG, pressure development of the LV was inversely correlated with NOS3 transgene expression.[123,124] On the other hand, the contractile response to norepinephrine and acetylcholine was not affected by TG expression. Janssens *et al.*[125] and Champion *et al.*[126] confirmed overexpressed NOS3 localized to caveolae by confocal microscopy and immunoprecipitation studies. In short, the availability of mice in which NOS3 is overexpressed has enabled investigators to characterize the function of this enzyme in mouse models of cardiovascular disease.

CONDITIONAL EXPRESSION Gene targeting to generate gain or loss of function mutations in the mouse has yielded remarkable advances in understanding the roles played by specific gene products.[127] Not all biological processes, however, can be accessed and studied by gene-inactivation or transgene-expression strategies. Insights have been gained into both embryogenesis and later gene function; however obstacles exist that include indirect systemic defects that can complicate transgenic constructs in the germ line to elicit the role of genes in a specific pathophysiological context. For example, many genes have several roles during embryogenesis and adulthood for which their ablation results in an embryonic-lethal phenotype, precluding an analysis of its function in later development. To circumvent these limitations, mouse geneticists developed strategies that allow genes to be activated or silenced where and when the investigator chooses.

The ideal genetic "switch" results in low or zero basal gene expression when "off" and high levels of gene expression when "on." Furthermore, the switch ideally is reversible and specific for the target gene, and should not interfere with other cellular components or with general metabolism. Early attempts included use

of promoters that could be induced by heavy metals, heat shock, interferon, or steroids. Unfortunately, these strategies fell short due to high basal activity in the absence of induction.[128] More recently, success was reached with binary transgenic systems. Gene expression is controlled by the interaction of two components: an "effector" transgene and a "target" transgene.[45]

The most widely used binary transcription transactivation systems are the tetracycline-dependent regulatory systems developed by Mandfred Gossen and Hermann Bujard.[129] The effector is a fusion of sequences that encodes the VP16 transactivation domain and the *Escherichia coli* tetracycline repressor (TetR) protein, which specifically binds both tetracycline and the 19-bp operator sequences (*tetO*) of the *tet* operon in the target transgene, resulting in transcription. Two versions exist: (1) the tetracycline controlled transactivator (tTA) protein cannot bind DNA when the inducer is present ("tet-off"), and (2) the "reverse tTA" (rtTA) binds DNA only when the inducer is present ("tet-on"). Conditional expression with this *tetO* promoter system was used in a recent study to induce cardiac fibrosis and heart failure using an antisense mRNA of mineralocorticoid receptor targeted in cardiomyocytes.[130]

The first nonviral binary system to be used in mice was the Gal4/upstream activator sequence (UAS) system. Gal4, an isolated transcriptional activator of *Saccharomyces cerevisiae*, directs the transcription of Gal4-responsive genes by binding to (UASs). Two members of the integrase family of site-specific recombinases, *Cre* from bacteriophage P1[131] and *Flp* from *S. cerevisiae*[132] are currently used to conditionally control gene expression by site-specific DNA recombination.

Somatic, tissue-specific recombination has gained appeal more recently. One strategy for this exploits the *cre-loxP* system derived from bacteriophage P1.[133,134] The 38-kDa Cre protein functions as a site-specific recombinase, splicing DNA between specific 34-bp sequences known as *loxP* sites. Mating mice that contain a *loxP*-flanked gene with mice expressing Cre under the control of a cell specific-promoter result in Cre-mediated excision selectively in targeted cells. The cre–loxP system is entirely contingent on the exogenous recombines, so that recombination can be regulated via the timing and tissue specificity of *Cre* transgene expression.[135,136] A strategy has been generated for cell type-specific plus temporal control by tissue-restricted expression of a conditionally functional chimeric Cre protein, comprising a fusion between Cre and the mutated ligand binding domain (LBD) of a steroid hormone receptor.[135–140] These chimeric proteins become selectively active on binding a synthetic ligand, in preference to endogenous progesterone and estrogen, respectively.

PHARMACOLOGICAL MANIPULATION OF AIDS TRANSGENIC MURINE MODELS

We extensively used the NL4-3Δ *gag/pol* TG and the WT littermates (FVB/n mice) in both AZT and d4T monotherapy and combination therapy studies. TG and WT received water *ad libitum* with and without AZT, for example, for 21 or 35 days. After 21 days, molecular indicators of cardiac dysfunction were identified. Abundances of mRNA for cardiac sarcoplasmic reticulum calcium ATPase (SERCA2), sodium calcium exchanger (NCX1), and ANF were determined individually. Depressed SERCA2 and increased ANF mRNA abundance were found in LV from AZT-treated TG. NCX1 abundance remained unchanged. Eccentric LV hypertrophy was determined echocardiographically. After 35 days, cardiac dysfunction was worse in TG, with or without AZT treatment. Decreases in the first derivative of the maximal change in LV systolic pressure with respect to time ($+dP/dt$) occurred at baseline in TG. The increased half-time of relaxation and ventricular relaxation ($-dP/dt$) occurred in TG as well, independent of treatment. However, increased time to peak pressure was found only in AZT-treated TG. Histopathological and ultrastructural (transmission electron microscopy) changes were also identified. Ultrastructurally, mitochondrial destruction was most pronounced in AZT-treated TG, but was also found in AZT treated WT. In short, TG mice that express HIV-1 demonstrate cardiac dysfunction. AZT-treatment of WT causes mitochondrial ultrastructural alterations and $-dP/dt$ changes. Therefore, data collectively suggest that HIV-1 and AZT each contributes to cardiac dysfunction in this transgenic model of AIDS CM.[33]

Additional studies have been performed using a combination HAART [AZT, lamivudine (3TC), and indinavir] or vehicle control treatment for 10 or 35 days in NL4-3Δ *gag/pol* TG and FVB/n WT mice. This "2 × 2" protocol provides a systematic determination of the effect(s) of TG and/or treatment. At the termination of the experiments (day 35), mice underwent echocardiography, quantitation of ANF, SERCA2, and determination of plasma lactate.[141] Myocardial histological features were also analyzed semiquantitatively and results were confirmed by transmission electron microscopy. Echocardiographic analysis revealed a 160% increase in LV mass in the TG + HAART cohort. Molecularly, ANF mRNA increased 250% and SERCA2 mRNA decreased 57%. Biochemically, plasma lactate was elevated (8.5 ± 2.0 mM). Pathologically, granular cytoplasmic changes were found in cardiac myocytes indicating enlarged, damaged mitochondria. Findings were confirmed ultrastructurally. Surprisingly, no changes occurred in the other cohorts. Cumulative HAART causes mitochondrial CM in AIDS TG mice.

GENERAL HEALTH OF THE GENETICALLY MANIPULATED MOUSE

Mouse genetic research has provided an important biological tool resulting in remarkable advances in the understanding of disease, pathogenesis, and treatment strategies. Important concerns remain, however, regarding the specificity of genetic manipulations of the cardiovascular system and other physiological systems. Concerns that the resultant changes yield an authentic model of human disease and that the degree of accurate phenotypic characteristics of the disease the genetic manipulation displays have been raised by clinicians and researchers alike. More importantly is the concern that nontargeted organ systems remain intact and functional. This is the rationale for a complete evaluation for general health parameters in genetically manipulated mice.

Establishing a mouse "strain-specific baseline" for routine parameters is the key to identifying and ensuring that phenotypic characteristics of the particular strain remain, overall, intact when evaluating the phenotypic changes that occur as a result of a particular genetic manipulation. Phenotypic parameters of size, weight-to-age ratios, for example, can offer basic, observational, noninvasive assessments when comparing a native (WT) strain to a genetically manipulated mouse line. Overall appetite, feeding and activity patterns can also serve as observational comparisons.

Table 41–3
Relevant murine cardiac analytes[a]

Atrial natriuretic peptide (ANF)[142] Brain natriuretic peptide (BNP)[143]
Troponin I[144]
Troponin T[145]
Lactic acid[146]
Lactate dehydrogenase (LDH)[147]
Creatinine kinase[148]

[a]All of the above assays are based on enzymatic colorimetric or immunoturbidometric assays and have been tested for feasibility.

Commercially available assays exist to address the general health of domestic animals. A slight modification of these assays could prove specifically useful in the mouse model, for various strains. Blood sampling, for example, is ideal for repetitive sampling as a function of age and disease development or in response to treatment of disease while preserving the living organism. Previous experience with obtaining blood from FVB/n and our own genetically manipulated mice indicates that retroorbital bleeding was rapid, safe, and effective. Collection of 200 µl of blood into heparinized capillary tubes yields approximately 100–120 µl of plasma. From this total volume, ~90 µl is usable for the analyte panel and ~10–30 µl plasma for other analyses.

The panel of analytes shown in Table 41–3 may serve as a marker for cardiovascular disease to evaluate the genetically manipulated mouse and the controls.[142–148]

CONCLUSIONS

Cardiomyopathy associated with HIV-1/AIDS is important clinically, and increasingly may impact the epidemic of AIDS as survival with HIV-1 increases due to effective antiretroviral therapies. The mechanisms of AIDS CM are not yet completely understood. TG models, however, particularly murine models, provide useful biological tools to study the impact of HIV-1, its gene products, as well as side effects of NRTI-HAART therapy on the pathophysiology and pathogenesis of CM.

42 Primate Models for the Assisted Reproductive Technologies and Embryonic Stem Cell Biology

Don P. Wolf, Shoukhrat Mitalipov, and James A. Byrne

ABSTRACT

Nonhuman primates (NHPs) represent clinically relevant animal models used in studies on the etiology and treatment of human diseases. In the context of reproduction, NHP models are relevant to research interests as diverse as the etiology and treatment of infertility and contraceptive development to an evaluation of cell or tissue-based therapies of disease employing embryonic stem cell-derived phenotypes. The assisted reproductive technologies (ARTs) are used in the production of animals carrying desired MHC alleles for HIV vaccine development and could be used in the production of genetically identical animals by somatic cell nuclear transfer (SCNT). SCNT in turn is relevant to rescuing the unique genetics of aging or even deceased animals, to testing the efficacy of therapeutic cloning, and in combination with gene targeting, to creating monkey models of genetically based, neurodegenerative diseases. Since most NHP experience in applying the ARTs and in deriving embryonic stem cells (ESCs) involves Old World monkeys, principally rhesus and cynomolgus macaques and baboons, studies with these species will be featured in this chapter.

Key Words: Nonhuman primates, Assisted reproductive technology, Embryonic stem cells, Cloning.

GENERAL CHARACTERISTICS

Nonhuman primates (NHPs) are among the least available and most costly of animal models employed in biomedical research and their use is carefully regulated and should be exhaustively justified. While there are approximately 200 species in the order Primates, representatives from seven genera are most commonly used in research including both Old World and New World primates (see Chapter 28, this volume, on nonhuman primates). Among the great apes, the chimpanzee (*Pan troglodytes*) has played a unique role in biomedical research predicated on its susceptibility to human infectious diseases including HIV.[1] Of obvious relevance to their role in biomedical research, NHPs resemble human beings much more closely in anatomy and physiology than do other commonly employed animals such as rodents. A case in point, because NHP brains more closely resemble those of humans in size and complexity, they exhibit complex behavior and cognitive skills that are difficult to discern in lower mammals. This feature is particularly important in assessing whether treatments designed to ameliorate subtle cognitive defects are safe and effective. Other unique characteristics of NHPs include their susceptibility to human infectious agents and their responses to experimentally induced diseases.[1] They also serve as relevant models for stress or nutrition-related research. In the more specific context of assisted reproductive technologies (ARTs) and stem cell biology, NHPs models are relevant to research interests as diverse as the etiology and treatment of infertility and contraceptive development to evaluations of cell or tissue-based treatments of disease using embryonic stem cell (ESC)-derived phenotypes. The ARTs are used in the production of desired genotypes for HIV vaccine development and could be used to produce genetically identical animals for nature versus nurture comparisons. When also considering somatic cell nuclear transfer (SCNT) or reproductive cloning, the rescue of the unique genetics of aging or even deceased animals is possible as is the creation of genetically identical animals, testing the efficacy of therapeutic cloning and in combination with gene targeting, producing monkey models of genetically based diseases.

ADVANTAGES OF THE MODEL Rhesus monkeys are recognized as an important preclinical model. For instance, the methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated monkey is the best animal model of Parkinson's disease (see Chapter 35, this volume, on transgenic models of neurodegenerative diseases). With regard to the reproductive and embryonic stem cell technologies, monkeys show menstrual cycles that are similar to humans in length and characteristics. This analogy is also true for spermatogenesis, early preimplantation development/embryology, and placentation. ESCs derived from NHP embryos are similar to those from humans and markedly different from murine ESCs. Relevant areas of research include intracytoplasmic sperm injection (ICSI) or spermatid injection,[2] *in vitro* oocyte maturation,[3–7] optimizing embryo culture conditions, therapeutic and reproductive cloning, and models of contraception and implantation. NHP ESCs could also be employed in preclinical studies involving cell or tissue-based treatments of human degenerative diseases, in the prospective systematic evaluation of health consequences of the ARTs, and even in the development of female fertility preservation strategies.[8] The availability of NHP ESCs and the ability to use federal monies to generate addi-

tional lines represent advantages over current efforts with human ESCs. Applications of the ARTs in conjunction with SCNT should eventually allow the creation of NHP models, for instance, of genetically based diseases.

DISADVANTAGES ASSOCIATED WITH NONHUMAN PRIMATE RESEARCH Features of NHP research include high costs in animal lease and per diem fees and limited access or availability. Obviously, unique facilities are required in terms of animal husbandry, caging, and surgical facilities. There is also substantial public concern over the use of such highly sentient animals in biomedical research. As is true for all animal models employed in research there are and should be restrictions on use, that is, when rodent models are not available or when the unique features of the NHP necessitate it. Other restrictions that impact the use of the model include limits on the number and types of surgeries to which animals can be exposed and the large number of animals required in animal production using the ARTs—egg donors and embryo transfer recipients—or in studies involving infrequent events, for instance, investigations into intracytoplasmic sperm injection-related abnormalities in newborns.

HUSBANDRY AND AVAILABLE STOCKS

As significant increases in our knowledge of the biology and care of NHPs have been realized, the number of NHPs imported has declined (the 2002 estimation of the number of NHPs imported annually is 50–60,000) because of bans on exportation from countries of origin (case in point, Indian-origin rhesus macaques), the impact of conservation movements, animal activist group activities, and more efficient animal use.[1] Domestic breeding programs initiated in the 1970s have become the major supply source of rhesus monkeys, baboons, chimpanzees and squirrel monkeys (consult Chapter 28, this volume, on NHPs and psic@bart.rprc.washington.edu for an Annual Resource Guide concerning animal suppliers). The National Primate Research Center system is a major supplier of animals for National Institutes of Health (NIH)-sponsored research with infrastructural support from National Center for Research Resources (NCRR). There are currently eight Centers in this system with a major emphasis on the propagation of rhesus and cynomolgus macaques and baboons. Specific pathogen-free production colonies are currently under development with NCRR sponsorship that might, parenthetically, benefit from the use of the ARTs, and should eventually become the standard resource. For ARTs and ESC biology, only a few NHP models have been developed sufficiently to allow itemization of reproducible protocols. In several contexts, the human serves as the model for the NHP as clinical applications of the ARTs are now responsible for the production of over 1% of the births in Western nations accounting, cumulatively, for millions of children. Furthermore, federally sponsored research on human ESCs dwarfs funded efforts employing NHP ESCs.

The great apes can be eliminated from consideration simply based on economic, practical, and ethical arguments. Indeed, in this case, it is more likely that the ARTs may ultimately be used to propagate endangered animals rather than serve as useful models in translational research. As for the more commonly available New World monkeys, such as owl or squirrel monkeys, extensive efforts to establish routine protocols for the ARTs have met with limited success, allocating this group into species currently requiring protocol development.[9] In a few applications, specific advantages may be compelling in the selection of a species for study, for instance in polyovulatory marmosets where dizygotic twinning is the rule[1] or baboons where external signs, such as sex skin changes, can be used to conveniently monitor the menstrual cycle or where seasonal anovulation may not be limiting as it is in rhesus macaques.

Based on the extensive experience and success achieved in the past two decades, Old World macaques, rhesus and cynomolgus monkeys, will be featured in this chapter. The baboon is still limited by suboptimal *in vitro* embryo culture conditions and while proof of principle experimentation has been reported recently in *Macaca nemenstrina*, the experience is limited.[10] As an example of the robust experience now available with the rhesus monkey, a highly unique and valuable resource exists in the ART Core at Oregon National Primate Research Center (ONPRC) (http://www.onprc.ohsu.edu/) established in 1988 under the co-direction of Drs. Don Wolf and Richard Stouffer. The focus of the core has been and continues to be on utilizing the rhesus macaque as a NHP model for research on gametogenesis, fertilization, embryogenesis, and implantation. This facility is responsible for 11 of the first 15 test tube rhesus monkeys produced in the world. Parenthetically, Dr. Barry Bavister's group at the University of Wisconsin is responsible for the other four including Petri, the first success.[11] The ART Core was, in part, responsible for the first monkey produced following the transfer of an embryo that had been frozen, cryobanked, and thawed after successful *in vitro* fertilization,[12] the first twin pregnancies,[12] the first infants produced by nuclear transfer of embryonic cells,[13] the first infant born following the transfer of an ICSI-produced blastocyst employing a nonsurgical procedure,[14] the first live birth resulting from the transfer of a demiembryo created by blastomere separation at the two-cell stage,[15] the first animal produced from transplanted ovarian tissue,[8] and the first pregnancy to result from embryo transfer (ET) during a controlled ovarian stimulation (COS) cycle (unpublished result). The program has contributed to improvements in COS[16] and in its more recent configuration has added an ESC component to its activities. Currently the ART/ESC Core program provides oocytes, sperm, embryos, follicular fluid, cumulus, and granulosa cells and distributes rhesus monkey ESC lines along with mouse embryonic fibroblasts, media, protocols, and expertise to the global scientific community.

It is worth noting that a major limitation in developing the ARTs or ESC technology in NHPs is the focus by NIH scientific reviewers on basic or applied research as opposed to protocol development. One approach to overcoming this limitation has been to couple protocol development with the production of a highly desirable but rare product such as monkeys with specific major histocompatibility alleles or with efforts to produce specific pathogen-free colonies, in both cases reflecting the unmet needs of the HIV vaccine development community. However, despite these limitations remarkable progress has been made in the rhesus monkey with implantation rates from ART-produced embryos comparable to those obtained in humans at approximately one in six embryos transferred. Of relevance to investigators interested in gene expression is the recently released gene chip with probe sets interrogating over 47,000 rhesus monkey transcripts (www.affymetrix.com/products/arrays/specific/rhesus_macaque.affx).

METHODS

ASSISTED REPRODUCTIVE TECHNOLOGIES A general pitfall in the application of ARTs in NHPs is the realization that

it is not necessarily possible to extrapolate technologies from one species to another. Typically there are advantages and disadvantages associated with each species, for instance, in their availability, health, size, relevance to a specific project, and availability of established disease models. However, the trump card at present in selecting an NHP animal model has to be the existence of established protocols and relevant experience in that species. Fortunately, as noted above, much of the methodology involved in the routine application of the ARTs in rhesus monkeys has been worked out and published in detail.[17–19] A comprehensive itemization of references available in NHPs on gamete collection, fertilization, embryo culture, and transfer is included in Table 42–1.[20–72] A few specific recommendations or potential concerns are discussed below.

Generally sperm collection involves penile or rectal electroejaculation or needle biopsy of the caudal epididymas or vas deferens. Rhesus monkey sperm collected by penile electroejaculation is notable for its uniform nature and high motility, for example, at ONPRC, only animals with sperm concentrations greater that 60 million/ml and with more that 70% motile cells with normal morphology are acceptable. Inducing sperm capacitation in the rhesus monkey is more that simply washing sperm as is the case in humans. Typically, washed sperm must be exposed to an intracellular cAMP enhancer such as caffeine or the cell-permeable dibutyryl derivative.[37] This exposure is associated with a transition in sperm motility and a tendency of sperm to agglutinate, which can create real problems when *in vitro* insemination is involved. While there are several reports on the cryostorage of NHP sperm, a notably loss of motility in the rhesus macaque makes the prospect of using frozen/thawed sperm for artificial insemination by donor (AID) or *in vitro* fertilization (IVF) from a wide spectrum of donors questionable. In situations in which IVF is involved, ICSI can be employed to overcome sperm motility limitations (see below).

Egg collection for ARTs in rhesus macaques now typically involves subjecting females to COS using recombinant human follicle-stimulating hormone, luteinizing hormone, and chorionic gonadotropin. COS does not always result in the achievement of preestablished thresholds in animal response and the percentage of "nonresponders" varies by season showing an increase during the summer months, reaching over 35% in June and July. During summer, despite housing in controlled environments, many females also become anovulatory and it is impractical to attempt COS. Females can be recycled for COSs, however, the response to recombinant human gonadotropins is gradually decreased with increasing numbers of stimulations, apparently due to an immune reaction.[16,73] Practically, up to three stimulations on average can be performed per female with the recovery of a reasonable number of high-quality oocytes. The availability of monkey recombinant gonadotropins may allow the more efficient and extended use of females. This immune response, although greatly reduced compared to when animal or human urinary preparations were employed, still limits animal responses and the number of repeat cycles that are possible. The egg yield is highly variable in rhesus monkeys from a few to over 100 using such fixed stimulation protocols and, not surprisingly, oocyte quality is also variable.[14] The recovery of high oocyte numbers, in our hands, is associated with poor performance as measured by fertilization and/or *in vitro* developmental potential. Fertilization by IVF or ICSI is feasible with the latter conveniently used with frozen-thawed sperm or whenever poor motility compromises IVF. We have previously reported that fertilization rates by ICSI with cryopreserved sperm injected shortly after thaw are significantly lower than with fresh sperm.[19] However, preincubation times of more than 3 h after thaw were associated with ICSI fertilizing capacity similar to that seen with fresh sperm. Piercing the plasma membrane during the ICSI procedure is critical and often difficult to assess since the needle can grossly invaginate the membrane without breaking through. For that reason, the injection pipette should be inserted through the zona pellucida and "into" the oocyte across approximately one-third of the egg's diameter. Cytoplasm is slowly aspirated into the ICSI pipette (as far back as the needle junction with the zona pellucida) until the plasma membrane breaks. A "pop" or sudden movement of cytoplasm into the pipette indicates the release of membrane tension. Once the membrane is penetrated, the sperm can be expelled into the cytoplasm.

Table 42–1
Gamete collection, fertilization, embryo culture, and transfer in nonhuman primates[a]

	ART procedures

[a]ART, assisted reproductive technology; COS, controlled ovarian stimulation.

Embryo culture has progressed from BRL cell coculture to reliance on chemically defined medium such as HECM-9 or -10 fortified with a protein source, usually fetal bovine serum (FBS), at later stages in preimplantation development. Development of the primate embryo as in other mammals includes morphologically distinct developmental stages from the formation of the zygote after fertilization to cleavage, morula formation, compaction, and finally cavitation of the blastocyst. In HECM-9aa + FBS, blastocysts containing 100 or so cells can be seen by day 6 or 7 *in vitro* at a control rate of approximately 50% in the rhesus monkey.

Embryo transfer in the context of producing animals can be accomplished by laparoscopy or by minilaparotomy with direct deposition into the oviduct. A nonsurgical transcervical route, although evaluated, has proven troublesome in the rhesus monkey secondary to difficulties in passing a cannula through the tortuous cervix in this species.[14,19] For information on optimal timing of embryo transfer see Wolf *et al*.[19] Pregnancy outcomes in NHPs following ET of ART-produced embryos have been evaluated; however, a significant experience is available only in the rhesus macaque where approximately 100 infants have been born following IVF/ICSI.[17–19]

PRODUCTION OF IDENTICAL ANIMALS The ARTs can, in theory, be employed for the production of genetically identical animals by twinning, embryonic cell nuclear transfer (ECNT), or SCNT. This would be a highly significant accomplishment as there is a need among the research community for monkeys with specific genotypes that cannot be satisfied by the importation of animals from the wild or by the identification and propagation of founder animals using conventional breeding. Moreover, spontaneous or naturally occurring NHP models of human genetic diseases are exceedingly rare and not currently available in useful numbers. If a technology for preserving, propagating, and indeed creating NHP models was available, it could be a key to understanding factors involved in disease progression, and it would also provide a relevant platform for testing therapies.

Embryo twinning alternatives, as perfected in domestic animal species, have been evaluated in efforts to create genetically identical monkeys. The limitation of this approach is that sets of only two or possibly four identical animals could be produced by embryo separation at early developmental stages or by blastocyst splitting. Monkeys have been produced following the transfer of demiembryos or split embryos[15,18,74] into a single recipient; however, the outcomes have been disappointing with only a few twin pregnancies resulting and none progressing to term. Nuclear transfer using embryonic blastomeres is an alternative option for the production of identical animals, but it is also restricted theoretically by a small clone size.[13,17–19,75] Protocols for ECNT in the rhesus monkey, including oocyte and embryo production, micromanipulation, and embryo transfer, are described in detail in the *Methods in Molecular Biology Series*.[76]

With success in producing identical animals by SCNT in the past decade, attention has focused on the use of this technology in nonhuman primates. Several advantages accrue to SCNT including the potential to introduce precise genetic modifications into cultured cells, and then use these cells as nuclear donors for the production of transgenic or loss-of-function monkey models of human diseases. SCNT embryos could also provide a resource for the derivation of autologous ESCs and the subsequent therapeutic use of these cells in preclinical trials of therapeutic cloning. Initial efforts at SCNT by conventional protocols in the rhesus monkey were disappointing because SCNT embryos seldom progressed beyond the eight-cell stage *in vitro* when fetal fibroblasts were used as the source of donor nuclei.[75] While this failure to develop was likely related to incomplete or erroneous reprogramming, the depletion of essential microtubule and centrosomal proteins during oocyte enucleation has also been implicated,[75] to the extent that reproductive cloning in nonhuman primates was thought to be impossible.[77] However, these obstacles were subsequently overcome, to some degree, by technique alteration[78] with normal spindles present after the introduction of somatic nuclei into enucleated cytoplasts.[79,80] An encouraging outcome was achieved in a prospective study comparing SCNT outcome in the monkey with fibroblasts as the nuclear donor source using a conventional protocol versus a one-step method. SCNT-derived embryos developed to the blastocyst stage at a rate in excess of 20% using the one-step method.[80] In the latest rendition of this technique, we incorporated several modifications.[81] First, to prevent premature degradation of cytoplasmic reprogramming factors, the manipulation medium was modified to exclude calcium and magnesium. As before, the electrofusion step was replaced by direct donor cell injection. The latter was performed with a Piezo drill similar to procedures described for mouse SCNT. Cultured donor cells were dispersed and a blunt transfer pipette (5–7 μm outer diameter) was used to disrupt plasmalemma integrity by aspiration before a lysed cell with intact nucleus was injected into a cytoplast. A second modification was implemented to avoid possible deleterious effects of Hoechst staining and ultraviolet (UV) exposure on cytoplast integrity. Visualization of the metaphase spindle during enucleation was accomplished using Oosight Imaging System (CRI, Inc., Woburn, MA) that allowed noninvasive, polarized light imaging and detection of the spindle based on birefringence. Using this innovative approach, we were able to locate and quickly enucleate the spindle, real-time with 100% efficiency. Several fetal and adult somatic cell types supported significant blastocyst development and these achievements represent breakthroughs that allow, for the first time, the *in vivo* and *in vitro* characterization of SCNT blastocysts in this species.

EMBRYONIC STEM CELLS ESCs can proliferate indefinitely, maintain an undifferentiated pluripotent state, and differentiate into any cell type. These pliable embryonic cells are derived from the inner cell mass (ICM) of mammalian blastocyst-stage embryos. Embryonic stem cells—or at least ES-like cells—have been derived from the embryos of multiple species, most notably mice,[82] rhesus monkeys,[83] marmoset monkeys,[84] cynomolgus monkeys,[85] and humans.[86] The ability of ESCs to differentiate into any cell type means we may be able to utilize these cells to cure or alleviate the symptoms of many degenerative diseases. However, unresolved issues regarding cellular survival, maintenance of functionality, and tumor formation mean a prudent approach should be taken toward advancing ESCs into human clinical trials. The short-term and long-term efficacy and safety of ESCs must be thoroughly examined. Due to practical and ethical considerations these studies cannot be performed *in vivo* in humans and clinically relevant nonhuman models are therefore essential. ESCs derived from NHP or human blastocysts demonstrate extensive similarities not observed in murine ESCs.[87,88]

There are currently 42 NHP ESC lines available: 26 in the rhesus monkey, of which eight were derived from *in vivo* produced embryos,[83,89] and 18 from *in vitro* efforts,[90] five cynomolgus monkey ESC lines, of which four were derived from *in vitro* fertilized embryos[85] and one from a parthenogenetically generated embryo,[91] and 11 common marmoset ESC lines that were all derived from *in vivo* produced embryos.[84,92] A summary of the ESC lines currently available in the nonhuman primate is presented in Table 42–2.

To produce these lines, blastocysts were either obtained following *in vivo* fertilization and nonsurgical uterine flushing[83] or though *in vitro* production[90] including conventional *in vitro* fertilization,[85] ICSI,[90] and parthenogenesis.[91,93] Once the blastocyst is obtained, the same basic technique is generally used to derive an ESC line. Zonae pellucidae are removed by a brief exposure to pronase. The blastocysts are then exposed to an animal serum containing anti-rhesus antibodies that can bind to the trophectoderm cells that surround the embryo's ICM. Next, the embryos are moved into serum complement. The complement serum proteins respond to the trophectoderm-bound antibodies and induce lysis. The lysed trophectodermal cells are gently removed with a small bore pipette and the isolated ICM is plated onto dishes containing a monolayer of mitotically inactivated mouse embryonic fibroblast (MEF) feeder cells in ESC culture media. The ICMs attach to the feeder layer and produce small outgrowths after a few days that are manually dissociated into small cell clumps and replated onto fresh dishes of MEFs. Colonies with an ESC-like morphology (flat monolayer colony with distinctive cobbled stem cell morphology, prominent nucleoli, and a high nucleocytoplasmic ratio) are manually selected for further propagation, characterization, and low temperature storage. Medium is changed daily and ESC colonies are split every few days onto dishes with fresh MEF feeder layers. The nondividing MEF feeder cells provide various growth factors that help maintain the NHP ESCs in an undifferentiated state and encourage proliferation. It should be noted that NHP ESC culture is technically difficult. The majority of novice groups supplied with NHP ESCs have had severe difficulty in maintaining their colonies in an undifferentiated state. It is therefore highly recommended that investigators interested in NHP ESCs seek out and attend a relevant training workshop such as an NIH-sponsored workshop on human ESCs or an NHP ESC workshop provided by an active laboratory in this field.

Manual passaging of ESCs is, of course, labor intensive and is incompatible with the scaled up production numbers required for *in vivo* transplantation. Theoretically, combining enzymatic passage to produce multiple subclones with continuous passage-by-passage karyotypic analysis could be used to discard aneuploid subclones and select for an enzymatically passaged karyotypically stable NHP ESC line that would be ideal for scaled up production. This type of NHP ESC line would be an important addition to any NHP ESC bank. NHP ESC lines have, for the most part, been maintained on mouse feeder layers that may contaminate the primate cells with murine pathogens and/or xenoepitopes, either of which could induce a severe immune response following transplantation. Possible solutions to this problem would be to grow NHP ESCs either on NHP feeders[94] or in feeder-free conditions.[95,96] Our research has suggested that NHP ESCs are best cultured on MEFs in DMEM/F12 medium supplemented with 15% FBS, 0.1 mM 2-mercaptoethanol, 1% nonessential amino acids, 2 mM L-glutamine, 4 ng/ml fibroblast growth factor 2 (FGF2) (pH adjusted to 7.2 with NaOH) at 37°C in 3% CO_2, 5% O_2, and 92% N_2.[90]

NHP ESC lines derived from *in vivo*-produced embryos have been characterized by a normal karyotype; they express the same stem cell markers as human ESCs, such as OCT-4, SSEA-3, SSEA-4, TRA-1–60, and TRA-1–81, and possess the ability to differentiate into multiple cell types *in vitro* and into teratomas *in vivo*.[83,84,92] NHP ESC lines derived from *in vitro*-produced embryos also express the aforementioned stem cell markers and can differentiate into multiple cell types both *in vitro* and *in vivo*.[85,90–92,97] However, abnormal karyotypes were discovered in three of the six *in vitro*-derived rhesus monkey ESC lines that were enzymatically passaged during their initial derivation. Primate ESCs appear to be particularly prone to karyotypic aneuploidy during enzymatic passaging as none of the 12 *in vitro*-derived rhesus monkey ESC lines that were manually passaged demonstrated any aneuploidy.[90] Most of the other biological characteristics of NHP ESCs have been elucidated using rhesus monkey ESCs. The cell cycle of rhesus monkey ESC is characterized by an extremely rapid transition though G_1, which is not arrested by serum starvation, pharmacological inhibition, or gamma irradiation, reflecting an absence of a G_1 checkpoint similar to murine ESCs.[98]

NHP ESCs can be either differentiated *in vitro* or *in vivo*. For *in vitro* differentiation, embryoid bodies (EBs) are formed and then placed into various culture conditions until the desired cell types are obtained. For *in vivo* differentiation, the ESCs are injected into a mouse and allowed to spontaneously form a tumor. To obtain embryoid bodies, entire ESC colonies are detached from the feeder cells and manually transferred into feeder-free ultralow adhesion dishes and cultured in suspension in ESC medium without FGF for several days. The NHP ESCs initially clump up into a ball and then cavitate to form a blastocyst-like embryoid body. To induce spontaneous differentiation, the embryoid bodies are attached to gelatin-coated culture dishes and cultured for 1 month in FGF-free ESC culture media. This allows

Table 42–2
A summary of the NHP ESC lines currently available[a]

Primate species	*Blastocyst origin*	*ESC lines (number)*	*Reference*
Rhesus monkey (*Macaca mulata*)	*In vivo*	8	83, 89
Rhesus monkey (*Macaca mulata*)	*In vitro*	18	90
Cynomolgus monkey (*Macaca fascicularis)*	*In vitro*	4	85
Cynomolgus monkey (*Macaca fascicularis)*	*In vitro*	1 (parthenote derived)	91, 93
Common marmoset (*Callithrix jacchus*)	*In vivo*	11	84, 92

[a]NHP, nonhuman primate; ESC, embryonic stem cell.

the ESCs to differentiate down all possible pathways and produces a wide spectrum of cell types. To form teratomas, large numbers of NHP ESCs (usually 10^6–10^7) are injected into the leg muscle of a severe combined immune deficient (SCID) mouse. These mice have no functional immune systems, so the NHP ESCs are tolerated and survive. Over 2 months the NHP ESC differentiate into a tumor composed of many different cell types and containing representatives of all three germ layers. This type of tumor is referred to as a teratoma.

Finally a few of the limitations associated with NHP ESCs will be noted. ESC cloning strategies have proved successful using human ESCs,[99] but are not yet available in the NHP. However, the initial difficulties in genetically modifying NHP ESCs have been largely solved using lentiviral vectors for transfection, resulting in high-level sustained transgene expression in both NHP and human ESCs.[100,101] This lentiviral-based ability to produce gene knockout and transgenic NHP ESCs has significant implications for the use of NHP ESCs in developmental biology, disease pathology, and gene therapy. In the mouse, genetically modified ESCs are inserted into tetraploid host blastocysts and the implanted chimeras produce transgenic and gene knockout animals.[102] If these chimera techniques eventually proved transferable to NHP ESCs then it would permit the generation of gene knockout and transgenic primates. Chimera research in the NHP is still in the preliminary stages. We have demonstrated that membrane marked NHP ESCs—when transferred to a host embryo at the four- to eight-cell stage—have the capacity to proliferate and contribute to the ICM and trophectoderm of the resulting NHP chimeras[90] and when green fluorescent protein (GFP)-marked NHP ESCs have been transferred into NHPs at the fetal stages they have successfully integrated into the host tissues.[103]

Recent evidence has demonstrated that multiple NHP ESC lines demonstrate a loss of imprinting.[104] Aberrant imprinting has also been observed in mouse ESCs[105] and in high passage human ESCs,[106] although it should be noted that low-passage human ESCs appear to demonstrate normal imprinting.[106] How this loss of imprinting will affect the therapeutic potential of ESCs is still unknown, but as the loss of imprinting has been associated with germ cell tumors[107] this question becomes yet another reason for extensive research into the safety of ESC-based therapy in the NHP before human clinical trials are initiated.

43 Rat Models of Polycystic Ovary Syndrome

KRISHNA B. SINGH

ABSTRACT

Polycystic ovary (PCO) syndrome is a common endocrine disorder of unknown etiology. This condition is a major cause of menstrual irregularity and infertility in women with chronic anovulation. This chapter reviews the literature on methods of producing experimental PCO models in the laboratory rat, and the findings that support their resemblance to the human condition. The principal rat PCO models that have been validated include constant light exposure, hypothalamic lesions, sex steroid-induced models, and the mifepristone (RU486) model. The biological systems involved in developing chronic anovulation and PCO in these models include the hypothalamus, the pituitary gland, the adrenals, and the ovary with its paracrine, autocrine, and intracrine regulators. Animal models are central to making the transition from scientific concepts to understanding the reality of a human disease. Validated animal models can be used for therapeutic screens, in preclinical trials, and for basic research in reproductive biology. However, animal models of chronic anovulation and PCO may not fully reproduce the reproductive events seen in the human syndrome.

Key Words: Animal models, Persistent estrus, Polycystic ovary, Polycystic ovary syndrome, Chronic anovulation.

INTRODUCTION

Polycystic ovary (PCO) syndrome is a common but complex endocrine disorder among women of reproductive age. Women with this disorder present with menstrual irregularity, hirsutism, chronic anovulation, and infertility. Despite many clinical and basic animal studies reported in the literature, the etiology and pathogenesis of chronic anovulation and PCO syndrome remain enigmatic.[1,2]

The first systematic studies on a rat PCO model were reported in the 1960s.[3–5] Since then newer rat PCO models have been developed and validated. These studies provide unique concepts in understanding the nature of chronic anovulation and polycystic ovary.[6–11]

This chapter first provides background information on the estrous cycle in rats and explains the terminology frequently used in basic research. It then reviews the literature on various methods of producing experimental PCO models in the laboratory rat, and the findings that support their resemblance to the human condition. The focus of the review will be on morphological and hormonal data on the validated rat PCO models. In the final section, the key issues pertaining to animal models in PCO research are discussed.

ESTROUS CYCLE

The short estrous cycle (4–5 days) in rats and mice makes them ideal for exploring many physiological changes that occur during a reproductive cycle.[12] The ovarian cycle once initiated at puberty is characterized by repeating patterns of cellular growth, differentiation, and transformation of ovarian tissues. The dynamic events include follicular development and ovulation with subsequent formation and regression of the corpora lutea. The sequence of these events is orchestrated by several interacting ovarian factors and the cyclic production of hormones from the anterior pituitary and hypothalamus.

Estrogen exerts a critical regulatory influence upon the biosynthetic and secretory activity of the gonadotropin-releasing hormone (GnRH) neurons. It seems likely that estrogen regulates the behavior of the GnRH neuron through multiple transsynaptic, neuronal–glial, and direct membrane modes of action. Preovulatory GnRH and luteinizing hormone (LH) surges depend on activation of estrogen (E_2)-inducible progesterone (P) receptors in the preoptic area. Surges do not occur in males or in perinatally androgenized females (see below).

TERMINOLOGY

The term persistent estrus means failure of two or more consecutive estrous cycles in adult rats. Persistent estrus is documented by precornified and cornified vaginal smears lasting for more than 10 days. The term PCO disease means the presence of persistent estrus, chronic anovulation, and polycystic or polyfollicular ovaries.[4,5,7,11] The term polycystic ovary syndrome refers to the clinical disorder or syndrome in women of reproductive age.

The following section describes studies in female rats according to the methods for induction of persistent estrus, chronic anovulation, and polycystic ovaries.

CONSTANT LIGHT

The constant-light rat model is a simple, reversible, inexpensive, and reproducible model to study the pathogenesis of chronic anovulation and its reproductive outcomes. The exposure of young female Sprague–Dawley rats to continuous light gradually

causes failure of the estrous cycle and infertility because of chronic anovulation associated with persistent estrus. During the early stages of constant light exposure the rats show regular estrous cycles, but the cycles become irregular and persistent estrus develops with increased duration of constant light. On changing the light schedule from constant light to light and dark, persistent estrus was interrupted in 32 of 34 (94.1%) rats after an average of 7.5 days. The ovaries of rats exposed to constant light for 56 days, then to light and dark for 28 days, were normal in appearance.[3–5] When placed in darkness for 10 h, 80% of the animal ovulated 46 h later.[13]

The onset of persistent estrus in female rats depends on the intensity, duration, and spectral characteristics of the environmental light. The absence of 24-h time cues contributes to the induction of persistent estrus when the animals are housed under constant light.[14] Constant light exposure of female rats for as little as 3 days causes a shift in phase of the LH surge related to decreased sensitivity to E_2/P involved in GnRH release at the hypothalamus.[15] The exposure of constant light disrupts the estrous cycle and decreases fertility in young female rats by inducing chronic anovulation associated with persistent estrus. However, light–dark cyclicity is not critical for postpartum ovulation in constant-light rats.[16]

Histological examinations of the ovary in constant-light rats show occasional primordial or secondary follicles, several cystic follicles, and the absence of corpora lutea.[4–6] Electron microscopic studies have further revealed abnormal findings in the tunica albuginea, granulosa cells, and theca cells compared with age-matched controls.[17]

The hormonal findings reported in constant-light rats have been consistent among published studies by various authors. Compared with control values, serum LH levels are normal, follicle-stimulating hormone (FSH) levels are low, E_2 levels are high and P levels are low.[17–20] With high E_2/P ratios the constant-light rat model represents an estrogen-dominant condition.

In our laboratory, the constant-light PCO rat models have been studied for several medical and surgical methods of ovulation induction, and for mating and pregnancy outcomes. Results show the rats exposed to constant light resume estrous cycles when exposed to the light and dark laboratory environment. The constant-light rats ovulate following mating with healthy male partners, and when treated with injections of P and human chorionic gonadotropin (hCG) or unilateral ovariectomy. Pregnancy outcomes are normal, and the pups raised in the constant-light environment do not develop polycystic ovaries until they reach puberty.[3–5,21,22]

The mechanism of chronic anovulation in constant-light rats is not fully understood. The GnRH sensitivity of the pituitary gland for releasing LH is decreased in constant-light rats with persistent estrus.[3] Giving injections of naloxone elevates serum FSH and LH during ovulation and significantly increases the hypothalamic levels of β-endorphin compared with saline-injected controls. Blockade of opiate receptors increases β-endorphin production and uptake and/or decreases its release from the hypothalamus.[23]

There is evidence that anovulation in constant-light rats may result from activation of the sympathetic nervous system that results in adrenal gland hypertrophy during light exposure.[4,5] In animals exposed to chronic lighting, the absolute and relative volumes of zona fasciculata are significantly increased. The serum concentration of corticosterone is also significantly increased in these rats in comparison with controls. These findings suggest that exposure of female rats to constant light increases growth and secretory activity of zona fasciculata cells, which may be related to chronic stress.[24]

Chronic anovulation during continuous light exposure in rats may also be caused by decreased pineal gland activity and suppression of melatonin production. Treatment with melatonin induces ovulation in about 70% of constant-light rats.[25] Feeding precooked maize devoid of tryptophan to light-exposed rats suppresses persistent estrus and significantly reduces estrus–proestrus frequency.[26]

LIMBIC SYSTEM

The limbic system of the brain consists of the hippocampus, hypothalamus, thalamus, amygdala, and the pineal gland. The neural elements obligatory for GnRH release in female rats are found within and or immediately close to the medial preoptic nucleus of the hypothalamus. Preovulatory GnRH and LH surges depend on activation of estrogen-inducible P receptors in the preoptic area of the hypothalamus. Estrogen signaling to GnRH neurons is critical for coordinating the preovulatory surge release of LH that leads to full follicular maturation and ovulation. The preovulatory surges of GnRH and LH are activated by increased E_2 concentrations in blood.[27] The mechanisms for the blockade of the GnRH surge in persistent estrus rats are poorly understood.

Several experimental approaches to manipulate the limbic system have been taken to induce persistent estrus in female rats. Electrolytic lesions using 5 and 10 μA of direct current into the anterior medial preoptic nucleus or the suprachiasmatic nucleus of female rats induced persistent estrus or irregular estrous cycles about 5 weeks after lesions. The preovulatory surges of LH and prolactin (PRL) were eliminated in both groups of persistent estrus rats.[28]

Amygdala kindling in adult female rats causes persistent estrus and development of PCOs associated with high serum E_2 and increased pituitary weight. The ovary shows many cystic follicles, as well as follicles in various stages of growth and atresia. Treatment with P restored cyclicity in the persistent estrus kindled rats. The amygdaloid-lesioned rats provide powerful tools to investigate the association of PCO and epilepsy.[29,30]

Pinealectomy in female rats induces persistent estrus with morphological features of PCO as seen in the constant light rat model.[31]

ANDROGENS

Several studies have shown that giving an androgen such as testosterone propionate (TP) to female rats during early postnatal life results in persistent estrus and polyfollicular anovulatory ovaries during adulthood.[5–7,11] In one study Wistar female rats were injected with testosterone (T) or 5β-dihydrotestosterone (5β-DHT) for the first 5 days of life. Neonatal treatment with 1 mg of T resulted in persistent estrus in all of the animals; however, among the females injected with 1 mg of 5ß-DHT, 74% of rats became sterile at 120 days of age. When the daily dose of 5β-DHT was reduced to 0.1 mg, only 33% of the rats became sterile.[32] In another study, the androgenized rats showed hyperprolactinemia 40 days after they were given 1.25 mg TP at 5 days of age. The polycystic ovaries showed hyperthecosis, but no thickening of the tunica albuginea.[33]

The serum LH, FSH, T, and E_2 values in TP androgenized rats were not different from control values, and treatment with FSH did not increase serum E_2 concentrations or the ovarian weights. The androgenized rats showed a similar postunilateral ovariectomy increase in serum FSH, and compensatory ovarian hypertrophy was not noted compared with controls. Because of these findings it was suggested that the androgenized rat is not a proper model for the human PCO syndrome.[34]

Daily treatment with 4 or 20 mg of danazol in the TP androgenized rats caused regression of cystic follicles. Serum levels of LH, T, and E_2 were significantly decreased, and the vaginal smears changed to diestrus suggesting inhibition of estrogenic activity.[35] Giving an antiandrogen flutamide caused partial normalization of the hormonal and morphological characteristics and recovery of fertility in the animals.[36] Long-term persistence of hormone imbalances in androgen-sterilized rats can induce atypical hyperplasia and adenocarcinoma of the uterus after 500 days of age.[37]

An androgen-sterilized rat (ASR) model that showed obesity was established by subcutaneous injections of 1.25 mg TP to Sprague–Dawley female rats at the age of 9 days. The rats sacrificed around 112 days of age showed polycystic ovaries, anovulation, high food intake, increased body weight, and obesity. High levels of serum E_2 and leptin were noted, but serum FSH and LH levels were reduced significantly compared with normal rats. After feeding herbal tea to the animals, the endocrine changes were normalized, ovulation was induced, and the animals also lost weight.[38] Another ASR model of obesity and polycystic ovaries was developed in Wistar-Hannover rats that showed a significant increase in body weight starting at the fifth week of life compared with control rats.[39]

Implanting androstenedione (ADO) Silastic capsules that released 63.2 ± 4.4 µg/24 h ADO into cyclic rats resulted in significant prolongation of the estrous cycles; most rats showed 5-day cycles after the first normal cycle. There was a decline in ovulation rate with low serum LH levels and normal FSH on the morning of estrus.[40]

Giving dehydroepiandrosterone (DHEA) to neonatal female rats results in persistent estrus and polycystic ovaries with or without corpora lutea. Serum FSH and LH levels showed an ovulatory surge on day 30 at the time of precocious ovulation. Serum FSH levels were comparable to control rats, LH levels were low, and serum PRL was raised significantly. The withdrawal of DHEA treatment resulted in restoration of cyclicity in this model.[8,9,41,42] In DHEA-induced PCO rats, serum FSH, LH, and PRL levels did not differ significantly compared with controls, and the levels of serum DHEA, T, and ADO were high.[43] In another study, the DHEA-treated rats showed normal serum LH and FSH levels, increased DHEAS, ADO, T, and E_2, and reduced serum P level.[44]

With pharmacological doses of androgens given to female rats, the acyclic pattern of gonadotropin secretion is associated with irreversible changes in the hypothalamic cyclic centers normally responsive to steroid feedback. Dose–response studies using various androgens in the neonatal pups to induce persistent estrus during adulthood are limited. According to one study, the majority (99%) of the rats treated with androgens other than DHEA were in persistent estrus by 90 days of age.[45]

In another dose–response study, female rats were androgenized by giving a single injection of 10 or 100 µg TP at 5 days of age. Treatment with 100 µg TP resulted in persistent estrus while treatment with 10 µg TP resulted in regular estrous cycles followed by persistent estrus vaginal smears.[46] Dose–response studies of the reproductive and developmental effects of exposure to prenatal TP and other sex steroids provide unique androgenized rat models.[47]

ESTROGENS

Like androgens, giving estrogens to female rats during early postnatal life results in persistent estrus and polyfollicular anovulatory ovaries during adulthood.[5–7,11] Female rats injected with 2 mg estradiol valerate (EV) develop persistent estrus and small polyfollicular ovaries within 2 months. Plasma E_2 concentrations are high while LH and FSH concentrations are within the high and low normal range, respectively. This model has been used to study the pathogenesis of chronic anovulation in female rats.[48–53]

Increased sympathetic activity plays a role in forming polyfollicular ovarian cysts in EV-treated rats. This theory was tested using a combined cold and restraint stress that induced an increase in the ovarian sympathetic nerves.[54] The activation of the sympathetic nervous system precedes the induction of polycystic ovaries in EV-treated rats. The mechanism involves both direct and neurogenic components.[55,56] There is evidence that persistent estrus in estradiol benzoate (EB)-treated rats is associated with delayed maturation of the tonic GnRH systems and that it affects estrogen receptor synthesis in the uterine tissues during adulthood.[57,58]

ANTIPROGESTERONE

Mifepristone (RU486) is an 11ß-dimethylaminophenyl derivative of norethindrone with a high affinity for P and glucocorticoid receptors. Subcutaneous administration of 4 mg of RU486 to cyclic rats over 8 consecutive days induces persistent estrus and anovulatory cystic ovaries. In this model, serum LH/FSH and T/E_2 ratios are high.[59] Giving RU486 to cyclic rats on proestrus advances the preovulatory surge of LH, which results in 3-day estrous cycles.[60]

The mechanism of inducing chronic anovulation in the RU486 rat model is not fully understood. Several studies in RU486 rats have been conducted to elucidate the pathogenesis of chronic anovulation and to show the validity of the model.[61] Like the constant light and DHEA rat models, the RU486 rat PCO model is also reversible.

AROMATASE INHIBITORS

Giving a third-generation aromatase inhibitor letrozole daily for 21 days induces polycystic ovaries in cyclic female rats. The ovaries a showed high incidence of subcapsular polyfollicular cysts, capsular thickening, incomplete luteinization, and a decreased number of corpora lutea. Serum E_2 and P levels were reduced in a dose-dependent manner and serum LH and T levels were high. Serum levels of FSH were increased at higher doses of letrozole (0.5 and 1.0 mg/kg), contrary to a low dose of letrozole (0.1 mg/kg) at which a slight decrease was observed. The low-dose letrozole persistent estrus rat model shows morphological and hormonal findings that mimic the human PCO syndrome.[62]

DISCUSSION

This chapter reviews various methods of producing persistent estrus, chronic anovulation, and PCO in the laboratory rat. The principal validated models are constant light exposure, hypotha-

lamic lesions, androgen- and estrogen-induced models, and the mifepristone (RU486) model. The vast literature on other animal models has been reviewed by the author at http://obg.lsuhsc-s.edu/pco/index.html.

The main biological systems involved in the development of chronic anovulation and PCO in animal models include the hypothalamus, the pituitary gland, the adrenals, and the ovary with its paracrine, autocrine, and intracrine regulators. The arrested follicular growth, lack of dominant follicles, and thecal and stromal hyperplasias in the polycystic ovaries may represent expressions of several pathogenic pathways including the ovarian paracrine, autocrine, and intracrine regulators.[63]

The pathogenesis of chronic anovulation, the hallmark feature of the PCO syndrome, has been recently studied using animal models such as the prenatally androgenized sheep and rhesus monkey.[1,2] The laboratory rats and mice have key advantages over the androgenized sheep and monkey models to study chronic anovulation and PCO because of their small size, high reproductive index, genetic diversity, and low maintenance costs.

The newer animal models and their implications for future research should be considered in the context for replicating the human disorders. For example, the transgenic mice models have been investigated to determine how excess LH leads to cyst formation in the ovary associated with infertility. Targeted overexpression of LH in transgenic mice leads to obesity, infertility, polycystic ovaries, and the formation of ovarian tumors.[64,65] The prenatally androgenized transgenic mice show irregular estrous cycles and elevated testosterone and luteinizing hormone levels, suggesting altered hypothalamic–pituitary–gonadal axis function.[66] Hormone receptors and knockout mouse models may also provide new insights into the interacting roles of hormones, receptors, and enzymes in chronic anovulation.[67–69]

Environmental factors that cause significant stress can also trigger chronic anovulation and PCO both in animal models and in women with this syndrome.[70–72] Studies in our laboratory have shown, for example, that exposure of adult female Sprague–Dawley rats to continuous noise for more than a month produces persistent estrus and PCO much like the constant-light rats. The ovaries of the noise-exposed rats after 150 days of high-intensity noise showed morphological features similar to the constant-light rats.[73]

Polycystic ovary syndrome is a complex and heterogeneous disorder characterized by hyperandrogenemia, hyperinsulinemia, insulin resistance, and chronic anovulation. Currently PCO syndrome is considered a polygenic trait that might result from the interactions of susceptible and protective genomic variants and environmental factors during either prenatal or postnatal life. Prenatal androgenization of the female fetus induced by genetic and environmental factors, or the interaction of both, may program differentiating target tissues toward the development of the PCO syndrome phenotype in adult life.[1,2,74] Computer models and *in vitro* cell culture studies have enhanced our understanding of physiologically important phenomena in reproductive biology.[75]

Animal models are central to making the transition from scientific concepts to understanding the reality of a human disease. Validated animal models can be used for therapeutic screens, in preclinical trials, and for basic research in reproductive biology. However, animal models of chronic anovulation and PCO may not fully reproduce the reproductive events seen in the human syndrome.

44 Murine Models for Reproduction

Damayanti Chakraborty and T. Rajendra Kumar

ABSTRACT

Recent developments in mouse manipulation techniques have resulted in the generation of various single gene knockout mouse models. It is estimated that approximately 300 novel strains of mice with mutations in loci directly or indirectly affecting reproductive development have already been generated. Furthermore, the ability to spatiotemporally inactivate or activate gene expression *in vivo* using the "Cre-lox" technology has recently emerged as a powerful approach to understand various developmental processes involved in reproduction in a physiological setting. In parallel with these gene-targeting approaches, large-scale mutagenesis programs have been initiated with the goal of uncovering novel genes important for reproduction. These and other related transgenic approaches are offering unlimited opportunities to systematically analyze the complex process of reproduction. The principles of conventional and conditional gene targeting technologies, the recent advances in functional genomic approaches, and their applications to reproductive biology will be discussed.

Key Words: Mice, Transgene, Knockout, Hypothalamus, Pituitary, Gonads.

INTRODUCTION

Reproduction is a complex process that involves multiple interactions. The mammalian reproductive axis consists of three major centers, namely, the hypothalamus, pituitary, and gonads. Defects in regulation of the reproductive axis may lead to cancers, hyperstimulation syndromes, and infertility.[1–3] The majority of the genes and the corresponding proteins they encode are evolutionarily conserved across various mammalian species.[1,4]

In recent years, the mouse has emerged as a useful model to manipulate the reproductive axis and several murine models of reproduction have been generated.[5–9] There are several advantages of using mice to study basic aspects of reproduction and model human reproductive diseases. First, mice are relatively cheap, easy to maintain in a laboratory setting, and have a short gestation time and life span. Second, an exhaustive amount of data exist with regard to their genetic make-up and linkage of genes. Third, techniques to manipulate the mouse genome have been well established.[10] Finally, mouse genome sequencing has been completed and the information is disseminated into public databases. There is a high degree of sequence similarity between mice and humans in many of the loci, important for reproduction.[4]

Both gain- and loss-of-function mouse models have been generated that have defects ranging from primordial germ cell specification, migration, sex determination, somatic and germ cell development and function, fertilization, implantation, and embryo development. Furthermore, models with defects in pituitary gonadotrope and hypothalamus development and function and their reproductive consequences have also been characterized. Studies with these random or targeted transgenic and knockout mouse models have also been complemented with analysis of naturally occurring mutant strains. Here, we will present a summary of various ways to manipulate the mouse genome and provide lists of representative models that have reproductive phenotypes.

TRANSGENIC APPROACHES

Nearly 25 years ago, transgenic mice expressing human growth hormone were successfully developed.[11] This work revolutionized various fields of biology including reproductive biology and provided a basis for many gain-of-function experiments. Several hundreds of transgenic mice related to reproduction have since been produced. In this approach, foreign genes or cDNAs are first injected into fertilized one-cell mouse embryos usually obtained following a superovulation protocol.[10] Next, these transgene-injected embryos are transferred into oviducts of pseudopregnant foster females.[10] Subsequently, pups produced are screened for the presence and number of copies of the injected transgene. Independent lines will then be established by breeding the transgene-carrying founder mice. Because the transgene is injected into the mouse genome prior to the first round of replication, the foreign DNA is randomly integrated into multiple tissues.[10]

Most often, the transgenes are expressed in a tissue/cell-specific manner using either homologous (i.e., mouse) or heterologous (for example, rat, cow, sheep, human, pig) gene regulatory sequences.[12,13] Mouse genes or cDNAs appropriately marked with random oligos or engineered with heterologous downstream polyadenylation DNA sequences are also used.[12,13] The effects of overexpression of such transgenes on reproductive function are then monitored. In some instances, ectopic expression of the transgene is also achieved by purposefully directing its expression into tissues/cells different from those in which the corresponding mouse gene is normally expressed.[12,13]

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.),

MAPPING REGULATORY REGIONS OF GENES THAT CONFER TISSUE/CELL-SPECIFIC EXPRESSION Promoter or other regulatory elements that confer hormone responsiveness and cell-specific expression and dictate combinatorial binding of various transcription factors are routinely mapped using cell culture models.[14–20] However, many times these data may not correlate well with the *in vivo* expression data. In other instances, well-established cell lines may not be available for fine mapping studies of regulatory regions of some genes.[21] In these cases, transgenic mice can be used as a powerful *in vivo* expression system. First, a series of deletion constructs are engineered from a larger piece of the gene that is known to confer cell/specific expression.[21] Subsequently, the truncated transgenes are microinjected to produce transgenic mice and as an endpoint, its expression in the selected cell type is monitored at the RNA and/or protein level.[21] Similar strategies have also been used in which a known transcription factor-binding site is mutated on a given promoter driving the expression of a transgene and its functional consequence tested *in vivo*.[22–26]

TRANSGENIC MICE AND QUANTIFIABLE PROMOTER ACTIVITY If the promoter elements of a given gene are well mapped, then these can be used to direct the expression of useful reporters that can be assayed quantitatively. Strength or the effects of positive or negative factors that regulate gene expression or mutations in the promoter region that affect transcription factor binding can be quantified by this approach. The most commonly used quantifiable reporters include lacZ from *Escherichia coli*, chloramphenicol acetyltransferase, and the firefly luciferase.[10] Several promoter regions of genes involved in reproduction have been tested using these strategies (Table 44–1).

CELL LINEAGE MARKING AND PURIFICATION OF DESIRED CELL TYPES Developmental expression of many genes that have important reproductive function can be tracked using lineage marking and cell fate mapping. Depending on the

specificity and expressivity of the gene regulatory sequences and the earliest time at which these are activated during embryogenesis, expression of either lacZ, alkaline phosphatase, or various fluorescent reporters (for example, GFP, CFP, YFP or dsRed) can be targeted to specific cell types.[10] Tissues/cells are then harvested and the activity of lacZ (formation of a blue product), alkaline phosphatase (formation of a blue or red product), or the visualization of distinct colors under ultraviolet illumination is monitored starting from embryonic stages.[10] Tracking through distinct developmental stages will provide a novel way to study the linage specification and differentiation of desired cell types.

Because cells expressing fluorescent reporters can be sorted by fluorescence-activated cell sorting, these transgenic mice will provide novel resources to purify desired cell types from a tissue consisting of heterogeneous populations of various other cells.[27–29] These can be further used for gene/protein expression profiling under normal physiological conditions.

CELL ABLATION BY TARGETED EXPRESSION OF TOXINS Identification of cell/specific regulatory elements has also been useful for selectively ablating cells at desired times and studying the consequences of the loss of hormones secreted from these cells.[10] This has been achieved by expressing diphtheria toxin,[23] or herpes simplex virus thymidine kinase,[30] or viral-specific ion channels.[31] In the latter two cases, either an appropriate substrate (gancyclovir) or an ionophore (calcium or sodium channel activator or blocker) is used to produce either a cell-toxic product or changes in ion flux that affect hormone secretion. These approaches have been used to study the consequences of ablation of gonadotropes on gonadal development and reproduction.[30] More recently, ablation of Sertoli cells has been achieved to study the consequences on germ cell and consequently male reproduction.[32]

CELL-SPECIFIC IMMORTALIZATION Targeted expression of viral oncogenes in transgenic mice is a powerful way to immortalize desired cell types *in vivo*.[33] This strategy permits immortalization of rare cell types that are otherwise difficult to obtain in large numbers and good purity for routine cell transfection analyses.[34–39] Moreover, novel cell lines are derived from these tumors and established as useful *in vitro* tools for various studies. Since many cell types within the reproductive axis are postmitotic, this approach has been particularly useful for immortalizing these cell types and establishing novel cell lines.[34–39] Many of these cell lines have been used to investigate specific signal transduction pathways, and transcriptional regulation.[34–39] In some cases, these tumor-prone mouse models also phenocopy known human cancers and thus have tremendous potential to help in understanding the pathobiology of the human disease.[36] Furthermore, these models can also be a useful resource for identifying novel cancer biomarkers.

HIGH BASAL LEVELS AND INDUCIBLE EXPRESSION OF TRANSGENES Although expression of a given transgene is dependent on the promoter that drives its expression, the site of the integration, and the copy number, some promoters exhibit high basal activity in many tissues.[40,41] This feature has been exploited to ectopically express various hormones in multiple tissues at high basal levels; the consequences of this on reproduction have been analyzed.[42–44] Some of these promoters are also inducible, for example, metallothionein-1 is induced by heavy metals such as zinc and cadmium.[40,41]

An alternate strategy to temporally induce transgene expression has been developed. In this approach, the desired protein encoding cDNA or gene is engineered downstream of a conditionally activated "gene switch."[45,46] This "gene switch" consists of DNA sequences that encode a bacterial repressor protein and an operator region that is linked to the gene of interest. The repressor binds to the adjacent operator DNA sequence that is linked to the gene of interest and keeps it inactive. This entire "gene switch" cassette along with the gene of interest is under the regulation of a tissue/cell-specific promoter. When a drug that binds the repressor and prevents it from binding to the operator region is administered to transgenic mice, it allows the transcription of the desired gene at specific times. Based on this principle and using tet^{on},[47] ecdysone,[45,48] RU486,[49] and tamoxifen[50] as inducible gene expression models, transgenic mice have been developed.

Several representative models illustrating the application of the above strategies to reproduction research are listed in Table 44–1. Many transgenic approaches have also been successfully used in gene targeting experiments to genetically rescue mutant mice, spatiotemporally inactivate genes, cell fate mapping, and gene/protein expression profiling. These gene knockout models will be described in the following sections.

GENE KNOCKOUT APPROACHES

Loss-of-function mouse models are commonly produced through site-specific mutations at desired loci in embryonic stem (ES) cells by homologous recombination. ES cells are derived from the inner cell mass of blastocysts at embryonic day 3.5.[10] These are propagated *in vitro* on fibroblast cell feeder layers and in an undifferentiated state by providing selected growth factors. Desired mutations are engineered using considerable length of homologous gene sequences flanking the deletion and an appropriate drug selectable marker.[51–54] These engineered DNA sequences are called the targeting vectors and are usually electroporated into ES cells derived from agouti coat color mice.[10] Following appropriate drug selection, enrichment and expansion into individual clones, and identification of the correct gene-targeting event (i.e., one allele disrupted), the mutant ES cells are injected into host blastocysts derived from black coat color mice and transferred to uterine horns of pseudopregnant foster mice.[10] The injected mutant ES cells mix with the inner cell mass of the host and contribute to all parts of the body, including the germ line, and the resulting chimeric mice have patches of both agouti and black coat colors.[10,51] The chimeric mice, mostly males, are bred to normal females and germ line transmission of the mutant allele is achieved resulting in production of heterozygous mice. If viable and fertile, the heterozygous male and female mice are intercrossed to generate the homozygous gene knockout mice.[10,51] If the mutation in the homozygous recessive condition does not cause embryonic lethality, then 25% of knockout mice are produced according to Mendelian inheritance. The majority of the murine models of reproduction have been produced by this standard approach (Tables 44–2 to 44–4). More recently, application of several variations of this basic theme have resulted in production of numerous gene knockout models (Table 44–5). These approaches are described in the following sections.

TISSUE/CELL-RESTRICTED AND TEMPORALLY REGULATED CONDITIONAL GENE INACTIVATION MODELS Many proteins are expressed throughout the reproductive axis or,

Table 44–2
Examples of knockout mice with reproductive defects only in males

Mouse model	*Major reproductive phenotypes*	*Reference*
Acrosin	Delayed fertility	147
AMH or Amh-R	Infertility in males due to obstruction by uteri development	96, 148
Bax	Premeiotic stage block in spermatogenesis; infertility	149
Bclw	Infertile; progressive loss of Sertoli and germ cells	150
Bmp8a	Germ cell degeneration, spermiogenesis defects, epididymis degenerate and progressive infertility	151
Bmp8b	Infertility; defects in primordial germ cell proliferation	152
Calmegin	Infertility due to impaired sperm binding to zona pellucida of eggs	153, 154
CREM	Infertility; block at first stage of spermiogenesis	155, 156
Dhh	Defective germ, Sertoli, and Leydig cell development; infertility	157–159
Hoxd13	Defects in male accessory sex glands	160
HR6B	Infertility; defects in histone polyubiquitination and degradation during spermatogenesis	161
Hsp70	Infertility; increased spermatocyte apoptosis	162, 163
KLHL10	Haploinsufficiency causes asynchronous spermatid development; infertility	164
PC4	Impaired fertilizing ability of spermatozoa; infertility	165
RARα	Seminiferous tubule degeneration leading to male infertility	166
RARβ	Germ cell maturation defects and infertility	167
RARγ	Squamous metaplasia of seminal vesicles and prostate and male infertility	168
TEX14	Infertility; failure to form intracellular bridges after spermatogonia differentiate	169

additionally, in other tissues during distinct developmental stages.[55–57] A deletion of the corresponding gene throughout the body may often result in embryonic lethality.[56,57] Thus, it precludes analyzing the roles in adult physiology, for example, in gonad development and function. This commonly encountered problem is circumvented by a conditional or tissue/cell-specific gene deletion approach. In this approach, first, within the gene of interest, typically in introns flanking the exon to be deleted, two loxP (a 34-bp sequence that consists of two 13-bp inverted repeats and an 8-base pair asymmetric spacer region) sites, one on each side, are engineered in the same orientation.[58–60] A "floxed" mouse is generated in a heterozygous or homozygous condition by standard gene targeting approaches, and this introduction of loxP sites does not interfere with the normal expression of the gene of interest. Second, a transgenic line of mice is produced in which cre, a phage P1 recombinase, is selectively expressed in desired tissue/cells.[58–60] When the flox mice are intercrossed with the cre line, in desired cells, the DNA between the loxP sites is deleted by cre-mediated recombination, leaving one loxP site intact at the locus.[58–60]

Table 44–3
Examples of knockout mice with reproductive defects only in females

Mouse model	*Major reproductive phenotypes*	*Reference*
Activin/inhibin βB	Large litters but delayed parturition and nursing defects	170
Caspase-2	Excess number of germ cells in ovaries; oocytes resistant to cell death following drug treatment	171
C/EBPβ	Infertility; defects in ovulation and corpora lutea formation	172
c-mos	Ovarian cysts and teratoma formation, decreased fertility	173, 174
Connexin 37	Infertility; defects in late stage ovarian folliculogenesis	175
Connexin 43	Defects in primordial germ cells, block at the primary follicle stage	176
Cox2	Infertility; defects in ovulation and corpora lutea formation	177
Foxo3a	Oocyte death, early depletion of functional ovarian follicles, and secondary infertility	178
Gdf9	Defects at one layered follicle stage; infertility	179
IL-11 R	Infertility; implantation defects	180
NGFI-A	Infertility; suppressed luteinizing hormone and ovulatory defects	181, 182
Nobox	Infertility; postnatal oocyte loss, arrest in folliculogenesis at primordial stage	183
Npm2	Nucleolar defects in oocytes and preimplantation embryos, subfertility	184

PRL	Infertility, irregular estrus cycles	186
Prostaglandin F-R	Infertility; lack of induction of oxytocin receptor	187
Ptx3	Subfertility due to defects in the integrity of the cumulus cell–oocyte complexes	188
Srd5a1	Reduced litter size; parturition defects	189
Stat5a/5b	Infertility; absence of corpora lutea and implantation failure	190
Zar1	Infertility; developmental arrest of one-cell embryos	191
ZP3	Infertility; no zona pellucida formation	192, 193

Table 44–4
Examples of knockout mice with reproductive defects in both males and females

Mouse model	*Major reproductive phenotypes*	*Reference*
α-Inhibin	Infertility in both sexes, granulosa/Sertoli cell tumors	194
Acvr2a	Hypogonadism in both sexes, infertility in females, subfertility and male sexual behavioral defects in males	55, 195
α-GSU	Infertile; hypogonadism and hypothyroidism	196
Atm	Male and female infertility; absence of germ cells	197, 198
A-myb	Male infertility; pachytene arrest of spermatogenesis; nursing defects in females due to impaired mammary gland development	199
β1,4-Galactosyltransferase	Male and female infertility due to abnormal glycoprotein hormone glycosylation	200
Cyclin D2	Females infertile; block in folliculogenesis at the preantral stage; hypogonadism in males	201
Dazla	Male and female infertility; loss of germ cells	202
Emx2	Accelerated degeneration of Wolffian duct and mesonephric tubules without formation of Mù1llerian duct	203
ERα	Uterine/ovarian defects in females; small testes, reduced sperm number	204, 205
FSH-β	Hypogonadism, males fertile with reduced sperm number and motility; females infertile, preantral stage block in folliculogenesis	206
IGF-1	Hypogonadal and infertile; preantral block in folliculogenesis; defects in Leydig cell development	207, 208
LH/LH-R	Hypogonadism and infertility in both sexes; spermiogenesis block, reduced testosterone levels, reduced estrogen, and an ovulation defect in females	209–212
Mlh1	Male and female infertility; pachytene stage defects in males; meiosis II defects in females	213, 214
Nhlh2	Males infertile; females fertile only in the presence of males; hypothalamic defects	215
$p27^{kip1}$	Female infertility; corpus luteum defects; males exhibit macroorchidism	216–218
PRL-R	Females infertile due to irregular estrus cycles and implantation defects, idiopathic infertility in males	219–221

Table 44–5
Examples of various mutagenesis approaches

Approach	*Mouse model*	*Reference*
Knockin		
	Activin βB knockin to the βA locus	69
	Cre knockin to the *Amhr* locus	222, 223
	lacZ knockin to the ROSA locus	224, 225
Cre/lox		
	Sertoli cell-specific deletion of androgen receptor	226–228
	Granulosa cell-specific deletions of follistatin, SMAD4	223, 229
	Gonadotrope-specific deletions of GATA2, SF-1	230, 231
	Hypothalamus-specific deletion of SF-1	232, 233
Long-range deletions		
	Down's syndrome	70
	Padre–Willi syndrome	70
Large-scale mutagenesis		
Gene trap	LRG 4-R	234, 235
ENU	GnRH-R	236
Multiple mutations		
	Inhibin/AMH	237
	Acvr2a/FSH-β	92
	Inhibin/FSH-β	43
	ERα/ERβ	90
	Protamines 1 and 2	238
	Transition proteins 1 and 2	239
	Cyclins D1, D2, and D3	240
Genetic rescue		
	FSH-β null mice with human FSH-β transgenes	97
	Dax1 null mice with a human DAX1 cDNA	241, 242
	SF-1 null mice with a rat YAC containing SF-1 genomic sequences	124, 243

Although the above approach provides spatially restricted gene deletion, temporal control is not possible with this cre/lox-based system. Recently, inducible strategies similar to those previously described have been developed in which cre enzyme expression is induced in desired cells at distinct times.[58,61–68] A combination of spatially and temporally regulated gene inactivation offers limitless opportunities to study cell-specific gene expression and function throughout the course of development without affecting the same gene in other tissues.

GENE KNOCKIN STRATEGIES A gene targeting approach can eliminate many of the drawbacks with transgene-based approaches. For example, reporters can be knocked-in to the desired loci (lacZ or GFP or Cre); thus random integration or effects of site of integration can be avoided.[10] In this way, transgenes can be expressed as a single copy from the same endogenous locus. Moreover, bicistronic cassettes can be introduced into endogenous loci and thus gene disruption along with expression of two markers from the same disrupted locus can be achieved.[10] If a known gene is already disrupted in ES cells, variants or mutant forms of the same gene can be knocked-in at the same locus and the effects monitored directly *in vivo*.[10] The other advantage of the knockin strategy is that genes encoding related family members with overlapping patterns of expression are replaced with one another.[69] Thus while disruption of one member is achieved, the other member is transcribed from the disrupted locus using the same regulatory sequences.[69] Most importantly, knockin of cre gene sequences into desired loci and subsequent generation of mice provide a powerful genetic tool for conditional gene deletion purposes.[58,61–68]

LONG-RANGE DELETIONS AND CHROMOSOME ENGINEERING The advent of cre-lox-mediated recombination has led to the emergence of another genetic approach, called chromosome engineering.[70] In this strategy, long-range deletions of desired DNA sequences are achieved in ES cells, although at a low frequency, by selectively engineering loxP sites over megabase intervals on a given chromosome.[70] By altering the orientation of the loxP sites, various chromosomal events including duplication and inversion are also achieved, similar to those originally pioneered in classical *Drosophila* genetics.[70–72] Mice bearing these global chromosomal rearrangements are often maintained as balancer stocks.[70–72] These models coupled with other genetic approaches provide an *in vivo* platform for systematic functional analysis of all the genes that lie within the long intervals on chromosomes.

LARGE-SCALE RANDOM MUTAGENESIS SCHEMES TO GENERATE MULTIPLE DOMINANT OR RECESSIVE MUTANT MODELS It is estimated that ~30,000 genes are expressed in the genome, and about a third of these are believed to be important for reproductive function.[4] Conventional gene targeting approaches are relatively time consuming and mostly aim at mutations in single genes. To rapidly and randomly generate hundreds of mutations in ES cells, several approaches have been used. In one approach, special vectors designated gene trap vectors are randomly introduced into ES cells, and individual vector integrated ES cells are identified and used to produce mutant mice.[73] These vectors are usually designed to disrupt either exons or promoter regions and carry a lacZ reporter expressed from the inserted locus. This facilitates tracking the expression of the gene and eventually cloning the gene itself.[73]

In another approach, *N*-ethyl-*N*-nitrosourea (ENU), an alkylating agent, is injected into wild-type male mice. ENU is a powerful mutagen in mouse spermatogonial stem cells and the goal is to saturate the mouse chromosomes with point mutations.[74–79] The mutagenized males are bred to propagate scores of these mutations into subsequent generations.[74–79] By designing appropriate phenotypic screens, mutants with reproductive defects are further characterized. With the aid of additional genetic tools, the transmission of the mutant allele can be followed visually by coat color and the gene of interest cloned.[74–79] One advantage of this random mutagenesis scheme is that it is possible to recover many types of mutations: null, hypomorphic, and dominant or recessive. Thus, an allelic series of mutations in a given locus can be generated by this approach.[74–79] ENU mutagenesis in ES cells has also been achieved, and methodologies have been developed to identify the mutant alleles in these mutagenized ES cells. The ES cells with desired point mutations are subsequently used to derive mutant strains of mice.[80,81]

Finally, transposon-mediated recombination is also being used to create random mutations in mice.[82–85] Transposons are mobile genetic elements that can integrate into DNA, disrupt the gene, and move over to another region within the same locus or genome-wide.[82–85] This genetic event is facilitated by transposase, the enzyme that recognizes specific sequences to carry out this process, called transposition. Initially, two strains of transgenic mice are generated, one that carries the transposon vector along with a green fluorescent marker between the transposon recognition sequences and the other, transposase. These two lines are bred together and double transgene-positive mice are produced. They are then mated to wild-type mice and several progeny are screened for transposition events that took place in the germ line. By this approach, various mutations clustered within the 3–4 megabase range and outside this region have been produced.[86,87] Although considered not as efficient as the ENU method, transposon-mediated mutagenesis appears mostly useful for region-specific mutagenesis schemes.

COMBINATION OF MULTIPLE MUTATIONS The availability of mutations in desired loci permits a simple genetic intercross strategy to combining these mutations. This is possible if the targeted mutations are on distinct chromosomes or sufficiently apart on the same chromosome.[88–96] Multiple mutations in different loci have been combined for various studies. This approach is useful to analyze the synergistic and/or redundant roles of related family members in a given pathway, or to understand the effect of several modifier factors that regulate a tumorigenesis pathway.[88–96] Similarly, targeted or ectopic expression of transgenes in the null genetic background results in a genetic rescue.[97] If the rescue can be achieved conditionally, then it will provide a useful tool to developmentally follow the effect of the transgene at desired times in the absence of the corresponding endogenous mouse gene.

RESOURCES

Although we have summarized various principles of generating mouse mutations, the reader is encouraged to browse through excellent mouse and mouse genome resources available. The Jackson Labs in Barr Harbor, ME and the mouse genome informatics are great resources for all the mouse genome-based information. This is tightly linked to the National Center for Biotechnology Information (NCBI) that provides various mouse genomics tools. Similarly, the ENSEMBL website maintained by

the Sanger Institute in Cambridge, UK has numerous genetic tools related to mouse and human as well as other species. Two authoritative reference collections of knockout mouse models are available through The American Endocrine Society and The BioMed Central. A number of institution-based websites list and periodically update mutations obtained with their ENU schemes or provide information particularly focused on reproductive phenotypes. Some of these useful sites are listed in Table 44–6. Finally, ready-to-use practical manuals are also available that describe details of transgenic and ES cell technologies.[10,98,99]

CONCLUSIONS AND FUTURE DIRECTIONS

There are now several mouse manipulation approaches available to study the *in vivo* roles of genes at a whole organism level. These include global or conditional (cell-specific or temporally inducible) gain- or loss-of-function mouse models. These models are powerful genetic tools and when used in combination with genomics and proteomics, they offer limitless opportunities to study reproduction.[100–103] New methods of rapid germline modification can be anticipated using spermatogonial stem cells instead of ES cells.[104–106] Recent advances in RNA-interference, and micro-RNA-regulated pathways are readily feasible *in vivo* using transgenic/ES cell-based techniques.[107–114] These novel *in vivo* approaches will enable us to achieve more tightly controlled regulation of gene expression *in vivo*. Large-scale mutagenesis programs coupled with long-range deletions can be used to mimic microdeletions on the Y-chromosome that commonly occur in several cases of male infertility.[115,116] Moreover, the genetic tools will facilitate identification of candidate genes responsible for many naturally occurring mouse mutations that have not yet been characterized.[117] Finally, several new targets for either fertility control or enhancement may also be identified by these genetic approaches.[100,118]

ACKNOWLEDGMENTS

We wish to emphasize that for simplicity's sake, in preparing this chapter, we have chosen only representative examples to illustrate the principles and applications of transgenic and knockout mice. We acknowledge the financial support received from the National Institutes of Health, The Moran Foundation, Houston, TX, and The Hall Family Foundation, Kansas City, MO. D.C. is a graduate student in and is supported by the Integrated Graduate Program in Biomedical Sciences, University of Kansas Medical Center.

45 Pig Model to Study Dynamics of Steroids During Ovarian Follicular Growth and Maturation

Damodar K. Mahajan

ABSTRACT

The pig is a polyovular farm animal and its prolificacy differs in different breeds. The female pig has an estrous cycle of 20–21 days with a short follicular phase of only 3 days and a long luteal phase. The luteal phase starts at day 1 after ovulation to day 15 of the estrous cycle and it overlaps the early follicular phase on day 16–17. The follicular phase lasts only 3–4 days. The early follicular growth is initiated while a high concentration of progesterone (P) is secreted by active corpora lutea, circulating it in the peripheral blood. In this study, P, androstenedione (A), testosterone (T), estrone (E_1), and estradiol-17β (E_2) were measured in peripheral blood, ovarian venous blood, follicular fluid, and perifollicular blood at various stages of the pig estrous cycle. Concentrations of P in peripheral blood, ovarian venous blood, follicular fluid, and perifollicular blood (blood from the vasculature surrounding the follicle) during the active luteal phase of gilts were 19.0 ± 2.4, 59.2 ± 12.7, and 3937 ± 710 ng/ml, respectively. Interestingly, the high concentration of P in perifollicular blood did not equilibrate with the follicular fluid and it appears that there is a blood barrier between the two. This level of P was significantly lower in the late luteal, follicular, and estrous stages. The follicular fluid in the follicular phase contained the highest concentrations of A (163 ± 37.9 ng/ml) of all the stages of follicular growth. During this stage the perifollicular blood also contained a concentration of A higher than that observed at any other stage of the estrous cycle. On the day of estrus the amounts of both A and T in the follicular fluid as well as in ovarian venous blood were at their lowest. Concentrations of T in perifollicular blood were higher in the luteal phase than in the follicular phase. The high levels of E_1 (22.94 ± 2.95 ng/ml) and E_2 (18.96 ± 1.80 ng/ml) in the follicular fluid during the follicular phase may be due to aromatization of A and T, which are also present in high concentrations in follicular fluid and are in contact with granulosa cells. On the day of estrus E_1 and E_2 in the follicular fluid were 7.42 ± 1.45 and 6.93 ng/ml, respectively, which may precede the onset of the preovulatory surge. The lower levels of E_1 and E_2 in perifollicular blood than in follicular fluid suggest that the main site of aromatization could be the granulosa cells in the follicles.

INTRODUCTION

The pig is an ideal animal model to study reproductive endocrinology and, in particular, to understand ovarian physiology. The ovarian morphology, tissue differentiation, and actions of individual cell types have been extensively studied. The ease of obtaining ovaries from abattoir facilitated the initial basic investigation of ovarian function, though the background of the gilts or sows were in question. However, availability of defined breeds, knowledge of their ages, nutrition, and any hormonal treatment and assessment of the estrous period made it easy to study carefully defined protocols of investigation. The pig is polyovular and the important limiting factor affecting sow productivity is prolificacy, which is defined as the number of viable piglets born per litter. Chinese Meishan farrow have an average of three to five more piglets per litter than the European breed White Composite. Other mixed breeds vary with a minimum of 12 to 20 piglets.[1,2] The ovulation rate is a major determinant of reproductive efficacy, which is genetically controlled within a particular breed. After recruitment of the primordial follicles, the preovulatory follicles are selected, which then become dominant and progress toward ovulation. Growth, maturation, and ovulation are dependent on endocrine and paracrine control. The sequential effect of follicle-stimulating hormone (FSH) and leutinizing hormone (LH) on the development of the follicles is controlled by a hypothalamic–pituitary–ovarian feedback mechanism. Binding of insulin to various follicular cells as well as the action of insulin-like growth factors IGF-I and IGF-II and their binding proteins,[3,4] such as inhibin and activin,[5] produced within the follicle exert metabolic actions directly or indirectly on the follicular cells and overall follicular growth. Follicular angiogenesis is promoted by vascular endothelial growth factor (VEGF), which is produced by the granulosa cells within the follicle. Steroids produced by interstitial, theca, and granulosa cells are distributed within and out of the ovary through the basement membrane and the follicular vasculature of the follicle to reach various organs to exert or promote metabolic actions.

Synthesis of various steroids in the ovary and their secretion into the circulation are a complex process because of the ovarian–

pituitary feedback system. The two-cell type theory of steroid synthesis in ovarian tissue postulating that the theca interna cells of the follicle produce mainly androgens and estrogens, while the luteinized granulosa cells secrete progestins[6] was suggested by Short in 1962, and it was based on steroid concentrations in the follicular fluid and luteal tissue. In the following year it was reported that equine corpora lutea have a low level of 17α-hydroxylase ($P450_{17\alpha}$) and 17α-hydroxyprogesterone-20-lyase ($P450_{c17}$) enzyme activity.[7] Thus, the large amount of progesterone (P) produced by the corpus luteum was not converted to C_{19} steroids within the luteal tissue. The theca cells of the Graafian follicle are able to produce P and contain all the necessary enzymes to convert P to androgens and estrogens.[7–9] The granulosa cells appear to have lower $P450_{c17}$ activity than theca cells but possess very active aromatase ($P450_{arom}$), which converts Δ^4-androstenedione (A) and testosterone (T) to estrogens.[10–12] When steroid synthesis by theca and granulosa cells in culture was studied, it was observed that the combined cell culture more efficiently synthesized estradiol-17β (E_2) than either of the cell types alone.[13–15]

From these *in vitro* studies and the data on steroid concentrations in follicular fluid at various stages of follicular growth, it is postulated that P, A, T, estrone (E_1), and E_2 are synthesized in different compartments of the ovary and that the ability of these different tissues to produce steroids changes during various stages of follicular growth. These compartments do not appear to be isolated and there appears to be an active exchange of steroids between different types of steroid-producing cells. Since the corpus luteum, stroma, and theca are vascularized, steroids produced by these cells would be readily mixed into the follicular circulation and may accumulate in the follicular fluid. There is sufficient evidence to indicate that substances in the follicular fluid constantly equilibrate with the ovarian blood,[6,16] although no correlation was found between the concentration of steroids in follicular fluid and the corresponding steroid level in peripheral plasma of the same pig during the estrous cycle.[17] Based on the observation that very high amounts of ovarian steroids were present in the follicular fluid of preovulatory follicles, it was theorized that follicular fluid serves as a storage for steroids, particularly E_2 and P, which are required by the uterus for implantation. In the present investigation P, A, T, E_1, and E_2 were measured in peripheral blood, ovarian venous blood, follicular fluid, and perifollicular blood during the entire estrous cycle of gilts; there is speculation as to whether they correlate and whether the active corpus luteum could be a source of progesterone to theca and granulosa cells for conversion into C_{19} and C_{18} steroids and serve as one of the regulators of steroidogenesis in the pig.

The quantitative determination of steroidogenic enzyme mRNAs and certain steroids in follicular tissue and follicular fluid was carried out during either the regumate or altrenogest-synchronized preovulatory period of follicular growth of the gilts.[18–20] Day 1 was considered the prefollicular phase, day 3 the early follicular phase, day 5 the mid-follicular phase, and day 7 the late follicular phase. It was concluded that the $P450_{arom}$ enzyme mRNA increased successively from day 1 to day 5, dropped significantly on day 7 to a level less than day 1, and correlated only partially with the E_2 in follicular fluid. A similar poor correlation was true for $P450_{17\alpha}$ mRNA to testosterone and cholesterol side chain cleavage ($P450_{scc}$) to progesterone. In animal husbandry when the pigs are grown for the meat industry, all animals are treated with progestational compound or progestational compound plus estrogenic compounds to arrest ovulation or continuation of cycling and also to increase their weight. By rules and regulations, steroid treatment is stopped at least 2 weeks before they are brought to abattoirs. Therefore ovaries collected at the abattoir have small, immature follicles of 2–5 mm or so, and the results of studies conducted on these ovaries could be different from studies conducted on naturally cycling gilts. In the cycling gilts after ovulation, days 3–5 are early luteal phase with active corpora lutea producing a large amount of progesterone. At this stage the surface of the ovary is covered with corpora lutea and the small immature follicles are situated among the corpora lutea in close proximity. It is reported that follicular fluid contains a large amount of progesterone,[21] which may not be produced by the follicular tissue, but may be accumulated from the vasculature of the corpora lutea. This progesterone may inhibit some enzyme activity, specifically $P450_{17\alpha}$ and $P450_{c17}$,[7] and at the same time it may act as a precursor for steroid-producing enzymes. Hence, in such situations the follicular steroid enzymatic mRNA may not correlate with steroids present in the follicular fluid of these small follicles, some of which may be destined to become atretic follicles.

VARIOUS BLOOD SAMPLES AND FOLLICULAR FLUID COLLECTION

Ovarian follicular fluid, perifollicular blood, and peripheral blood samples were collected from 40 gilts at the swine research farm at Ohio Agricultural Research and Development Center, Wooster, OH. Gilts 1–2 years of age were observed for regularity of their estrous cycles according to a method previously described[22] and only those having three consistent consecutive estrous cycles of 19–21 days were chosen for the study. The first day of estrous behavior was designated day 0 of the cycle. For each gilt on the appropriate day of the estrous cycle, surgical anesthesia was induced with 1.5–2 g of sodium thiamylal (10% solution) intravenously via an ear vein, and surgical anesthesia was maintained by methoxyflurane and oxygen inhalation with a closed circuit anesthesia machine. First, a 20-ml peripheral blood sample was withdrawn from the anterior vena cava and allowed to clot. Laparotomy was performed and the ovaries were exposed. Follicular fluid from an individual "healthy-looking" follicle (a follicle full of fluid, reddish in color, and transparent without white deposit in it) was withdrawn with a tuberculin syringe fitted with a 26-gauge hypodermic needle until the follicle had completely collapsed. Then, within a few seconds, the empty follicle was filled with blood, which was then withdrawn over a 1-min period with 1-min intervals between samples. These samples were considered to be perifollicular blood.[17,23] Five such consecutive samples of perifollicular blood were collected. Sometimes external pressure was applied on the surrounding side of the follicle to fill the empty antrum with blood. Follicular fluid and perifollicular blood samples from two or three follicles were collected from both ovaries. Blood samples less than 25 μl were discarded. The remaining follicles on each ovary were aspirated, and that fluid was pooled for the right or left ovary. The volume of the follicular fluid or blood sample was measured immediately by a capillary pipette or by a narrow graduated tube. The individual blood volume varied from 30 μl to 600 μl and steroids were measured in the whole blood of perifollicular blood samples. Fluid from nonovulated follicular cysts of the previous estrous cycle were not

included in the pool of follicular fluid of an individual ovary, but were processed separately. The follicles up to day 5 of the estrous cycle were too small in size (<2 mm in diameter) to permit follicular fluid collection as individual samples from a single follicle or perifollicular blood, hence only samples from day 5 to day 21 were included in these studies.

STEROID QUANTITATION

The various steroids were measured by specific radioimmunoassay (RIA). The following radioactive steroids were obtained from New England Nuclear, Boston, MA, as reference steroids and their purity was tested by paper chromatography before use: [1,2,6,7-^{3}H]progesterone (114 Ci/mmol), Δ^4-[1,2–^{3}H]androstenedione (60 Ci/mmol), [1,2,6,7-^{3}H]testosterone (93.9 Ci/mmol), [2,4,6,7-^{3}H]estrone (95.5 Ci/mmol), and [2,4,6,7-^{3}H]estradiol-17β (90 Ci/mmol). Steroids with 1% or more impurities were further purified by thin-layer chromatography. The radio inert steroids for references were obtained from Steraloids (Wilten, NH) and Sigma Chemical Company (St. Louis, MO), and were crystallized from organic solvents before being used as standards for the radioimmunoassays; their purity was checked by melting point determination and/or absorption spectra. Stock standard solutions were made by dissolving weighed amounts of steroids in methanol and the concentrations were confirmed by ultraviolet (UV) absorption.

The steroids were measured using the double antibody procedures for steroid RIA.[24,25] Antibodies used to measure P, A, and E_2 were highly specific. For example, the highest cross-reactivity of 20α-hydroxyprogesterone (OHP) with antiprogesterone antibody was only <0.001% and 17α-OHP did not cross-react with this antiserum. The cross-reaction of E_1 with the anti-E_2 antibody was <1.0% and estriol cross-reacted at 0.1%. The anti-A antibody was very specific and cross-reacted at <0.01% with T. The anti-T antibody cross-reacted at 2% with dihydrotestosterone (DHT) and 0.3% and 0.2% with androstan-3β,17-diol (3β-A-diol) and androstan-3α,17-diol (3α-A-diol), respectively. The E_1 antibody cross-reacted about 1% with E_2 compared to E_1 and did not cross-react with estriol. The follicular fluid samples were extracted with diethyl ether and P, A, and E_2 were fractionated by paper chromatography.[25] The intraassay coefficient of variation ranged between 5% and 14% depending on the concentration of steroids in the samples. The interassay coefficients of variation for all the various steroids were >12.5%.

Student's *t* test was used for statistical comparison of values of different steroids for different sera and follicular fluid at various stages of the estrous cycle. Two-tailed *p* was calculated using Graphpad Instate software to compare differences between the groups; differences were considered statistically significant at $p < 0.05$. The results are expressed as mean ± standard error (SE).

STEROIDS IN PERIPHERAL BLOOD, OVARIAN VENOUS BLOOD, FOLLICULAR FLUID, AND PERIFOLLICULAR BLOOD DURING THE ESTROUS CYCLE OF GILTS

PROGESTERONE Most breeds of female pigs have an estrous cycle of 20–21 days with a short follicular phase of 3 days and a long luteal phase. The luteal phase is from day 1 to day 15 of the estrous cycle and the late luteal phase overlaps the early follicular phase on day 16–17. The follicular phase lasts for only 3–4 days and estrus is on day 20 or 21.[22] The concentration of P in peripheral blood serum, ovarian venous blood serum, follicular fluid, and perifollicular blood on various days of the estrous cycle is shown in Figure 45–1A. The secretory activity of the corpora lutea of the ovary could be judged from the concentration of P in ovarian venous blood and in peripheral blood. In the active luteal phase (days 5–12) the peripheral blood serum contained 19.0 ± 2.4 ng/ml, which decreased to 7.9 ± 1.3 ng/ml in the late luteal phase and was further significantly reduced to 2.5 ± 0.7 ng/ml ($p < 0.01$) during the follicular phase. A similar pattern of P concentration was observed in ovarian venous blood. Ovarian secretion of P was higher during the luteal phase, 97.8 ± 12.0 ng/ml, but significantly declined to 4.0 ± 0.7 ng/ml ($p < 0.001$) during the follicular phase, then increased to 10.3 ± 2.0 on the day of estrus, which suggests that the granulosa cells could have started luteinization prior to ovulation. Interestingly, follicular fluid on days 5–12 of the estrous cycle contained high amounts of P, though the follicles were small (2–3 mm) in size. In the active luteal phase, between 5 and 12 days of the estrous cycle, after the removal of follicular fluid from the follicle antrum, in the first minute collection of perifollicular blood, the concentration of P was 3937.2 ± 710.6 ng/ml and did not vary significantly in the subsequent four blood samples collected at 1 min intervals over a period of 8 min (Figure 45–1B). It appears that such a high amount of the progesterone is produced in the adjacent active corpora lutea, mixes with the venous blood, and enters the follicular antrum. On days 14–15 of the estrous cycle the concentration of perifollicular blood P was lower (848.0 ± 205.7 ng/ml) and did not vary significantly in the subsequent four blood samples obtained at 1 min intervals over a period of 8 min. In the late luteal phase, as well as in the follicular phase, the P content further declined. On the day of estrus, when the follicle size was about 0.8–1.2 cm, though the follicular fluid contained a high concentration of P, the perifollicular blood level of P was at its lowest (Figure 45–1B).

Δ^4-ADROSTENEDIONE The concentrations of A in peripheral blood serum, ovarian venous blood serum, follicular fluid, and perifollicular blood samples are given in Figure 45–2A. The amount of circulating A during days 5–12, i.e., during the active luteal phase, was 2.5 ± 0.3 ng/ml, which was similar to that in the late luteal phase. It decreased slightly during the follicular phase and on the day of estrus. In the ovarian venous blood serum, the concentration of A in the early luteal phase was 6.0 ± 0.7 ng/ml and rose to 16.1 ± 3.4 ng/ml at the late luteal–early follicular phase; this venous concentration of A did not change during the short follicular phase and significantly declined at estrus. Follicular fluid from small follicles during the active luteal phase contained an average concentration of 81.0 ± 11.0 ng/ml of A, which further declined in the late luteal or early follicular phase to 29.2 ± 3.4 ng/ml. During the active follicular phase when the follicles are large in size (0.8 ± 1.2 cm), the concentration of A in the follicular fluid rose to 163.6 ± 37.9 ng/ml and varied considerably among animals. The high concentration may be due to the presence of a large number of active theca cells surrounding the follicle, and as estrus approached, greater amounts of A were converted to E_1 and E_2. Therefore, the amount of A in the follicular fluid was reduced significantly on the day of estrus.

During the active luteal phase when the follicles were small and corpora lutea were proliferative and highly vascularized, the concentration of A in the perifollicular blood was 88.5 ± 16.3 ng/ml, but successively declined in the subsequent four 1 min blood

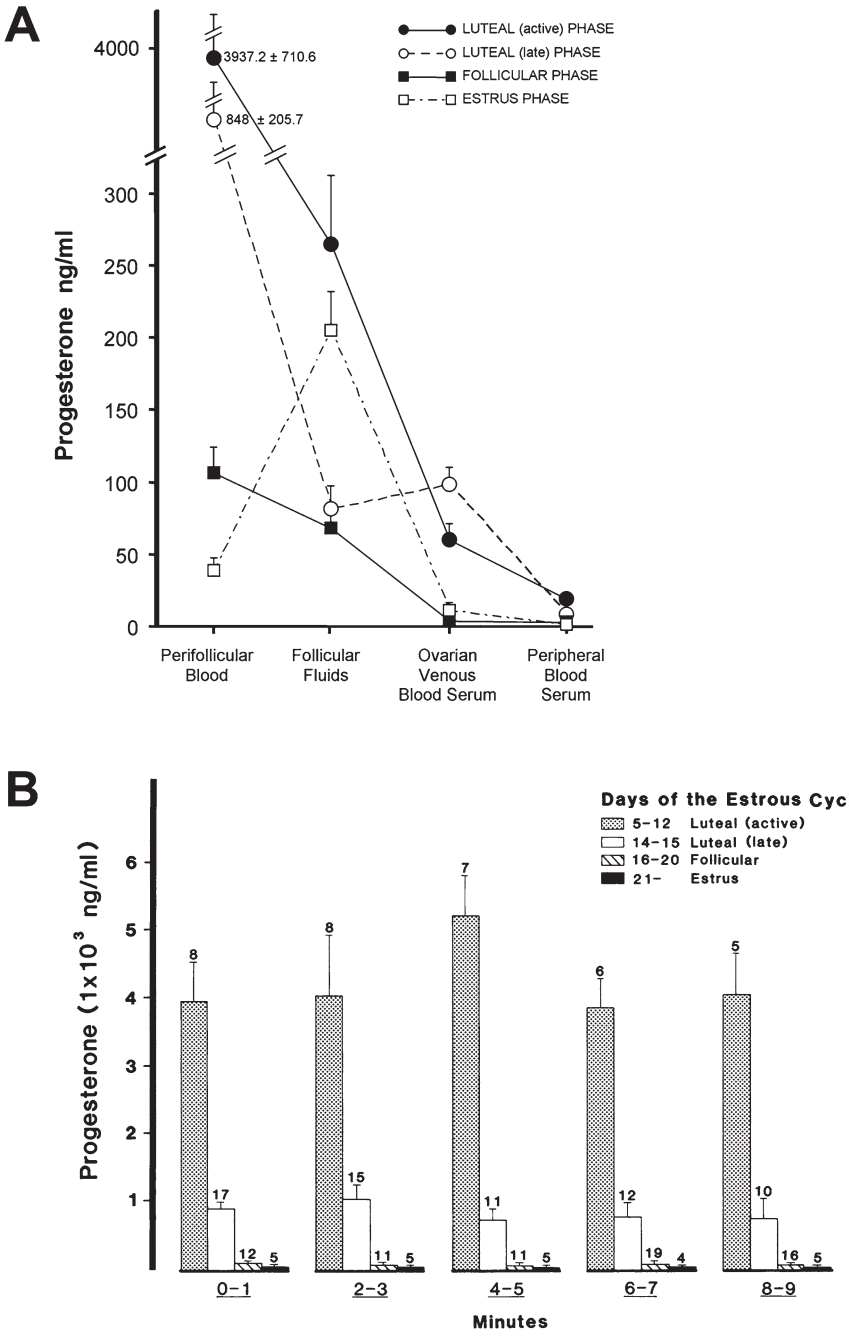

Figure 45–1. Progesterone. (A) Concentration of P in the peripheral blood, ovarian venous blood, follicular fluid, and perifollicular blood in various phases of the estrous cycle of pig. In the luteal (active) and luteal (late) phases the concentration of P in perifollicular blood was 3937.2 ± 710.6 (SE) and 848 ± 205.7 (SE) ng/ml, indicating that the source was the corpora lutea. Even in follicular fluid in the active luteal phase it was 264.5 ± 48.0 (SE) ng/ml, which appears to be from the corpora lutea. At this stage, the follicles are 2–3 mm in size and contain a small number of theca and granulosa cells. In the follicular phase, the concentration of P in the follicular fluid was 67.9 ± 16.9 (SE) ng/ml, which could be synthesized within the follicle. In ovarian venous blood, the concentration of P was then <97.8 ± 12.0 (SE) ng/ml in the luteal phase and peripheral blood contained <10.3 ± 2.0 (SE) ng/ml. (B) The perifollicular blood samples were drawn from the follicle continuously for 1 min at 1 min intervals. In the active luteal phase, the concentration of P was 3937.2 ± 710.6 (SE) ng/ml and remained at high levels in all subsequent four samples. The concentration of P was reduced to 848.0 ± 205.7 (SE) ng/ml and remained constant in all the remaining samples. The concentration of P decreased to <100 mg/ml in the follicular phase and was only <28.4 ± 7.2 (SE) ng/ml during estrus. The number above each column indicates the number of animals used to collect the perifollicular blood samples.

samples. However, when the follicular size increased during the late luteal phase the A content of perifollicular blood did not change significantly in five 1 min samples drawn consecutively (Figure 45–2B). However, on the day of estrus the concentration of A in the perifollicular blood was the lowest. This phenomenon could be due to the beginning of the process of luteinization of the theca cells surrounding the follicle.

TESTOSTERONE The concentration of T in the peripheral blood of mature gilts was approximately one-tenth the concentration of A, the highest being at the time of estrus and the lowest during the late luteal phase. During the estrous cycle, the overall concentration of T in peripheral blood serum was 0.10 ± 0.01 ng/ml on days 14–15, and on the day of estrus it was 0.51 ± 0.13 ng/ml. The concentration of T in ovarian venous blood did not vary significantly during the entire estrous cycle; however, a higher level of T was observed during the luteal phase (5–12 and 14–15 days of the estrous cycle). Similar differences in the concentration of T were also observed in the follicular fluid during the estrous cycle, the highest concentration (17.81 ± 3.2 ng/ml), occurring during days 5–12 and the lowest (6.78 ± 0.64 ng/ml) at the time of estrus (Figure 45–3A). The concentration of T in all five samples of perifollicular blood was approximately the same on days 5–17 of the estrous cycle and decreased at estrus. The pattern of T concentrations was similar to that of A except for the follicular fluid (Figure 45–3B).

ESTRONE The concentration of E_1 in peripheral blood serum in the active luteal phase of the estrous cycle was 0.018 ± 0.006 ng/ml, but increased through the late luteal and early follicular phase

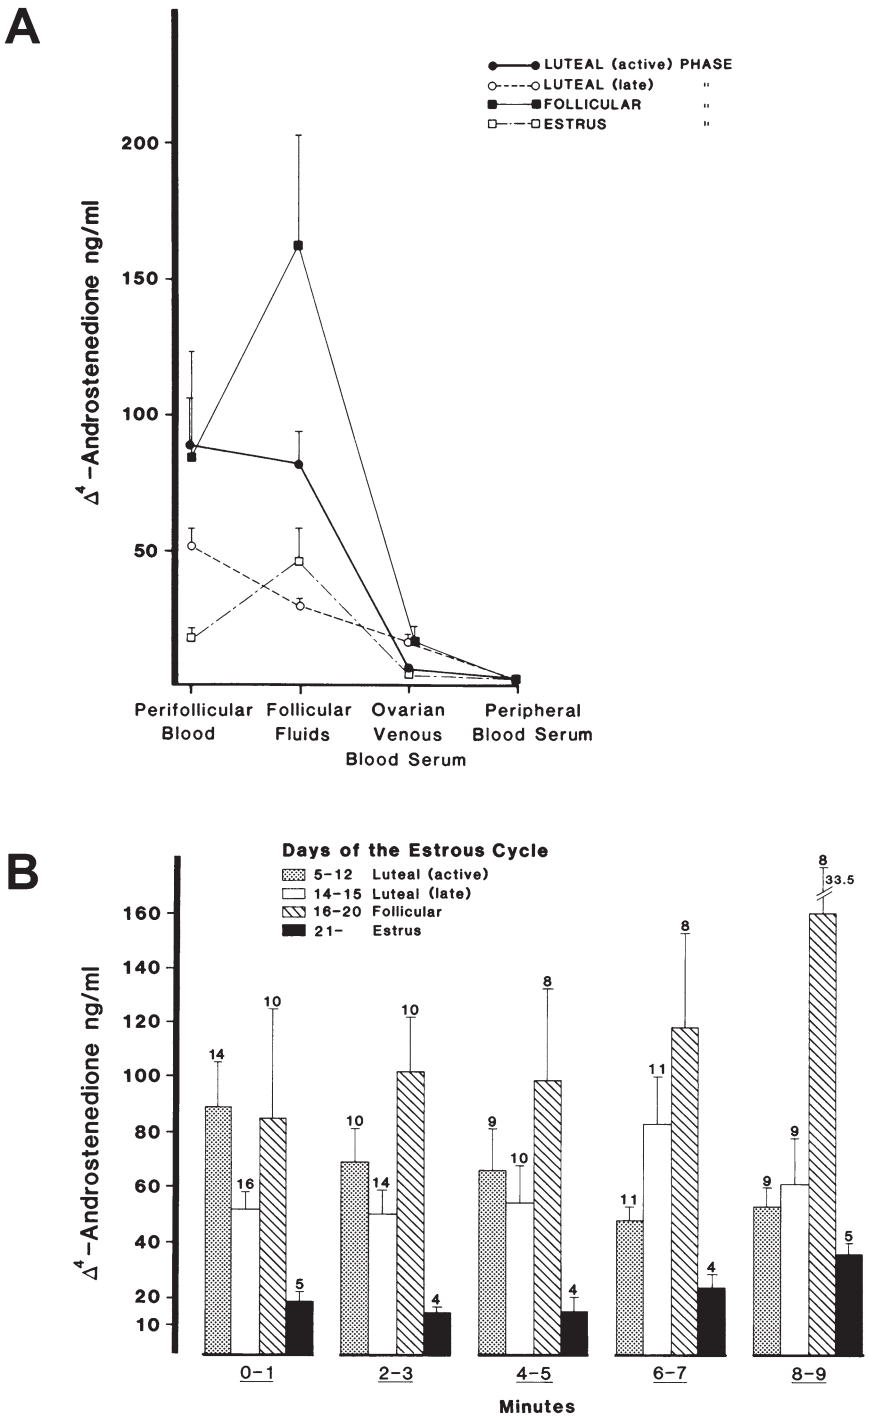

Figure 45–2. Δ^4-Androstenedione. (A) Concentration of A in the perifollicular blood, follicular fluid, ovarian venous blood serum, and peripheral blood serum during the estrous cycle of pig. Follicular fluid in the follicular phase contained 163.6 ± 37.9 (SE) ng/ml A, which did not equilibrate with ovarian venous blood; its concentration in ovarian venous blood serum was only 16.0 ± 6.8 (SE) ng/ml. The concentration in the peripheral blood serum was <1.8 ± 0.3 (SE) ng/ml. The presence of A in perifollicular blood drawn from the follicle after removal of follicular fluid suggests that the perifollicular blood drawn from the follicle may secrete A, which is contaminated in perifollicular blood, or it may be partially secreted by the active luteal tissue. (B) Concentration of A in perifollicular blood during different days of the estrous cycle in pig. The concentration of A increased gradually from 84.3 ± 4.0 (SE) ng/ml to the fifth sample of the perifollicular blood reaching 159.6 ± 33.1 (SE) ng/ml, suggesting that in the follicular phase the perifollicular blood mainly comes from the follicular vasculature. Since the perifollicular blood in both active and late luteal phases contained A, A must also be the product of the corpora lutea. The number above each column indicates the number of animals used to collect the perifollicular blood samples.

(Figure 45–4A). The amount of E_1 in the ovarian venous blood serum was about 10 times higher than in peripheral blood and did not significantly change during the luteal or early follicular phases of the estrous cycle. On the day of estrus just prior to ovulation, the concentration of E_1, similar to E_2, was low in the ovarian venous blood, follicular fluid, and perifollicular blood (Figure 45–4A and B). The concentration of E_1 in the follicular fluid remained constant during the luteal and follicular phases. The E_1 content in perifollicular blood was lower during the active luteal phase (days 5–12) than during the late luteal or early follicular phases and decreased to its lowest level on the day of estrus (Figure 45–4B).

ESTRADIOL-17β The overall change in the pattern of E_2 concentration in peripheral blood serum did not correspond to the changes of E_2 levels in ovarian venous blood serum or the E_2 content of follicular fluid. The peripheral blood concentration of E_2 varied between 0.09 ± 0.01 ng/ml and 0.31 ± 18 ng/ml throughout the estrous cycle of the gilts, and was higher than E_1. The concentration of E_2 in ovarian venous blood serum in the early follicular phase was higher than that in the luteal phase and fell to its lowest level (0.28 ± 0.1 ng/ml) on the day of estrus (Figure 45–5A). Similarly, the concentration of E_2 in the follicular fluid varied between 13.04 ± 3.07 and 21.29 ± 4.18 ng/ml during the estrous cycle and significantly decreased to 6.93 ng/ml on the day

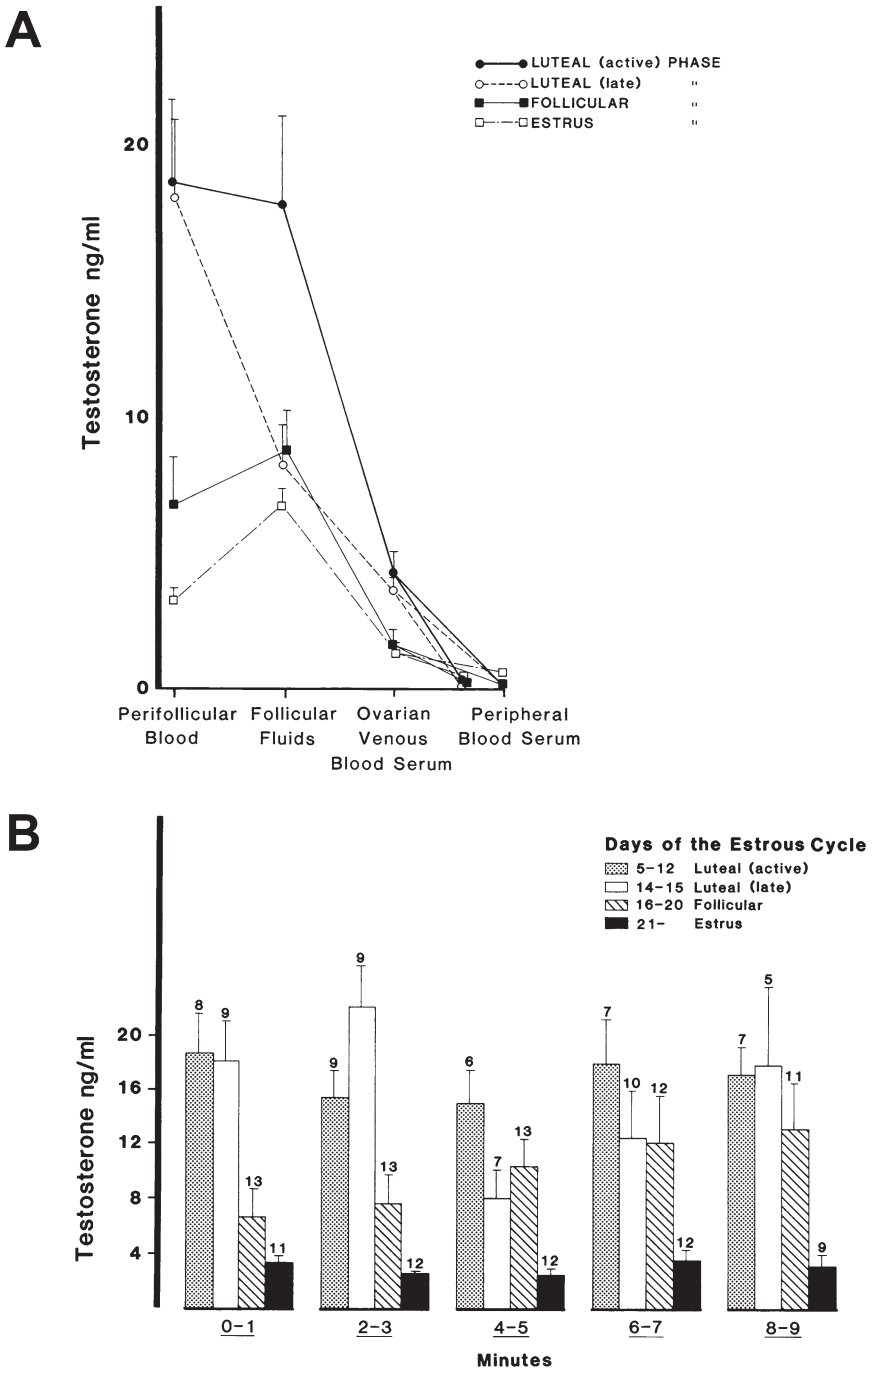

Figure 45–3. Testosterone. (A) Concentration of T in the perifollicular blood, follicular fluid, ovarian venous blood serum, and peripheral blood serum. The overall concentration of T in the perifollicular blood, follicular fluid, and ovarian venous blood serum is approximately 10% of the concentration of A in these fluids. This suggests that A is a preferred substrate for estrogen synthesis in both follicle and luteal tissue. However, the presence of T in the perifollicular blood in amounts such as 18.63 ± 3.03 (SE) ng/ml and 18.10 ± 2.84 (SE) ng/ml in luteal active and late phases indicates that T is also synthesized in luteal tissue, which may serve as a substrate for the $P450_{arom}$ enzyme. (B) Concentration of T in the perifollicular blood in various stages of the estrous cycle of pig. The amount of T in the first minute samples of perifollicular blood varied from 18.63 ± 3.03 (SE) ng/ml in the early luteal phase to 6.78 ± 0.64 (SE) ng/ml in the estrous phase, and it continued to be present in all the second, third, fourth, and fifth samples of perifollicular blood. This suggests that the source of testosterone is from both luteal tissue and the follicular vasculature. In follicular and estrous phases, its main source must be from the follicular vasculature, probably from theca cells and interstitial tissue. The number above each column indicates the number of animals used to collect the perifollicular blood samples.

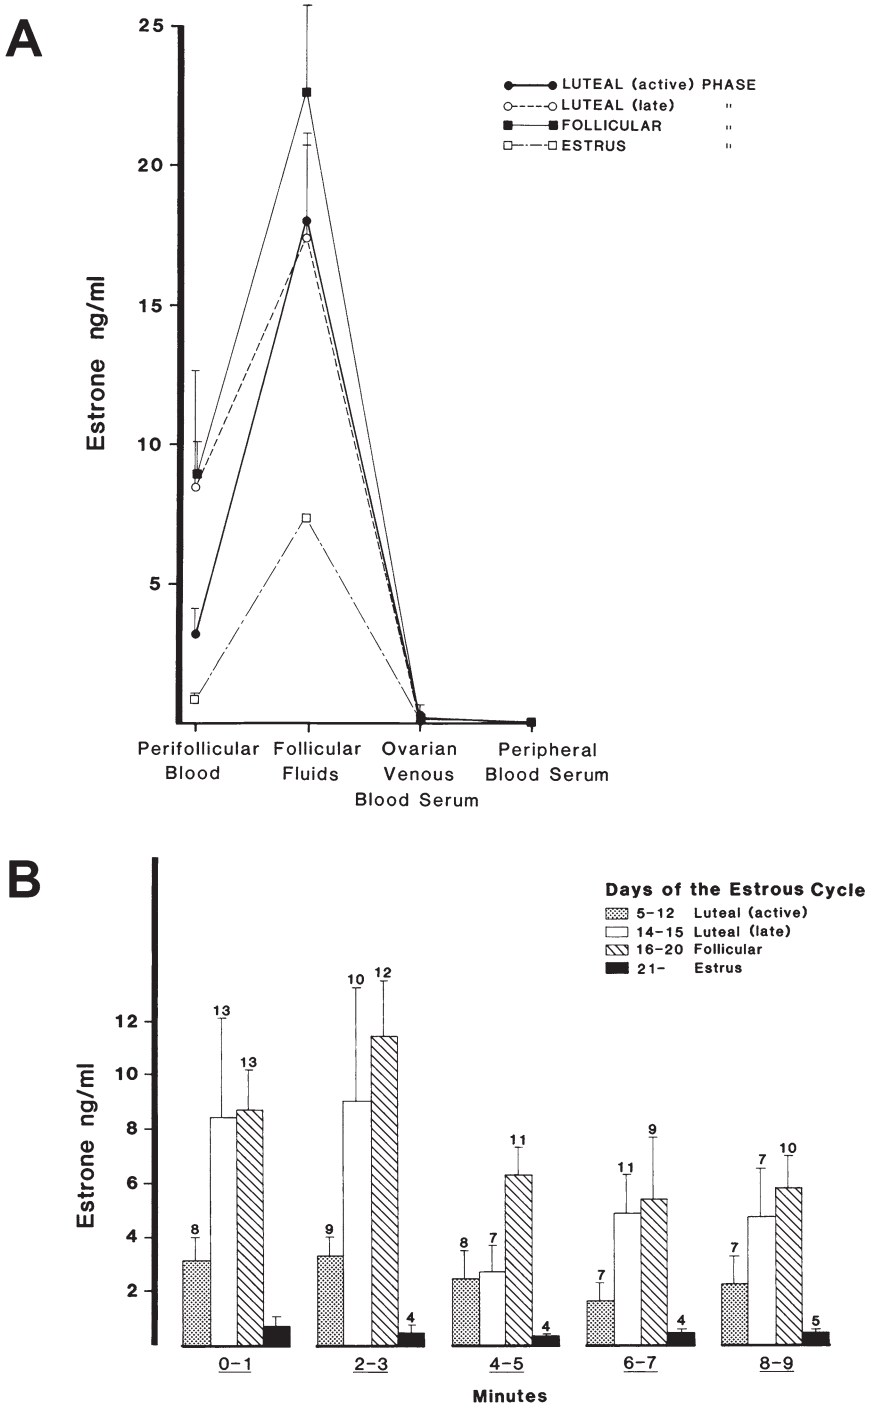

Figure 45–4. Estrone. (A) Concentration of E_1 in the perifollicular blood, follicular fluid, ovarian venous blood serum, and peripheral blood serum during the various stages of the estrous cycle in pig. Since E_1 is synthesized mainly by the granulosa and theca cells, the highest concentrations were observed in the follicular fluid of all the phases of the estrous cycle. The amount of E_1 in the follicular phase was 22.94 ± 3.0 (SE) ng/ml and in the ovarian venous blood serum it was only 0.23 ± 0.11(SE) ng/ml. In the peripheral blood serum of all the estrous cycle phases the concentrations of E_1 were <0.28 ± 0.01 (SE) ng/ml. Its presence in the perifollicular blood during the late luteal and follicular phases, 8.44 ± 4.21 (SE) and 8.68 ± 1.50 (SE) ng/ml, respectively, suggests that its origin is mainly from the follicular vasculature. (B) Concentrations of E_1 in five consecutive perifollicular blood samples collected for 1 min at 1 min intervals during each phase of the estrous cycle. High concentrations of E_1 were present in the perifollicular blood of the late luteal and follicular phases, indicating that E_1 is synthesized by both luteal and follicular granulosa and theca cells. The number above each column indicates the number of animals used to collect the perifollicular blood samples.

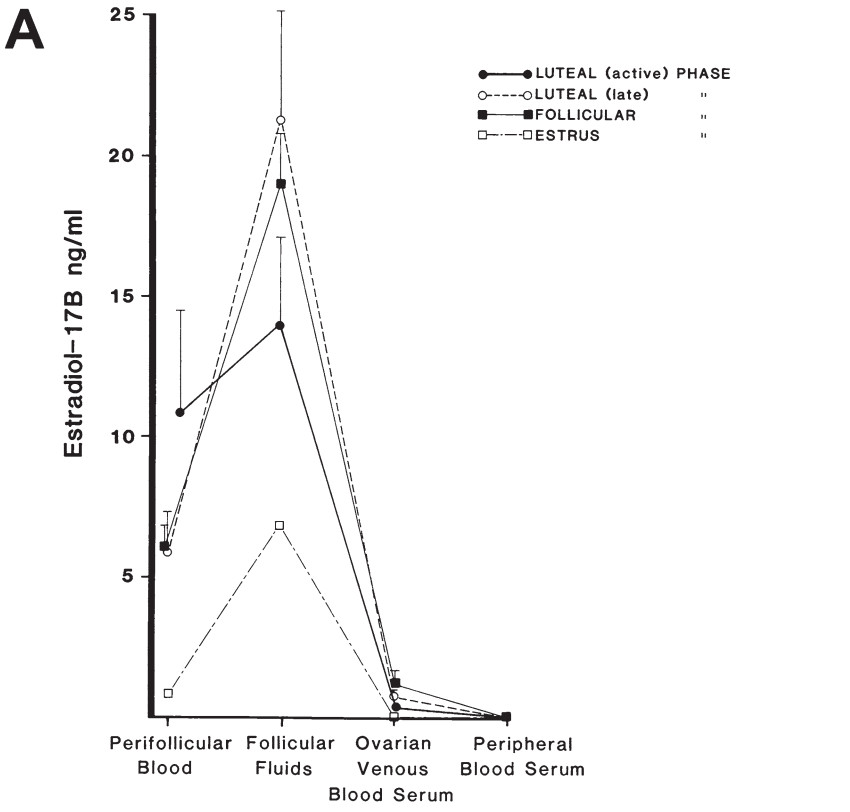

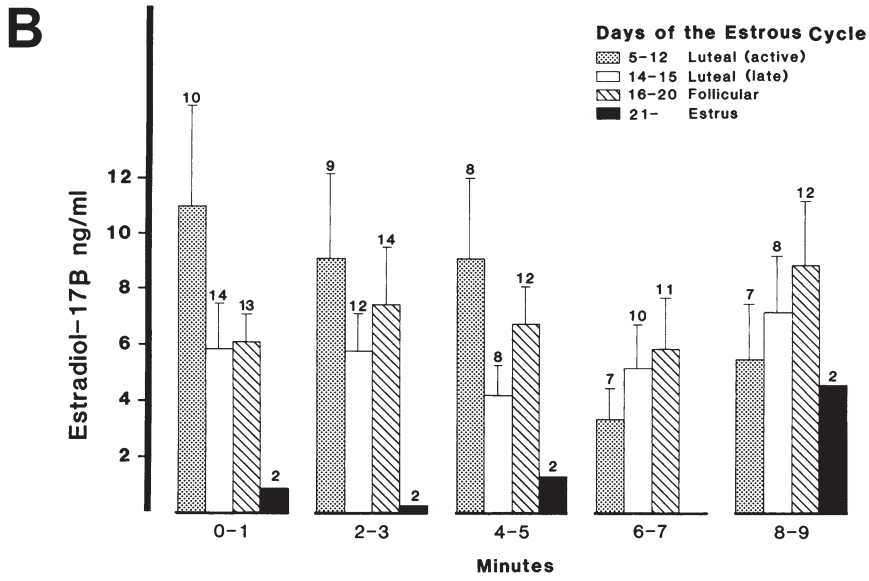

Figure 45–5. Estradiol-17β. (A) Concentration of E_2 in the perifollicular blood, follicular fluid, ovarian venous blood serum, and peripheral blood serum. The amount of E_2 [21.29 ± 4.18 (SE), n = 24] in the follicular fluid of the late luteal phase was not significantly different from the amount of E_2 [18.96 ± 1.80 (SE), n = 21] in the follicular fluid of the follicular phase (p = 0.63). This may be due to the growing follicles in the late luteal phase, in which both the theca and granulosa cells are actively synthesizing E_2. The concentrations of E_2 in the perifollicular blood of both the late luteal and follicular phases were nearly equal, suggesting the perifollicular blood may be mainly from the follicular vasculature. The amount of E_2 in ovarian venous blood was <1.2 ng/ml in all phases of the estrous cycle. (B) E_2 was determined in perifollicular blood samples drawn for 1 min with 1 min intervals in all the four phases, as described for the estrous cycle of pig. The first perifollicular blood sample of the active luteal phase had 10.88 ± 3.6 (SE) ng/ml of E_2, indicating that a part of these values may be contributed by the active luteal tissue in addition to theca and granulosa cells of the follicle. During the estrous phase, the values of E_2 were <1.0 ng/ml, except for the fifth minute sample which was 4.52 ng/ml. The number above each column indicates the number of animals used to collect the perifollicular blood samples.

of estrus. In perifollicular blood E_2 concentrations during the luteal and early follicular phases varied between 3.31 ± 1.12 ng/ml and 10.88 ± 3.59 ng/ml and there was no significant change in the concentration of E_2 in the samples taken at 1 min intervals; however, at days 5–12 of the estrous cycle a sequential reduction from 10.88 ± 3.59 to 3.31 ± 1.12 ng/ml was observed from the first to the fourth blood sample (Figure 45–5B). Such a significant variation was not observed during the early follicular phase. The concentration of E_2 in perifollicular blood was significantly reduced on the day of estrus and did not vary during the time of collection of five consecutive samples of perifollicular blood (Figure 45–5B).

DISCUSSION

The presence of various steroids including progestins, androgens, and estrogens in follicular fluid has been demonstrated by a number of investigators.[26] In these studies the follicles were obtained from mares, cows, sows, and ewes, and most of the time

they were collected at slaughterhouses. It has been shown that the data obtained from slaughterhouse material do not agree with those obtained with follicular fluid at the time of laparotomy of sows with well-monitored estrous cycles.[17] Usually, these studies measured fewer steroids than measured in the present report. It is still not known if the various steroids secreted by the ovary are always synthesized by individual cell types or whether a particular precursor is synthesized in one compartment and transferred to another for further metabolism.

Is P present in the follicular fluid in the luteal phase synthesized by the granulosa and theca cells surrounding the follicular fluid, or is it also a fraction of a large quantity of P synthesized by the corpus luteum? The present data reveal that the follicular fluid collected from follicles at days 5–12 of the estrous cycle contained higher concentrations of P than did follicular fluid collected on days 14–15, days 16–20, or on the day of estrus. The peripheral blood and ovarian venous blood levels of P at days 5–12 were also higher than at any time during the estrous cycle. Interestingly, all five of the consecutive perifollicular blood samples collected during the active luteal phase when the corpora lutea are proliferative and highly vascularized (5–12 days of the estrous cycle) contained very high concentrations of P, which varied between 3.9 and 5.2 μg/ml. The concentration of P in perifollicular blood did not decrease during the 8-min withdrawal of perifollicular blood, suggesting that P may be synthesized continuously at a high rate and secreted into the blood. It has been shown that in the newly formed corpus luteum of the ewe P values reach about 2 μg /ml of luteal fluid.[27] The P values in perifollicular blood of the gilt in the active luteal phase (days 5–12) appear to be slightly higher than those in the luteal fluid of the ewe. These high values would suggest that in perifollicular blood P is produced by the corpora lutea. If the ovarian blood flow in the luteal phase is assumed to be similar to the ewe, approximately 20 ml/min,[28] the production rate of P by the ovary at the peak activity of the corpora lutea could be approximately 4.6 mg/h. However, this value may be far from accurate as the blood volume withdrawn per minute in the present study varied greatly, and the first of the five consecutive samples of perifollicular blood drawn is most likely contaminated with follicular fluid.

Second, if the steroids in sample 4 or 5 had been lower than in earlier samples, it could be assumed that the steroids in the blood had been from intracellular spaces and not from an active secretory process. The concentrations of P in all five consecutive samples were similar, which suggested that P in the perifollicular blood is likely to be a continuous secretory process (Figure 45–1B.) The concentration of P observed during the active stage of the corpus luteum fell by about 20% on days 14 and 15 of late luteal phase of the estrous cycle, indicating that the corpus luteum at this stage was less active in the synthesis of P; it appears that P in perifollicular blood was still from the luteal tissue. The level in perifollicular blood decreased during the follicular phase when the luteal tissue was degenerated and most of the P must have been secreted by theca and mainly by the granulosa cells. Ovarian venous blood, peripheral blood, and follicular fluid during the follicular phase also contained very low values compared to the concentration of P in these fluids during the luteal phase. This suggests that theca cells are capable of producing and secreting low levels of P. It is interesting that the P content in the follicular fluid on the day of estrus had sharply increased from its lowest level, but this was not true for P in the perifollicular blood. All the ovarian steroid concentrations declined to their lowest values just prior to ovulation. It is not known whether this phenomenon is due to a sudden increase in the follicular fluid volume so that the contents of the follicular fluid are diluted, or whether the cellular composition of the follicle is in the process of changing to new types of cells with decreased steroid output during the transitory phase, or if there is a temporal downregulated response of the cells to elevated, cyclic surges of gonadotropins. The luteal tissue has lower $P450_{17\alpha}$ and $P450_{c17}$ activity compared to theca cells.[11] These enzymatic changes could explain the lower concentration of A, T, E_1, and E_2, but the drop in concentration of P in estrus remains to be explained.

The role of P in the control of ovarian follicular growth and development remains unclear. It was observed that exogenously administered P to 27-day-old rats increased the human chorionic gonadotropin (hCG) response to E_2 accumulation and aromatase activity in small antral follicles and can stimulate the growth of these follicles to the preovulatory stage in intact prepubertal rats.[29] Since the theca and granulosa cells of antral follicles have not developed the receptors for LH and FSH in sufficient number, P may serve as a precursor for C_{19} and C_{18} steroids and may not act as a direct stimulant to steroidogenesis or follicular growth. On the other hand, it has been shown that P inhibits $P450_{c17}$ enzymes in rat testicular homogenates, but may not greatly reduce the formation of C_{19} because P itself is metabolized to form C_{19} steroids by the action of the $P450_{17\alpha}$ and $P450_{c17}$ enzyme system without accumulating 17α-OHP.[11] The synthetic P analog (R5020) inhibited the FSH binding to granulosa cells and estrogen synthesis was reduced.[30] It was demonstrated that the reduction in E_2 synthesis due to R5020 was not the result of an inhibitory effect of R5020 on the aromatase enzyme but the result of an inhibition of the action of FSH on granulosa cells. It was suggested that R5020 and P inhibited the binding of FSH to granulosa cells by impairing the receptor sites for FSH. The actual mechanism of the reduction of FSH receptor sites is not explained. Furthermore, it was observed that due to the reduction of FSH receptor sites on granulosa cells, induction of the receptors for LH/hCG was inhibited. This effect is specific to P because 17α-OHP and 20α-OHP had no effect on FSH binding to granulosa cells or induction of the LH/hCG receptor.[31] This may be why estrogen synthesis is reduced in the antral follicle due to a high concentration of P that seeps from an adjacent corpus luteum resulting in inhibition of growth.

Attempts have been made to explain the inhibitory effect of P on folliculogenesis in the monkey by luteectomy in one ovary, thereby raising FSH secretion, and by supplying exogenous P. It was observed that the monkeys that did not receive P had an expected LH surge at day 14 ± 0.8 after luteectomy. In contrast, in monkeys implanted with Silastic capsules containing P for 10 days, the LH surge occurred on day 25 ± 2.7 after luteectomy and when these capsules were removed, they ovulated on day 14 ± 2.7. These observations suggest that P has a regulatory action on folliculogenesis and on the maturation of follicles.[32] Exogenous administration of 17α-OHP after luteectomy did not have any effect on the day of LH surge or ovulation, indicating that the delay of LH surge or follicular growth was specifically due to P. The average concentration of A in peripheral blood ranged between 1.6 and 2.5 ng/ml and did not show significant changes during the estrous cycle, though a trend for slightly higher values is shown during the luteal phase (Figure 45–3A). The ovarian

venous blood and peripheral blood levels of A do not show a close correlation. This could be due to a significant amount of A secretion by the adrenal cortex. Such findings were also previously reported.[17]

The follicular fluid concentration of A showed two significant peaks, one during the active luteal phase (days 5–12) and the other at the follicular phase (days 16–20), and the level of A was much higher during the follicular than the luteal phase. The values of A were lower during the late luteal phase and also on the day of estrus (Figure 45–2). In another study it was observed that in the cycling pig during early and late estrus the range of concentration of E_2 was 6–848 ng/ml, of A was 7–1001 ng/ml, of T was 1–272 ng/ml, and of P was 69–612 ng/ml in the follicular fluid, which suggested that the concentrations of E_2, A, and T in the follicular fluid were correlated significantly with the concentration of LH and FSH in circulating blood serum, but P was negatively correlated with other steroids.[33] The decrease in these steroid concentrations in the follicular fluid was associated with the reduced expression of $P450_{c17}$ in theca cells and reduced expression of $P450_{arom}$ in theca and granulosa cells of the follicle.

During the follicular phase, if it extends from day 16 to day 21, the concentrations of E_2 and T were higher on day 20 than on day 21, but the concentration of P was 497.2 ± 175.8 ng/ml on day 21. This high concentration of P could be the result of the theca and granulosa cells having started luteinization just prior to ovulation. The mean $P450_{arom}$ activity (ng E_2/2 h/follicle) was higher on day 16 (7.3) and day 18 (6.2) than on day 20 (2.6) and day 21 (0.2), suggesting that the granulosa cells were becoming luteinized by day 21.[34] In another study, ovaries were collected in a local abattoir and assigned to functional stages of the estrous cycle by checking for corpora hemorrhagica, corpora lutea, corpora albicantia, and developing follicles and by determining their size, color, and number. The luteal and follicular phases were each subdivided into early, mid, and late stages. It was not determined whether the sows were cycling normally. Steroids were measured in the combined follicular fluid of two follicles of the same ovary. Androgens and estrogens were at their lowest level during mid and late luteal phases, whereas progesterone was about 250 ng/ml of follicular fluid. All the steroids were at their highest level during late follicular phase; P was about 550 ng/ml, A was about 375 ng/ml, T was about 100 ng/ml, and E_1 and E_2 were about 80 and 200 ng/ml, respectively. These steroids decreased to 10% or less during the follicular ovulatory stage.[35]

When P, A, and E_2 were measured in the follicular fluid of cycling pigs in nonatretic follicles during the luteal phase, P was about 200 ng/ml in the preovulatory follicle on day 7, which decreased gradually to 100 ng/ml on day 13. The A and E_2 values were also high on day 7 and decreased to their lowest values on day 13. The high concentration of P in the follicular fluid of nonatretic follicles on day 7 may be difficult to attribute to steroid-producing theca, interstitial, and granulosa cells.[36] Furthermore, in altrenogest-treated noncycling pigs, the 3β-hydroxysteroid dehydrogenase in the follicular tissue at day 7 was below detectable levels.[20] These studies indicate that P must be entering the follicle from the perifollicular blood of the surrounding vasculature. The higher levels of A and E_2 in the follicular fluid on day 7 could be synthesized by the active theca and granulosa cells. The levels of A in the follicular fluid of women vary during the menstrual cycle.[37] The high levels of A in the follicular fluid during these stages of follicular growth might serve as a precursor for synthesis of E_1 and E_2. The perifollicular concentration of A was significantly higher during the follicular phase than during other stages of the estrous cycle. At this period the vascularized theca cells are active in producing A, which appears in perifollicular blood and in follicular fluid. Thus, it reaches the granulosa cell where aromatization to E_2 can occur. The high concentration of A in perifollicular blood also suggests that A is a more important C_{19} steroid precursor than T for the synthesis of estrogens. Diffusion of A from the vasculature of theca and interstitial tissue of the follicle to perifollicular blood may also take place; however, granulosa cells have a lower $P450_{c17}$ enzyme activity than do theca cells.[11,38]

Although conclusive data regarding the rate of transmission of steroids from blood to follicle and from follicular fluid into circulating blood are not available, based on the transfer of radioactive steroids injected into the follicle, the passage of A from the follicle into the circulating blood is slower than the passage of E_2 from the follicle into the circulation.[25] The amount of T in the follicular fluid was higher in the active luteal phase than in the late luteal or follicular phases. It was lowest on the day of estrus. The concentration of T in the follicular fluid corresponded approximately to the amount of T in perifollicular blood. The overall level of T during the luteal phase was about 20% of the level of A in the ovarian fluids, and similar to the concentration of A in the follicular fluid and perifollicular blood, it did not peak during the follicular phase (days 16–20 of the estrous cycle), suggesting that A may be the principal androgen secreted by thecal and stromal tissue and may serve as a precursor for estrogen synthesis. Furthermore, thecal tissue from healthy human follicles[13,39] or from porcine ovarian follicles[15] cultured *in vitro* produced higher amounts of A than T. The low values of T in perifollicular blood may be caused by enzymatic changes occurring in theca cells, which become luteinized after ovulation. In ovarian venous blood, the level of T was much lower than that in perifollicular blood and tended to be higher during the luteal phase than the follicular phase. The concentration of T in peripheral blood did not change significantly during the estrous cycle. The concentration of T in perifollicular blood was significantly higher in the luteal phase than the concentration in follicular fluid. However, levels of E_1 and E_2 were higher in the follicles of the follicular phase, which is also true in humans[37,40] and in monkey ovarian follicles.[41] Although granulosa cells have a very active $P450_{arom}$ enzyme system, large amounts of estrogens are produced *in vitro* only when the granulosa cells are mixed with theca cells.[14] The concentrations of E_1 and E_2 were similar in the follicular fluid at all stages of the estrous cycle of the gilts; however, the level of E_2 in perifollicular blood was two to three times higher during the active luteal stages. Luteal tissue has an active $P450_{arom}$, which could convert A and T into E_2. In addition to luteal tissue the vascularized theca cells could also contribute to E_2 synthesis and release into perifollicular blood. On the day of estrus levels of both E_1 and E_2 were very low, similar to that of P and androgens in ovarian venous blood, follicular fluid, and perifollicular blood. The high concentrations of E_2 and other steroids such as P and A in follicular antral fluid probably play an important role locally in regulating follicular development. Estrogens are essential for inducing the receptor sites for FSH first and then E_2; FSH increases the LH receptor sites on granulosa cells,[42,43] thereby increasing the steroid-producing enzyme activity of granulosa cells.[44,45]

The follicular fluid and perifollicular blood are in very close proximity. Substances injected in the general circulation were found in the follicular fluid. Peptides such as insulin, FSH, and LH are secreted elsewhere, but they enter the follicle and bind to the receptors of granulosa, theca, and interstitial cells. Although the follicular compartment containing the granulosa cell layer and cumulus is avascularized, the majority of the constituents of the follicular antral fluid are derived from serum. The barrier that separates the antrum from the circulation has properties that admit most blood proteins into the fluid.[45] However, when the ratio of the quantities of steroids in the follicular fluid to the quantities of steroids in the perifollicular blood was calculated, none of the steroids showed a ratio of 1 (unity) at various phases of the estrous cycle (Figure 45–6). These ratios indicate that the steroids in the follicle are not at equilibrium with the steroids of the perifollicular blood. It appears that at the follicular–blood barrier there is a selective process of exchanging steroids from the surrounding vasculature. E_1 and E_2 have positive ratios in all phases of the estrous cycle while P, A, and T have negative ratios during luteal phases. That is, during all the estrous phases the quantities of E_1 and E_2 are higher in the follicular fluid and the quantities of P, A, and T are lower in the follicular fluid than in the perifollicular blood.

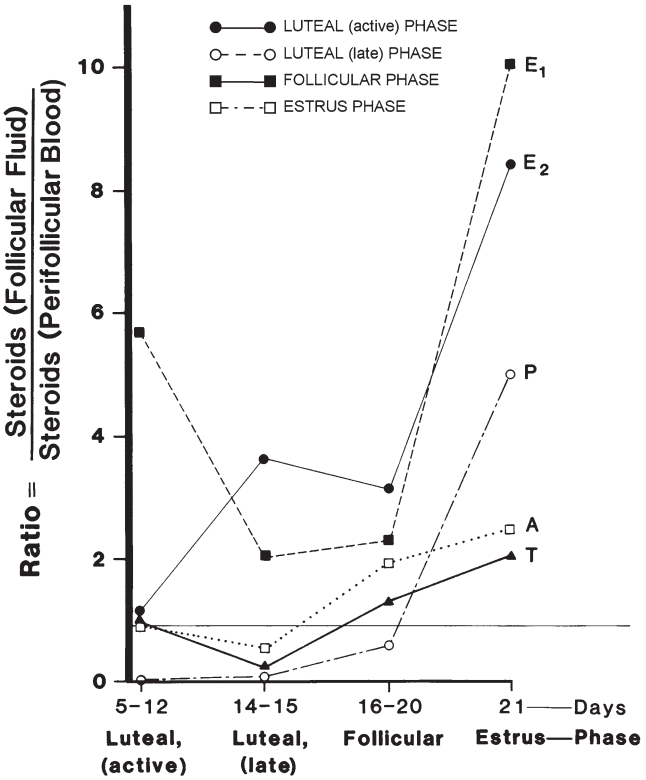

Figure 45–6. The ratios of steroids in the follicular fluid to the corresponding steroids in the first 1 min collection of perifollicular blood. During active follicular growth such as in the late luteal stage of the estrous cycle, the ratio did not reach 1. This suggests that none of the steroid was in an equilibration state. It demonstrates that at the follicular–blood barrier a selective process of exchange exists. E_1 and E_2 have a positive ratio at all the stages of the estrous cycle, indicating high $P450_{arom}$ activity in the follicle, whereas P, A, and T have negative ratios except during estrus.

CONCLUSIONS

This study was undertaken to observe steroid dynamics in the ovary during the estrous cycle of regularly cycling gilts. Forty cycling gilts were examined for three consecutive cycles to select regularly cycling gilts for this study. On the appropriate day of the cycle needed for the study laparotomy was done and the peripheral blood, ovarian venous blood, follicular fluid, and five samples of perifollicular blood were collected at 1 min intervals. P, A, T, E_1, and E_2 were measured in the blood serum samples, follicular fluid, and perifollicular blood using specific RIA methods.

Concentrations of P in peripheral blood, ovarian venous blood, follicular fluid, and perifollicular blood (blood from the vasculature surrounding the follicle) during the active luteal phase of gilts were 19.0 ± 2.4, 59.2 ± 12.7, and 3937 ± 710 ng/ml, respectively. These values were significantly lower in the follicular phase. The concentration of P in perifollicular blood in the late luteal phase was 848.0 ± 205.7 ng/ml, which was reduced to approximately one-tenth of this value in the follicular phase. Conversely, concentrations of A in the follicular fluid from the follicles in the follicular phase contained the highest concentration (163 ± 37.9 ng/ml) of all the stages of follicular growth. During this stage the perifollicular blood also contained a higher concentration of A than that observed at any other stage of the estrous cycle. On the day of estrus, the level of A in the follicular fluid as well as in ovarian venous blood was at its lowest. During the follicular phase the follicular fluid contained 8.74 ± 1.15 ng/ml of T, which did not significantly vary in the late luteal phase and was about twice as much as that in the follicular phase. Higher concentrations of T were also found in perifollicular blood in the luteal phase than in the follicular phase.

The high level of E_1 (22.94 ± 2.95 ng/ml) and E_2 (18.96 ± 1.80 ng/ml) in the follicular fluid during the follicular phase may be due to aromatization of A, which is also present in high concentrations in the follicular fluid and is in contact with granulosa cells. On the day of estrus E_1 and E_2 in the follicular fluid were 7.42 ± 1.45 and 6.93 ng/ml, respectively, which may be prior to the onset of the preovulatory surge. The lower levels of E_1 and E_2 in perifollicular blood than in follicular fluid suggest that the main site of aromatization could be the granulosa cells, with the product then partially equilibrating with the perifollicular blood. The concentration of A and T appeared to be higher or at least similar in these two ovarian fluids indicating that theca may be the main source of A and T. Interestingly, very high concentrations of P in the perifollicular blood suggest its origin in the corpus luteum, which may act as a precursor for C_{19} and C_{18} steroids in the follicle and may also regulate the sequential events that occur during follicular growth. The follicular fluid and perifollicular blood are in very close proximity, but the steroids present in them are not in perfect equilibrium.

ACKNOWLEDGMENTS

Dr. Finnie A. Murray, Jr., Ph.D., Associate Professor, Department of Animal Science, Ohio Agriculture Research and Development Center, Ohio State University, Wooster, Ohio, deserves profound acknowledgment for his professional supervision on cycling and skillful surgery of laparotomy of the gilts. Thanks also to Dr. David S. Knight, Ph.D., Associate Professor, Department of Anatomy and Cell Biology, L.S.U.H.S.C., Shreveport, LA, for reading through the manuscript.

46 Molecular Genetic Approach to Identify Inhibitors of Signal Transduction Pathways

Fission Yeast as a Model System for Drug Discovery

Shunji Ishiwata, Takayoshi Kuno, Hirofumi Takada, Atsushi Koike, and Reiko Sugiura

ABSTRACT

The fission yeast *Schizosaccharomyces pombe* (*S. pombe*) has become a valuable model system to elucidate the mechanisms of basic cellular functions of higher eukaryotes, including cell cycle control, membrane trafficking, and signal transduction. Having the smallest genome size among eukaryotes and with its powerful genetics, this organism is also an excellent model system for drug discovery. In addition, many signaling molecules targeted by the drug or the homologues of disease-linked human genes are highly conserved. We have been studying the signal transduction pathway in fission yeast with special emphasis on calcineurin phosphatase and mitogen-activated protein kinase (MAPK) signal transduction pathways. Our molecular genetic approach, which utilizes a cross-talk between calcineurin and MAPK signaling, has identified several regulators of Pmk1 MAPK, which is a homologue of extracellular signal-regulated kinase (ERK) in mammals. As MAPK signal transduction pathways are one of the most attractive targets for cancer therapy, inhibitors that target this signaling appear to be promising drug candidates for the treatment of cancer. Here, we first give an overview of the use of yeast as a model system for drug discovery and then we introduce our molecular genetic strategy to identify regulators of MAPK signaling and the application of this approach to drug discovery.

Key Words: MAP kinase, Fission yeast, Drug discovery, Pharmacogenomics.

INTRODUCTION

Recent progress in molecular sciences has enabled the identification of molecular alterations in human tumor cells, which frequently involve the conditional or constitutive activation of signaling pathways. Such cellular signaling pathways can operate to promote cancer development. The conservation of several components of these cancer-related signaling pathways with higher eukaryotes combined with the emerging genomics technologies and their sophisticated genetic approaches makes yeast an excellent model to study the molecular mechanisms of tumorigenesis as well as a valuable tool for drug discovery for cancer therapy.

THE CHARACTERISTICS OF THE RESEARCH USING YEAST

ADVANTAGES OF YEAST AS A MODEL FOR DRUG DISCOVERY Many of the genes that are frequently altered in human tumors have structural or functional homologues in model genetic systems, including the yeasts, *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, the nematode *Caenorhabditis elegans*, and the fruit fly *Drosophila melanogaster*. The genetic methods have been established in these model organisms. Since fission yeast has the smallest genome size, the study using this yeast allows us to elucidate the complex signaling pathways and provides insight into the molecular mechanisms of fundamental cellular processes.[1]

The characteristic features of the yeast as the model in drug research are summarized as follows.

1. The yeast has essential functions similar to those observed in eukaryotic cell and many of its proteins are conserved in higher eukaryotes. The gene expression profiles in nematode, as a representative of multicellular organisms, and yeast, as a representative of monocellular organisms, are similar in that both have the essential genes observed in eukaryotic cells. They are different from each other in that they do not have the genes observed only in multicellular organisms. This suggests that the functions of the nervous and vascular systems, which are observed only in multicellular organisms, were formed by the arrangement and evolution of the genes in monocellular organisms. Therefore, yeast is an excellent model organism that possesses a minimum and essential genome set, especially useful in drug research.

2. Powerful genetic techniques are available in yeast. Genetic methods such as gene disruption and replacement can easily be

carried out by homologous recombination in yeast. Most importantly, genetic strategies such as "synthetic lethality" and "multicopy suppressor" as described in the following sections can also be used. These genetic approaches are difficult to be utilized in other eukaryotes and allow us to identify unexpected genes and to reveal functional interactions between signaling pathways.

3. Abundant genetic resources are available in yeast. Since yeast research played a pioneering role in genetic research, almost all yeast genes have been cloned and analyzed. These accumulated findings can be advantageous, especially when identifying the genes influenced by drug administration. The databases on yeast genome are abundant as well. For budding yeast, SGD (*Saccharomyces* Genome Database) maintained by Stanford University and CYGD (the MIPS comprehensive yeast genome database) provide abundant information on the genome such as sequences, localizations, expression levels, and their related subjects. For fission yeast, the *S. pombe* gene database is maintained by the Wellcome Trust Sanger Institute. The *S. pombe* postgenome database has been recently constructed by Riken, which provides information on fission yeast ORFeome cloning as well as basic information on genes and proteins.[2] A bioknowledge library maintained by Incyte Corporation is also available. The strains and plasmids can be made available from National-Bio-Resource-Project Yeast (http://yeast.lab.nig.ac.jp/nig/english/index.html) and other public resources.

4. Rapid growth of yeast enables accelerated research. Yeast divides once in 2–3 h and this accelerates the speed of experiments. The methods of culture and storage are easily maintained and the costs of experiments are low.

BUDDING YEAST AND FISSION YEAST

BUDDING YEAST The analysis of the whole genome structure of the budding yeast has been the first to be completed among eukaryotes.[3] The budding yeast has 16 chromosomes and its whole length is 12 Mb, which is approximately 1/300 of those of humans. Approximately 6300 genes have been identified to date. The budding yeast usually grows as a diploid cell and a haploid cell can be readily obtained by induction of meiosis. The haploid cell can grow stably, and more than 6000 sets of gene disruption mutants are established and available.[4] The high-throughput screening aiming to identify the targets of the drugs can be planned using these gene disruption sets. The sensitivity to the drug is enhanced in haploid cells, since it has only one copy of the gene. However, the excessive sensitivity to the drugs can induce cell death, and this will make it difficult to analyze the target molecules encoded by essential genes. These drug targets can be studied using the deletion sets of diploid cells. The combination of these gene disruption sets and the drugs acting on signaling molecules makes it possible to clarify the complex signal transduction pathways affected by the drug.

FISSION YEAST The fission yeast is a monocellular organism and usually grows as a haploid cell. It has three chromosomes and its whole length is approximately 14 Mb, which has more than 4800 genes.[1] The genome size of the fission yeast is the smallest among the eukaryotes to date. However, its genome structures with regulatory mechanisms such as splicing resemble those of higher eukaryotes compared to those of budding yeast. More than 100 types of genes related to human disease, such as Down's syndrome, are conserved in yeast, which suggests the applicability of the fission yeast as a model organism.

GENETIC STRATEGIES

As mentioned above, genetic strategies such as "multicopy suppressor" and "synthetic lethality" are utilized in yeast to allow the identification of unexpected genes and to reveal functional interactions between signaling pathways.

HIGH GENE-DOSAGE SUPPRESSION OF THE DRUG EFFECT AND ITS APPLICATION TO THE IDENTIFICATION OF TARGET MOLECULES If a drug exerts its action by inhibiting the function of a target protein thereby inducing a specific phenotype including cell growth arrest, we can identify the unknown target molecules by utilizing yeast genetics of high-dosage suppressors. Moreover, it is also helpful to detect and reveal novel gene products that functionally interact with the drug.[5] It is also possible to identify the human genes related to drug resistance using a human cDNA library instead of a yeast genome library. For example, from genetic studies in *S. cerevisiae*, the TOR1 and TOR2 gene products were found to be targets of rapamycin, and from *S. pombe* studies, the cellular target of leptomycin B was identified as Crm1.

SYNTHETIC LETHALITY Synthetic lethality has been extensively used both to characterize interactions between genes previously identified as likely to be involved in similar processes as well as to uncover new interactions. The term "synthetic lethality" was first used by Dobzhansky to describe the phenomenon in which alleles of different genes are separately viable, but inviable when combined in a double mutant. The possibility that a certain agent can be a candidate anticancer drug was tested by using the mutant of DNA repair genes, in which the sensitivity for the agent was compared among the mutants.[6]

The budding yeast has approximately 6000 genes; of these approximately 1000 genes are essential and the deletion mutants remaining genes are viable. Parson *et al*. analyzed the sensitivity of 12 drugs on approximately 4700 deletion mutants and isolated 647 hypersensitive mutants.[7] They made a chemical genetic-interaction profile in which the genes are plotted on the horizontal axis and the drugs are plotted on the vertical axis. The results showed that the drug and its suggested interactive genes form a cluster. The chemical-genetic profile of benomyl, the inhibitor of polymerization of microtubules, forms a cluster consisting of the genes related to cell structure, chromosome, and mitosis. Cyclosporin A and FK506, the inhibitors of calcineurin, were reported to form similar clusters that include the genes containing cell wall integrity and the function of the vacuole.

We also utilized this "synthetic lethality" screening method to identify genes that are functionally interacting with calcineurin, the Ca^{2+}/calmodulin-dependent protein phosphatase in fission yeast. Calcineurin is an *in vivo* target of FK506 in fission yeast, and inhibition of calcineurin activity by gene disruption or by the addition of FK506 to the media does not affect the vegetative growth of fission yeast. This suggests that other regulatory pathways in the cell exist, and that they perform overlapping functions with calcineurin. Thus, mutants that require calcineurin activity for vegetative growth would not grow in the presence of FK506. A genetic screen to search for the mutations that show sensitivity to the immunosuppressive drug FK506 has been performed, and eight complementation groups (*its1-8* for immunosuppressant and temperature sensitive) were identified.[8–13] The gene products

identified in our screen include various genes involved in membrane trafficking, such as Ypt3 (Rab11 homologue), Ypt3 (Rab6 homologue), Apm1 (μ1 subunit of the clathrin-adaptor complex-1), and Gid1 (GDI1), as well as signaling molecules such as PI4P5K. These genetic approaches contribute to the identification of previously unknown genetic and functional interactions between signaling molecules that are affected by the drug and also contribute to revealing the unexpected action of the drug.

GENOMIC TECHNOLOGY: DNA MICROARRAY The cDNA chip for the all genes of budding yeast is used in the research on the effects of the drug on genomic expression.[14] Comparing the gene expression profiles between the deletion mutants and the yeast cells under drug treatment on the cDNA chip, the targets of the drugs will be identified. Moreover, an analysis of a profile change of genes induced by a certain drug in the cells in which the primary target of the drug is disrupted revealed secondary target of the genes, thereby leading to the discovery of a new drug and an unknown pathway of the drug.

Examples Marton *et al*. examined the change of the gene expression profile in the cell treated with cyclosporine A and FK506, and they showed that both drugs targeted calcineurin similar to mammals.[15] Moreover, the correlation coefficient between the difference in FK506-treated yeast and the wild type and the difference in the deletion mutant of the calcineurin gene and the wild type is not more than 0.80, suggesting an alternative pathway not through calcineurin. An analysis of the deletion mutant of Gcn4, a transcriptional factor, suggests that the pathway not via calcineurin is via Gcn4.

THE DISCOVERY OF MITOGEN-ACTIVATED PROTEIN KINASE INHIBITORS USING A FISSION YEAST GENETIC APPROACH In this section, we will introduce our genetic strategy to identify regulators of the mitogen-activated protein kinase (MAPK) signaling pathway based on our discovery that the Pmk1 MAPK and calcineurin phosphatase act antagonistically in the Cl^- homeostasis in fission yeast and its application for drug discovery.

Isolation of Multicopy Suppressors of Calcineurin Deletion Calcineurin (CN) is a highly conserved Ca^{2+}/calmodulin-dependent protein phosphatase and two important immunosuppressive drugs, cyclosporine A and tacrolimus (FK506), are potent and specific inhibitors of calcineurin activity in animal cells as well as in fission yeast. We demonstrated that knockout of the fission yeast calcineurin gene *ppb1*$^+$ or inhibition of calcineurin activity by immunosuppressants results in hypersensitivity to Cl^-, and that calcineurin and Pmk1 MAPK, a homologue of extracellular signal-related kinase (ERK)/MAPK in mammals, play antagonistic roles in Cl^- homeostasis[16] (Figure 46–1).

Based on this genetic interaction between calcineurin and Pmk1 MAPK, we screened for multicopy suppressors of the Cl^--hypersensitive phenotype of the calcineurin knockout. Notably, all the genes we identified turned out to negatively regulate Pmk1 MAPK signaling, thereby suppressing the Cl^- hypersensitivity of the calcineurin knockout. The *first* gene we identified encodes the MAPK phosphatase Pmp1. Pmp1 is a homologue of the mammalian dual-specificity phosphatase CL100/MKP-1, and dephosphorylates the MAPK Pmk1, thereby inhibiting Pmk1 signaling (Figure 46–1). The *second* gene identified was *pek1*$^+$, encoding MAPK kinase (MAPKK), which phosphorylates and activates Pmk1 in its phosphorylated form, thus acting as an upstream

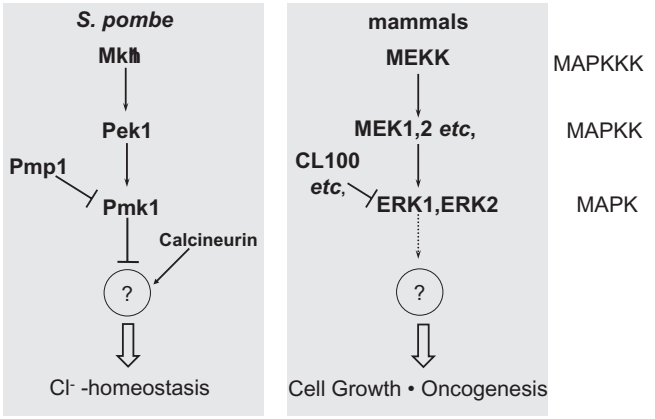

Figure 46–1. MAPK signaling pathway is conserved from *S. pombe* to mammals.

MAPKK for Pmk1 (Figure 46–1). Surprisingly, Pek1 in its unphosphorylated state binds phosphorylated Pmk1, thereby inhibiting Pmk1 MAPK signaling, and hence Pek1 acts as a phosphorylation-dependent molecular switch. The *third* gene was *rnc1*$^+$, encoding a novel KH-type RNA-binding protein. Rnc1 was shown to bind to and stabilize the inherently unstable mRNA of Pmp1, an MAPK phosphatase for Pmk1. Consistently, Pmp1 mRNA was dramatically destabilized and Pmp1 protein was barely detectable in Rnc1 knockout cells. Moreover, Pmk1 MAPK directly phosphorylates Rnc1 *in vivo* and *in vitro*, and this phosphorylation by Pmk1 MAPK regulates the RNA-binding activity of Rnc1. Thus, the identification of Rnc1 as a target of the MAPK signaling cascade has revealed a novel feedback mechanism for the posttranscriptional regulation of MAPK phosphatase gene expression.

Altogether, our screen for multicopy suppressors of calcineurin deletion efficiently identified negative regulators of Pmk1 MAPK signaling.

Isolation of *vic* (Viable in the Presence of Immunosuppressant and Chloride Ion) Mutants We recently developed a novel genetic screen to identify new components of the Pmk1 MAPK pathway. As shown above, knockout of the components of the Pmk1 MAPK pathway, such as Pmk1 (MAPK), Pek1 (MAPKK), Mkh1 (MAPKKK), or Pck2 (protein kinase C), complemented the Cl^--hypersensitive phenotype of calcineurin knockout. Notably, these knockout strains are viable in the presence of immunosuppressant FK506 and high concentrations of $MgCl_2$, while the wild-type cells are inviable in the same condition[16,17] (Figure 46–2). We therefore hypothesized that if we isolate mutants that can grow in the presence of FK506 and 0.15 M $MgCl_2$, the genes responsible for the mutation are expected to function in protein kinase C–Pmk1 MAPK signaling (Figure 46–2). These may include mutations in the unknown factor downstream of Pmk1, or in novel factors required for the activation or function of Pmk1 MAPK. We then isolated the mutants that are viable in the presence of immunosuppressant and chloride ion, and hence named these *vic* (viable in the presence of immunosuppressant and chloride ion) mutants.

Based on this rationale, we identified the *vic1-1*/*cpp1-v1* mutant, in addition to the mutation allele in the known components of the Pmk1 MAPK pathway including *pmk1*$^+$, *pek1*$^+$, *mkh1*$^+$, as well as *pck2*$^+$.[13] The *cpp1*$^+$ gene encodes a β subunit of the

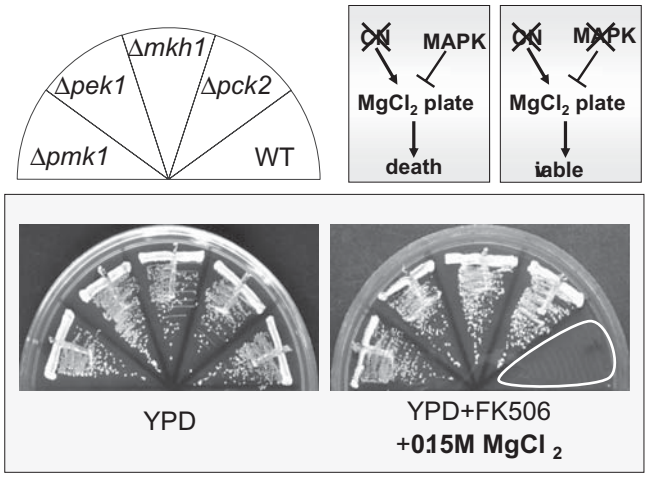

Figure 46–2. Calcineurin and Pmk1 MAPK play antagonistic roles in Cl^- homeostasis.

farnesyltransferase (FTase) that is highly conserved through evolution. We further showed that a small GTPase Rho2 is a novel target of Cpp1. Moreover, Cpp1 and Rho2 act upstream of the Pck2–Pmk1 MAPK signaling pathway, thereby resulting in the *vic* phenotype upon their mutations. Thus, our genetic screen of *vic* mutants utilizing the antagonistic interaction between calcineurin and Pmk1 signaling successfully identified Cpp1 as a novel upstream component of Pck2–Pmk1 signaling.[13]

A Genetic Approach to Screen for Inhibitors of Mitogen-Activated Protein Kinase Signaling We next wished to apply this powerful genetic strategy to screen for compounds that target MAPK/PCK signaling and we established a unique method based on the following rationale. MAPK/PCK signaling plays an important role in cell growth as well as in oncogenesis, and compounds that target MAPK signaling may help contribute to the discovery of anticancer drugs. As shown in Figure 46–2, there was a complementation of the Cl^--hypersensitive phenotype of calcineurin knockout cells upon the inhibition of Pmk1 MAPK signaling. Thus, treatment with a chemical compound that allows calcineurin knockout cells to be viable in the presence of $MgCl_2$ suggests that the compound might act as an inhibitor of MAPK/PKC signaling (Figure 46–3).

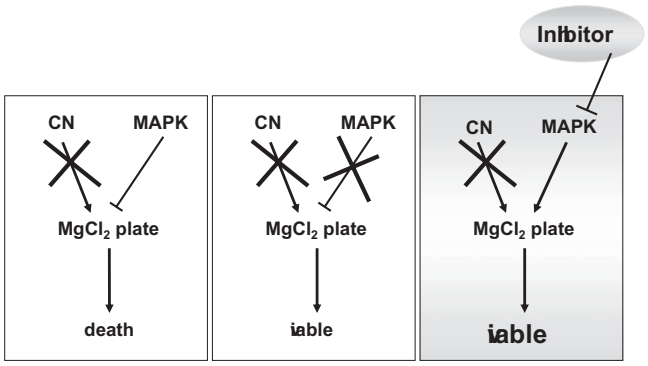

Figure 46–3. A strategy for screening for inhibitors of MAPK/PCK signaling.

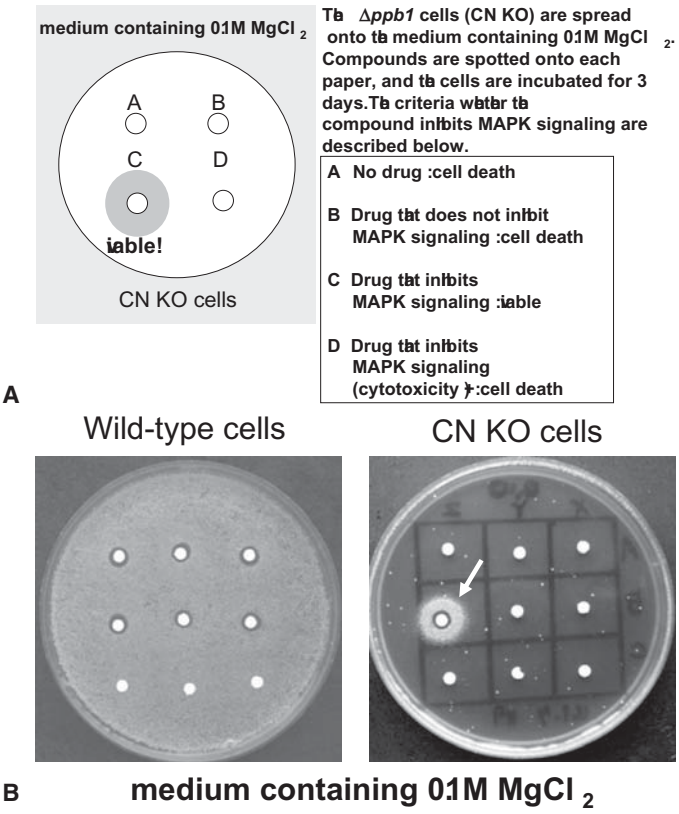

Figure 46–4. (A) A scheme to identify inhibitors of MAPK signaling. (B) Hit compound that may target fission yeast MAPK signaling.

To identify compounds that target MAPK/PKC signaling, the screen was performed as described in Figure 46–4A. First, spread calcineurin knockout cells onto the medium containing 0.1 M $MgCl_2$ and then put a filter paper disc in each section. Next, add the chemical compound onto each disc then grow the cells at 27°C for 3 days. Notably, the addition of a known human MAPK inhibitor makes calcineurin knockout cells viable in the presence of $MgCl_2$, indicating that the human MAPK inhibitor inhibits MAPK Pmk1 signaling in fission yeast (our unpublished results). Screening a chemical library of more than 8000 compounds resulted in the identification of three hit compounds that may target fission yeast MAPK signaling; one of the hit compounds is shown in Figure 46–4B. The three hit compounds that target fission yeast MAPK signaling may inhibit human MAPK signaling.

This method has several advantages. First, this screen is unique in that the ability to inhibit MAPK signaling can be assayed by the growth of calcineurin knockout cells in the presence of $MgCl_2$. Therefore, the compound with a cytotoxic effect will not be isolated in our screen. In a screen for an inhibitor wherein the inhibitory effect is evaluated by the inhibition of cell growth, it is difficult to discriminate between an inhibitory effect on the signaling and a toxicity of the compound. The cytotoxic effect of the compound is also examined by the addition of compounds to the wild-type cells (Figure 46–4B). Second, in our assay, the compound was added onto a paper disc, which enables the diffusion of the compound into the medium, thereby establishing a gradient concentration. Therefore, the optimum concentration of the

compound is efficiently achieved in our assay, which allows a high-throughput screening of a chemical compound library. And third, our assay evaluates the activity of the compound on Pmk1 MAPK signaling by the *in vivo* parameter of hypersensitivity of calcineurin deletion. Therefore, the compound that has *in vitro* activity but is unable to pass through the plasma membrane is automatically eliminated as a drug candidate, resulting in a more cost-effective and time-saving method.

CONCLUSIONS

In summary, our genetic approach has effectively identified regulators of Pmk1 MAPK signaling, including negative regulators, upstream activating factors, as well as candidate inhibitors of the signaling. Given that MAPK/PCK signaling plays an important role in cell growth as well as in oncogenesis, the application of these powerful genetic approaches to screen for compounds that target MAPK/PCK signaling emphasizes the potential contribution of these compounds to the discovery of anticancer drugs. Also, the targets of these drugs may be one of the genes that will be identified by our screening of the *vic* mutants.

47 Yeast as a Model System to Study DNA Damage and DNA Repair

ANTONIO CONCONI

ABSTRACT

This chapter provides procedures for determining cell survival and the extent of DNA damage and repair after treatment of yeast cultures with DNA-damaging agents such as bleomycin, methyl methanesulfonate, dimethyl sulfate, and ultraviolet light. Comprehensive protocols for basic methods in yeast biology such as how to prepare different media, how to grow and store yeast cells, how to isolate nucleic acids, how to transform and prepare yeast mutant strains, and how to use Internet-based yeast resources are available.

Key Words: Benzo[*a*]pyrenediol, Bleomycin, CPD, Dimethyl sulfate, Double-stranded breaks, Methyl methanesulfonate, Nucleotide excision repair, Single-stranded breaks, 2,3,5-Triphenyltetrazolium chloride.

INTRODUCTION

The budding yeast *Saccharomyces cerevisiae* is classified as a safe microorganism and has been used for many years as a biological model.[1–3] It has provided important contributions to our current understanding of basic eukaryotic cellular functions. Furthermore, yeast is employed as a model to investigate mammalian diseases. For instance, at least 31% of yeast proteins have human homologues and nearly 50% of human genes implicated in heritable diseases have yeast homologues.[4] Although its nuclear genome is only 3.5 times larger than that of *Escherichia coli*, the yeast genome displays most of the hallmarks of higher eukaryotic genomes. The genome of haploid yeast cells is about 1.2×10^7 bp and is organized into 16 chromosomes, ranging in size from 200 to 2200 kb.[5] Finally, yeast DNA is found within a nucleus and its nucleosomal organization of chromatin is similar to that present in higher eukaryotes, except that there is no histone H1.[6,7]

The powerful yeast genetics and its relatively high rate of recombination facilitate the insertion of DNA sequences at specific locations in the genome, allowing the creation of yeast strains carrying gene knockouts,[8] the tagging of proteins with different epitopes,[9] and the engineering of regulated promoters upstream of a given open reading frame (ORF).[10] In yeast there are 6466 ORFs.[11,12] Their functions, information on the corresponding proteins, and their cellular localization are available through databases such as the *Saccharomyces* Genome Database (SGD; www.yeastgenome.org), Yeast Protein Database (YPD; www.proteome.com), Munich Information Center for Protein Sequences (MIPS) Comprehensive Yeast Genome Database (CYGD; mips.gsf.de/genre/proj/yeast/index.jsp), the Yeast Resource Center (depts.washington.edu/~yeastrc), and yeast green fluorescent protein (GFP) fusion localization database (yeastgfp.ucsf.edu). Furthermore, 5916 ORFs were deleted to construct a heterozygous diploid collection that contains deletions in both essential and nonessential genes.[13] About 4800 nonessential deletions were generated as haploid MATa and MATα strains or as homozygous diploids, and these collections can be obtained from Research Genetics (ResGen) (www.resgen.com/products/) or the Euroscarf consortium (web.uni-frankfurt.de/fb15/mikro/euroscarf/col_index.html) in readily usable forms.[14] Among numerous applications of the ORF deletions libraries, they have been employed to understand the genetics that determine cell sensitivity and resistance to drugs, and some multidrug resistance genes have already been identified.[15] Also, the toxicity of chemicals is currently tested in yeast that present metabolic defects similar to those observed in human cancers,[16] and high-throughput screenings are employed to determine the mode of action of DNA-damaging agents such as those employed in chemotherapy.[17] Finally, studies on cytotoxic compounds such as methyl methanesulfonate (MMS) and hydroxyurea,[18] bleomycin (BLEO),[19] and cisplatin,[20] on ionizing radiation,[21] and on ultraviolet light (UV) radiation[22] have revealed genes that are involved in DNA repair, cell cycle checkpoints, DNA recombination, and DNA replication. The results have highlighted the importance of the nucleotide excision repair (NER) mechanism together with homologous recombination, postreplication repair, and cellular responses to DNA damage.

MMS and DMS are DNA methylating agents that produce a variety of damaged bases, of which N^7-methylguanines and N^3-methyladenine constitute about 80% and 10% of the lesions, respectively.[23] In yeast, *N*-methylpurines are enzymatically removed by the base excision repair pathway (BER), and the sensitivity to MMS increases in cells lacking genes involved in BER. However, homologous recombination (HR) may also participate in the repair of methylpurines. Bleomycin is a radiomimetic drug that in the presence of cofactors creates single strand breaks (SSB) and double strand breaks (DSB) by a concerted free radical attack on the sugar moieties of the DNA backbone.[23] DNA strand breaks block DNA replication, and the difficulty of repairing DSBs is the major source of BLEO's cytotoxicity. The

recombination and postreplication DNA repair pathways are involved in the repair of BLEO-induced DNA lesions. UV light induces the formation of two major photoproducts: *cis-sin* cyclobutane pyrimidine dimers (CPD) and (6-4) pyrimidine–pyrimidone dimers [(6-4)PD].[23] These lesions block gene transcription and DNA replication, and are repaired by the NER pathway. Although UV photoproducts induced by UV-C serve as the paradigm to study the mechanisms of NER, this ubiquitous repair pathway operates on a large variety of chemical adducts to DNA.[23]

NER is characterized by the incision of the damaged DNA strand on both sides of the lesion, resulting in the removal of an oligonucleotide fragment (25~30 nucleotides long) containing the damage. This is followed by DNA repair synthesis and ligation. The yeast genes involved in NER can be grouped into two classes; the first consists of *RAD1*, *2*, *3*, *4*, *10*, *14*, and *25* genes, and the second consists of *RAD7*, *16*, and *23* and the *MMS19* genes. Mutations in the genes of class 1 cause a very high degree of UV sensitivity, whereas mutations in the genes of class 2 cause moderate UV sensitivity.[24] An additional factor encoded by the *RAD26* gene is involved in transcription-coupled repair (TCR), the subpathway of NER that is responsible for removing DNA lesions from the transcribed strand of active genes.[25]

Photoreactivation is an alternative mechanism to NER that specifically removes pyrimidine dimers. This process is catalyzed by one enzyme (photolyase) and is light dependent (blue light). Photolyases are widespread in nature, though there is no photoreactivation of DNA damage in human cells.[23] To inhibit the activity of photolyase, all the experiments done with UV-irradiated yeast cultures are performed in a dark room, under yellow light (e.g., Rapid Start Fluorescent lamps, Reprographic-Gold 40 W 2250 K°, Standard Products Inc.; catalog 6050RGO).

GROWING YEAST CELLS AND INDUCTION OF DNA DAMAGE

Culturing yeast is simple, economical, and rapid. They grow in liquid and on solid media, forming a bud that pinches off to originate daughter cells. During exponential growth (or log-phase) in rich media, yeast have a short life cycle of about 90 min. As cell density increases, nutrients drop and the rate of cell division slows. The log-phase is divided into three stages: early-log phase ($<10^7$ cells/ml), mid-log phase (between 1 and 5×10^7 cells/ml), and late-log phase (between 5×10^7 and 2×10^8 cells/ml). At a density of 2×10^8 cells/ml, yeast enter the stationary (G_0) phase. The growth curve of newly inoculated cells (e.g., at 2×10^5/ml) is characterized by a lag phase of two to three cell divisions (~5 h), exponential growth for about six cell divisions (~9 h), and the stationary phase (during this last phase, cells undergo about two more divisions). The optimal growth conditions can vary depending on the yeast genetic background but, in general, yeast grow very rapidly at 28–30°C in the most commonly used YEPD medium. The recipes for rich, minimal, and complete minimal dropout media and their uses have been reported.[1–3]

Below is described how we grow yeast cultures and incubate them with DNA-damaging agents and how we monitor DNA repair. However, optimal growth conditions and treatments with genotoxic compounds could vary from strain to strain. Thus it is advisable to carry out pilot experiments to follow the dose survival curves. Also, while small cultures provide enough cells for the survival tests, large quantities of cells are needed for DNA repair analyses.

GROWTH OF LARGE YEAST CULTURES AND PREPARATION OF CELLS FOR TREATMENT WITH DNA-DAMAGING AGENTS

1. For liquid cultures, add the YEPD medium (10 g yeast extract, 20 g peptone, 20 g glucose, and distilled water to 1 liter) to a flask that holds two to three times the required volume. For solid plates, prior to autoclaving add 2% (w/v) agar to the YEPD in a flask containing a stir bar. Autoclave at 121°C and 15 psi (1 atm) for 20 min. Gently mix the agar-containing medium on a stirrer and let it cool down to ~50–55°C before pouring the plates (20–25 ml/Petri dish). Allow the plates to solidify and dry at room temperature (RT) for 2 days; store them at 4ºC in plastic bags.

2. Streak out the cells on solid YEPD and incubate the plate at 28–30°C until colonies form (2–3 days). Prepare a preculture as follows: use one colony to inoculate ~7 ml YEPD in a sterile culture tube (e.g., borosilicate glass 16 × 150 mm, Fisher Scientific catalog no. 14-961-31). Usually, cells grow to a stationary phase when incubated overnight at 28–30°C with continuous rotation or shaking.

3. DNA repair experiments are done with exponentially growing cultures (2×10^7 cells/ml). One 2-liter flask containing 500 ml of YEPD is inoculated with 300–400 µl of preculture cells (final concentration ~10^5 cells/ml). The culture is incubated at 30°C with continuous shaking (~300 rpm) overnight. To monitor cell growth blank the spectrophotometer with sterile medium, remove an aliquot, and measure the absorbance of the cells at 600 nm [optical density $(OD)_{600}$]. Use dilutions to make sure that measurements are done in the linear range of the spectrophotometer, and calculate the number of cells/ml considering that OD_{600} ~ 0.1 is approximately 2×10^6 cells/ml. [*Note*: The correlation OD vs. number of cells varies not only from strain to strain but also for a given strain grown in different media. Therefore it is important to determine the cell number per OD unit using a counting chamber, and plotting the growth curves to determine the times of cell division.]

4. Cells are harvested when they are in mid-exponential phase (1 to 2×10^7 cells/ml) in a benchtop centrifuge (2000–3000 g/5 min), washed in ice cold phosphate-buffered saline (PBS) (8 g NaCl, 0.2 g KCl, 1.44 g Na_2HPO_4, 0.24 g of KH_2PO_4, pH 7.4 per liter), and reharvested to prepare them for treatment with DNA-damaging agents.

TREATMENT OF SMALL CULTURES OF CELLS WITH METHYL METHANESULFONATE AND BLEOMYCIN TO DETERMINE CELL SURVIVAL

1. Yeast strains (10 ml cultures) are grown exponentially (10^7 to 2×10^7 cells/ml), collected by centrifugation, washed with 10 ml of sterile water, and resuspended in 5 ml of water to 0.8×10^7 cells/ml.

2. MMS (Sigma, catalog no. M 4016) is used as the stock solution. BLEO (from MeadJohnson or Sigma) is dissolved in sterile water to 5 U/ml, and stored in aliquots at −20°C.

3. Chronic exposures of yeast cultures to MMS and BLEO are done in triplicate: 5 µl of cell suspensions (0.8×10^7 cells/ml in sterile water) is used to inoculate the wells of a microplate containing 95 µl of YEPD media and various concentrations of MMS (0 as control, 0.005, 0.01, and 0.02%; v/v) or BLEO (0 as control,

6 and 10 mU/ml). The microplates are incubated as described in the section on Measuring Yeast Sensitivity to Genotoxic Agents in Liquid Cultures. Alternatively, 10-fold serial dilutions of cells are prepared in sterile water and 5 µl of each dilution is spotted on YEPD plates containing different concentrations of MMS or BLEO (see above). The plates are prepared and incubated as described in the section on Measuring Yeast Sensitivity to Genotoxic Agents by Colony Spot Testing.

4. Acute exposures of yeast cultures to MMS are done in triplicate: 1 ml of yeast cultures in sterile water (prepared as in step 1) is collected by centrifugation, resuspended in 1 ml of fresh YEPD (0.8×10^7 cells/ml) containing different concentrations of MMS (0 as control, 0.01, 0.025, and 0.05%; v/v), and incubated at 30°C for 90 min under continuous rotation. Thereafter, cells are harvested by centrifugation, washed twice with sterile water, and resuspended in 1 ml of water. As described above, 5 µl of cell suspensions (4×10^4 cells) is used to inoculate the wells of a microplate containing 95 µl of fresh YEPD (without DNA-damaging agents; MMS). The microplates are incubated as described in the section on Measuring Yeast Sensitivity to Genotoxic Agents in Liquid Cultures. Alternatively, 10-fold serial dilutions of washed cells are prepared in sterile water and 5 µl of each dilution is spotted on YEPD plates (without DNA-damaging agents). The plates are incubated as described in the section on Measuring Yeast Sensitivity to Genotoxic Agents by Colony Spot Testing.

ULTRAVIOLET LIGHT IRRADIATION OF SMALL CULTURES OF CELLS TO DETERMINE CELL SURVIVAL

1. In sterile water 350 µl of 0.8×10^7 cells/ml is spotted on an autoclaved glass plate and irradiated (254 nm) with UV doses of 20, 80, and 150 J/m^2, as measured with a UVX radiometer (Ultra-Violet Products, Upland, CA). How to monitor UV intensities and convert them to UV doses is described in the section on Ultraviolet Light Irradiation of Large Cell Cultures (step 3).

2. Triplicates of 5 µl of UV irradiated, or mock treated (control), cell suspensions are used to inoculate the wells of a microplate containing 95 µl of YEPD media. The microplates are incubated in the dark to avoid photoreversal of DNA damage by photolyase as described in the section on Measuring Yeast Sensitivity to Genotoxic Agents in Liquid Cultures. Alternatively, 5 µl of 10-fold serial dilutions of irradiated and nonirradiated cells are spotted on YEPD plates. The plates are incubated in the dark to avoid photoreversal of DNA damage by photolyase as described in the section on Measuring Yeast Sensitivity to Genotoxic Agents by Colony Spot Testing.

TREATMENT OF LARGE CULTURES OF CELLS WITH DIMETHYL SULFATE

1. Yeast cells are grown at 30°C in YEPD to mid-log phase ($OD_{600} \sim 0.4$) as described in the section on Growth of Large Yeast Cultures. An aliquot of $1–2 \times 10^9$ cells is kept as control [no treatment with dimethyl sulfate (DMS)].

2. The rest of the culture is mixed with DMS (Sigma, undiluted solution) to give a final concentration of 0.03% (v/v), and incubated at RT for 2 min.

3. Cells are washed twice with PBS, resuspended in 200 ml of prewarmed YEPD at 30°C, poured into a 500-ml Erlenmeyer flask, and incubated at 30°C with continuous shaking (~300 rpm) for different repair incubation times (e.g., 0, 1, 2, and 4 h). Then 50-ml aliquots ($1–2 \times 10^9$ cells) are collected on ice and cells are harvested by centrifugation. [*Note:* If needed, to prevent DNA replication during repair incubation, hydroxyurea is added to a final concentration of 100 mM (e.g., 25 and 26 and references therein).]

4. Total genomic DNA is isolated as described in the section on Isolation of Genomic DNA from Yeast Cells.

TREATMENT OF LARGE CULTURES OF CELLS WITH BLEOMYCIN

1. Yeast cells are grown at 30°C in YEPD to mid-log phase ($OD_{600} \sim 0.4$) as described in the section on Growth of Large Yeast Cultures.

2. After washing twice with sterile ice-cold water, cells are resuspended in 50 mM NaCl, 2 mM $MgCl_2$, and 0.02% glucose to a cell density of 1 to 2×10^9 cells/ml.

3. Digitonin (Sigma, 10% stock) and $Fe(NH_4)_2(SO_4)_2$ (10 mM, freshly dissolved in H_2O) are added to the cell suspension to final concentrations of 0.05% and 50 µM, respectively.[26]

4. The cells suspension is divided into five aliquots and one aliquot is kept as the negative control (no treatment with BLEO). BLEO (Sigma, 20 units/ml stock) is added to final concentrations of 12.5, 25, 50, and 100 mU/ml, followed by a 12-min incubation at 30°C.

5. To stop the reaction, the five cell suspensions are mixed with 100 volumes of ice-cold YEPD and the cells are collected by centrifugation. [*Note:* BLEO can aggregate at cell plasma membranes and even in the presence of ethylenediaminetetraacetic acid (EDTA), DNA can be damaged during the extraction process. BLEO molecules are efficiently removed from mammalian cell membranes by trypsin,[27] and from yeast cells walls by washing the cells with yeast media.[26]]

6. Cells are washed a second time in ice-cold YEPD, collected by centrifugation and prepared for total genomic DNA extraction as described in the section on Isolation of Genomic DNA from Yeast Cells.

ULTRAVIOLET LIGHT IRRADIATION OF LARGE CELL CULTURES

1. Yeast cells are grown at 30°C in YEPD to mid-log phase ($OD_{600} \sim 0.4$) as described in the section on Growth of Large Yeast Cultures. The cell pellet from a 500-ml culture (total 5×10^9 cells) is resuspended in 300 ml PBS (~1.67×10^7 cells/ml). [*Note:* Cells are irradiated in PBS, as YEPD filters out 254 nm UV light.]

2. An aliquot of 50 ml is kept as the control (–UV) and the remaining cells are poured into trays (21.5×14 cm of mat gray plastic from Rubbermaid) and irradiated with primary 254 nm UV (UVC) light. [*Note:* For optimal and equal UV irradiation the thickness of yeast suspensions should not be above 2 mm, the maximal cell density should be kept below 3×10^7 cells/ml, and the UV lamps should be turned on about 5 min before use.]

3. Cell suspensions are irradiated with 254-nm emitting germicidal lamps (15 W; General Electric). The UV intensity is measured with a radiometer (UVX from Ultra-Violet Products, Upland, CA) and converted to UV dose with the following equation:

$$\text{Dose (J/m}^2\text{)} = \text{Time of irradiation (seconds)} \times \text{Intensity (µW/cm}^2\text{)/100}$$

For instance, to study DNA repair of chromatin in yeast, we routinely irradiate cells at ~150 J/m.[2]

4. Soon after irradiation, cells of a 50-ml aliquot are harvested by centrifugation and used as control (+UV, no DNA repair). The remaining 200 ml of the cell suspension is collected as previously described (see the section on Growth of Large Yeast Cultures, step 4), resuspended in 200 ml of 30°C prewarmed YEPD, poured into a 500-ml Erlenmeyer flask, and incubated at 30°C with continuous shaking (~300 rpm) to allow repair. At different time points (e.g., 30 min, 1 h, 2 h, and 4 h after UV irradiation) 50-ml aliquots are collected and cells are harvested by centrifugation. Isolation of total genomic DNA is described in the section on Isolation of Genomic DNA from Yeast Cells.

ASSESSING YEAST SURVIVAL RATES

To test cytotoxic compounds on yeast from the ORF deletions libraries, cells carrying deleted genes are plated onto solid media containing the drugs, and the strains that are sensitive to the drugs are recognized by their slow growth. By this assay, sets of multidrug resistance genes have already been identified.[15] However, analyses of cell growth in liquid media are better suited for the detection of weak sensitivities, and are thought to be more representative than the plating assays.[15,28] Finally, methods that measure cell metabolism are also used to determine the fraction of surviving cells.[29] One such test is the reduction of 2,3,5-triphenyltetrazolium chloride (TTC) to formazan by the mitochondria.

MEASURING YEAST SENSITIVITY TO GENOTOXIC AGENTS BY COLONY SPOT TESTING

1. The yeast strains are grown exponentially in YEPD at 30°C under continuous rotation. Cells are collected by centrifugation, resuspended in sterile water, and treated with the DNA-damaging agents (see the section on Treatment of Small Cultures of Cells and the section on Ultraviolet Light Irradiation).

2a. For chemical agents 10-fold serial dilutions of yeast cultures (0.8×10^7, 0.8×10^6, 0.8×10^5, 0.8×10^4, and 0.8×10^3 cells/ml) are prepared in sterile water and 5 µl of each dilution (corresponding, respectively, to 4×10^4, 4×10^3, 4×10^2, 4×10^1, and 4×10^0 cells) is spotted on YEPD plates containing different concentrations of DNA-damaging agents. The plates are incubated at 30°C for 48 h, and cell survival is scored by visual inspection such as comparing the size of the grown spots of yeast colonies.

2b. For UV irradiation 5 µl of 10-fold serial dilutions of irradiated and nonirradiated cells (0.8×10^7, 0.8×10^6, 0.8×10^5, 0.8×10^4, and 0.8×10^3 cells/ml) are spotted on YEPD plates. After UV irradiation, the plates are incubated at 30°C for 48 h in the dark (to avoid photo-reversal), and cell survival is scored by visual inspection of the plates.

SURVIVAL CURVES OF ULTRAVIOLET-IRRADIATED CELLS BY COLONY COUNTING

1. Yeast stock cultures are grown overnight in 5 ml YEPD at 30°C and under continuous rotation to early stationary phase.

2. Serial dilutions are prepared as follows:

- 10^{-4} to 10^{-6} dilutions of the stock cultures are made for the controls (no UV) and the WT (or *RAD*$^+$) strains irradiated at UV doses up to 150 J/m^2.
- 10^{-3} to 10^{-5} dilutions of the stock cultures are made for class I of *rad* mutant strains (see Introduction) when irradiated at doses between 5 J/m^2 and 10 J/m^2. For higher irradiations (up to 30 J/m^2) prepare 10^{-2} to 10^0 dilutions.

3. Of each yeast strain 100 µl is plated in triplicate for each UV dose and dilution. The plates are allowed to dry for 10 min at RT before irradiation (without a lid). After irradiation, the plates are incubated at 30°C for 48 h in the dark. The colonies are counted and plotted as percent survival versus UV doses.

MEASURING YEAST SENSITIVITY TO GENOTOXIC AGENTS IN LIQUID CULTURES

1. Yeast strains (10 ml cultures) are grown exponentially (10^7 to 2×10^7 cells/ml) in YEPD, collected by centrifugation, washed with 10 ml, and resuspended in 5 ml of sterile water to final concentrations of 0.8×10^7 cells/ml.

2. For a control, the OD_{600nm} of the 5-ml cell suspensions can be remeasured.

3. Yeast are treated with DNA-damaging agents as described in the section on Treatment of Small Cultures of Cells and the section on Ultraviolet Light Irradiation.

4. Prepare a 96-well plate (flat bottom, nontreated, low evaporation lid, polystyrene, sterile; Costar, catalog no. 3370) with 95 µl of sterile YEPD in each well with or without DNA-damaging agent.

5. Triplicates of 5-µl yeast samples (corresponding to 4×10^4 cells, treated or mock treated with DNA-damaging agents) are deposited in each well and mixed with the YEPD by pipetting up and down (it is convenient to use a multichannel pipette).

6. To avoid evaporation during the incubation period, the 96-well plates are sealed with Parafilm.

7. Cell growth is monitored with a PowerWave microplate scanning spectrophotometer (Bio-Tek). The OD of cell growth is recorded using KC4 microplate data analysis software (Bio-Tek), programmed as follows: running time, 48 h; OD reading interval, 10 min; OD wavelength, 660 nm; shaking, intensity 2 and duration of 595 sec before every reading; temperature, 30°C.

8. The data are exported to Excel (Microsoft) for plotting.[28]

MEASURING YEAST SENSITIVITY TO GENOTOXIC AGENTS BY THE REDUCTION OF 2,3,5-TRIPHENYLTETRAZOLIUM CHLORIDE The water-soluble and colorless tetrazolium salts are reduced in a variety of cells to red, water-insoluble formazan compounds. The reaction occurs in the mitochondria where these compounds are reduced at different sites along the electron-transport chain, with the exact site of reduction depending on their chemical substitution. Among these, TTC is one of the most commonly used. Its reduction to red formazan occurs at the site of the cytochrome oxidase complex in place of molecular oxygen reduction.[29] Consequently, measurements of cell metabolism by TTC reduction can be used to determine cell survival.

1. Yeast cultures are grown to mid-log phase, treated with DNA-damaging agents, and incubated for different times to allow cells to repair the DNA.

2. For each time point, 35 ml of cell culture (~7×10^8 cells) is pelleted, resuspended in 1 ml sodium phosphate buffer (0.05 M, pH 7.5), transferred to an Eppendorf tube containing 350 µl of TTC stock solution (0.5% TTC in 0.05 M phosphate buffer, Sigma), and mixed well.

3. Incubation is done for 20 h at RT in the dark (without stirring).

4. Cells are pelleted by centrifugation in a microcentrifuge for 2 min, washed in sterile water, and pelleted again.

5. An equal volume of glass beads (425–600 µm, Sigma) is added to the cell pellet, together with 500 µl ethanol : acetone (1 : 1). The suspension is vortexed vigorously to break open the cells.

6. Cell debris and beads are pelleted in a microfuge for 2 min and the supernatant is transferred into a 15-ml tube.

7. Steps 5 and 6 are repeated four times, followed by two extractions with 500 µl of 100% acetone.

8. For each DNA repair time point, all the supernatants are collected and adjusted to 3.5 ml final volumes with ethanol : acetone (1 : 1), followed by 5 min centrifugation at maximum speed in a benchtop centrifuge to pellet cell debris.

9. Absorbance of the combined washing extractions is read at 485 nm and measurements are conveniently taken in 1-ml plastic cuvettes. [*Note:* Dilute the sample if OD_{485} is above 2.]

10. OD_{485} measurements of mock-treated cells are considered as 100%, and the percents of OD_{485} are plotted versus the doses of DNA-damaging agents employed.

MEASUREMENTS OF DNA DAMAGE AND DNA REPAIR RATES

The quantification of the formation and removal of lesions is crucial to understanding the processes of DNA damage and repair, and the preparation of good-quality, high-molecular-weight DNA is an essential step of these analyses. Several methods are used to break the yeast wall, which are either based on mechanical or enzymatic assays (Zymolyase, Lyticase, Glusulase).[1–3] Because cells could rapidly remove some DNA lesions, it is important that the initial steps of the DNA isolation be carried out rapidly. In our laboratory, the method of choice is to break the cells by vigorous shaking in the presence of glass beads.

Currently, the most common techniques that are used to quantify the number of photoproducts in total genomic DNA are either immunological methods[30] or are based on the T4endoV assay. Monoclonal antibodies specific to CPDs and to (6.4)PDs [or to other types of DNA lesions that are not induced by UV light, such as benzo[*a*]pyrenediol (BPDE)] are commercially available, and antibody binding can be measured even with small quantities of antigens. Alternatively, the T4endoV assay developed in the Hanawalt laboratory[31] combines T4 enzymatic activity with Southern blotting. Namely, CPD formation and CPD removal are detected with CPD-specific endonuclease T4endoV, which makes single-DNA strand cuts at CPD sites. Southern blotting of denaturing (alkaline) agarose gels and hybridization with specific radioactive probes are used to quantify the frequency of CPDs in DNA. This technique also makes it possible to determine levels of DNA repair in small fractions of the genome such as single copy genes.

ISOLATION OF GENOMIC DNA FROM YEAST CELLS To follow NER of UV-induced photoproducts, the following steps are carried out under yellow lamps (peak at ~550–650 nm):

1. The cells are irradiated and 50-ml aliquots are collected by centrifugation as described in the section on Ultraviolet Light Irradiation of Large Cell Cultures. The cell pellets are resuspended in ice-cold 1.5 ml NIB (nuclei isolation buffer: 17% glycerol, 50 mM MOPS, 150 mM K-acetate, 2 mM $MgCl_2$, 0.5 mM spermine, and 0.15 mM spermidine, pH 8.0) and transferred to 15-ml tubes containing 1.5-ml glass beads (Sigma; ~425–600 µm) prewashed twice in NIB and prepared on ice.

2. The cells are vortexed vigorously 10–15 times for 30 sec each time with 30-sec gaps on ice.

3. The cells lysates are transferred to new 15-ml tubes on ice and the glass beads are rinsed twice with 1 ml NIB. The combined washing extractions are spun in a benchtop centrifuge at 3500 rpm (~2000 × *g*) for 2.5 min.

4. The supernatants (nuclei suspensions) are divided into two 2-ml Eppendorf tubes and spun in a microcentrifuge for 5 min at 4°C.

5. The pellets are resuspended in 500 µl TE total volume and collected into one 2-ml Eppendorf tube. After addition of 225 µl 3 M Na-acetate (pH 6.5), mixing, and 35 µl 10% sodium dodecyl sulfate (SDS), mixing (final volume 770 µl), the samples are extracted twice with phenol : chloroform : isoamyl alcohol (25 : 24 : 1) (equilibrated with Tris to pH ~ neutral) and once with chloroform (avoid taking the interphase). Finally, the nucleic acids are precipitated with one volume isopropanol at −20°C from 1 h to overnight.

6. After centrifugation for 30 min at 4°C, the white pellets are resuspended (without drying) in 500 µl TE; 10 µl RNase A (10 mg/ml) is added to each tube and the samples are incubated at 37°C for 30 min. Thereafter, 225 µl 3 M Na-acetate (pH 6.5) and 35 µl 10% SDS are added as described in step 5, followed by one extraction with phenol : chloroform : isoamyl alcohol (25 : 24 : 1) and one extraction with chloroform.

8. The samples are precipitated in isopropanol as described above. After centrifugation, the pellets are rinsed twice in 70% (v/v) ethanol, dried, resuspended in 200 µl TE, and stored at −20°C.

IMMUNOASSAY FOR THE DETECTION OF ULTRAVIOLET-INDUCED PHOTOPRODUCTS IN TOTAL GENOMIC DNA

1. Total genomic DNA is digested with two restriction enzymes to reduce its average size and resuspended in TE buffer. The samples are denatured at 95°C for 15 min and chilled on ice. [*Note:* the amounts of DNA must be determined empirically, e.g., 50–500 ng per slot.]

2. The nitrocellulose membrane (Protran, Schleicher & Schuell) is prewetted in ddH_2O and then equilibrated in 20 × SSPE (174 g NaCl, 27.6 g $NaH_2PO_4 \cdot H_2O$, 7.4 g EDTA, pH 7.4 per liter) for ~30 min. Using a slot-blot apparatus, the DNA samples are spotted in triplicate onto the membrane as follows:

- While applying a constant vacuum add 500 µl 20 × SSPE to each well.
- When all the liquid is adsorbed add the DNA samples in 250 µl.
- When all the liquid is adsorbed, wait an additional 5 min, keeping the vacuum constant. Then rinse the slots twice with 250 µl 20 × SSPE.
- When all the liquid is adsorbed, wait an additional 5 min, dismantle the slot-blotter, and place the membrane (DNA-side up) on 3MM papers and let it dry for 30 min.

3. After baking the membrane for 2 h at 80°C to fix the DNA, the membrane is rehydrated in PBS.

4. Blocking of the membrane is done in 5% nonfat dry milk in PBS-T (0.05% Tween-20 in PBS), at RT for 1 h.

5. The blocking solution is discarded and the membrane is briefly rinsed twice with PBS-T followed by four washes in PBS-T, 10 min each.

6. Incubation with antibodies for CPDs and (6,4)PDs (e.g., from Abcam, Affitech, Sigma-Aldrich, Trevigen) is done in 1% milk in PBS (~0.15 ml/cm^2 of membrane surface) for 3 h at RT or overnight at 4°C. [*Note:* The concentration of the antibodies is predetermined empirically.]

7. Washing of the membrane is done as described in step 5.

8. Secondary antibodies (Amersham) are prepared in 1% milk in PBS and the incubation is done for 1 h at RT, followed by the washing step as described above. [*Note:* The concentration of antibodies is predetermined empirically.]

9. Detection is done with chemiluminescence reagents (ECL; Amersham) according to the manufacturer's instruction, and the membranes are exposed to X-ray film or a PhosphorImager.

10. To normalize the amount of DNA in each sample and slot, DNA is spotted onto a parallel membrane (steps 1–3). Prehybridization and hybridization with ^{32}P-labeled DNA are done following standard protocols.

11. To determine the number of photoproducts and the DNA repair rates, normalize the signals obtained with the antibodies to the respective amounts of DNA in each slot. Subtract the signals generated from nonradiated samples (−UV, controls), which correspond to the nonspecific binding of the antibodies to DNA, and determine the percent repair (0 time repair = 100% photoproducts remaining). [*Note:* The same technique can be used to detect BPDE, the ultimate carcinogenic metabolite of benzo(*a*)pyrene.]

THE ALKALINE AGAROSE GEL ELECTROPHORESIS AND SOUTHERN BLOT ASSAY FOR THE DETECTION OF DNA STRAND BREAKS AND ULTRAVIOLET-INDUCED PHOTOPRODUCTS IN TOTAL GENOMIC DNA The strand breaks, for example, induced by T4endoV cleavage at CPD sites, cause a shift of the migration of DNA in denaturing agarose gel electrophoresis (Figure 47–1A; compare − and + T4endoV, − and + UV). The shift can be measured by separation of the DNA in alkaline agarose gels, transfer to nylon membranes, hybridization with ^{32}P-labeled genomic DNA (e.g., by random priming), and detection with a PhosphorImager.[32] The storage phosphor technology is very sensitive and has a linear response range over five orders of magnitude.

Discrete-step scans of images (Figure 47–1B) are recorded using ImageQuant software (Molecular Dynamics, Sunnyvale, CA). The half-area DNA migration points, or average length of the population of DNA molecules, are calculated on an Excel spreadsheet (Microsoft, Redmond, WA) from the migration profile of the population of DNA molecules, relative to DNA size standards. Finally, the number of CPDs/kb (or DNA strand breaks/kb) is calculated according to Freeman *et al*.[33]

1. The isolated DNA is treated with T4endoV (Figure 47–1A) as described in the section on The T4endoV Assay.

2. Alkaline agarose gels (1%) are prepared as previously described[34] and electrophoresis is run for about 13 h at 25 V (0.7 V/cm) with buffer circulation. Thereafter, gels are first neutralized for 1 h in 1.5 M NaCl, 1 M Tris–HCl (pH 7.5), then soaked in 0.25 N HCl for 30 min, and finally treated in 0.4 N NaOH for 15 min. The DNA is transferred in 0.4 M NaOH to a Hybond-XL membrane (Amersham) following the alkaline Southern blotting protocol.

3. The radioactive probe is generated from yeast total genomic DNA digested with *Eco*RI (to obtain shorter fragments) using random priming (Amersham). Prehybridization, hybridization, and washing are done as described in standard protocols, and the membranes are exposed to PhosphorImager screens.

4. Determination of the average DNA lengths (L^{av}) is done as follows:

- The image of one lane is overlaid with an array of duplicated rectangles, with the height that corresponds to 1 mm distance on the gel [Figure 47–1B; (−)T4endoV]. This array (1 to *n*) is copied onto the other lanes [Figure 47–1B; (+)T4endoV] and onto an empty lane that is used for background correction (Figure 47–1B; N).
- The image density (or volume) within each rectangle (1 to *n*) is measured with ImageQuant and the data are transferred to an Excel spreadsheet (Microsoft). A chart is generated showing the DNA profile of each lane (Figure 47–1C). [*Note*: Figure 47–1C is a schematic representation of a typical DNA profile of UV-irradiated genomic DNA, treated or mock treated with T4endoV.]
- Three backgrounds are subtracted from the image density data shown in Figure 47–1C. (a) The background generated from nonspecific binding of radiolabeled probe to the nylon membrane is removed by subtracting the density values obtained from an empty lane (Figure 47–1B, N) to the corresponding rectangles (1 to *n*) in the (−) and (+) T4endoV lanes and (b) the background due to random nicks generated during DNA isolation [visible in the lanes (−)T4endoV] is removed. (b1) First, the signal (smear) below the broad band corresponding to high-molecular-weight DNA [Figure 47–1B; (−)T4endoV, from 5 to *n*) or region "b1" (Figure 47–1D): each position in the (−)T4endoV lane is subtracted from itself and from its corresponding position in the (+)T4endoV lane. (b2) Second, region "b2" (Figure 47–1D), which corresponds to nicked high-molecular-weight DNA and is described as the area under the straight line ($y = ax$), which is generated from the origin of the high-molecular-weight DNA and the first data point of the smear (rectangle 5); the *y*-values are subtracted from each corresponding data point in the (−) and (+)T4endoV lanes. The results obtained after subtraction of the three backgrounds are shown in Figure 47–1E.
- The total areas encompassed by the corrected scans are calculated, and the data points corresponding to half of these areas are determined (Figure 47–1E; X_{med}). By using the standard curve generated from the migration of the DNA size markers (Figure 47–1A; M), X_{med} is converted to the median length L_{med} (in bases). The average molecular length (L^{av}) is then calculated using the following equation[35]:

$$L^{av} = 0.6 \times L_{med}$$

assuming a Poisson distribution of DNA fragments.

5a. For UV-irradiated DNA, the number of CPDs/kb is calculated using the following equation[33]:

$$\text{CPDs/kb} = (L^{av})^{-1}_{(+)\text{T4endoV}} - (L^{av})^{-1}_{(-)\text{T4endoV}}$$

where $(L^{av})_{(+)\text{T4endoV}}$ and $(L^{av})_{(-)\text{T4endoV}}$ are the L^{av} values for samples treated or mock treated with T4endoV, respectively.

5b. For DNA SSBs, for example, induced by BLEO, the number of SSBs/kb is calculated using the following equation[32]:

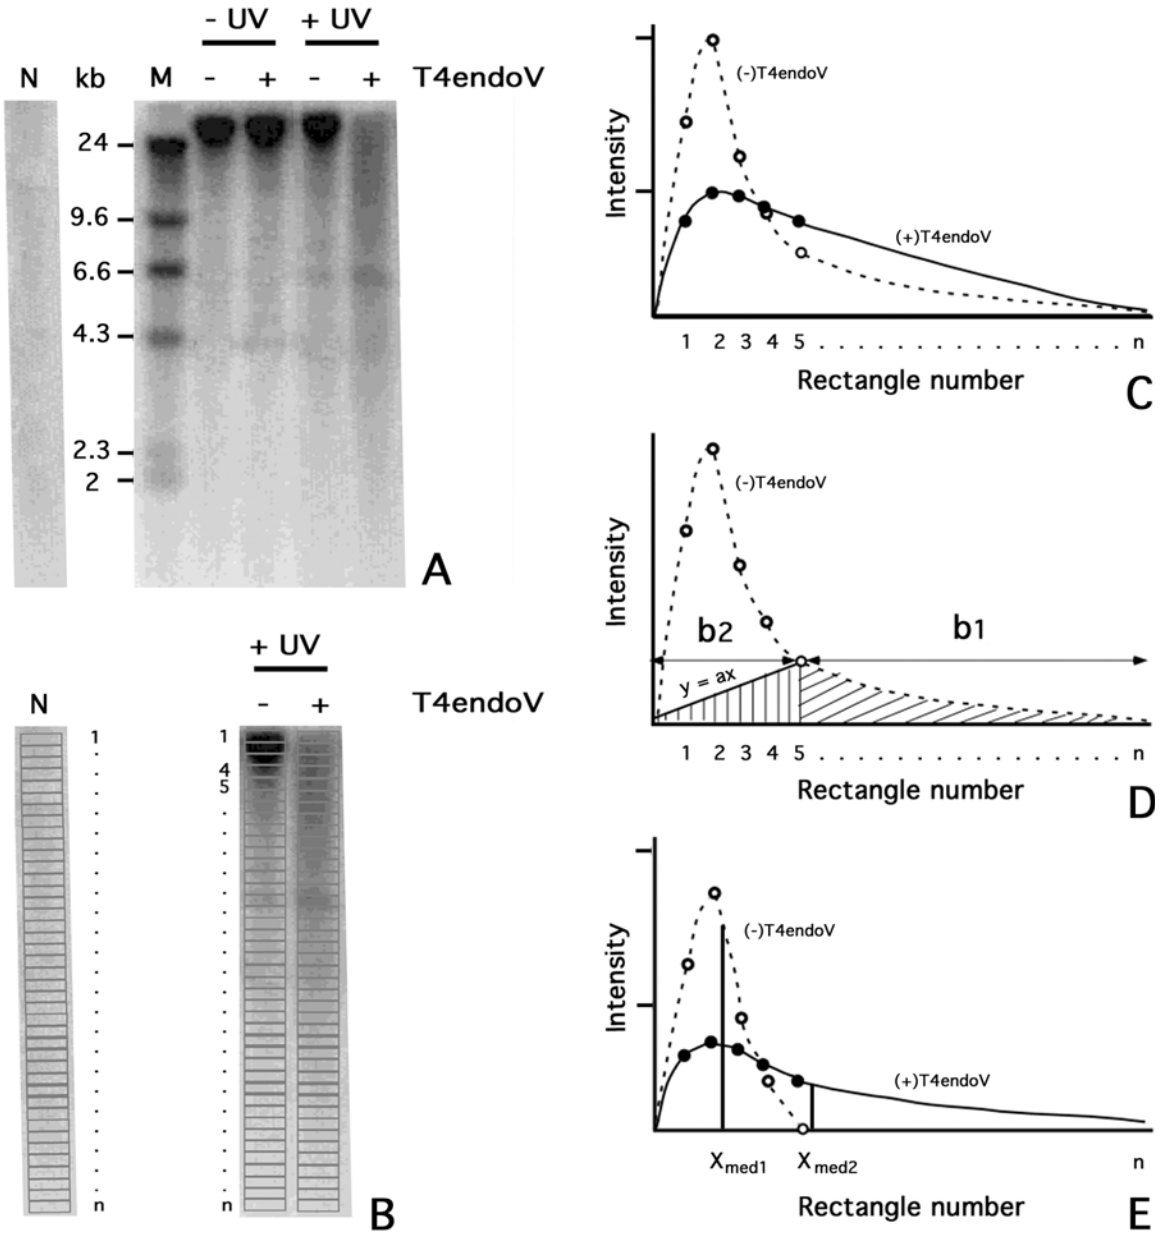

Figure 47–1. Measurements of DNA strand breaks (induced by T4endoV cleavage at CPD sites) by alkaline agarose gel electrophoresis and Southern blot.

$$\text{SSB/kb} = (L^{av})^{-1}$$

6. For repair experiments, CPDs/kb (or SSB/kb) at various repair times are expressed as percent of the damage measured at time of 0 repair (see the section on The T4endoV Assay).

THE T4ENDOV ASSAY TO MEASURE NUCLEOTIDE EXCISION REPAIR OF ULTRAVIOLET-INDUCED PHOTOPRODUCTS IN SPECIFIC DNA SEQUENCES

1. DNA is isolated before UV irradiation (–UV), soon after UV irradiation (+UV; 0 repair), and after various repair times (+UV; 1/2, 1, 2, and 4 h) (Figure 47–2A). About 6 µg of DNA for each time point is digested with the suitable restriction enzyme. [For example, in Figure 47–2A the DNA was digested with *Eco*RI, which releases an ~2.9-kb DNA fragment when blots are hybridized with a probe corresponding to the central portion of ribosomal genes (rDNA).]

2. After extraction with phenol:chloroform:isoamyl alcohol and chloroform, the DNA is precipitated in ethanol and resuspended in 32 µl of T4endoV buffer (50 mM Tris–HCl, pH 7.5, and 5 mM EDTA).

3. On ice, dilute 1 µl of T4endoV enzyme (e.g., from Epicentre) 1 : 50 in T4endoV buffer, and prepare the reactions in 0.5-ml Eppendorf tubes as follows:

- To the mock-treated samples [(–)T4endoV] add 2 µl of T4endoV buffer.
- To the test samples (+)T4endoV] add 2 µl of the diluted T4endoV enzyme.

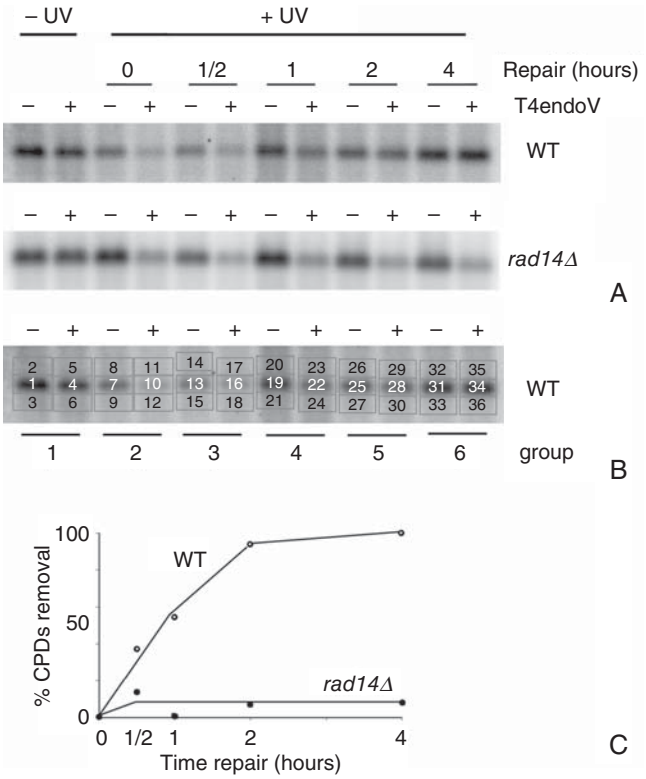

Figure 47–2. Measurements of repair of CPDs in defined DNA sequences by the T4endoV assay.

- Add 15 µl of the DNA suspensions (out of the 32 µl total) to the test samples and to the mock-treated controls, and incubate the reaction for 45 min at 37°C.

4. To each sample add 3 µl of 6× alkaline loading buffer [300 mM NaOH, 6 mM EDTA, 18% (w/v) Ficoll (type 400), 0.15% (w/v) bromocresol green, 0.25% (w/v) xylene cyanol], which brings the final volumes to 20 µl, and load the samples onto 1% alkaline agarose gels that are prepared as previously described.[34] The gel electrophoresis is run for about 13 h at 25 V (0.7 V/cm) with buffer circulation, and the DNA is transferred in 0.4 M NaOH to a Hybond-XL membrane (Amersham) following the alkaline Southern blotting protocol. Thereafter, the membrane is hybridized with ^{32}P-labeled specific DNA sequences. [In Figure 47–2A, the blots carrying DNA from the wild-type (WT) and from the NER-deficient mutants (*rad14Δ*) were hybridized with a rDNA probe.] Changes in bands intensities, compare lanes (–) and (+), reflect the number of CPDs. Whereas DNA repair is observed in WT, no removal of CPDs is found in *rad14Δ* cells.

5. Quantification of the image scans is done with ImageQuant software (Molecular Dynamics, Sunnyvale, CA) as follows:

- A rectangle is drawn tightly around the signal corresponding to –UV (–)T4endoV (Figure 47–2B; group 1, rectangle 1), taking care not to touch the band. Five duplicated rectangles are overlaid on the (+)T4endoV band (rectangle 4) and on the regions adjacent to the bands that are used for background correction (rectangles 2, 3, 5, and 6). This procedure is repeated for each of the six groups.
- The densities (or volumes, *V*) of each rectangle (1 to 36) are measured (ImageQuant) and the data are transferred to an Excel spreadsheet (Microsoft).
- The volume (*V*) of each band is corrected by subtracting its average background, which is generated from the nonspecific binding of radiolabeled probe to the membrane (rectangle above the band) and from random nicks generated during DNA isolation (rectangle below the band), and is called $\bar{V}$ [e.g., $\bar{V}_{19} = V_{19}\ (V_{20} + V_{21})/2$].
- The number of CPDs per DNA fragment (in Figure 47–2A; the ~2.9-kb *Eco*RI rDNA fragment) is calculated with the following equation:

$$\text{CPDs/DNA fragment} = \ln(\bar{V}_{(-)\text{T4endoV}} / \bar{V}_{(+)\text{T4endoV}})$$

6. The resistance of DNA cutting by T4endoV is monitored as a measure of repair, and the percent of CPD removal is plotted over the repair incubation time (Figure 47–2C). (In the rDNA of WT cells ~50% of CPDs is removed after 2 h and ~100% repair is achieved after 4 h. No repair is measured for the same DNA fragment in *rad14Δ* cells.)

ACKNOWLEDGMENTS

I would like to thank Dr. K. Kobryn at the Université de Sherbooke and D. Fahy at Washington State University for critical reading of the manuscript. Also, I would like to thank the students in my laboratory, M. Toussaint, M. Tremblay, G. Levasseur and J. Doyon for providing me with the most up to date protocols. The Natural Sciences and Engineering Research Council of Canada (NSERC) supported this project.

48 Human Models of Space Physiology

VICTOR A. CONVERTINO AND CAROLINE A. RICKARDS

ABSTRACT

Maintaining the health and fitness of astronauts is essential to the successful exploration of space. Consequently, the development of methods (i.e., countermeasures) designed to minimize potential adverse clinical effects of space flight depends on an understanding of the physiological mechanisms that underlie human adaptation to microgravity. However, uncontrolled conditions and mission logistics associated with spaceflight present significant limitations to the scientific study of human physiology in the space environment. Although no one model precisely simulates the actual space environment, the quantitative as well as qualitative comparisons of space physiology with the 6° head-down bed rest (HDBR) model are striking. Selective comparisons presented in this chapter demonstrate distinct qualitative and quantitative similarities in the underlying physiology of body fluids, cardiovascular and autonomic functions, muscle, bone, and metabolism in humans between HDBR and space. Because of these similarities, the use of the HDBR model has provided critical direction for the investigation of space physiology that otherwise could not be addressed adequately in the space environment. HDBR has proven to be one of the most effective and valuable models for assessing the effects of prolonged exposure to microgravity on human physiological functions by inducing physical and physiological changes similar to those that occur when humans are exposed to the actual environment of space.

Key Words: Head-down bed rest, Blood volume, Cardiovascular functions, Autonomic nervous function, Bone, Muscle, Metabolism, Orthostatic intolerance, Physical exercise.

INTRODUCTION

Since the beginning of human spaceflight, the value of understanding mechanisms of physiological adaptation to microgravity became apparent to life scientists who were interested in maintaining crew health and developing countermeasures against the adverse effects of a mission. However, several characteristics associated with the logistics of spaceflight presented significant limitations to the scientific study of human adaptation to microgravity. Because space missions are so infrequent and involve minimal numbers of crewmembers, meaningful statistical analyses of data are limited. The reproducibility of results from experiments conducted in space is difficult to assess since there are few repeated space missions involving the same crewmembers. Since the emphasis of space missions is placed on operations, human physiological experiments are often compromised by numerous confounding and uncontrolled factors (e.g., time, diet, physical activities, circadian rhythms) that can impact measured responses. With the limited time available to collect data in space, crewmembers are required to participate in numerous simultaneous experiments proposed by multiple investigators that can adversely affect the outcomes of each independent experiment. The technology and ability to measure physiological functions necessary to test specific hypotheses can also be severely limited by physical space and power constraints of the space environment. Finally, technical and logistical aspects of space missions such as launch delays, extended missions, and operational emergencies can significantly compromise the timing and control of experiments. These limitations have stimulated scientists to develop ground-based models of microgravity in an effort to investigate the effects of space on physiological function in a controlled experimental setting.

TRADITIONAL MODELS FOR SPACE PHYSIOLOGY

The term *microgravity* describes a condition in which gravitational forces acting on the long axis of the body are minimized in space. The key to effective simulation of microgravity on Earth is to remove this gravitational stimulus as much as possible. There are several methods that have been attempted to achieve this requirement in the simulation of microgravity on humans.

FREE FALL AND PARABOLIC FLIGHT Free fall occurs when an object plunges downward toward Earth at the rate of acceleration due to gravity (980 cm/sec^2). One model often used to investigate space physiology is a special aircraft that flies repeated parabolic arcs that result in a controlled, 45° nose-down, free-fall dive. The passengers inside the aircraft experience an immediate transition into free fall (weightlessness) from the top of the arc that persists during the downward portion of the parabola. Unfortunately, the average duration of weightlessness with this technique is only 20–25 sec, limiting the collection of data and the interpretation of physiological responses to a very acute

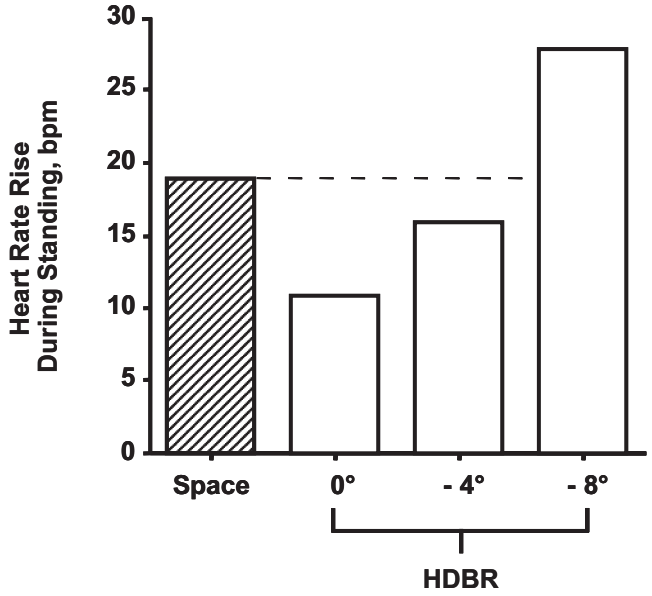

Figure 48–1. Elevation in heart rate during standing after exposure to space (closed bar) and 0°, 4°, and 8° HDBR (open bars). (Data modified from Kakurin *et al.*[1])

time course. Additionally, parabolic flight often induces symptoms of motion sickness such as nausea and vomiting that can potentially confound the measured outcome variables.

WATER IMMERSION Placement of human subjects in a small pool of thermoneutral (~34.5°C) water with their head just above water is used to simulate microgravity, as the buoyancy of the surrounding water removes the full effect of Earth's gravity. A major difficulty experienced in such studies is the high rate of heat transfer between the subject and the surrounding water, and prolonged exposure of the skin to the immersion fluid. To avoid such problems, models of "dry" immersion have been developed that enclose subjects in a waterproof material. This model of microgravity has obvious limitations for performing experimental investigations that require physical access to subjects, and there are also limitations on the amount of time a subject can be exposed to this environment.

SUSPENSION AND IMMOBILIZATION Musculoskeletal unloading similar to space can be produced by suspending subjects above the ground with springs, or by supporting them from below with air jets (air-bearing floors). Such methods create regions of tissue compression that can be tolerated for only short periods of time. Limb immobilization or casting has been used to study regional changes in muscle, but fixing the limb may not represent the conditions of spaceflight where astronauts move their limbs freely. Models of unilateral lower limb suspension have been developed that involve a support strap or high platform shoe allowing the subject to ambulate with crutches while the unloaded leg hangs freely. This model is primarily limited to the study of alterations in muscle and bone associated with space travel without inducing the headward fluid shifts associated with exposure to space.

HEAD-DOWN BED REST Bed rest has become the most popular model since it can be applied for prolonged periods of time (weeks to months) and affects most of the physiological systems of the body. The work of Kakurin and co-workers[1] represents one of the first comparisons of bed rest data to space data. These investigators determined that the magnitude of the heart rate response to a stand test following return from space was between the responses produced by exposure of human subjects to 4° and 8° head-down bed rest (HDBR) (Figure 48–1). As a result of this investigation, 6° HDBR has been adopted as the universal human model for the study of space physiology. Thus, the remainder of this chapter will focus on the comparison of select human physiological data collected from HDBR experiments with those obtained from space experiments.

BODY FLUIDS

One of the earliest effects on the human body upon entry into the microgravity of space is a headward fluid shift and enlargement of the heart.[2] A fundamental adaptation to this headward fluid shift is a reduction in plasma and blood volume.[3] The time course of the change in circulating vascular volume is characterized by a rapid reduction within 24–48 h followed by a newly stabilized hypovolemic state (Figure 48–2). Figure 48–2 demonstrates the striking similarity in magnitude as well as time course of plasma volume reductions during exposure to space and HDBR. Interestingly, the average magnitude of plasma volume reduction (13%) from the subsequent SLS-1, SLS-2, and D-2 NASA space missions after 9–14 days of flight is nearly identical to that predicted by the HDBR graph generated in Figure 48–2.[3] The alteration in body fluids with exposure to space is also reflected in similar reductions in body weight observed following similar durations of spaceflight (3%) and HDBR (4%).[4,5]Thus, the similarity in time course and magnitude between space and HDBR data suggests that the latter provides an effective model to investigate the mechanisms associated with reduced plasma volume and body fluid redistribution that cannot be readily studied in space.

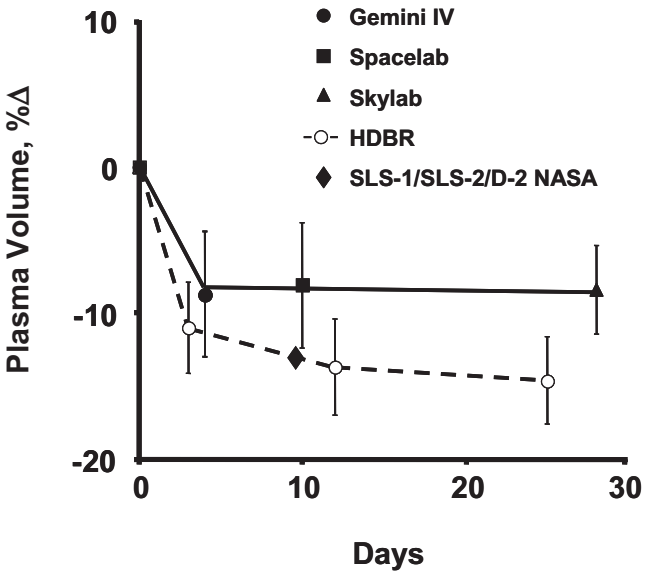

Figure 48–2. Comparison of time courses of plasma volume changes (%Δ) during adaptation to space (closed symbols and solid line) and HDBR (open circles and broken line). (Modified from Convertino.[3])

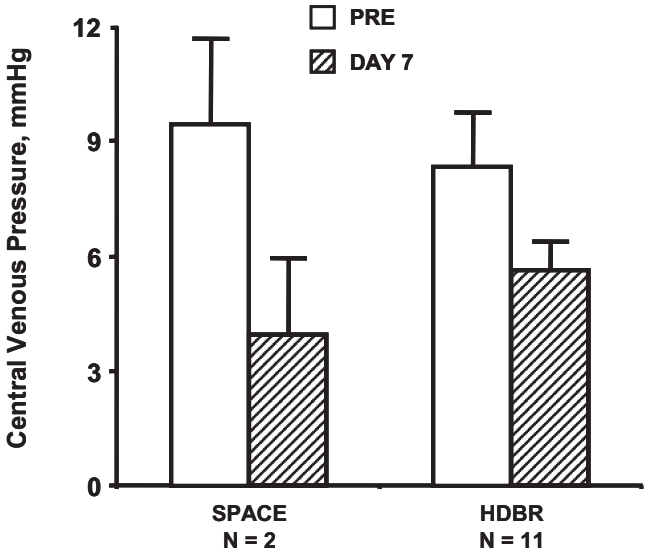

Figure 48–3. Comparison of estimated central venous pressure (CVP) before (open bars) and on day 7 of (closed bars) exposure to space and HDBR. Values are mean ± 1 SEM (lines). (Modified from Convertino.[8])

CARDIOVASCULAR

There is a vast collection of data on the physiology of the cardiovascular system and its adaptation to space, perhaps because of its important contribution to astronaut health and performance. In conjunction with the decrease in plasma volume, the general cardiovascular adaptation to space and HDBR includes a reduction in stroke volume with compensatory elevations in peripheral arterial vasoconstriction and heart rate leading to the maintenance of cardiac output and arterial blood pressures.[2,5,6] Magnetic resonance imaging measurements conducted on four astronauts who participated in the D-2 NASA space mission revealed an average 14% reduction in left ventricular mass, which is comparable to the 8% decrease in cardiac mass following HDBR.[7] Data obtained from peripheral catheters suggested a reduced central venous pressure (CVP) of similar magnitude after 7 days of exposure to both space and HDBR (Figure 48–3). This reduction in CVP was later verified with direct measurements from indwelling catheters placed in the right atrium of five astronauts while in space.[2] Venous compliance of the calf is also decreased in HDBR and in space.[8] These comparisons support the idea that HDBR represents an excellent model for the investigation of cardiovascular responses associated with the physiological adaptation to space.

AUTONOMIC NERVOUS SYSTEM

It is almost impossible to interpret responses of the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS) while in space because of wide variations in conditions such as physical activity, gender, energy balance, and diet. However, direct and indirect indices of SNS and PNS responses measured before and after exposure to space and HDBR are qualitatively similar. PNS activity, indicated by the high-frequency spectral power of R-R intervals calculated from an electrocardiogram, is reduced following adaptation to space and HDBR.[9,10] Conversely, direct measurements from muscle sympathetic nerves indicate that SNS activity is dramatically elevated following exposure to space and HDBR.[11] Autonomically mediated baroreflexes also appear to be affected in a similar fashion by HDBR and space.[8] A shift of the carotid–cardiac baroreflex stimulus–response relationship downward and to the right indicates that for a given reduction in arterial pressure, there will be a smaller compensatory increase in heart rate (i.e., less sensitivity of the baroreflex) after adaptation to microgravity or HDBR (Figure 48–4). The similarity in these data supports the notion that HDBR provides a valid model to investigate the effects of space on mechanisms of autonomic nervous function and regulation.

MUSCLE

Exposure to space and HDBR causes unloading of skeletal muscles, especially those of the lower weight-bearing extremities. The reduction in leg volume is similar in individuals exposed to space and HDBR and has been used as an indirect indication of muscle atrophy (Table 48–1). Actual muscle biopsies taken from

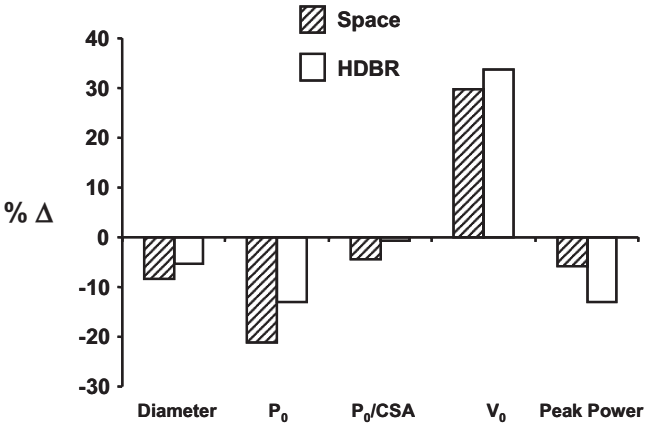

Figure 48–5. Average relative changes (%Δ) in single muscle fiber diameter, peak force (P_0), normalized peak force corrected for fiber size (P_0/CSA), unloaded shortening velocity (V_0), and peak power obtained from human muscle biopsies of the soleus (calf) muscle before and after exposure to HDBR (open bars) and space (closed bars). (Modified from Widrick *et al.*[13])

subjects before and after exposure to space and HDBR have confirmed significant muscle atrophy under both conditions as evidenced by similar reductions in cross-sectional areas of both slow-twitch and fast-twitch muscle fibers of the vastus lateralis (thigh) muscle.[4,12] Muscle atrophy was accompanied by similar reductions in the capillary-to-fiber ratio in slow-twitch fibers after exposure to HDBR (11%) and space (16%).[4,12] In a study specifically designed to compare the HDBR model to space exposure, measurements of muscle structure and function were performed on single soleus (calf) muscle fibers obtained from biopsies of four astronauts and eight subjects before and after 17 days of muscle unloading.[13] Measurements included muscle fiber structural (i.e., diameter) and contractile (i.e., peak force, unloaded shortening velocity, peak power) properties. Muscle fiber diameter, peak force, and peak power were reduced while unloaded shortening velocity increased (Figure 48–5). The comparisons revealed alterations of similar magnitude and direction for space and HDBR. Clearly, HDBR provides an effective model to investigate the unloading of muscle caused by space.

METABOLISM

In addition to changes in muscle morphology and function, exposure to microgravity has been associated with histochemical and biochemical alterations in muscle that can impact cellular metabolism. Although there were no significant changes in the activities of glycolytic enzymes (e.g., ATPase, lactate dehydrogenase, phosphofructokinase) in the soleus and vastus lateralis muscles following HDBR or space, the activities of enzymes associated with aerobic metabolic pathways (e.g., succinate dehydrogenase, citrate synthase) were reduced in both slow- and fast-twitch muscle fibers.[4,12] Measurements of energy intake and expenditure were performed using the doubly labeled water method on four astronauts and eight subjects before and after 17 days of exposure to space and HDBR.[14] Energy intake was 22% lower and energy expenditure was 32% higher in space compared with HDBR (Figure 48–6). As a result, astronauts experienced a significant negative energy balance and weight loss in space that were not observed in the HDBR subjects. Despite an experiment designed to match physical exercise regimens, the differences in energy exchange between space and HDBR are not unexpected given the additional energy requirements of spacecraft movement and extravehicular activities. It is clear from these data that adding more physical activity or decreasing dietary intake during HDBR would provide an improved model for the study of metabolism during space.

BONE

As with the muscular system, the absence of gravity has a profound impact on both the structure and function of bone, specifically the weight-bearing bones of the lower body. Generally, unloading of bone in space and bed rest has been associated with reduced bone formation, increased bone resorption (breakdown), and changes in the distribution of bone, ultimately leading to reductions in absolute bone mass and in bone mineral density.[15] Skeletal unloading leads to an altered regulation and metabolism of calcium as indicated by increased calcium excretion (urinary and blood), negative calcium balance, and alterations in bone-regulating hormones such as vitamin D. The magnitudes of these changes in bed rest are similar to those reported in space (Table 48–1) and are proportional to the time of exposure. Thus, bed rest provides a valid model to investigate the effects of space on the mechanisms of bone unloading.

OPERATIONAL FUNCTIONS

ORTHOSTATIC PERFORMANCE Syncopal events (i.e., fainting) reported in 28–65% of mission specialists studied during stand or tilt tests after returning from space are comparable with the rate of syncope (~40%) observed in subjects during a stand test following HDBR.[8] In orthostatic tests without symptomatic episodes, the magnitude of the elevation in heart rate with stable blood pressure is similar after exposure to both HDBR and space (Figure 48–7). However, subjects demonstrated elevated peripheral vascular resistance during orthostatic tests following

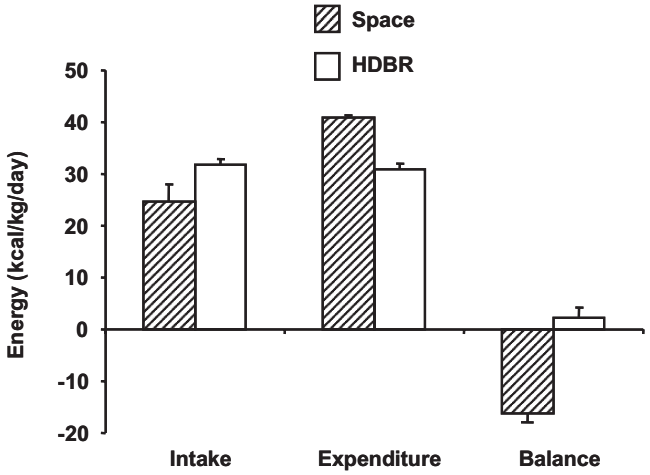

Figure 48–6. Energy intake, expenditure, and balance during 17 days of exposure to space (closed bars) and HDBR (open bars). Values are mean ± 1 SEM (lines). (Data from Stein *et al.*[14])

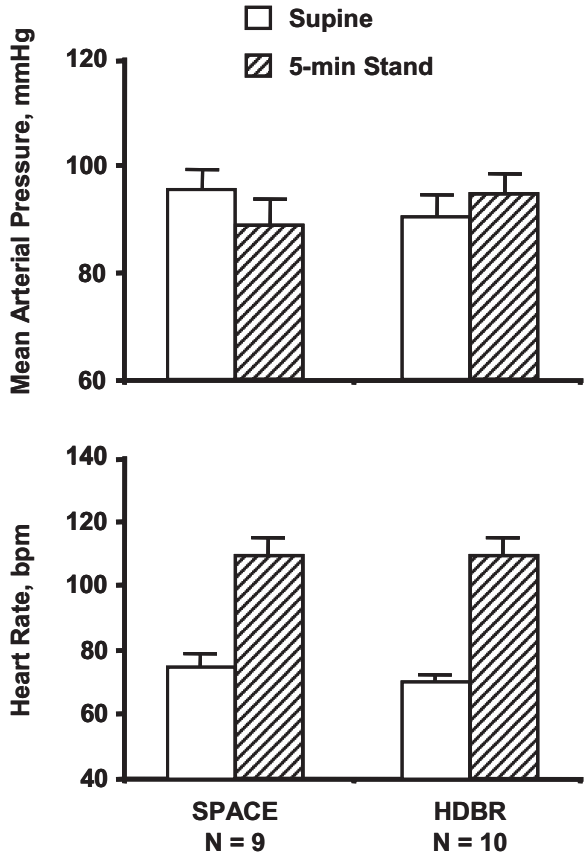

Figure 48–7. Comparison of heart rate and blood pressure responses during 5 min of standing after exposure to space and HDBR. Values are mean ± 1 SEM (lines). (Modified from Convertino.[8])

exposure to both space and HDBR.[6,16] Thus, similarities in cardiovascular responses during orthostatic challenges support the use of the HDBR as an appropriate model for the study of mechanisms that underlie orthostatic intolerance following return from space and for the development of effective countermeasures.

RESPONSES TO PHYSICAL WORK Exercise tests have proven to be one of the most effective methods of assessing the integrated effects of space on multiple physiological systems. Generally, cardiovascular responses to exercise in space and with HDBR are marked by decreased cardiac output and oxygen (O_2) pulse despite compensatory elevations in heart rate at a given intensity of physical work.[1,5,8,17] Exposure to space and HDBR results in similar reductions of stroke volume and increases in cardiac ejection fraction at a given intensity of physical work compared with prespace/HDBR measurements (Figure 48–8). The metabolic response to exercise during HDBR is also similar to space. The capacity of the body to utilize oxygen is decreased in space and HDBR.[5,18] In a study specifically designed to compare the HDBR model to space, cardiorespiratory and metabolic measurements were performed on four astronauts (VO_2 max decreased 10%) and eight subjects (VO_2 max decreased 7%) before and after 17 days of exposure to space and HDBR.[18] Figure 48–9 demonstrates that the relative change (%Δ) in oxygen uptake, heart rate, ventilatory volume (V_E), O_2 pulse, and ventilatory equivalent (V_E/VO_2) with maximal exercise was similar in space and HDBR. From these investigations, HDBR has become a primary model for simulating the effects of prolonged exposure to space on cardiorespiratory and metabolic functions.

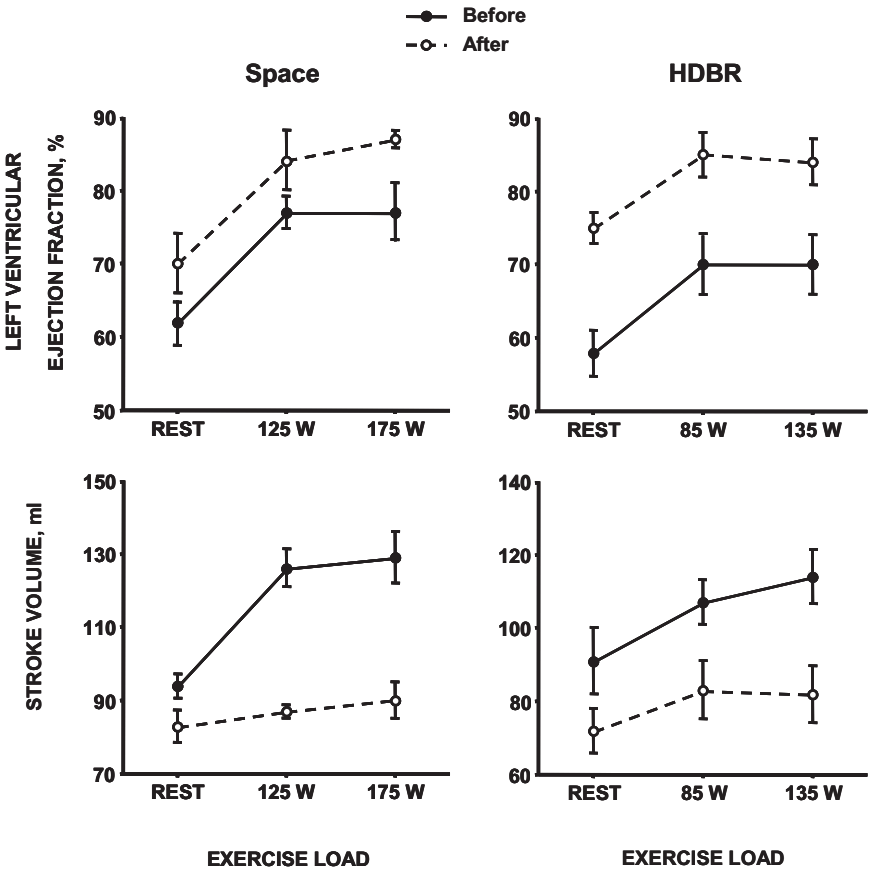

Figure 48–8. Left ventricular ejection fraction and stroke volume during rest and graded exercise before (closed circles and solid lines) and after (open circles and broken lines) space (left panels) and HDBR (right panels). Values are mean ± 1 SEM (lines). (Modified from Convertino and Cooke.[19])

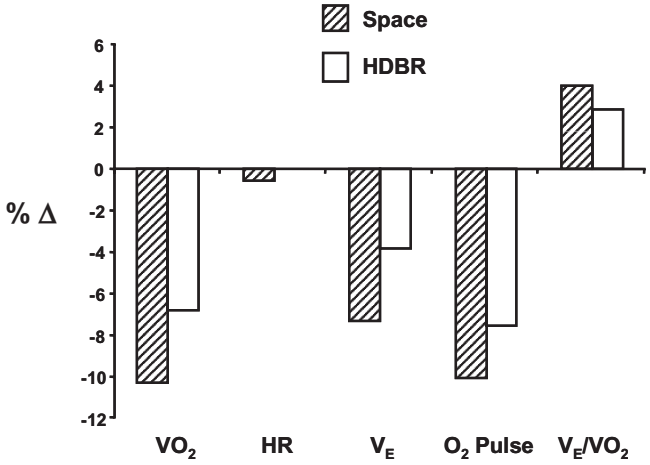

Figure 48–9. Average relative change (%Δ) in oxygen uptake (VO_2), heart rate (HR), ventilatory volume (V_E), oxygen (O_2) pulse, and ventilatory equivalent (V_E/VO_2) during maximal exercise following 17 days in space (closed bars) and HDBR (open bars). (Data from Trappe *et al.*[18])

CONCLUSIONS

No one model precisely simulates the actual space environment. In an attempt to assess the validity of various models for the simulation of microgravity effects on human physiological functions, difficulties arise with replicating the uncontrolled experimental conditions surrounding investigations conducted in space. In addition, space experiments suffer from the lack of true ground controls. Despite the extreme variability in experimental conditions and mission activities associated with space, the quantitative as well as qualitative comparisons of space physiology with the 6° HDBR model are striking (Table 48–1). Selective comparisons presented in this chapter demonstrate distinct qualitative and quantitative similarities in the underlying physiology of body fluids, cardiovascular and autonomic functions, muscle, bone, and metabolism in humans between HDBR and space. Because of these similarities, the use of the HDBR model has provided critical direction for the investigation of space physiology that otherwise could not be addressed adequately in the space environment. HDBR has proven to be one of the most effective and valuable models for assessing the effects of prolonged exposure to microgravity on function in humans by inducing physical and physiological changes similar to those that occur when humans are exposed to the actual environment of space.

49 Developmental Space Biology of Mammals

Concepts and Methods of Study

APRIL E. RONCA

ABSTRACT

In the past decade, emerging concepts and methods for studying mammalian development under altered gravitational fields have led to a new generation of space biology research. Studies of the Norway rat (*Rattus norvegicus*) provide unequivocal evidence that mammalian reproduction and ontogenesis can proceed under gravitational forces that deviate considerably from the constant force of the Earth's $1 \times g$. Mammalian birth has not yet been attempted within the microgravity of space, however, pregnant and lactating rat dams and their progeny have flown onboard the NASA Space Shuttle. Collectively, spaceflight and ground-based research have led to identification of important requirements for supporting developing mammals in altered gravitational fields, particularly the necessity of preserving the coordinated interactions between mothers and offspring, the ontogenetic context within which development occurs. Developmental studies utilizing gravitational manipulations are yielding new information relevant to health and disease on Earth, especially forces that shape and maintain the vestibular, balance, and motor systems and contribute to our understanding of body-weight regulation, prenatal stress, and adaptation to environmental change. Major concepts, approaches, and methods for studying the developmental space biology of mammals and prospective contributions of this nascent yet fertile area of scientific query to contemporary concerns in biomedicine are described.

Key Words: Prenatal, Postnatal, Maternal, Fetus, Infant, Pregnancy, Lactation, Microgravity, Hypergravity, Centrifugation.

INTRODUCTION

A major goal of space biology research is to broaden scientific knowledge of the Earth's constant gravitational force ($1 \times g$) on living organisms. To this end, studying the life cycles of mammals in space and in other altered gravitational environments promises to uncover exciting new insights into how gravity shaped life on Earth. The life cycles of different vertebrates are characterized by vastly differing adaptations that vary in number and complexity, yet no vertebrate has yet been raised from conception to sexual maturity in the absence of gravity.[1–4] A number of pioneering experiments with fish, amphibians, birds, and rodents flown at various phases during their reproductive and developmental cycles have shown that vertebrate reproduction and development can proceed in the microgravity of space.[5] For example, female frogs (*Xenopus laevis*) flown on the NASA Space Shuttle underwent ovulation and their eggs yielded larvae.[6] Medaka killfish *(Oryzias latipes)* mated and successfully fertilized then hatched fry in space.[7] Female Norway rats *(Rattus norvegicus*) spent the latter half of their pregnancies in space and gave birth to healthy offspring within 48 h of returning to Earth.[8] These and other space biology studies, many relying on established ground-based models,[9,10] have been instrumental in validating new approaches and methods for studying reproduction and development in altered gravity. Collectively, this research has opened the door to a new era of space and ground-based experimentation with vertebrates. Historically, the rat has served as the primary model for mammalian developmental space biology experimentation, and therefore will be the primary focus of this chapter.

WHY STUDY DEVELOPING MAMMALS?

Mammalian reproduction and development are comprised of an intricate and complex series of biological events. Internal fertilization, pregnancy, placentation, embryogenesis, fetal growth and development, labor and birth, lactation, parental care, and postnatal development, including sexual maturation, are major steps involved in the reproductive cycles of mammals. Throughout development, rapid and continuous change occurs within the context of correlated environmental transformations.[11] The fetus begins life within a warm uterine enclave with physiological resources automatically supported. At birth, profound neural and biochemical changes foster the emergence of new behaviors, including postpartum breathing and feeding.[12] The mother's caretaking behavior helps direct and regulate postnatal development.

These and other patterns that characterize development and the context in which it occurs are unique to and universal among mammals. Commonalities among developmental processes represent the shared ancestry of contemporary mammalian species.[11] Because mammals share many biological processes throughout the life cycle, the Norway rat has become a predominant model

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.),

for human function and disease in both space flight and ground-based experiments. Developmental analysis provides an especially useful approach. Whereas organisms change and adapt throughout their life span, changes that occur during development are far more rapid and are expressed more dramatically ("magnified") as compared to slow, subtle changes in adulthood (for further discussion, see Alberts and Ronca[11]). The developmental approach, which provides an important resource for space studies, can be used in various ways.

DEVELOPMENTAL HISTORY One strategy used for understanding biological processes in adult forms is to study the developmental history of a physiological process or behavior. Determining the sequential organization of a biological phenomenon during maturation may provide clues about how that system is organized and its underlying mechanisms. For example, the appearance of particular morphological changes during development may correspond to specific functional changes. Some complex functions may have multiple, intertwined components with separate developmental histories. Of course, in the infant, the process may differ from the adult or may not be fully developed. This developmental strategy has been used extensively to study the organization of ingestive behavior and has revealed multiple and separate regulations.[13] Applied to space biology, this approach would entail perturbing the system during development by altering the gravitational milieu, then determining how the specific changes observed correlate with the response of individual components in the adult system. In this way, it is possible to learn how the system is built or assembled.

DEVELOPMENTALLY DISTINCTIVE BIOLOGICAL PROCESSES There is a vast array of biological processes and behaviors specific to particular developmental phases. Suckling for milk in early life, for example, is a behavior that appears to be under separate physiological regulation than is adult or infant feeding.[13] The developing animal has a specific ecological and physiological niche, and there are many illuminating examples of the adaptive strategies that young use to thrive in their unique ontogenetic setting.[11] Studies of processes specific to development, including those that are gravity sensitive, can reveal how the environment shapes early behavior and function. Thus, placing a newborn rat on its back on a surface quickly elicits a body turn *against* the gravity vector to achieve the prone position.[14] However, during nipple attachment the neonate performs a similar motor sequence to orient itself *toward* the gravity vector and attain a supine posture.[15]

DEVELOPMENT AS A MODEL SYSTEM Another perspective on studying developing animals is that the immature animal can provide a model system for analyzing relationships between environmental change and biological function. The use of maturing animals can provide information that cannot readily be obtained in adult animals—not because young animals are simpler than adult animals, because they are likely to be more complex. As we begin to better characterize responses and adaptations of animals of different ages to altered gravity, we can relate their patterns of response to age-specific changes in physiological and behavioral systems.

FUNDAMENTAL CONCEPTS IN SPACE AND GRAVITATIONAL BIOLOGY

A basic appreciation for the space environment and the physical stimulus of gravity is a prerequisite to space biology research.

THE SPACE ENVIRONMENT Spacecraft orbiting the Earth are in continuous "free-fall," balanced by equal and opposite forces toward (gravitational) and away from (centripedal) the Earth. The term "microgravity" refers to the small amount of gravity present on an Earth-orbiting spacecraft that is estimated to be approximately one-millionth of its value on Earth.[16]

Microgravity is a major component of the space environment. Radiation, arising from charged particles, neutrons, or ionizing photons, is a significant factor as well. Radiation levels in space exceed both background exposure at the Earth's surface and occupational exposure levels for radiation and health workers. Accurate dosimetric profiles of the space environment, including information on fluence, charge, velocity, specific energy and time course of dose deposition, and potential synergistic effects of microgravity and radiation require detailed analyses within the space environment and cannot be answered by ground-based studies.[16]

Acceleration, vibration, and noise encountered during launch and reentry are significant variables in spaceflight experiments that are difficult to reliably duplicate in ground-based simulations. For these reasons, studies incorporating $1 \times g$ controls in the space environment must eventually be performed. The centrifuge accommodation module planned for the International Space Station (ISS) is essential for validating space biology studies and answering critical questions about the space environment.

GRAVITY AS A CONTINUUM Gravity (g) is the universal force of attraction between bodies. It is a continuum beginning at zero and continuing through infinity. Table 49–1 shows gravitational loads associated with different environments. Models used to study gravity's effects on humans and animals rely on removing or adding gravity, usually within about $1 \times g$ of the Earth's gravity in rats.

Early space life science investigators viewed the application of gravitation force as a continuum with applications of varying magnitude producing graded biological responses. Unfortunately, they did not have the opportunity to test their ideas using spaceflight.[10] Although there is a lack of definitive data obtained in space, growing evidence suggests that dose–response relationships exist across gravity levels exceeding $1 \times g$.[10,17] Thus, some biological systems respond to increased and decreased gravity with responses that are opposite in directionality. For example, antigravity muscles undergo hypotrophy in weightlessness, but *hyper*trophy in response to gravitational loading.[18] We recently

Table 49–1
Range of g-loads associated with different gravitational environments

Spaceflight	*Earth's moon*	*Mars*	*Earth*	*Centrifugation*	*Ultracentrifugation*
10^{-5}–$10^{-2} \times g$	$0.17 \times g$	$0.3 \times g$	$1 \times g$	$>1 \times g$	10^{3}–$10^{5} \times g$

observed a strong ($R^2 = 0.98$) linear relationship between mammary metabolic activity and gravity loading at 0, 1.25, 1.5, 1.75, and $2 \times g$.[19] In other cases, responses appear in an "all or none" fashion at and above a certain gravity threshold, with no response observed below that threshold. Still other systems may show the same response to deviations from $1 \times g$ in opposite directions. In this case, a biological system that evolved for maximal efficiency at $1 \times g$ may show a degraded efficiency at g loads that are sufficiently greater or less than the Earth's $1 \times g$.

METHODS OF STUDY

In addition to reducing the risks of manned spaceflight, a major objective of space life science research is to use the space environment to broaden scientific knowledge about the influence of gravity on living systems. While spaceflight studies are critical to this venture, it is both difficult and costly to conduct research in space. For these reasons, ground-based approaches have been developed for simulating some of the major physiological effects of microgravity ($0 \times g$). These models include bed rest, water immersion, and hindlimb unloading. To increase gravitational loading (induce hypergravity), centrifugation is used. Both spaceflight and ground-based approaches require specialized methodologies and considerations, particularly when applied to reproducing and developing animals.

RATS IN SPACE The first adult rodents were flown in space in the 1950s.[16] Studies of mating, pregnant, and lactating rats and their developing offspring were begun in 1979 with a total of six missions launched through 1998. (Pregnant mice were flown on the last of these flights.) Table 49–2 shows the year, mission, flight duration, and subject characteristics corresponding to each spaceflight. Collectively, these studies (1) established the feasibility of spaceflight experimentation on reproducing and developing rodents, (2) permitted identification of critical requirements for proper husbandry and support of animals flown at sensitive developmental phases, and (3) led to new scientific discoveries, thereby advancing our understanding of spaceflight and gravitational influences on reproductive and developmental processes of mammals.

Characteristic of spaceflight studies, these efforts involved multiple analyses by different investigative teams, small numbers of animals, and detailed and systematic data collection techniques. With few exceptions, the experiments were designed to maximize the quantity and quality of the data obtained. In some cases, unexpected problems during flight afforded less interpretable data but revealed important "lessons learned."[20,21] The methods that were developed and the fundamental observations that emerged from these different spaceflights are reviewed here. Detailed review of the experimental results can be found elsewhere.[3,11]

Space Habitats A variety of different habitats have been used to fly reproducing and developing rats in space. Figure 49–1 illustrates caging configurations that have been used. These different systems all provide for automated food and water delivery, ventilation, waste control, and light timers to regulate the circadian cycle. For each depiction, the rats are shown in the $1 \times g$ configuration.

Figure 49–1 (upper left) shows the BIOS-Vivarium cage. In the only mammalian mating experiment attempted in space (Cosmos-1129), male and female rats were launched in separate compartments and a partition was removed during flight to enable copulation. As for most Cosmos flights, animals were fed a formulated paste diet. For unknown reasons, neither experimental nor control females showed clear evidence of conception or pregnancies.

The BIOS-Vivarium cage was also used on the unmanned Cosmos-1514 mission. Although the flight dams weighed 18% less than identically housed synchronous $1 \times g$ control dams, this important study demonstrated the feasibility of flying pregnant rats in space.

NASA's STS-66 mission carried 10 pregnant rats into space as part of a joint NASA–NIH venture, NIH.Rodent (R)1. Considerably longer in duration than Cosmos-1514, NIH.R1 and its sister experiment NIH.R2 were flown 2 years later on STS-70. R1 and R2 collectively yielded valuable new information on the biological and behavioral responses of mothers and offspring to prenatal spaceflight. For each mission, rats were housed in the NASA Animal Enclosure Module (AEM), depicted in the upper right of Figure 49–1. The AEM has a habitable volume of 863 cm^2, thus five rats can be housed in each unit. Food bars line the walls of the AEM and continuous water access is provided by a central lixit system.

The growth and well being of suckling rat pups in space were evaluated on the STS-72 mission. Family units (mothers and their litters) were pair-housed in the AEM-Nursing Facility (NF), separated by a bisecting partition (Figure 49–1, lower left). A small compartment fitted with a "nursing wedge" afforded physical support to the dam during nursing. This was critical for the young

Table 49–2
Spaceflight missions using rats (*Rattus norvegicus*) and mice (*Mus musculus*)[a]

Year	*Mission number*	*Duration (days)*	*Subjects characteristics*
1979	Cosmos-1129	18.5	Adult male and female rats
1982	Cosmos-1514	4.5	Pregnant and fetal rats (G[b]13–18)
1994	STS[c]-66	11	Pregnant and fetal rats (G13–18)
1995	STS-70	9	Pregnant and fetal rats (G13–18)
1996	STS-72	9	Nursing rat litters (P[d]5, 8, 14)
1998	STS-90	16	Nursing rat litters (P8, 14)
			Pregnant mice (G3, 5, 8)

[a]Data associated with each flight are reviewed by Ronca.[3]

[c]STS, Space Transport System.
[d]P = postnatal day where P0 = day of birth.

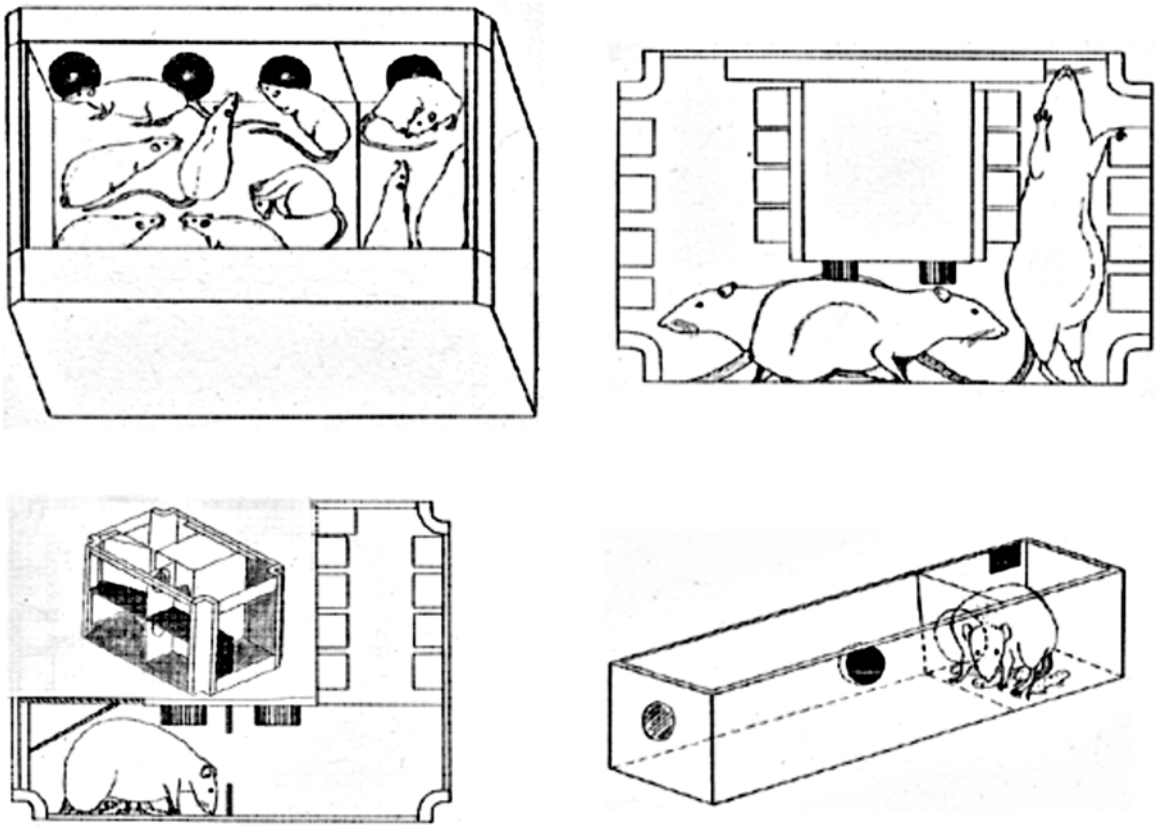

Figure 49–1. Flight housing used for studies of reproducing and developing rats in space. For each image, rats are shown in the 1 × *g* configuration. Upper left: The Russian Bios-Vivarium cage was used for the rodent mating experiment flown on Cosmos-1129 and Cosmos-1514. For Cosmos-1129, a partition (demarcated by the solid interior lines) separated male and female rats prior to launch. (Redrawn from Gazenko, 1993.) Upper right: The Animal Enclosure Module (AEM) carried mid-pregnant rats on the NASA Space Shuttle for the NIH.Rodent (R)1 and NIH.R2 experiments. Lower left: The Animal Enclosure Module-Nursing Facility (AEM-NF, a modified AEM) carried the first lactating dams and litters into space (NIH.R3); an experiment to house older (P14) litters on the Neurolab mission. Two dams and their litters were housed in each AEM-NF. The inset shows a perspective drawing of the AEM-NF with the darker shading depicting the partition between litters and the lighter shading illustrating the habitable areas of a single compartment. Lower right: The Research Animal Holding Facility (RAHF) was used to house rat litters that were P9 at launch on the Neurolab mission. (Drawings by Kenneth E. Johnson. Reprinted from Ronca,[3] with permission from Elsevier.)

ages tested since rat pups do not wean from the mother until around P21. NIH.R3 was a prelude to the Neurolab SpaceLab Mission and provided a "proof-of-concept" that suckling rats could survive and thrive in space. In contrast to the R3 mission, 9-day-old Neurolab litters were housed in the Research Animal Holding Facility (RAHF), a rectangular design with a habitable volume of approximately 1100 cm^3 (Figure 49–1, lower right). Pups of similar age flown on the R3 and Neurolab missions had vastly different outcomes, as many of the Neurolab pups died in space.[20,21] The results of these studies led to important insights regarding habitat requirements for nursing rat litters in space.[3,11,20,21]

Methodological Considerations in Spaceflight Studies Space comprises a unique laboratory environment. Spaceflight studies are highly specialized, extremely costly, labor intensive, and typically will not be repeated. For these reasons, it is imperative to utilize methods and controls that will optimize interpretation of the data.

Habitat Controls Spaceflight studies require custom designed caging (see Figure 49–1), necessitating the use of multiple 1 × *g* control conditions. One of these is the Vivarium Control in which animals are housed in a standard colony environment in vivarium caging. Synchronous Controls are also needed. In this condition, subjects are housed in flight caging and treated identically to animals in the flight condition, except that they are not exposed to spaceflight. In NASA studies (e.g., NIH.R1 and R2), in-flight temperature, humidity, and lighting have been simulated in the 1 × *g* Synchronous Control AEMs using data down linked from the Space Shuttle to the Kennedy Space Center (KSC).

Spaceflight is known to induce atrophy in most skeletal muscles; however, the flight cage configuration alone is sufficient to cause hypertrophy in some skeletal muscles.[22] A second consideration in interpreting spaceflight data is that animals are weightless during flight and can therefore utilize the full expanse of cage volume, whereas Synchronous Controls are Earth bound and may be relatively more crowded.

Video Footage of Rats in Space There are very few experiments in which video footage of the animal subjects has been collected in flight. In the NIH.R1 and R2 experiments, the

Figure 49–2. Video image of the Animal Enclosure Module (AEM) and five weightless rats onboard the space shuttle during the 11-day NIH.R1 mission.

astronauts collected daily video segments of the weightless pregnant rats through the lexan wall of each AEM (Figure 49–2). This was invaluable for assessing the rats' overall well being, behavior, and social interactions. Preflight, the rats' fur was colored with a nontoxic hair dye, which proved useful in relating the individual dams' in-flight behaviors to the pups' postflight vestibular reactions.[23] In the NIH.R3 experiment, video footage of lactating dams and pups provided evidence for maternal nursing and maternal care (pup retrieving and licking) during the flight.[24] These behaviors persisted in flight despite the lack of overall coherence and drastically changed dynamics with the litters.

Surgical Manipulation and Treatment of Pregnant Dams Sixteen NIH.R1 and R2 science teams collected data from pregnant and lactating rats dams and their fetal and neonatal offspring.[3] Dams were selected for inclusion in the study based on surgical laparotomies performed at 1 week postconception that enabled us to visualize fertilization sites preflight, thereby ensuring adequate numbers of specimens. At landing, unilateral hysterectomies provided both prenatal and postnatal subjects from each dam.[8,25] Excision of one of each dams' paired uterine horns yielded fetal specimens. Births of pups from the intact uterine horn occurred 48–72 h later (at the expected time, G22/23). R2 dams were not surgically manipulated following flight, affording a rare opportunity to validate the findings across two spaceflights and differing methodologies.[8]

Following birth, the dams were euthanized and their tissues harvested for study. Pups from all conditions were fostered to nonflight dams for extended postnatal study.[26,27]

GROUND-BASED MODELS Ground-based models continue to provide valuable information on effects of gravity on developing animals, and lend important insights into the design and interpretation of spaceflight experiments. Centrifugation is a commonly used technique for studying responses of reproducing and developing animals to gravitational loading.[28–32] In contrast, the Morey–Holton hindlimb suspension (HLS) model[9] is used to simulate certain features of microgravity exposure. In this model, the hindquarters are elevated 30° to produce head-down tilt with resulting cephalad fluid shift. Although used in just a few reproductive and developmental studies, HLS has produced some interesting findings.[33–35] Highly detailed information on HLS can be found elsewhere,[9] therefore discussion of ground-based methods in this chapter will focus on methods for centrifugation.

Centrifugation Centrifugation induces hypergravity by summing the normal gravity of Earth with acceleration forces that are produced by changing the direction or linear rate of motion.[10] While centrifugation can be used to simulate the relatively brief accelerations associated with launch and landing, most developmental gravitational biology studies involving centrifuges are designed to induce long duration gravity loading.

The use of centrifugation in developmental gravitational biology studies has grown immensely in recent years. Using this technique, fractional increments in g-load exceeding $1 \times g$ can be continuously applied to biological specimens for extended periods and dose–response relationships established.[10,17]

Figure 49–3 shows an image of the 24-foot-diameter centrifuge of the NASA Ames Research Center for Gravitational Biology Research, an apparatus designed to create a hypergravity environment spanning >1 to $3.5 \times g$ for small animal research.

The centrifuge has 10 radial arms with two opaque enclosures situated on each arm. Each enclosure holds four standard rat vivarium cages. Each arm has multiple enclosure mounting locations at different distances from a central vertical shaft spindle, thereby allowing various combinations of gravity levels to be introduced to different groups of rats in a single experiment. In quadripeds, gravitational forces are applied from the back through the feet.[10] To accomplish this, the animal housing units on the centrifuge must be gimbaled such that the resultant gravitational force is applied through the floor.

Investigators have used centrifugation to study acute responses and adaptation to increased gravity environments.[10] Responses of pregnant and lactating rats to centrifugation are generally similar to those observed in nonreproducing adult animals, namely, an initial decline in feeding, drinking, body mass, physical activity, and temperature, with a return, following 4–6 days of acclimation, to an approximate 8–15% reduction in body mass relative to controls.[36] Increased mortality may be observed in postnatal animals, depending upon their age at the onset of centrifugation

Figure 49–3. The 24-foot small animal centrifuge at the Center for Gravitational Biology Research (CGBR), NASA Ames Research Center, Moffett Field, CA. (Photo by Thomas Trouwer. Reprinted courtesy of NASA Ames Research Center.)

and gravity-induced changes in the mother.[37,38] (See the section on Novel Challenges in the Study of Space Biology in Developing Mammals.)

Methodological Considerations in Centrifugation Studies Necessary control groups in centrifugation experiments involve placing subjects at or near the center of rotation to control for rotational stimulation, and stationary controls. Numerous factors need to be considered in the design and interpretation of centrifuge studies.[10] These include (1) scaling (the larger the mass of an animal, the greater the impact of gravitational loading), (2) rotation (more apparent at shorter diameters from the center of the centrifuge), (3) Coriolis forces (produced when the orientation of the animal's body varies in relation to the direction of acceleration), (4) duration of exposure (acute versus chronic responses), and (5) resultant level of gravity. The interested reader is referred to Wade[10] for a detailed review of the attendant issues.

NOVEL CHALLENGES IN THE STUDY OF SPACE BIOLOGY IN DEVELOPING MAMMALS

A key feature of mammalian development is the presence of the mother. The biological and behavioral interactions that exist between mothers and their young evolved under the constant force of the Earth's $1 \times g$ gravitational field. It is therefore reasonable to predict that maternal–offspring interactions will be altered in the weightless environment of space and the hyperweighted environment of the centrifuge. The mother's role in development also makes it more challenging to accurately determine the source of gravitational effects on the offspring. Finally, the young are dependent upon nursing, licking, and retrieving by the dam, behavioral responses that may change in altered gravity environments.[3,11,38]

THE MOTHER–OFFSPRING SYSTEM Development of the young progresses within the context of an intact, integrated system composed of a mother and her young.[3,11] This family system, as a unit, is characterized by coordinated changes within and between a mother and her young. As the offspring are developing within the womb and nest, the maternal–offspring system follows its own ontogenetic trajectory. Mammalian development involves bidirectional linkages between mothers and infants that are important for normal growth and development.

SOURCES OF GRAVITATIONAL INFLUENCE A major challenge in studies of the developing mammal is separating effects of altered gravity on mothers and offspring. Due to the fact that the maternal–offspring system is so highly intertwined in mammals, it is difficult to differentiate among "direct" and "indirect" effects of gravity on the young. "Direct" effects of gravity are those that operate through a primary relation with the recipient organism, tissue, or cell.[3,11] In contrast, "indirect" effects of gravity are those expressed through avenues of the mammalian system. For example, if mothers cannot stabilize their bodies in the nursing posture or if pups cannot retain metabolic heat because their huddling behavior is disrupted, the altered growth effect would clearly be an indirect consequence of weightlessness.

MATERNAL CARE AND REPRODUCTIVE EXPERIENCE Altricial species, such as the Norway rat, are born in a highly immature state with relatively undeveloped sensory and motoric capabilities. The mammalian mother affords vital resources that lead to proper growth and development. She does this through maternal behavior, a constituent set of behavioral activities including nursing, touching, and carrying the young.[39] The neonate relies on stimulation by the mother for induction and maintenance of normal behavior and physiology.[11–13] Because the mother plays a major role in the regulation of developmental processes in her young, the quality and integrity of maternal care are vital to making accurate assessments of direct and indirect effects of altered gravity on the pups.

Prior birth experience facilitates the appearance of maternal care patterns when pups are present.[39] Reproductive experience, or parity, is an important consideration in developmental space biology studies.[38] Second-time (bigravid) dams exposed to $1.5 \times g$ hypergravity gave birth to more live newborn pups as compared to first-time (primigravid) dams (94% versus 82% survival), and pup mortality was strongly associated with changes in the dams' maternal behavior. Under unusual or stressful conditions, parity can be an important factor in promoting the health and longevity of the young.

CONSEQUENCES OF DISRUPTING MATERNAL–OFFSPRING INTERACTIONS Factors that disrupt either the mother or her offspring are liable to disrupt the maternal–offspring system.[3,11] If this occurs, the organizing influence of the system on its constituent parts is likely to change and the ontogenetic processes within the individuals can be disrupted. In spaceflight studies, upsetting the important interrelations between mothers and their young can pose major interpretive problems by obscuring meaningful results or creating false impressions of how microgravity affects development. Maternal behavior and physical relationships between mothers and pups are apt to be altered in the weightless space environment. The mother's maneuverability of pups and her proximity to them may be impeded during attempts to huddle and nurse; pup licking may be diminished. Retrieving behavior, important for maintaining pups within a coherent nest, may not be possible if pups continuously float away from the nest. Pup milk intake, warmth, and tactile stimulation normally provided by the mother may be diminished and compromise the pups.

CONTRIBUTIONS TO BIOMEDICINE

Developmental space biology research affords unique perspectives on biomedical concerns on Earth and in space. Gravity is a fundamental factor in the external environment, stimulating vestibular organs and exerting major forces on the body. The tools of space biology, namely, spaceflight, centrifugation, and other ground-based methods, can be applied to induce identifiable and meaningful changes in physiological systems, brain areas, nerve pathways, and gravity sensors. Developmental analysis is especially useful for studying gravity-induced changes in structure and function. It is widely recognized that activity-dependent processes and experience play important roles in the establishment of neural architecture and function. Researchers are utilizing developmental space biology approaches in new studies of vestibular development, equilibrium, and locomotion. The population of the United States is living longer than ever before, with a nearly 30-year increase in life span in the past century. It is predicted that the number of people over 85 will double by the year 2020 and that by 2050, over 20% of the population will be over 65. Vestibular and equilibrium disorders are frequent symptoms of aging, related to "multisensorial decay," age-related conditions, Parkinson's disease, and other degenerative conditions. Due to vestibular and proprioceptive dysfunction, the elderly suffer disastrous falls from which many never recover. Fetuses with vestibular disorders are

prone to breech births. Babies born after maternal bedrest during pregnancy appear to crave vestibular simulation and require more rocking to be quieted. Altered gravity is a useful method for studying the development of body-weight regulation and metabolism. Changes in body mass and energy balance induced by gravitational loading may provide clues to developmental factors that contribute to obesity. Recent gravitational biology research is addressing prenatal contributions to the establishment of body-weight regulation in later life, and the effects of chronic exposure to stress prior to birth. These are central issues in the field of prenatal programming of adult disease. Adaptation, a prominent feature of living organisms in general, and developing organisms in particular, can be analyzed in altered gravity. Adaptation to extreme environments is relevant to a range of biomedical concerns, including shifts experienced in high-altitude and oceanic environments on Earth. In addition to major contributions to the concerns of astronauts facing long-duration missions, developmental space biology can provide immense benefits on Earth, and will undoubtedly contribute to the foundation of knowledge needed for the development of effective therapies and cures in contemporary biomedicine.

50 A Practical Approach to Animal Models of Sepsis

Bryan Belikoff and Jon A. Buras

ABSTRACT

The underlying mechanisms active during the pathogenesis of sepsis are not clearly defined; however, several animal models of sepsis have been used in an attempt to understand these complex cellular and molecular interactions that result in disease. There are three general categories of sepsis models, the host barrier disruption model, the chemical shock model, and the exogenous infection model. Host barrier disruption sepsis models initiate infection with the release of endogenous bacteria into normally sterile compartments. The chemical shock model employs intravenous or intraperitoneal administration of a toll-like receptor (TLR) agent, such as lipopolysaccharide (LPS or endotoxin) or zymosan, to initiate a state of proinflammatory cytokine-induced shock. The exogenous infection model of sepsis utilizes administration of an exogenous viable pathogen, typically bacteria, directly (by an intravenous or intraperitoneal route) into the host. Each of these models has particular strengths and weaknesses with respect to their ability to mimic the clinical progression of sepsis in human patients.

Key Words: Sepsis, Animal models, Peritonitis, Inflammation, Infection, Septic shock, Cecal ligation and puncture (CLP), Endotoxemia.

SEPSIS OVERVIEW

Sepsis is defined as the dysregulation of the immune and inflammatory responses following infection resulting in an immunocompromised state with microvascular dysfunction and organ damage that eventually leads to death of the host.[1–3] The immune system serves as the host's defense against pathogens from invading and disrupting normal cellular function. Paradoxically, immune dysfunction and the subsequent excess of inflammation can progress to extensive, irreversible cell damage in inflamed or infected tissue, as well as to the surrounding tissues. These processes eventually result in impaired microvascular and organ function, ultimately resulting in host death if the infection is not successfully contained. Sepsis is a complex state of immunoinflammatory dysfunction that is typically a consequence of unsuccessful infection containment.[4]

The inflammatory response during sepsis may be divided into two overlapping, nonexclusive stages: the systemic inflammatory response syndrome (SIRS) and the compensatory antiinflammatory response syndrome (CARS).[5] SIRS is characteristic of the early stage of sepsis and is thought to result from innate immune cell activation caused by increases in the circulating proinflammatory cytokines interleukin-1 (IL-1), IL-6, tumor necrosis factor-α (TNF-α), and IL-12, and chemokines such as IL-8.[4,5] The overwhelming proinflammatory response results in epithelial and endothelial cell dysfunction, dissemination of the inciting pathogen, and ultimately may lead to multiple organ dysfunction (MOD) and septic shock. Normally, the host immune system is able to effectively regulate the proinflammatory response through increased production of antiinflammatory cytokines IL-4, IL-10, IL-13, IL-1 receptor antagonist, and tumor growth factor-β (TGF-β), expressed during the CARS response.[4,5] Sepsis progression remains unchecked when the host immunoinflammatory response is unable to modulate the SIRS–CARS system appropriately, resulting in a dysfunctional immune response and an immunocompromised state with a reduced ability to contain infection.

The central goal of sepsis research is to understand the mechanisms of sepsis pathogenesis in order to develop effective therapeutic modalities for the treatment of human sepsis. Human sepsis pathogenesis develops in gradual, sequential stages that have been difficult to characterize due to a lack of adequate staging markers.[6,7] In the most simplistic characterization, the progression of sepsis is thought to involve two generalized components of the inflammatory response.[5] The initial (early) inflammatory stage of human sepsis is proinflammatory and characterized by SIRS. The early physiological response to the septic insult involves physiological alterations characterized by high cardiac output (CO), increased heart rate (HR), and low total peripheral (vascular) resistance (TPR), and is collectively referred to as the hyperdynamic phase of sepsis.[8–12] In this phase, the drop in TPR is balanced by an increase in CO, resulting in maintenance of a normal blood pressure. Subsequent to the hyperdynamic phase, blood pressure drops in the hypodynamic (late) phase sepsis, as a result of impaired cardiac function (i.e., decreased HR and low CO with sustained low TPR).[9] The hypodynamic phase reflects the condition of septic shock. The late, hypodynamic phase of sepsis is associated with the development of host immunocompromise.[13] This state of immune dysfunction results in part from upregulation of antiinflammatory cytokine production during the CARS response, which normally assists in termination of the initial early SIRS.[5]

INDIVIDUAL SEPSIS MODELS

There are three categories of animal sepsis models including exogenous toxin administration models, exogenous bacterial infection models, and host barrier disruption models.[14] Review of the advantages and disadvantages of each model class suggests that there is no perfect model in the study of sepsis; however, understanding the limitations of each model assists in correlating experimental results with the human disease state. Detailed discussion of animal sepsis models may be found in several reviews.[14–18]

ENDOTOXEMIA MODEL In the early 1940s, Andre Boivin first isolated endotoxins from Gram-negative bacteria; Bordon and Hall[19] later suggested that they induce human endotoxic shock. Today, lipopolysaccharide (LPS) is the more common endotoxin used to induce endotoxicosis in sepsis models; however, other toll-like receptor (TLR) ligands have been used to illicit the shock state, including the TLR2 synthetic lipopeptide agonists and the TLR9 agonist CpG-DNA.[20–22] LPS/mCD14 binding and recruitment of TLRs on monocytes and macrophages trigger the release of IL-1α, IL-1β, IL-6, and TNF-α. The release of these proinflammatory cytokines is capable of inducing physiological hemodynamic changes that are in some ways similar to those observed in septic shock.

Endotoxemia sepsis models represent an easily controlled single variable model in both humans and in animals, making it an attractive experimental model. Unfortunately there are significant differences with the endotoxemia model and true sepsis. Similar physiological effects of LPS may be observed in both humans and rodents; however, higher doses of LPS are required to achieve the same increase in serum TNF-α in rodents.[23] Furthermore, despite the general similarities of the LPS response to those seen in septic shock, the hemodynamic alterations after a bolus injection of LPS in human patients are not identical to alterations observed in sepsis patients.[24] The hemodynamic changes in murine endotoxemia models do not completely mimic hemodynamic changes in sepsis patients, as there are no distinct hyperdynamic and hypodynamic phases.[16,17] A bolus injection of LPS induces a rapid reduction in HR and mean arterial blood pressure (MAP) that may be transient and not lethal (Figure 50–1), or persistent and lethal (Figure 50–2), depending on the dose administered. Shortcomings of the endotoxemia model likely contributed to a number of failed sepsis clinical trials that were based on false assumptions extrapolated from the use of this model system.[25] Despite these shortcomings, the endotoxemia model overall has allowed significant contributions to sepsis research by providing knowledge about the pathways activated by pathogen TLR agonists during the host response to infection.

EXOGENOUS INFECTION MODELS Infection with a load of exogenous bacteria has been used to study mechanisms of sepsis.[15–17] Unfortunately, the doses of bacteria required to elicit mortality do not mimic the responses of typical host infection as these bacteria do not colonize and replicate due to complement-mediated lysis.[26] Furthermore, significant differences are noted in the host cytokine response depending on the exact bacterial strain.[27,28] Also, the compartment of infection (blood versus peritoneal) may affect the host cytokine response.[29,30] Based on these findings, exogenous infection has been utilized more as a system to study the host response to a particular pathogen infecting a particular compartment than as a generalized sepsis model. Based on these facts, this class of model system is not considered further in this chapter, which focuses on general sepsis models.

HOST BARRIER DISRUPTION MODELS Host barrier disruption models utilize the host's normal mixed bacterial flora as the infecting insult and allow passage of these organisms into a previously sterile body compartment through an existing protective barrier such as skin or intestinal wall. The most commonly used methods involve disruption of the intestinal barrier and include the cecal ligation and puncture (CLP) and colon ascendens stent peritonitis (CASP) models.

Cecal Ligation and Puncture Model In 1980, Irshad Chaudry developed the CLP procedure from a previous rat sepsis model consisting only of ligation, which was thought to allow bacteria to spill out of the necrotic cecum into the peritoneum.[15,31]

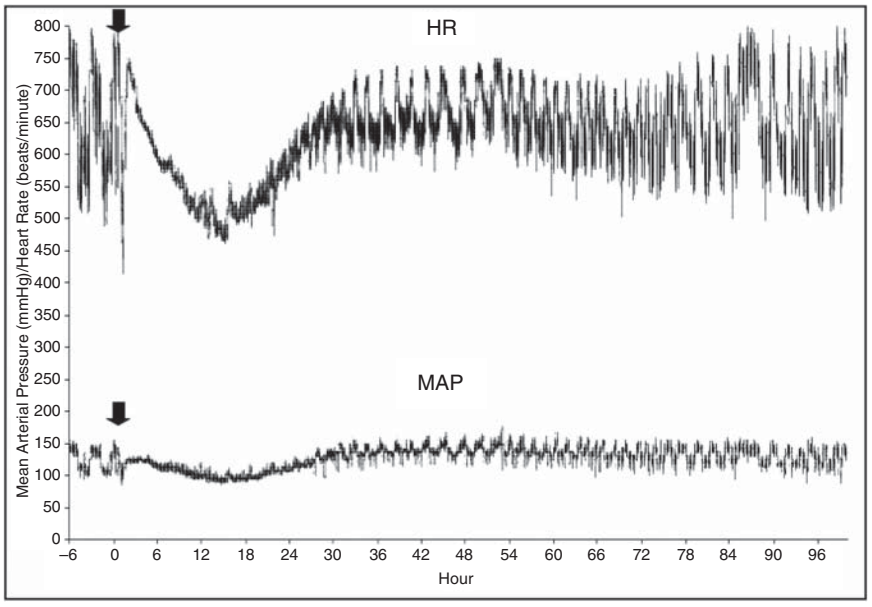

Figure 50–1. Telemetry analysis of physiological responses to sublethal LPS exposure. An example of a single mouse implanted with a wireless PA-C10 catheter (Data Scientific International) in the carotid artery with baseline measurements of heart rate (HR) and mean arterial pressure (MAP) beginning at –6 h from LPS injection. Normal variability of HR and MAP is observed in this time period. At time 0, the mouse received an intravenous LPS injection of 5 mg/kg (black arrow). Note the rapid onset of bradycardia and reduction in MAP occurring within 3 h of LPS injection. LPS-induced hemodynamic changes are transient and return to baseline approximately 28 h after injection.

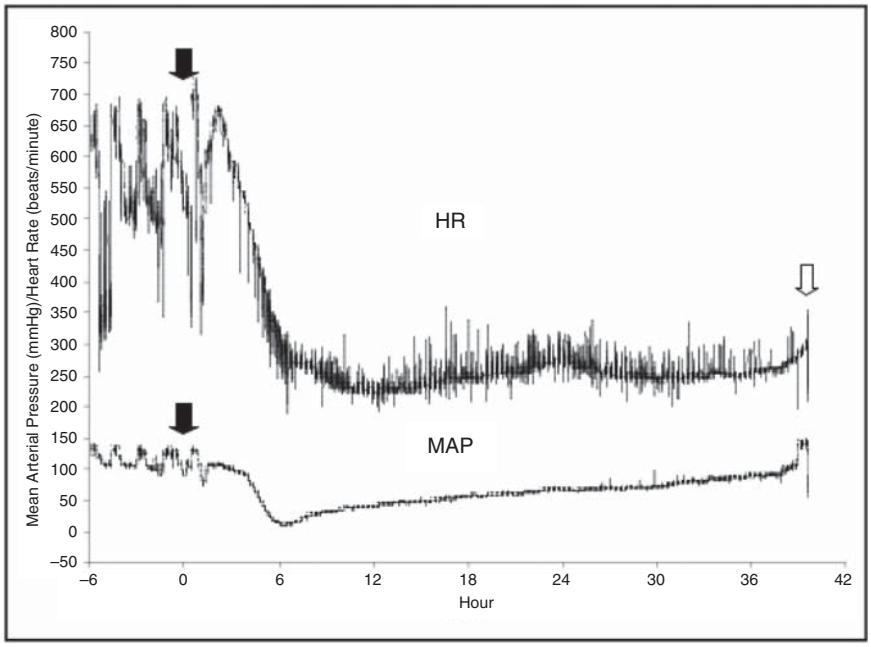

Figure 50–2. Telemetry analysis of physiological responses to lethal LPS exposure. An example of a single mouse implanted with a wireless PA-C10 catheter (Data Scientific International) in the carotid artery with baseline measurements of heart rate (HR) and mean arterial pressure (MAP) beginning at −6 h from LPS injection. Normal variability of HR and MAP is observed in this time period. At time 0, the mouse received an intravenous LPS injection of 10 mg/kg (black arrow). Note the rapid onset of bradycardia and reduction in MAP occurring within 3 h of LPS injection. Altered hemodynamics persist until death of the mouse at 38 h (white arrow).

Chaudry was unable to induce septic shock via ligation alone and modified the existing procedure by puncturing the ligated cecum. Cecal puncture allowed controlled bacteria spillage into the abdominal cavity resulting in a simple reproducible model of sepsis.[15] The CLP sepsis model mimics the human clinical disease of perforated appendicitis or diverticulitis. The CLP model has evolved into the "gold standard" and has been used to characterize the inflammatory stages of early sepsis.[32] It is an eloquent model as it is a simple procedure, and survival rates are controllable and reproducible. Also, sepsis physiology in rodents shares similarities with the biphasic hemodynamic patterns observed during the clinical course of human sepsis is an early hyperdynamic phase followed by a hypodynamic phase (Figure 50–3). Furthermore, similar metabolic, immunological, and apoptotic responses are observed in the CLP model as in human disease, strengthening the validity of this model.[15,33,34]

Advantages of the Cecal Ligation and Puncture Model There are many features of the CLP model that contribute to its effectiveness as a model in sepsis research. The model is highly reproducible, cost effective, and can be performed on small and large animals. Telemetry data using a wireless hemodynamic transmitter implanted in the carotid artery (Data Scientific International; PA-C10) demonstrates that CLP mice progress through a hyperdynamic phase from 12 to 24 h and subsequently to a hypodynamic phase of sepsis mimicking the clinical progression of human sepsis (Figure 50–3). This is in clear distinction to the physiological response to bolus administration of LPS in either a sublethal or lethal dose (Figures 50–1 and 50–2). As compared to endotoxemia, CLP generates live circulating polymicrobial organisms in the blood that are capable of distant organ colonization. The dissemination of multiple strains of bacteria through the bloodstream allows evaluation of distant organ bacterial seeding mechanisms that the endotoxemia model cannot provide.

Another appealing aspect of the CLP model is the ability to control the rate and degree of mortality for a given experimental group.[35] This is accomplished by varying the size of the needle used for cecal puncture (Figure 50–4). It is important to realize, however, that altering the mortality rate by changing needle size is a relative variable and different results may be observed between laboratories.[36,37] Another factor affecting the severity of the CLP model is the percentage of cecum ligated, with a larger amount of necrotic, stool-filled tissue creating a greater infectious and inflammatory insult.[38] The amount of cecum ligated should be reproducibly maintained between experiments and reported in subsequent publications. The exact needle size and percentage of cecum ligated must be established empirically in each investigator's laboratory and for each operator.

The CLP model has been criticized as not being representative of human disease since perforated appendicitis is treated surgically. The CLP model does have the advantage that surgical resection of the cecum may be performed after the initial CLP procedure.[39–41] Furthermore, it appears that there is a critical point in the host response when sepsis has progressed into a stage at which cecal resection is no longer capable of rescuing the animal from mortality.[40,41] This time may vary with the severity of the initial CLP insult and needs to be established empirically within the investigator's laboratory.

Disadvantages of the Cecal Ligation and Puncture Model Host response to local infection promotes abscess formation around the septic focus, to prevent dissemination of the inciting pathogen. A disadvantage of the CLP model of sepsis is the host's ability to form an abscess and successfully contain the infection, abrogating the development of sepsis. While abscess formation is the desired host response to the local infection source, it may interfere with the interpretation of experimental results regarding sepsis therapies. It is possible that an experimental intervention may enhance abscess formation rather than preserve some other systemic pathway unrelated to direct infection containment. In this case, a therapy might be erroneously identified as protective during sepsis in a general sense, whereas in reality it may merely improve a local response to infection. The problem of abscess formation can be circumvented in part through invasive

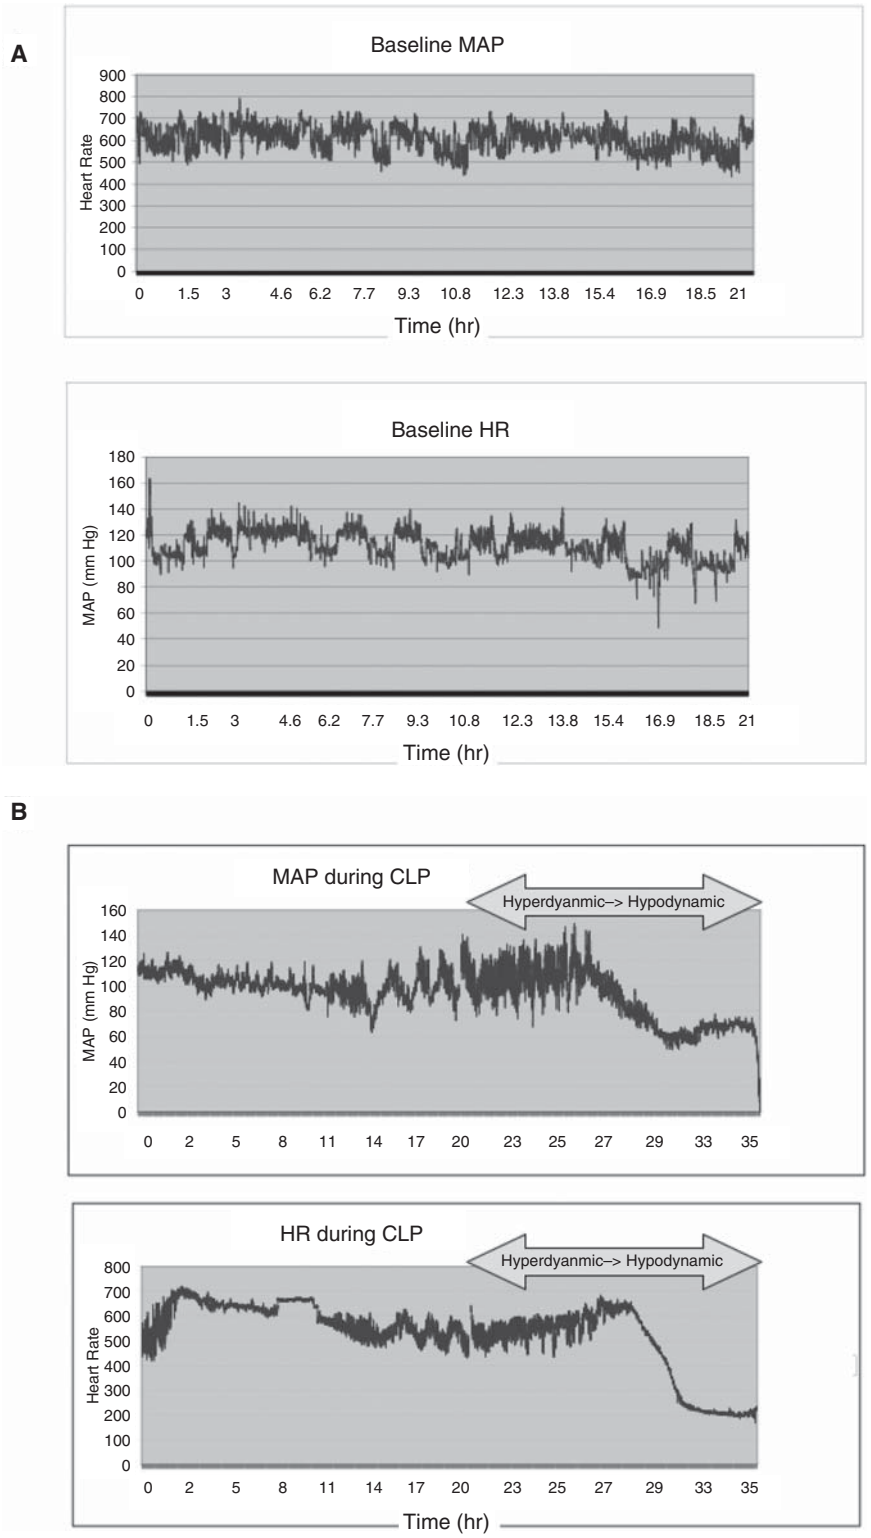

Figure 50–3. Telemetry analysis of physiological responses following CLP. (A) Continuous baseline HR and MAP data are shown over a 21-h period following wireless PA-C10 catheter monitor implantation (Data Scientific International) in the carotid artery. (B) Telemetry analysis following induction of CLP sepsis. After a 3-day recovery period, sepsis was induced via CLP with a 21-gauge needle at time 0. Blood pressure and heart rate were recorded continuously over a 35-h period until the death of the animal. The figure demonstrates the reduction of MAP and initial compensatory increase in HR, followed by the decline in both MAP and HR. This demarcates the hyperdynamic and hypodynamic phases of sepsis (depicted by arrowhead).

telemetry monitoring, biomarker evaluation, and necropsy evaluation of abscess formation. By monitoring these parameters, the investigator should be able to determine whether the animal had progressed to a stage of critical illness.

Colon Ascendens Stent Peritonitis Model Fewer data exist on the CASP model, since it represents the newest animal sepsis model.[42,43] The CASP model of abdominal sepsis was developed to complement the CLP model. The CASP technique is performed by implanting a stent with its origin in the cecum and an exit point in the normally sterile peritoneum. The CASP model induces diffuse peritonitis through the continual release of bacteria from the implanted stent, and is less prone to abscess formation as compared to the CLP model. Changing the stent diameter controls the severity of sepsis. A smaller gauge size stent correlates with an increase in bacterial peritoneal load and sepsis severity. The hemodynamic responses to CASP are not well

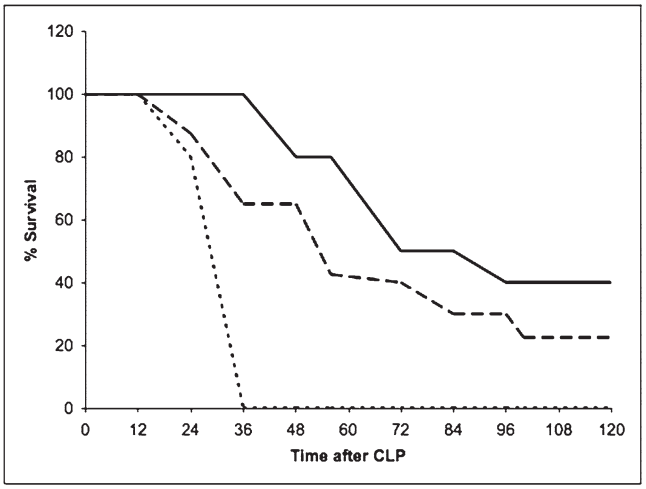

Figure 50–4. Altering cecal puncture and ligation alter CLP sepsis model severity. CLP was performed in male C57/B6 mice using a 20-gauge needle through and through (double) puncture with 40–50% cecal ligation (dashed line, $n = 10$), a 21-gauge needle single puncture (only one hole is made in the cecum) with 30–35% cecal ligation (broken line, $n = 40$), and a 27-gauge needle through and through puncture with 30–35% cecal ligation (solid line, $n = 10$). Both 20-gauge (0 survivors by 36 h) and 21-gauge (approximately 20% survivors by 120 h) CLP are considered severe models of sepsis, with the 20-gauge model being the most severe. The 27-gauge CLP is considered a moderate model of sepsis (40% survivors by 120 h). In severe sepsis the majority of mortality occurs between 24 and 36 h, whereas the majority of mortality occurs between 56 and 72 h in moderate sepsis.

characterized and the disadvantages of this model are relatively unknown.[14] Further studies characterizing the pathophysiology of the CASP model are required to validate this promising sepsis model.

Comparison between Cecal Ligation and Puncture and Colon Ascendens Stent Peritonitis Models The host-barrier disruption sepsis models, CLP and CASP, use endogenous gut flora as a source of infection and retain the advantage of evaluating bacterial clearance by the host, as opposed to endotoxemia models of sepsis that lack a replicating pathogen. A closer look at these two models reveals subtle yet significant differences, indicating that they represent independent sepsis models. Although both are peritonitis models, the CASP model reflects a diffuse peritonitis versus the peritonitis model of CLP.[43] Arecent study compared CLP and CASP.[43] Unlike CLP mice, bacteremia in CASP mice constantly increased significantly at regular time intervals, over 18 h, suggesting continual bacterial leakage from the stent. At 18 h, CASP mice demonstrated a more diffuse peritonitis through an increased number of bacteria found in vital organs, particularly in the lungs, liver, and kidney, compared with CLP mice.[43] These results suggest that CASP may represent a better diffuse peritonitis sepsis model, complimenting the CLP model of intraabdominal abscess formation.

METHODS FOR SEPSIS MODELS

The following represents a generalized description of techniques for the CLP, CASP, and endotoxemia models. The focus of this chapter is primarily the CLP method, which represents the current "gold standard" of sepsis models because it most closely approximates the physiological and immunological responses observed in human sepsis.[14]

CECAL LIGATION AND PUNCTURE METHOD

1. All procedures must follow the Institutional Animal Care and Utilization Committee (IACUC) or an institutionally approved animal care protocol. Animals are maintained on a standard *ad libitum* diet including water throughout the experiment. Methods in the early literature describe fasting animals 12 h prior to CLP surgery.[15] Fasting animals helps to promote uniform stool consistency, leading to a subsequent similar flow of fecal contents into the peritoneum between experimental animals. Initial rodent experiments in our laboratory followed this procedure. We have determined in our laboratory that there was no benefit to fasting animals before CLP. In a rat CLP model, Singleton and Wischmeyer found fasted animals varied in individual cecum size length and thus cecal stool content, introducing heterogeneity in animals.[38] In the unlikely event of problems with heterogeneous stool consistency, fasting animals may assist in promoting stool homogeneity. Otherwise, fasting animals any time before CLP is not recommended or required for reproducible results.

2. Anesthetize the animal using a mixture of isoflurane and 100% oxygen. Other agents may be administered for animal anesthesia, including intraperitoneal ketamine (80 mg/kg) and xylazine (10 mg/kg); however, we favor inhalational agents delivered with a precision vaporizor via a tight-fitting nosecone as it allows for rapid performance of procedures with a reproducible depth of anesthesia and a rapid recovery time.

3. Prepare the animal for surgery by shaving and thoroughly disinfecting the abdominal area with an appropriate agent such as 7.5% povidone iodine cleansing solution and sterile gauze. Note that a heating pad or other source should be utilized in an attempt to ensure normothermia throughout the procedure. Meticulous attention to detail, organization of materials, and excellent surgical technique represent the cornerstone of successful reproducibility in this procedure.

4. Perform a 1.5-cm midline laparotomy to expose the cecum. The peritoneal cavity is protected by two layers: skin and the muscular abdominal wall. Once an incision is made to expose the underlying abdominal musculature, the second incision will be made through the translucent linea alba. The linea alba is a vertical midline of connective tissue running from the breast bone to the inguinal region that can be determined through appearance. An incision made in the linea alba will not bleed since the connective tissue lacks blood vessels, in contrast to the vascularized abdominal muscles. Use the contrast of the pink color of the abdominal muscle to find the translucent linea alba.

5. Locate and carefully exteriorize the cecum, making sure not to disrupt any vessels while untwisting the cecum (Figure 50–5A). Initially, locating the cecum can be time consuming. It is best to develop a systematic approach to this method. If the abdominal cavity is divided into four regions, the cecum is typically located in the upper left abdominal quadrant in the region of the spleen or it is immediately visible following laparotomy. A very effective method for locating the cecum developed in our laboratory is the "reverse 'N'" technique and is used if the cecum is not immediately found. With the mouse in a supine position, start at the traced end of the "N," the upper left abdominal compartment equivalent. Inspect each compartment systematically by reverse

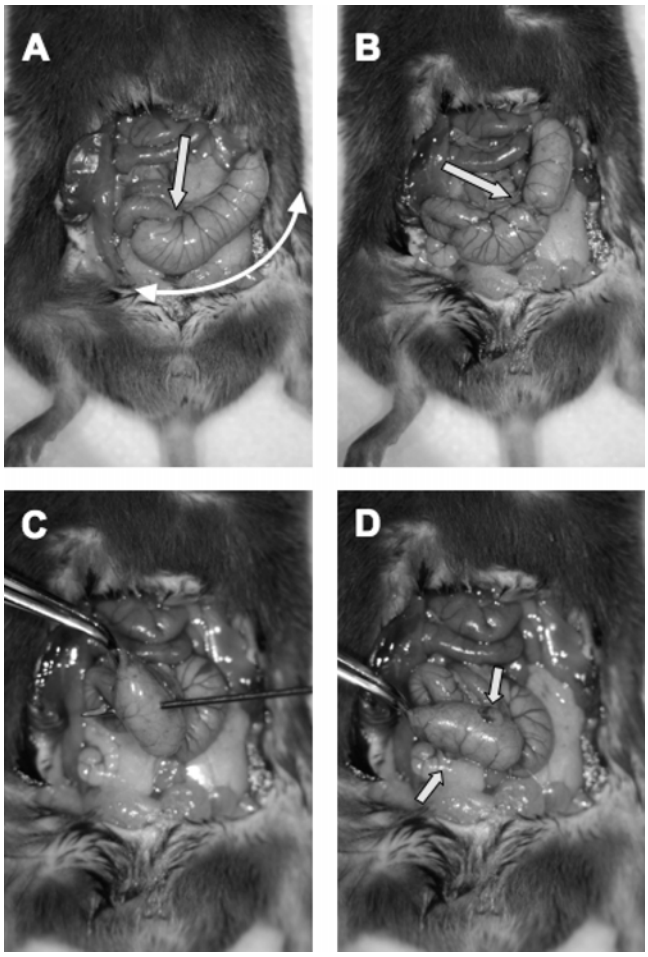

Figure 50–5. CLP Methods. (A) Normal cecal anatomy. The ileocecal junction (arrow) is exposed following midline laparotomy. The white double arrow demonstrates the entire length of the cecum, corresponding to 100% of the cecal length. (B) Cecal ligation. Cecal ligation is performed at approximately 50% of the length of the cecum in this case (the arrow denotes the site of cecal ligation). Care is taken to avoid damage to arterial branches during ligation and ligature is placed through the mesentery inferiorly to arterial branches. (C) Cecal puncture. A through and through (double) puncture is made while carefully immobilizing the ligated distal end of the cecum with a 21-gauge needle. (D) Milking of stool from cecum. Both arrows point to a 2-mm-diameter collection of stool milked from the cecum to the exterior to ensure puncture site patency.

tracing the "N," subsequently, moving to its lower left, skipping through the middle to the upper right, and finally to the lower right compartment until the cecum is located. This method of detection is a quick and efficient way to search the entire abdominal cavity. Remember that the cecum is the only blind-ended part of the intestine in rodents and is ultimately used for its positive identification. Care should be taken not to damage the cecum or intestines during handling. The operator should keep a body-temperature bowl of sterile saline nearby to keep gloves moist, which will assist in easier manipulation of the intestines.

6. Now that the cecum has been removed from the abdominal cavity, milk the stool contents within the cecum distally starting below the ileocecal valve to fill the blind-ended pouch that will subsequently be ligated.

7. Place 3.0 cm of 6.0 vicryl suture underneath the cecal artery and ligate the cecum (Figure 50–5B). To insert the 3.0-cm vicryl suture underneath the cecal artery, first carefully blunt dissect the connective tissue, connecting the cecal artery to the cecum with curved tweezers. Once this is complete, leave the tweezers in place and grab the suture with a second pair of tweezers. Transfer the suture to the first pair of curved tweezers and pull it through, underneath the cecal artery, subjacent to the cecum. Care must be taken to avoid trauma to the cecal artery and its branches.

8. Fold the cecum over the suture, remilk the cecum, and double tie the ligature loop tightly to completely ligate the cecum (Figure 50–5B). Gas bubbles may introduce variability within the model and consequently alter mortality. Before ligating the cecum, look for the presence of gas bubbles while milking the stool distally to fill the blind ended pouch patent with stool. Make sure that there are no gas bubbles present in the section distal to the ligation site. It is also important to make note of the stool consistency; many unpublished observations indicate that suprahydrated stool increases mortality. It is plausible that watery stool could be the result of an unknown gastrointestinal infection and may alter the severity of the CLP model. It is recommended that mice with either severely dehydrated stool or overly hydrated stool not be used for experimental purposes as the quality of the stool may limit or enhance the spread of infection, respectively.

An important step in the CLP procedure is the ligation of the cecum; remaining consistent with the distance of cecum ligated between animals as a higher percentage of cecum ligated correlates with increased sepsis severity.[38] The mouse's anatomy is an easily used reference control. Branching off from the main cecal artery are several perpendicular small arteries that can be used as a good point of reference for ligation. Starting distally, count the number of branch points up to the location chosen for ligation. The branch point number can be used on subsequent mice to approximate the total cecum length that was ligated in the previous procedure(s) to ensure consistent measurements. When publishing an article, the percentage of cecum ligated should be reported in the Methods section, as it represents important and frequently omitted information.

9. Puncture the ligated cecum as desired (Figure 50–5C). More severe models use needle gauge sizes ranging from 18- to 21- gauge and less severe models use needle gauge sizes ranging from 21- to 27-gauge depending on the number of puncture(s), percent of ligated cecum, and amount of feces manually extruded from the ligated cecum (see step 10).

10. Manually extrude 1–2 mm of feces from the ligated cecum (Figure 50–5D). With the same gauge size needle, the model could be made more or less severe as a sepsis model by adding or taking away approximately 1.0 mm of extruded feces. To improve the control over the amount of extruded feces, hold the ligated cecum parallel with straight tweezers while inserting the needle for puncture; this permits greater pressure control to extrude the feces from the cecum. With the tweezers, add a slight amount of pressure to the cecum before completely withdrawing the needle from it. Continue to exert pressure while retracting the needle from the cecum. The feces will flow out as a continuum with the retracting needle, mitigating the chances of the puncture hole closing off, which can lead to difficulties in controlling the amount of stool removed from the ligated cecum.

11. Carefully place the cecum back inside the abdominal cavity. Holding the abdominal muscles rather than holding the skin with tweezers facilitates replacement of the cecum back within the abdominal cavity. When there is an excessive loss of extruded feces from the cecum prior to placing it back into the abdominal cavity, the severity of the model may be diminished.

12. Close the abdominal cavity with 6.0 vicryl suture.

13. Administer 1 ml of saline fluid resuscitation subcutaneously using a 25-gauge needle. Fluid resuscitation replaces fluids lost during the course of surgery that may cause a premature decrease in blood pressure and early mortality.

14. Administer an analgesic, such as buprenorphine (1.6 mg/kg), for pain control every 12 h for 3 days.

15. Continually warm the animal on a heating pad for 5–10 min or until normal body temperature is reached and the animal has recovered from anesthesia by demonstrating self-righting ability.

16. Place the animals in separate cages. The animals should be housed in separate cages to prevent them from chewing another mouse's surgical incision. To increase the accessibility of food, gel food may be substituted for normal chow and placed directly into the cage along with the recovering animals during periods of reduced mobility.

17. Administer antibiotics if desired. When including antibiotics, a potent broad-spectrum antibiotic, such as imipenem (25 mg/kg), should be administered by intraperitoneal injection every 12 h. Additionally, antibiotic therapy should be initiated more than 2 h postprocedurally to better mimic the human clinical situation of delayed presentation and antibiotic administration. Note that when using imipenem for antibiotic therapy, the selective dihydropeptidase inhibitor cilastatin must be coadministered to prevent degradation of imipenem.

GENERAL FEATURES OF THE CECAL LIGATION AND PUNCTURE SURVIVAL STUDY The central goal of any animal model is to reproduce the clinical scenario of a disease as closely as possible. The time of deaths that occur during a survival CLP study is an important determinant of whether the model is correct in its severity. The severity of the CLP model ranges from sublethal to lethal with differences in the rate of mortality as well as the absolute percentage of mortality in the experimental group. In general, the first death should occur 24 h after the procedure to rule out iatrogenic effects, such as hemorrhage, that may also cause death. In the more severe CLP model, most deaths will occur between 24 and 36 h after CLP with mortality typically greater than 70% within 5 days (Figure 50–4). In the less severe CLP model most deaths occur between 48 and 72 h after CLP with a 30–40% range of mortality at the end of 5 days (Figure 50–4). These rates and percentages are presented as a guideline and the actual characteristics will vary based on the technique and experimental needs.

COLON ASCENDENS STENT PERITONITIS METHOD Before surgery remove the needle from the desired size venous catheter (14, 16, or 18 gauge).

1. Follow steps 1–4 as for the CLP procedure.

2. Locate the antimesenteric side of the ascending colon, and make an incision approximately 1 cm from the ileocecal valve where the stent will be surgically inserted. The ascending colon is connected to the small bowel at the ileocecal valve junction.

3. With 7-0 Ethicon thread stitch the stent into the lumen of the ascending colon.

4. Anchor the stent in place with two stitches.

5. Remove the inner needle of the stent, followed by cutting the stent at the prepared site.

6. To ensure the proper placement of the stent into the lumen of the ascending colon, squeeze a small amount of feces out of the stent.

7. Replace the intestinal content back into the abdominal cavity.

8. Follow steps 12–16 of the CLP procedure.

ENDOTOXEMIA METHOD

1. Weigh the animal.

2. Intraperitoneally inject (1 ml) LPS at the desired milligram/killogram dose from the desired *Escherichia coli* serotype, or other chemical agent (e.g., zymosan or CpG DNA). Do not stir the LPS solution vigorously to prevent aggregates from forming. Sonication of the LPS solution for 2 min will help mitigate the presence of aggregates. Anesthetize the animal using isofluorane. When delivering an intraperitoneal injection, carefully insert the needle shallowly into the abdomen to avoid damage to underlying blood vessels and organs by tenting the abdominal wall. For intravenous injection, ensure that the LPS solution does not extravasate from the vein and infiltrate surrounding tissue.

3. Monitor the animals to ensure proper recovery from anesthesia.

IMPORTANT GENERAL CONSIDERATIONS FOR SEPSIS MODELS

HUMANE ENDPOINTS IN SEPSIS RESEARCH The use of fair and ethical animal treatment throughout sepsis research and any other experiments that cause pain or distress to animals must be strictly maintained at all times. This often presents challenges to scientists, as early termination may lead to inaccurate results, especially in experimental models involving complex longer-term pathogenesis such as the CLP model.[44] Organizations that advocate more humane endpoints in research animals and create guidelines for research animal care include Public Health Services (PHS), the National Research Council, and the United States Department of Agriculture (USDA) (www.grants.nih.gov/grants/olaw/references/phspol.htm, www.nap.edu, *Fed Reg.* 54). It is the responsibility of all researchers to be familiar with these guidelines and understand how they should be applied to their model(s). Guidance should also be sought from local experienced investigators and the institutional veterinarian and IACUC.

An outstanding review of the issue of humane endpoints in sepsis research has recently been published by Nemzek *et al.*[44] Death as an endpoint should be avoided whenever possible and any animal in a perimoribund state should be euthanized. However, as mentioned above, the limitations of current mortality predictors prevent development of any "gold standard" recommendation. Each investigator must determine the degree of illness and moribund state dictating euthanasia for the model in question. Clearly, implementing early termination of any experiment increases the risk of data collection errors that may lead to erroneous conclusions. Consequently, fastidious decisions regarding early endpoints must be taken to prevent these types of errors. The decision to terminate the experiment is a complex one. To prevent hasty

Table 50–1
Morbidity findings during development of sepsis

Objective	*Subjective*
Abnormal respiration	Aggression
Absence of bedding preparation	Decreased activity
Ataxia	Decreased movement in response to external stimuli
Reduced food/water consumption	
Body temperature reduction	
Body weight reduction	
Diarrhea/constipation	
Hunched posture	
Orbital exudates	
Ruffled hair/fur	

decisions multiple parameters should be evaluated before euthanizing an experimental animal. For example, in the murine CLP model physiological parameters, such as body temperature, blood pressure, and IL-6 levels, may represent predictors of CLP mortality.[44] Defining these parameters, in conjunction with the physical signs of CLP morbidity (Table 50–1), can potentially be used to successfully predict CLP mortality in mice.[44] However, the use of such predictors must be established empirically within the investigator's laboratory and be tested for reproducibility.

MONITORING As a general rule, animals should be closely monitored every 4 h for the first 48 h postprocedure. Depending on the severity of the model, particular timeframes following surgery are critical and require more attention. For example, in a severe sepsis model the majority of deaths occur between 24 and 36 h. Within this critical time frame, it is important to frequently assess for animal pain and distress caused by illness, in addition to checking for mortalities to ensure proper animal care and data collection, respectively. Analgesia with an agent such as buprenorphine may be administered at an increased frequency during this period. In the event that death occurs overnight, an average time of death can be calculated by taking the average of the last hour the animal(s) were found alive and the hour of death. When the animals have passed the critical period when most succumb to sepsis and exhibit normal behavior (survivors), observation times may be less frequent. A thorough understanding of these timeframes during the course of animal sepsis is beneficial to both the animals and the investigator. This knowledge serves to ensure that proper animal care is given at all times, and will reduce valuable labor while maintaining a high standard of animal care.

REPRODUCIBILITY Successful development of a functional sepsis model requires a significant amount of experience with the chosen technique. The level of experience is directly proportional to the complexity of the procedure in question. The simplest model involves a bolus injection of endotoxin and the most surgically complex and demanding model is the CASP technique. Regardless of which model is chosen, the investigator must perform several pilot experiments to define the timing and survival rate to ensure reproducibility. It is also highly recommended that experiments be performed in a randomized and blinded manner whenever possible. This becomes an issue as the control group for each study must be run with every experiment and this increases the number of animals required for completion of the study. However, historical controls unfortunately do not suffice as there may be variability in the experiments based on subclinical infections, alteration of food or bedding lots, and operator dependence. When possible, it is optimal to retain the same operator for the experiment, as subtle differences in surgical style may significantly alter the timing of illness progression and survival rates.

Attention to detail and repetition are paramount in the successful development and utilization of sepsis models. Animal survival remains the primary outcome measurement in study of sepsis mechanisms and in preclinical therapy studies because there are limited markers for predicting mortality or defining sepsis stages, and also because the use of *in vivo* telemetry is complex. To ensure that the operator has enough experience to initiate the end experiment, several independent control experiments should be conducted. For example, using the CLP model, our experience dictates an expected profile of mortality for a given needle gauge used (Figure 50–4). An inexperienced operator, after becoming generally familiar with the CLP technique, typically must perform three to five independent experiments with a sufficient number of animals (typically 10 per experimental group) to demonstrate that the operator can reproduce the expected profile and rate of mortality. The concept of generating reproducible illness is critical when conducting experiments that do not use the mortality endpoint, as in these shorter studies there is no other way to ensure that the proper level of illness has been established. Hopefully, advances in our understanding of sepsis staging markers will assist with this issue and make mortality studies obsolete.

BIOMARKERS IN SEPSIS The complexity of the dysregulated immune response in sepsis makes it difficult to predict clinical outcomes in patients and animal models. Over the years, immunological studies performed to unravel this enigmatic process have also unveiled potential biomarkers predictive of sepsis mortality in attempts to classify the development of sepsis.[45,46]

Translation of therapeutic agents successful in animal model studies to the clinic represents the current stumbling block of sepsis therapy developments.[14] Biomarkers are particularly useful in discriminating between populations of patients who may benefit from particular therapies and for animal model purposes in discriminating sepsis stage and severity when designing sepsis therapies.[14] Many studies have demonstrated a strong association between interleukin 6 (IL-6) levels and sepsis severity in both humans and animal models of sepsis, suggesting that serum IL-6 level may represent a possible biomarker of sepsis mortality.[32,40,47,48] In fact, endogenous IL-6 was utilized successfully to stratify patients into groups of sepsis severity in a recent clinical trial evaluating the efficacy of the antitumor necrosis factor antibody $F(ab')_2$ fragment afelimomab.[49]

The lethal predictive threshold level of circulating IL-6 has been shown to vary with genetic background in murine studies, and it is not associated with disease severity and antibiotic administration.[50] In less severe CLP sepsis with 77% survival after 3 days, serum IL-6 levels were measured 6 h after the CLP procedure and ranged from 83 pg/ml to 10,000 pg/ml.[32] Female BALB/c mice used in this experiment with serum IL-6 levels greater than 2000 pg/ml had significantly more rapid onset of mortality and greater mortality rates compared with those mice with IL-6 levels less than 2000 pg/ml.[32] In the study by Turnbull *et al.,* male ND4 mice demonstrated that the "lethal predictive threshold" of serum IL-6 levels was at 14,000 pg/ml.[50] The difference in the "lethal predictive threshold" of IL-6 described in these two studies was attributed to the consequences of strain differences.

It is likely that the gender, age, strain, or all variables in combination account for differences in lethal predictive threshold IL-6 levels, as there is clear variability within the CLP model depending on the age, gender, and animal strain employed.[14] The effect of age is difficult to assess between the above two studies due to the lack of consistency in age descriptions. The ages for BALB/c mice were ambiguously described as "adult," as opposed to the more accurately identified 6- to 8-week-old ND4 mice. Conclusions drawn from these experiments emphasize the importance of careful documentation of the characteristics of animal subjects so that potential confounding variables may be identified when comparing the interpretation of results among studies.

ANTIBIOTICS The successful control of a systemic infection is an important component of the body's response to infection and involves both innate and adaptive immune responses. Broad-spectrum antibiotics are routinely prescribed for human sepsis patients once the infecting agent is identified, to help in the destruction of bacterial pathogens.[51] To more closely mimic the clinical scenario of sepsis, antibiotics have been used in a variety of sepsis models, including CLP, CASP, and exogenous bacterial implantation models. Currently, imipenem (25 mg/kg) represents a broad-spectrum antibiotic and is commonly used in sepsis models. Dosing of antibiotic also affects agent selection as less frequent administration reduces the number of injections each animal will receive. Imipenem is attractive in this regard as it may be dosed at 12 h intervals.

It has long been a concern that the administration of antibiotics results in the acceleration of cytokine-induced septic shock due to the release of endotoxin bacterial products after bacterial killing.[52] Antibiotic administration may increase the circulating levels of endotoxin in murine sepsis models, and may theoretically lead to a more robust host inflammatory response. However, further studies have demonstrated that the effects of increased serum endotoxin levels resulting from antibiotic administration have no effect on inflammation and prognosis in the CLP sepsis model suggesting that antibiotics will not artifactually alter mortality.[53] In a murine sepsis lung injury model, antibiotics delayed mortality time points but did not improve overall survival.[54] In conclusion, administration of antibiotics appears to decrease the severity of sepsis but does not necessarily decrease mortality in polymicrobial sepsis models and does not appear to increase model severity due to endotoxin release.

CONCLUSIONS

Successful development and use of sepsis models in research require a thorough theoretical understanding of the advantages and disadvantages of each model system, as well as a meticulous technical approach to establishing a reproducible model system. With such understanding and attention to detail, experiments utilizing these complex models can generate important data that will assist in further defining sepsis pathophysiology and identify novel sepsis therapies.

51 Animal Models in Functional Magnetic Resonance Imaging

Afonso C. Silva and Bojana Stefanovic

ABSTRACT

Functional magnetic resonance imaging (fMRI) has significantly advanced brain research, both in basic sciences as well as in translational and clinical studies. Animal models have been at the forefront of research into the mechanisms of magnetic resonance imaging (MRI) and fMRI. The use of animal models in fMRI has been particularly advantageous in preclinical and translational studies of various models of brain disease, and fundamental in the exploration of basic neuroscience questions, such as the mechanisms of perception, behavior, and cognition. This chapter describes the practical aspects of the use of animal models in fMRI studies of the brain.

Key Words: Brain, BOLD, Cat, Cerebral blood flow, Cerebral blood volume, Cerebrovascular coupling, Nonhuman primate, Rodent, Songbird.

INTRODUCTION

Since its inception in the early 1990s, functional magnetic resonance imaging (fMRI) has had a profound impact on brain function research, particularly in cognitive neuroscience[1] and in translational and clinical studies.[2] Like positron emission tomography (PET) and diffuse optical tomography, fMRI relies on the cerebrovascular coupling, a tight relationship between changes in neural activity and local cerebral blood flow (CBF), cerebral blood volume (CBV), and oxygen consumption ($CMRO_2$).[3] fMRI provides excellent contrast to noise ratio, submillimeter spatial resolution, coverage of the whole brain, and relative ease of implementation. On the other hand, the underlying fMRI signal mechanism and its functional specificity are still subjects of research. Moreover, the temporal resolution of fMRI is relatively low (particularly with respect to the time scale of neuronal events), and the magnetic resonance imaging (MRI) environment poses stringent restrictions on subject positioning and movement.

While the brain is a particularly difficult target for translational studies, critical insight into its functioning has been gained through animal models. Indeed, the use of animal models has been of fundamental importance to the development of fMRI techniques. The first study employing blood oxygenation level-dependent (BOLD) contrast was performed in rats[4,5] as were the first CBF measurements using exogenous MRI tracers, such as deuterium,[6,7] fluorine,[8,9] and gadolinium chelates,[10,11] which allowed estimation of CBV in addition to CBF. The advantages of using an endogenous tracer led to the development of arterial spin labeling (ASL) techniques, with the first demonstrations occurring in rodents.[12,13]

Animal models of functional activation of the brain have been widely employed to address issues related to spatial localization of the functional signals, the magnitude of signal changes as a function of stimulation parameters, as well as temporal aspects of the hemodynamic response. Furthermore, the use of animal models in fMRI has been particularly advantageous in preclinical and translational studies of various models of brain disease. This chapter is aimed at describing the practical aspects of the use of animal models in fMRI studies of the brain.

BASICS OF FUNCTIONAL MAGNETIC RESONANCE IMAGING

ACTIVATION PHYSIOLOGY At the heart of brain function lies the generation and integration of electrical and chemical signals. Electrical signals arise via transient changes in the neuronal membrane potential, with >~15 mV depolarization[14] leading to action potential generation or neuronal firing. In most instances, this depolarization arises from temporal and spatial summation of the graded potentials generated by the synaptic input to the neuron, with coincidental activation of hundreds of the thousands of synapses of a typical neuron. While only a miniscule amount of charge is transported across the membrane in the course of the 1-msec activation potential,[14] the long-term preservation of the ionic gradients[15] and hence the excitability of the neuron is ensured by the continued operation of the Na,K-ATPase pump.

Under normal steady-state conditions, almost all of the brain's global energetic demands (in the form of ATP, the primary energy currency in the body) are supplied by oxidative metabolism of glucose (CMRGlc), the O_2-to-glucose ratio being ~5.5 mol/mol.[16] Whereas glucose consumption is closely correlated with local functional activity,[17–20] only ~50% of the glucose extracted by tissue from blood is actually catabolized by neurons and glia.[21] Indeed, it is frequently surmised that under normal physiological conditions blood flow upregulation following functional activation is not subserving the increased demand for glucose.[22]

Increases in local $CMRO_2$ following functional activation are typically much smaller than the accompanying rises in CBF, translating into a higher blood oxygenation level at activation relative to baseline. The customarily quoted reason is that the efficiency of oxygen extraction from the capillary network

[i.e. oxygen extraction fraction (OEF)] decreases with increases in flow,[23] so that a much larger CBF increase is required to support a given rise in $CMRO_2$. In other words, given low tissue PO_2 yet constant parenchymal geometry, the O_2 concentration gradient and hence O_2 diffusion are increased through a rise in the capillary PO_2 achieved by a drop in the O_2 extraction.[22]

In addition to increased metabolism, a focal rise in neuronal activity is accompanied by an increase in the local CBF. One or more vasodilatory substances[24] thus act on the smooth muscle in the arteriolar wall, causing a drop in the arteriolar vascular resistance following functional activation. On the level of capillaries, the focal rise in CBF is thought to be predominantly mediated by an increase in capillary blood velocity rather than capillary dilatation or recruitment.[25] The ensuing rise in the pressure seen at the veins causes their passive dilatation and results in a significant increase in the total blood volume. Consistent with this view of CBV changes being the result rather than the cause of the blood flow increase is the observation of delayed CBV relative to CBF response in rodent somatosensory cortex following forepaw stimulation.[26]

BOLD FUNCTIONAL MAGNETIC RESONANCE IMAGING CONTRAST The magnetic properties of the heme iron of a hemoglobin molecule change following oxygenation,[27] constituting the source of contrast for BOLD fMRI. Specifically, the deoxygenated heme iron ion is paramagnetic, i.e., it has a small positive magnetic susceptibility, ($\chi > 0$). Upon binding with oxygen, the iron ion changes to a low-spin state and becomes diamagnetic, exhibiting a very small, yet negative magnetic susceptibility.[22,28] Overall, the magnetic susceptibility of blood changes linearly with its oxygen saturation.[29] Upon an increase in local neuronal activity, the blood oxygenation level rises (i.e., assuming normal conditions, the fraction of deoxygenated heme iron atoms decreases), so that the magnetic field profile across a vascularized tissue element becomes more homogeneous.

The signal measured in a typical BOLD fMRI study reflects a nonequilibrium value of coherent transverse water magnetization, generated by radiofrequency (RF) excitation. In particular, the timing parameters of BOLD fMRI experiments are chosen to produce a weighting of the signal that emphasizes the activation-induced changes in the time constant of the roughly exponential decay of spin phase coherence in the plane orthogonal to the direction of the external static magnetic field. Such activation-induced differences in the apparent transverse relaxation rate (R2*) arise from the changes in the magnetic flux density (B) experienced by a spin ensemble under investigation following focal functional activation. A higher BOLD fMRI signal will be measured at activation, relative to baseline, as a result of the slower decay (smaller R2*) produced by the increased homogeneity in the focal microscopic magnetic field profile, arising from the activation-induced increase in the blood oxygenation levels.

OTHER FUNCTIONAL MAGNETIC RESONANCE IMAGING CONTRASTS In addition to BOLD fMRI, fMRI measurements of blood flow and blood volume have also been frequently employed to track brain function.

Cerebral Blood Flow fMRI affords noninvasive means of direct CBF measurements using arterial water as a perfusion tracer.[30–32] The general principle behind ASL techniques is to differentiate the net magnetization of endogenous arterial water flowing proximally to the organ of interest from the net magnetization of tissue. As arterial blood perfuses the tissue, water exchange occurs, effectively changing the net magnetization of tissue proportionally to the blood flow rate. Therefore, CBF can be quantitatively related from the difference of two images acquired consecutively: one with and one without spin labeling. ASL MRI techniques can be implemented with either pulsed labeling or continuous labeling.[30,32,33] The pulsed ASL (PASL) methods use single or multiple RF pulses to label arterial blood water spins. The continuous ASL (CASL) technique uses a long RF pulse in the presence of a longitudinal field gradient to label the arterial spins according to the principles of adiabatic fast passage. ASL techniques have major advantages over other techniques based on the administration of exogenous tracers. They are completely noninvasive and because of the very short half-life of the labeled spins, repeated measurements of CBF can be performed freely. Moreover, the techniques preserve the high spatial resolution of ^1H MRI, enabling a direct and precise anatomical localization of CBF changes. On the other hand, proper perfusion contrast is achieved only when enough time is allowed for the labeled arterial spins to travel into the region of interest and exchange with tissue spins, making it difficult to detect changes in CBF with a temporal resolution greater than the decay time of the label.

Arterial spin labeling affords absolute quantification of a uniquely defined physiological parameter; it is specific to tissue signal change, better localized to the focus of the increased electrical activity (as it is sensitive to the arterial side of the vascular tree, in particular to capillaries), and it involves a shorter delay following the neuronal activity increase when compared to the BOLD technique. It is also less affected by venous drainage and is largely insensitive to scanner drift and local susceptibility gradients, in contrast to BOLD. Overall, then, it offers a more sensitive and specific measure of the neuronal activity, with respect to the assessment of its magnitude, spatial extent, and temporal evolution. It is thus the tool of choice for longitudinal functional imaging and has been used in a variety of clinical applications.[34] Nonetheless, ASL has a significantly lower contrast-to-noise ratio and temporal resolution than BOLD and is arguably harder to implement.

Cerebral Blood Volume Most of the existing MR data on CBV come from contrast-enhanced MRI studies. Indeed, the first human fMRI brain maps, obtained by Belliveau *et al.* in 1991,[35,36] were of CBV changes accompanying visual stimulation. The passage of a bolus of gadolinium-DTPA (Gd-DTPA, an intravascular MR contrast agent) was rapidly imaged using T2*-weighted acquisitions.[36,37] The effect of Gd-DTPA is to produce microscopic magnetic field inhomogeneities, thus enhancing the rate of spin–spin relaxation. The analysis relies on the application of the indicator dilution theory to establish the relationship between the contrast agent and CBV in addition to the observed linear dependence of the tissue transverse relaxation rate on the contrast agent concentration.[35,36] Specifically, as the contrast agent passes through the brain, signal attenuation directly proportional to the concentration of the contrast agent is observed. Integrating the area under the concentration–time curve provides a measure of CBV. By repeating this experiment in baseline and activation conditions and subtracting the calculated CBV images, a functional activation map can be produced. The major shortcomings of the method, however, are poor temporal resolution and the limited number of functional measurements that can be performed, due to the administration of the contrast agent.

Unlike dynamic bolus methods, steady-state techniques require a contrast agent with a long intravascular half-life (e.g., ultrasmall superparamagnetic particles) that alleviates the requirement for a bolus injection and affords continuous monitoring of CBV changes. One such agent is MION (monocrystalline iron oxide nanocolloid), which has been used in anesthetized rats to provide a 5-fold increase in signal-to-noise ratio (SNR) over BOLD contrast at 2 T[26] and in awake, behaving macaques, resulting in a three-fold increase in sensitivity over BOLD at 3 T.[38] While MION concentrations used in these experiments are considerably higher than those approved for humans, initial testing of stable blood-pool contrast agents in humans is underway.[39] This approach provides high SNR and temporal resolution, though as with Gd-DTPA bolus methods, toxicity issues limit the number and frequency of studies that can be performed on an individual.

PERFORMING FUNCTIONAL MAGNETIC RESONANCE IMAGING IN ANIMALS

THE CHOICE OF THE ANIMAL MODEL The use of animals in biomedical research is governed by the scientific rationale that a living organism provides a whole, integrated biological system that is the best surrogate for humans in the laboratory. Animal research has led to a greater understanding of living systems and has generated knowledge that can be generalized to humans, facilitating the development of effective therapies, cure, and/or prevention of diseases. When applied to neuroscience, the use of animal models has afforded a better grasp of the biophysical mechanisms of neuroimaging techniques, a greater understanding of neurodegenerative diseases and the underlying mechanisms of neuronal cell damage and death, aided in the development of effective pharmacological therapies and treatments, and facilitated the study of the mechanisms of sensory perception, cognition, and emotion.

There are several factors that influence the choice of the animal model to be used in biomedical research. First, the investigator must consider not only the appropriateness of a particular species, but also whether the information obtained from the research can be extrapolated to human beings. Second, the investigator must be equipped with the experimental setup necessary to collect physiologically meaningful data. This is particularly important when performing fMRI experiments in animal models, when the type of instrument poses constraints on data acquisition, such as spatial and temporal resolution, spatial coverage, SNR, etc. Broadly, the fMRI experiments employing animal models focused on three major areas: the study of biophysical models of fMRI contrast; the investigation of neurological disorders, such as stroke, Alzheimer's disease, Parkinson's disease, and epilepsy; and the exploration of basic neuroscience questions, such as the mechanisms of perception, behavior, and cognition. Examples of each of these applications are described below.

Use of Animal Models to Understand the Biophysical Mechanisms of Functional Magnetic Resonance Imaging Animal models have been at the forefront of basic science research into the mechanisms of MRI and fMRI. From the early days of MRI, mostly rodents, but also dogs and cats, provided a stable and useful platform for the development and characterization of several intravascular contrast agents, such as Gd-DTPA[10,40–43] and iron-oxide particles.[44] These studies led to the use of such intravascular agents for the measurement of CBF and CBV,[10,11,37,45] angiography,[46,47] detection of brain tumors,[48–53] brain infarct,[54–56] and of defects in the blood–brain barrier.[57–59] At the same time, MRI techniques sensitive to blood flow were developed in rodents[6,7,60] and cats[9,61–68] using first exogenous agents, and later endogenous arterial water as a perfusion tracer.[12,13] It was long known that changes in CBF and CBV accompanied changes in neural activity due to brain stimulation.[69] Thus, MRI techniques sensitive to blood flow and blood volume were employed to probe brain function. The first experiments used intravascular contrast agents and were performed in dogs[35,70] and then in humans.[36,71,72] In fact, the discovery of the BOLD effect (see Figure 51–1) was made in rodents (rats and mice).[4,5,73] Thus, the use of animal models had a profound impact on the development of fMRI techniques.

The rodent model has been the workhorse for the investigation of theoretical issues and development of experimental approaches aimed at elucidating quantification of regional CBF and CBV, as well as for the studies of BOLD signal mechanism. In arterial spin labeling, for example, the rodent model has been of fundamental importance in the study of issues such as the effects of magnetization transfer,[74,75] the transit-time from the labeling plane to the detection voxel,[76,77] the perfusion territory of specific arterial vessels,[78] and the exchange of arterial water with tissue water.[75,79–82]

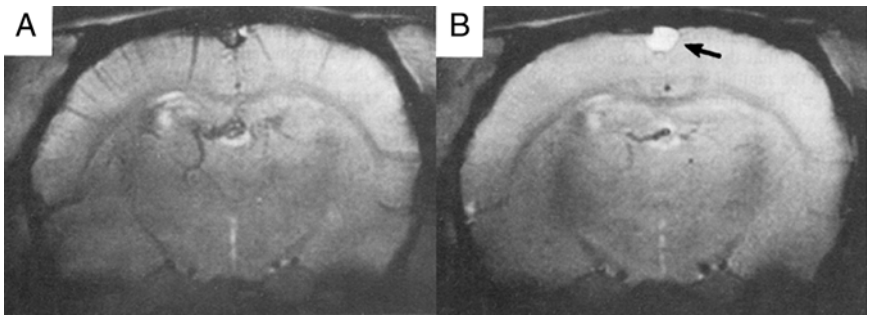

Figure 51–1. A demonstration of the effect of inspired CO_2 on BOLD contrast in a urethane-anesthetized rat. (A) T_2*-weighted coronal image obtained when the animal breathed 100% O_2. Venous blood vessels appear dark due to a short T_2* associated with a reduced venous blood oxygenation level *Y*. (B) The same image obtained when the animal breathed a mixture of 90% O_2/10% CO_2. In response to hypercapnia, CBF increases, elevating *Y* and thus increasing the MRI signal in the veins, such as the sagittal sinus (arrow). (Modified from Ogawa *et al.*[4] Copyright 1990 National Academy of Sciences USA.)

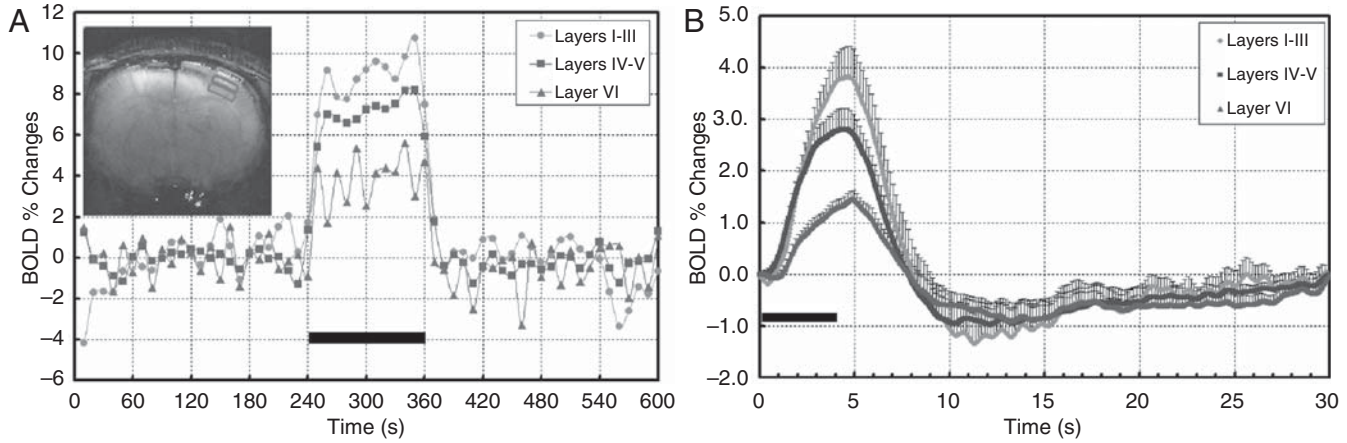

Figure 51–2. (A) Laminar-dependent spatial heterogeneity of BOLD signal changes to electrical stimulation of the rat forepaw, obtained at $50 \times 50 \times 2000\ \mu m^3$. The BOLD response in the supragranular layers was 44% larger than the one in the intermediate layers and 144% larger than the one in the bottom layer. (B) BOLD time courses obtained at 40-msec temporal resolution averaged across nine animals. Layers IV–V present the fastest onset time to stimulation, followed by layers I–III and VI. The inset shows the difference in onset times. (Modified from Silva and Koretsky.[110] Copyright 2002 National Academy of Sciences USA.)

These studies were aimed at improving the accuracy of quantification of CBF and its changes during functional brain stimulation. The use of intravascular contrast agents to quantify CBV proliferated in the 1990s in both rodents[83–88] and cats.[56,89–91]

Subsequent rodent studies focused on comprehending how changes in blood oxygenation related to BOLD signal changes[92–96] and on the use of sensorimotor functional paradigms as robust models of brain functional activation.[26,97–105] More recently, animal models of functional activation of the brain have been employed to investigate the spatial localization of fMRI techniques,[99,101,105–115] the dependence of signal magnitudes on stimulation parameters,[86,116–120] as well as the temporal aspects of the functional time-courses.[110,121–126] Recently, in a rat model of somatosensory stimulation, we were able to show that the BOLD signal changes have distinct amplitude and temporal characteristics that vary spatially across cortical layers, providing strong evidence that functional hemodynamic signals encode and preserve the temporal evolution of neuronal events (Figure 51–2).

Use of Animal Models to Study Neurological Disorders A second major area of application of animal models in fMRI is the study of neurological disorders, such as stroke, epilepsy, Parkinson's disease, and Alzheimer's disease, which involve a disruption in cerebrovascular and cerebrometabolic coupling. Animal models were extensively used to establish experimental, translational, and preclinical protocols aimed at understanding human diseases. Moreover, fMRI provided an invaluable tool for disease characterization, as well as the assessment of the functional recovery and reorganization of the brain.

Several experimental models of brain ischemia have been developed, involving global and focal reductions in CBF.[127,128] Rodent[129–135] and, in particular, feline[56,63,136–142] models of brain ischemia helped establish robust experimental platforms for preclinical and translational therapeutic approaches,[143–145] although their relevance to human disease merits further consideration.[146–148] The use of fMRI techniques in experimental animal models of stroke has provided an important tool in the evaluation of brain plasticity and the recovery of function of the infarcted brain tissue. In a rodent model of stroke, there was no functional response in the ischemic side following either electrical stimulation of the forepaw or bicuculline administration[149,150] from 24 to 216 h following the permanent occlusion of the middle cerebral artery (MCA).[151] However, two other studies using a permanent[152] and a temporary occlusion model[153] have shown a functional reorganization of the cortex following unilateral stroke, which induced a large ipsilateral infarct and acute dysfunction of the contralateral forelimb, accompanied by loss of stimulus-induced activation in the ipsilesional sensorimotor cortex in spite of preservation of cerebrovascular reactivity as measured by CO_2 challenges. At 3 days following stroke, activation-induced responses were detected in the contralesional hemisphere; at 14 days, significant responses were observed in the infarction periphery. The authors thus suggested that limb dysfunction was related to loss of brain activation in the ipsilesional sensorimotor cortex and that restoration of function was associated with biphasic recruitment of perilesional and contralesional functional fields in the brain.

Reese *et al.* also used a transient MCA occlusion model to study local changes in CBV elicited by systemic infusion of the GABA(A) antagonist bicuculline, and found that the CBV response was negatively correlated with the duration of ischemia.[154] More recently, Shen *et al.* combined functional, perfusion, and diffusion MRI to study the effects of permanent and transient focal ischemic brain injury in rats during the acute phase, and concluded that with permanent ischemia, forepaw stimulation BOLD fMRI response in the primary somatosensory cortices was lost, while with temporary ischemia, vascular coupling and forepaw BOLD fMRI response remained intact.[155] On the other hand, Kim *et al.* showed that 2 weeks after stroke, animals displayed variable degrees of fMRI activation in ipsilesional cortex that did not correlate with structural damages as measured using apparent diffusion coefficient, fractional anisotropy, blood volume, and vessel size index.[156]

Animal models have been of fundamental importance in the study of focal seizures and in the preclinical evaluation of antiepileptic treatments.[157] There are several different models of epilepsy available, spanning a wide range of etiologies, acute or chronic presentations of partial seizures, and models for complex partial seizures.[157] Animal models of generalized seizures include rodents, cats, chicken, and nonhuman primates.[157,158] Because

animal models that present spontaneous seizure activity can yield invaluable information on the molecular epileptic mechanisms, transgenic rodents are widely used,[159–163] although cats present epileptic symptoms more akin to the ones seen in humans.[164] MRI and fMRI of epilepsy have focused on mapping changes in the apparent water diffusion coefficient during seizure discharges,[165] the changes in local CBF and $CMRO_2$ during spontaneous spike-wave seizures,[166,167] and the detection of tissue damage in kainic acid-induced epilepsy.[168]

Parkinson's disease (PD) is characterized by a progressive loss of motor control caused by degeneration of the nigrostriatal dopaminergic (DA) pathway. There are two major categories of experimental animal models of PD[169–171]: one based on depletion of dopamine by a reversible pharmacological treatment with either reserpine[172] or amphetamine and the other involving permanent lesioning with neurotoxins such as intranigral injection of 6-hydroxydopamine (6-OHDA)[173–176] or systemic administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).[177–180] Both rodent and nonhuman primate models of PD have been particularly useful in providing data on the disease progression and the effects of therapy.[169,171,179,181–183] While most of the work in animal models of PD is done via PET, MRI and fMRI techniques are increasingly providing complimentary information on the changes in functional brain activity at the onset of the disease,[174,176] or the regional alterations in CBV in response to an amphetamine challenge,[183,184] as shown in Figure 51–3. MRI has also been used to follow the differentiation of mouse embryonic stem cells into DA neurons in the rat striatum,[185] a gradual and sustained behavioral restoration of dopamine-mediated motor asymmetry suggesting stem cell-based therapy can restore cerebral function and behavior.

Alzheimer's disease (AD) is the most common brain dementia afflicting the aging population. Thus, there has been great effort in creating animal models of AD, most notably using transgenic mice models.[186–193] The major role that MRI has played in the study of AD is to provide noninvasive, longitudinal structural information[194] about the neuronal death and myelin breakdown typical of the disease,[195] as well as the development and evolution of amyloid plaques.[195–206] In addition, the combination of MRI and angiographic techniques has been particularly useful in revealing cerebrovascular abnormalities and CBF disturbances associated with AD.[207,208] More recently, fMRI has been combined with behavioral tests to investigate functional deficits in a rat model of AD.[209]

Use of Animal Models to Study Basic Neuroscience Questions Several different animal models have been used to investigate brain function, including rodents, cats, songbirds, and nonhuman primates. Examples of contributions of each animal model to basic neuroscientific work are given below.

Rodents The most common use of rodents in fMRI experiments has been in the study of the somatosensory system. Complimentary to a vast literature based on electrophysiology, histological techniques, and autoradiography, fMRI allows a noninvasive and repetitive view of the entire somatosensory pathway in rodents. The first fMRI experiments in the rodent somatosensory cortex established electrical stimulation of the forepaw as a robust functional paradigm for producing BOLD,[97,98] CBV,[26] and CBF[94,105] contrast in the forelimb area of the primary somatosensory cortex. In the forepaw rat model, BOLD and CBF tuning curves were obtained[94,105] showing maximum responses at low frequencies (1–3 Hz) and no responses above 9 Hz. However, the tuning curve can be greatly affected either by the stimulus parameters[210] or by anesthesia,[211] which may shift the peak response to the 8–12 Hz range (alpha band), which is the natural tuning frequency of the whisker barrel cortex, another functional paradigm used in fMRI of rodents.[99,101,212,213] In addition to distinguishing responses as a function of the stimulus frequency, fMRI has also been used to reveal the functional representation of the entire somatosensory pathway,[112,113,214,215] enabling the investigation of the changes that occur in the activated network during learning or after injury.[152,153,156] The ability of fMRI to reveal functionally interconnected brain regions has been exploited in a recent study of the visual system in the rat,[210] whereby flashing light displayed at different frequencies evoked maximum BOLD response at low frequencies (1–5 Hz) in the visual cortex (VC) and in the flocculus-paraflocculus (FL-PFL) of the cerebellum, and at high frequencies (8–12 Hz) in the superior colliculus (SC). These observed correlations between frequency-dependent responses of different visual areas suggested a functional relationship between the VC and FL-PFL rather than between the SC and FL-PFL.

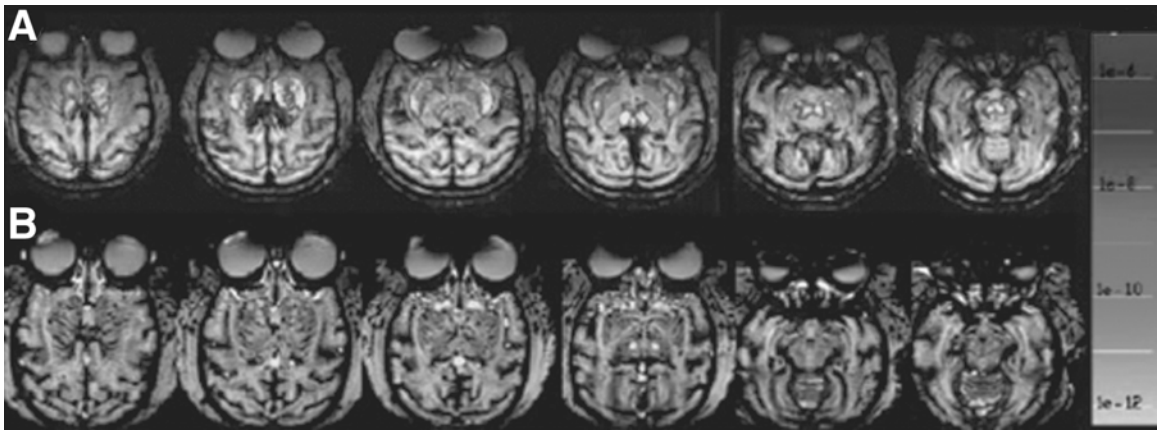

Figure 51–3. Changes in the CBV response to amphetamine (A) before and (B) 4 months after cessation of MPTP treatment in a cynomolgus monkey, showing an almost complete loss of amphetamine-induced CBV signal changes in dopaminergic regions. Parkinsonian primates had a prominent loss of response to amphetamine, with relative sparing of the nucleus accumbens and parafascicular thalamus. (Modified from Jenkins *et al.*[183] Copyright 2004 Society for Neurosciences.) (See color insert.)

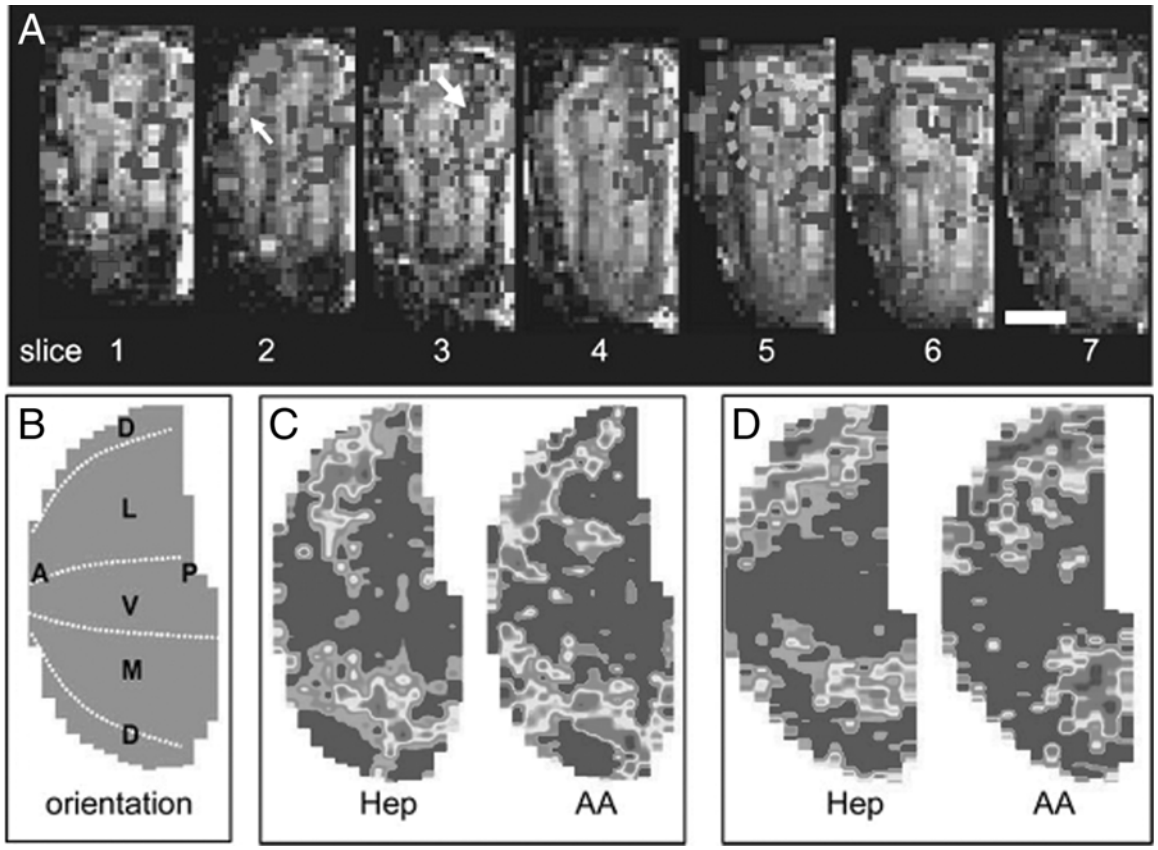

Figure 51–4. (A) Patterns of the fMRI response in the mouse main olfactory bulb (MOB) and accessory olfactory bulb (AOB, pink circle in slice 5) to the pheromone 2-heptanone, one of the urinary chemosignal compounds in mouse. The arrows point to two foci of activation suggestive of a pair of the nearly mirror projections of the receptor neuron subsets to the same MOB. Scale bar = 500 μm. (B) A flattened view of the olfactory bulb indicating the orientation of the odor maps shown in (C) and (D): A, anterior; D, dorsal; L, lateral; M, medial; P, posterior; V, ventral. (C, D) The odor maps of 2-heptanone (Hep) in two different mice show that this pheromone not only activates large regions of the MOB but also generates similar patterns across subjects. Interestingly, the odor map for amyl acetate (AA), a common odorant with an odor quality similar to that of 2-heptanone, was also similar to that of 2-heptanoneb. (Adapted from Xu *et al.*[217] Copyright 2005 Wiley-Liss, Inc.) (See color insert.)

Another prominent rodent sensory system amenable to fMRI investigation is olfaction.[103,109,111,216–218] The spatial resolution of BOLD fMRI allows discrimination of laminae in the olfactory bulb.[103,109] BOLD fMRI has hence been used to describe the spatial activation patterns in the glomerular layer in response to different odors,[111,216] and to reveal the responses in the main olfactory bulb (MOB) and accessory olfactory bulb (AOB) to odors and pheromones[217] (Figure 51–4), and map their ability to adapt to the presence of background odors.[218]

Cats Cats have been most frequently employed in studies of the visual system. The first fMRI experiment in cat visual cortex targeted the establishment of a robust stimulus protocol consisting of a high-contrast drifting grating, whose speed and spatial frequency were optimized for area 18 (V2).[219] Since then, experiments in cat visual cortex have focused on detection of isoorientation columns in the primary visual cortex using the early negative BOLD signal,[220] which was reportedly better suited to resolve the isoorientation columns than the early positive BOLD response.[221] The cat model has been used frequently to determine whether fMRI can provide high enough spatial specificity to resolve subcortical domains, such as functional columns (Figure 51–5) or layers.[114,222–229]

Songbirds Songbirds have evolved a vocal communication system responsible for the production of songs of various complexities. Songbirds make a good model of neuroplasticity in the auditory system since they can learn to produce specific vocalizations. The song control nuclei control the learning and vocalization of songs with seasonal periodicity, providing an ideal system to study brain plasticity and the interactions between neuroplasticity and learning. The group of Annemarie Van der Linden has been studying the song control system in starlings, canaries, and zebra finches using manganese-enhanced MRI (MEMRI),[230] which allows mapping of the song control nuclei and changes in their volume and connectivity as a function of seasonal and hormonal influences. More recently, BOLD fMRI has been employed to observe functional activation in the auditory regions of the telencephalon in starling birds.[231] Distinct spatiotemporal properties of the BOLD response to white noise, to music, and to a conspecific song of a male starling bird recorded during the breeding season were found (Figure 51–6). Only primary auditory regions responded to white noise, but both complex music and the socially relevant conspecific song elicited activation in the descending auditory pathway, indicating a more complex neuronal processing of complex sounds.

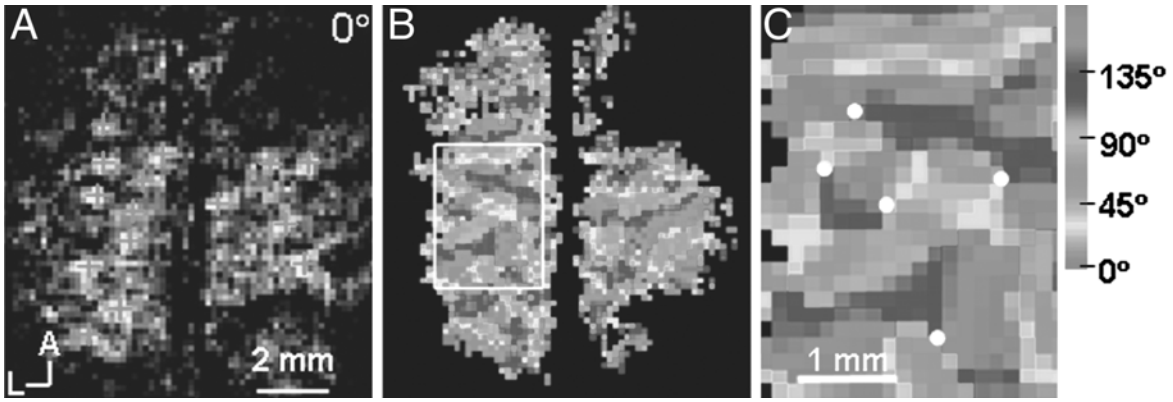

Figure 51–5. Signal changes in CBV-weighted fMRI obtained during stimulation of the cat visual cortex according to predetermined stimulus orientations. (A) Raw gray-scale functional map obtained by subtraction of images during 0º stimulation from prestimulus control. The center of each patch is marked with a green + sign. (B) Four different grating orientations (0º, 45º, 90º, and 135º) were presented in the study of one animal, enabling a composite angle map to be generated through pixel-by-pixel vector addition of the four single-condition maps. In the left hemisphere (marked by a white rectangular box), changes between pixels preferentially activated by a particular stimulus orientation were smoothed by a 3×3 Gaussian kernel. (C) A composite angle map was generated with the region indicated by the white ROI in (B). "Pinwheel" structures indicated by small white dots were observed where domains for all orientations converge. (Adapted from Zhao *et al.*[114] Copyright 2005 Elsevier.) (See color insert.)

Nonhuman Primates Since they are phylogenetically closer to humans, nonhuman primates have been the main model used in studies of perceptual, motor, and cognitive brain processes. Until the mid-1990s, the major experimental techniques in neuroscience-oriented studies of the monkey brain were invasive electrophysiology, histological neuronal tract tracing, and PET. In the late 1990s, the first fMRI experiments were performed in anesthetized or awake behaving monkeys during visual stimulation[232–234] or somatosensory stimulation.[235]

In practice, a number of methodological issues have to be overcome to enable fMRI experiments in awake, behaving monkeys. First, all components of the head and body restraining devices must be made of nonferrous materials, so they can be safely used in the magnetic fields. Second, to mimic the actual scanning environment, the monkeys must be trained to perform behavioral tasks in an extremely noisy and thus potentially distracting environment. A controversial issue related to the training of the monkeys lies in the orientation of the magnetic bore. Electrophysiological experiments are typically performed with the animal sitting erect. However, the majority of MRI magnets are oriented horizontally. While several research groups have successfully obtained results from animals trained and restrained in a horizontal position,[232,233,236] the group of Nikos Logothetis strongly advocated a vertical magnet.[234,237] Results obtained from such technical "tour de force" studies have been remarkable,[238] so that there are now multiple nonhuman primate vertical magnets in operation. However, it is still unclear whether the benefits justify the substantial additional costs associated with acquisition, site planning, and operation of such systems.

In isoflurane anesthetized monkeys, Disbrow *et al.* used fMRI to demonstrate the mediolateral topographic representation of the foot, hand, and face in primary somatosensory cortex,[235] and found about 55% concordance between the fMRI maps and maps obtained in the same animals with microelectrode recording

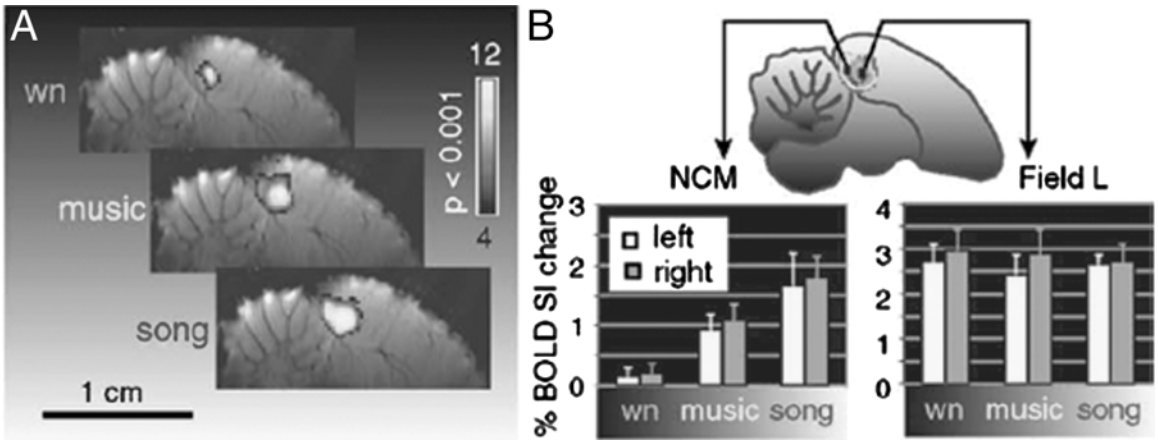

Figure 51–6. Auditory activation in the songbird telencephalon shows (A) statistical maps illustrating the localization of significant signal intensity changes during auditory stimulation consisting of white noise (wn), a concerto of Bach (music), and a stimulation with song from a male starling (song). (B) The location of the activated areas (top), together with the average BOLD response amplitude for each stimulus (bottom). (Adapted from Van Meir *et al.*[231] Copyright 2005 Elsevier.) (See color insert.)

techniques.[239] They concluded that most of the discrepancies were due to the sensitivity of fMRI to "draining veins." Another report demonstrated the separation of primary and secondary somatosensory areas of hand and face.[240] A recent fMRI study of the hand representation in macaques has revealed an ipsilateral hand input in area 3b of the primary somatosensory cortex that could not be distinguished from the fMRI response of the contralateral hand responses.[241] Comparison of the fMRI data to electrophysiology showed that the colocalized ipsilateral response was influenced by inhibition, suggesting that ipsilateral inputs may have modulatory effects on contralateral input processing.[241]

Most of the fMRI studies performed in nonhuman primates have investigated the visual system. In a seminal paper, Logothetis *et al.* described the presentation of checkerboard patterns or pictures to anesthetized monkeys during high spatial resolution (0.5 μl) fMRI experiments at a magnetic field of 4.7 T. Even under the influence of anesthesia, visual stimulation produced robust, reproducible, focal activation of the lateral geniculate nucleus (LGN), the primary visual area (V1), and a number of extrastriate visual areas, including areas in the superior temporal sulcus.[234] Using local RF coils implanted in the skull, the same group was able to push the spatial resolution down to 0.0113 μl and show laminae-specific activation in V1 and V2 by comparing the activity elicited by moving and flickering visual stimuli,[237] while moving to 7 T improved the image SNR.[242] Subsequent reports by the same group emphasized the effect of noise on the BOLD responses to visual stimulation,[243] the processing of motion by the visual pathway,[244] and the three-dimensional representation of shape in the "what" and the "where" pathways.[245] Meanwhile, other groups reported the use of intravascular agents as a way to enhance contrast in fMRI experiments of nonhuman primates,[38,236,246] which allowed definition of motion-sensitive areas in the visual cortex.[236,247] Other fMRI studies in macaques included mapping of the retinotopic organization throughout the visual cortex,[248] and comparing the monkey to human responses in the integration of local image features into global shapes,[249] with respect to the relative spatial extent and magnitude of activation in prefrontal cortex,[250] in higher visual areas,[251] in frontal and parietal eye fields,[252] and in object adaptation in shape-sensitive regions.[253]

THE USE OF ANESTHESIA The use of anesthetics offers important advantages of ensuring compliance, minimizing movement, and alleviating stress in addition to obviating the need for extensive training to both the MRI scanning environment and the functional paradigm of interest. Stress can be a significant confound in the study of brain function, particularly when hemodynamic variables are used as surrogate markers of neural activity. It is difficult to dynamically monitor the level of stress in the awake animals and almost impossible to establish its absence even with extensive training: indeed, continued research on training protocols and evaluation of stress indicators are subjects of much research.[254]

Urethane[124,255,256] and α-chloralose[94,97,98,102,105,113,257,258] are among the most widely used in studies of the somatosensory cortex. However, both substances are toxic and thus not adequate for longitudinal use.

Indeed, an additional challenge in the use of anesthesia is encountered in longitudinal studies of brain function. The inhalational compounds halothane[258] and isoflurane[211,259–263] are safer to use in repetitive studies in the same animal, but these anesthetics suppress neuronal activity and thus greatly influence the cerebrovascular coupling, making it necessary to redefine the proper stimulus parameters to produce robust activation.[211] Propofol is an injectable anesthetic with a rapid mechanism of action. It is increasingly used in fMRI experiments in animal models,[259,264–267] as the depth of anesthesia can be readily adjusted by varying the rate of infusion, and the animals quickly recovered at the end of the experiment, thus facilitating longitudinal studies. Another agent that has been recently proposed as suitable for repetitive studies is the α_2-adrenoreceptor agonist medetomidine hydrochloride,[68,269] which has been shown to allow robust fMRI responses[269] and whose sedative and analgesic effects can be quickly reversed with the application of atipamezole hydrochloride.

The influence of anesthetics on the neuronal responses and their coupling to hemodynamics severely restricts the choice of the functional paradigm and has been the subject of active research.[257,258,261,265,269–275] In addition to affecting the response magnitude and its evolution, the anesthetic frequently interacts with pharmacological agents administered.[276] It thus often represents another complex confound in the interpretation of the results and, most importantly, in the translation of findings from animal to human models.

ANIMAL PREPARATION AND PHYSIOLOGICAL MONITORING The use of anesthesia is predicated on some degree of preparatory surgical procedures: these are usually necessary to allow administration of anesthesia over the course of the experiment and/or facilitate physiological monitoring so as to ensure stable physiology under the influence of the anesthetic. The well-established anesthetics for functional experiments, namely urethane, propofol, and α-chloralose, are all injectable. Whereas urethane is usually given in a few intraperitoneal boluses and propofol and α-chloralose are administered as continuous infusion, either intraperitoneally or intravenously. Both urethane and α-chloralose typically require an additional anesthetic to be used during the preparatory surgery. The halogenated anesthetics (halothane, sevoflurane, and isoflurane) are the customary choices for induction of anesthesia prior to the commencement of rodent surgery. In contrast, an intramuscular bolus of ketamine (either alone or in combination with its potentiators xylazine, acepromazine, or medetomidine hydrochloride) is frequently used for induction in both cats and nonhuman primates.

Typically, following the induction of anesthesia, the animals are typically orally intubated or tracheostomized and mechanically ventilated to allow dynamic adjustments of respiratory parameters so as to ensure stable physiology—under the effect of the anesthetic—throughout the experiment. The importance of the maintenance of stable physiological conditions cannot be overstated, as the physiological condition of the animal exerts profound effects on its functional responses. Monitoring the physiological state of the animal typically includes continuous recording of the temperature (rectal or cutaneous), mean arterial blood pressure (via a pressure cuff or an indwelling arterial catheter), end-tidal CO_2 pressure (via capnography), and arterial blood oxygen saturation (via pulse oximetry). Periodic sampling of arterial blood is also performed to yield information on arterial blood gases, hematocrit, and electrolytes and is achieved through cannulation of a major artery, typically the femoral or the iliac. Data collected during unstable physiology are best discarded. Furthermore, large deviations in the arterial blood gases often call for administration of corrective pharmacological agents. The normal ranges on blood gas values are given in Table 51-1.

Table 51–1
Arterial blood gas values for animals breathing air[287]

Parameter	*Normal range*
PCO_2	28–40 mmHg
PO_2	82–94 mmHg
pH	7.35–7.45

MRI poses stringent requirements on immobilization. After surgery, the animals are thus placed in a stereotaxic-like head holder and strapped to a cradle/chair. The design of the cradle/chair requires considerable engineering effort.[232–234] A muscular relaxant (e.g., pancuronium bromide or tubocarine) may also be periodically administered intravenously to aid with immobilization.

FUNCTIONAL PARADIGM As with most other modalities for studying brain function, the environment of the MRI scanner and the statistical nature of the fMRI analysis restrict the nature of the functional paradigm employed. Functional paradigms need to be carefully designed so as to isolate the responses evoked by the stimuli/task from the "resting" activity. The definition of the control condition is a particularly difficult one and the evoked responses are arguably significantly modulated (and, at times, dictated) by the so called "baseline." Broadly, there are two categories of functional paradigms employed in fMRI research: the slow frequency "block" paradigms and the pseudorandom, brief on-period "event-related" paradigms. The choice of the two is influenced by the issues related to the neuroscience question at hand in addition to the signal detection versus estimation considerations.[22]

PHARMACOLOGICAL PERTURBATIONS Animal models have been widely employed in pharmacological MRI (phMRI) studies to address both basic science and clinical questions.[277] The latter have been frequently exploited to provide pharmacodynamic assays and identify the potential therapeutic agents, thereby guiding later research in human subjects.[278]

The spatial and temporal characterizations of neurotransmitter interactions have thus been undertaken in the rodent[184,279] and primate models.[183] For example, to shed further light on the progression of Parkinson's disease, BOLD responses to DA stimulation have been studied in both rats[280,184] and rhesus monkeys.[281] Ketamine has been administered to produce schizophrenia-like behaviors in anesthetized rodents.[276] Finally, pharmacological studies in animals have yielded important insight into addiction.[282,283]

COMBINATION WITH OTHER MODALITIES Whereas fMRI affords relatively straightforward noninvasive assessment of function, the complex mapping from hemodynamics to neuronal state has hindered the interpretation of many BOLD fMRI studies. To address these issues, a number of investigators have combined BOLD fMRI with other invasive modalities to provide validation and refine the interpretation of the BOLD fMRI measurements. Animal models are particularly well suited to such invasive, multimodal investigations. BOLD fMRI has thus been combined with optical imaging, histology and behavioral assessments,[281] immunoreactivity,[284] microdialysis,[285] and PET.[286]

CONCLUSIONS

The use of animal models in functional MRI investigations has had a profound affect on the development of fMRI techniques and the understanding of the biophysical processes underlying the various fMRI contrasts. It has provided much valuable data into basic neuroscience questions and aided the investigation of a plethora of neurological diseases and disorders. In light of the ever increasing demand on the sensitivity, specificity, and quantification of brain function, animal models will certainly continue to play a central role in the refinement of the existing techniques as well as in the development of novel contrast agents, new endogenous contrast sources, and more realistic models of various brain pathologies.

52 Animal Models in Aging Research

A Critical Examination

ROCHELLE BUFFENSTEIN, YAEL H. EDREY, AND PAMELA L. LARSEN

ABSTRACT

Understanding why different organisms show diverse rates of aging may provide useful insights into basic aging processes. Biogerontologists have converged on a few model organisms that represent only a minute fraction of the animal kingdom, but nevertheless span a considerable distance in animal evolution. Shared features of these evolutionary divergent animals have highlighted some conserved regulatory processes in animal aging. However, these traditional models are all short-lived and may have unintentionally constrained research to focus on only those areas in which their use is most appropriate. Surprisingly few studies focus on slow-aging organisms, or nontraditional model organisms that may be better suited to address successful aging and issues more relevant to long-living humans. This chapter critically assesses both traditional and nontraditional animal models used in aging research, and emphasizes the importance and judicious use of the comparative method to test the ubiquity of aging theories, mechanisms, and their potential translation for human application.

Key Words: Longevity, Slow-aging, Comparative approach, Life span extension, Oxidative damage, Phylogenetically independent contrasts, Disposable soma theory of aging.

INTRODUCTION

Humans are inherently fascinated by the aging process and fearful of growing old. The quest for immortality is a frequent theme in mythology and historical accounts, such that many people, both before and after the famed Spanish explorer Juan Ponce de Leon (1513), have searched in vain for the "Fountain of Youth," for to drink its water may bestow eternal youth. Despite this elusiveness, both human life expectancy and quality of life at advanced ages have increased dramatically since that time. These demographic patterns are a product of improved public hygiene, better nutrition, and biomedical advancements rather than the result of any retardation of the mechanisms of aging. Aging itself is often considered life-limiting, and is the major risk factor for the predominant causes of death (cardiovascular disease and cancer). To continue to enhance the longevity and quality of life, we need to convert the enigma of aging into an understanding of the mechanisms involved in this ubiquitous process.

Animal models have long facilitated the exploration of biological mechanisms, including research on aging. "Salacious animals and those abounding in seed age quickly," claimed Greek philosopher Aristotle in his 350 BCE treatise *On Longevity and Shortness of Life*. Aristotle cited the mule (typically a sterile hybrid) as living "longer than either the horse or the ass from which it sprang." Similar claims were made in "the rate of living theory" popularized as "live fast, die young," proposed by Pearl.[1] Although these theories are inherently logical, they were refuted following careful scrutiny based on numerous animal studies. Whether results supported or provided an exception to these theories depended in part on the species studied. Each animal model affords different strengths for physiological, biochemical, and genetic research. Since the aim is to uncover the full assortment of mechanisms that are important components of aging, the discussion here will focus on how to gain the most knowledge from the use of different animal models.

August Krogh, the Nobel laureate of 1920 and a founding father of comparative biology, was renowned not only for his research on regulatory processes in capillaries, but also for his insightful approach to setting the modalities of this field. His profound statement—"for many biological problems, there is an animal on which it can be most conveniently studied"—is often cited when animal models are chosen.[2] Biogerontologists have converged on a few model organisms (single-celled yeast, *Saccharomyces cerevisiae*, the nematode *Caenorhabditis elegans*, the fruitfly *Drosophila melanogaster,* and the laboratory mouse *Mus musculus*). These four species represent a minute fraction of the animal kingdom, but nevertheless span a considerable distance in animal evolution (Figure 52–1). Shared features of these evolutionary divergent animals strongly indicate the presence of some conserved processes. However, there is still considerable debate concerning the extent of generality of aging mechanisms. These traditional models have provided valuable insight into putative regulators of longevity including the genetic, molecular, and biochemical basis, and have contributed immensely to current understanding of aging processes.[3–6] Unintentionally though, they may have constrained research to focus on only those areas in which the use of these species is most appropriate.

Careful scrutiny of why these classical model organisms are selected suggests that as in many other areas of biomedical research, they are primarily selected for expediency, rather than for any specific biological properties that make them ideally suited for studying aging processes relevant to humans.[7,8] Regardless of the research field, they are used because they have many advantages in a laboratory setting: they are small, easy to care for,

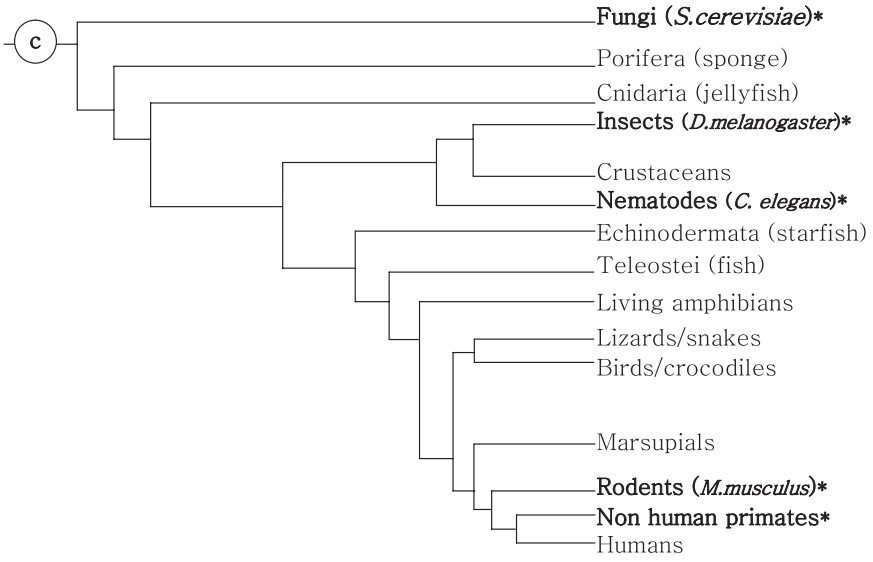

Figure 52–1. Phylogenetic relationships of model organisms used in aging research. "C" represents a common ancestor. Animals in bold are traditional models used in aging research. (Modified from the American Museum of Natural History website.)

and breed well in captivity, such that the cost of maintaining statistically significant numbers is not prohibitive.[9] Furthermore, their basic biology and genome are known. This, together with appropriate new genetic and molecular tools, has facilitated considerable advances in scientific endeavor.

A shared weakness of traditional aging models is that they do not show well-developed mechanisms that protect them from aging and they are all short-lived.[7] There are examples of slow-aging animals, which exhibit only slight age-related declines in physiological capacity, reproductive rate, and/or disease resistance. Surprisingly, few studies involve these animals, even though they display characteristics that we try to emulate in short-lived models. A complementary approach would be to assess how slow-aging animals attain their prolonged longevity. There is also a need to understand mechanisms of aging in species phylogenetically closer to humans (e.g., primates, Figure 52–1), as well as in vertebrates with life spans that approach the life span of humans. Research on aging could benefit from a comparative approach using traditional models and wise addition of nontraditional model organisms, especially those better suited to addressing aging issues more relevant to those related to humans.

AGING

Aging can be defined as a *progressive*, *irreversible*, *endogenous*, and *deleterious* process[10] that occurs postmaturation. This turns young healthy adults into older, more frail adults, increasingly susceptible to environmental challenges (such as extreme temperature or disease-inducing infectious agents), and with a concomitant greater risk of death. Its progressive character suggests that causes of aging are present throughout life. Thus, it may be discerned at all ages and is most pronounced in postmitotic tissues in which cells that are irreversibly damaged or lost cannot be replaced by mitosis. Irreversible damage (from reactive oxygen species (ROS), advanced glycation end products (AGEs), and DNA mutations) may accrue at different rates in different cell types. Exogenous factors (environmental stressors, e.g., toxic chemicals) may interact with genotype-dependent factors, either enhancing or diminishing their effects, and thereby determining rates of aging. These combined effects may explain why different species or strains, maintained under similar conditions, age at diverse rates and exhibit unequal organ-specific vulnerability. Regardless of these dissimilarities, the prominence of age-related declines makes it possible to distinguish young from old throughout the animal kingdom.

Certain strains or species are more prone to specific age-related changes and associated pathologies. For instance humans, and naked mole-rats have a far lower incidence of cancer than do mice at any age.[11–13] In contrast, some mouse strains (e.g., AKR/J) are so susceptible to neoplasia that if they survive more than 24 months, at death 100% of the individuals will present with a strain-specific tumor (AKR/J ~ thymic lymphoma), even if is not the determined cause of death.[14] Aging research in these animals thus may be compounded with disease effects.

Of critical concern is that a reductionist approach has been used in aging research. This limits the number of variables under study, and usually ignores synergistic interactions, thereby oversimplifying the process. For example, if higher levels of oxidative damage are found in an older cohort, a reductionist would conclude that this damage causes aging. However, this may potentially be a consequence of upstream mechanisms. Numerous similar features have been cataloged in young and old representatives within a species, without providing real insight into the aging process. Clearly, to make significant advances in aging research, an *in vivo* broad integrative approach needs to be taken and experimental data from the plethora of studies need to be collated, and thereafter used in a systems-based predictive modality.

ANIMAL MODELS

There are three primary criteria for employment of animal models: (1) their use must be feasible, (2) the specific question under investigation can be appropriately addressed with this model, and (3) the findings can be generalized.

MODEL SYSTEM SELECTION

Feasibility of Use Choice of animal model depends to a large extent on logistical considerations such as its ease of acquisition, housing and husbandry requirements, and costs of care in captivity. As such, it is highly unlikely that elephants or rockfish, despite exhibiting a life span that overlaps the human range, will

ever be considered an "ideal" animal model for aging research. There are many other species that would not present as logistical a problem and from which aging research could benefit. Their use would to a large extent depend upon prior knowledge of the basic biology and the nutritional and housing requirements of the selected species. For instance, guinea pigs, like humans, cannot synthesize vitamin C and require daily supplements to maintain good health, while other laboratory rodents can produce their own supply.[15] Furthermore, guinea pigs, like many wild-derived species, are particularly sensitive to light availability. Inadequate lighting may alter their endocrine profiles and physiological function, and markedly affect research outcome. This may contribute to the lack of interlaboratory reproducibility of findings. Similarly certain animals, in particular primates, do not function optimally when housed without enrichment activities, and may present with abnormal responses in cognitive tests and altered neuronal function and hormone profiles.[16] A thorough knowledge of species-specific needs makes it possible to better interpret findings and ensure the appropriate species are used for the hypothesis under investigation.[17]

Specificity of Question The organism of choice would depend upon the specifics of the study. For instance, an organism whose somatic cells are all postmitotic would not be suitable for assessing changes in rates of cell turnover. However, this organism with a postmitotic adult soma could be a powerful animal model with which to assess damage accrual, for new cells are not recruited to confound the interpretation.

General Application A key criterion in aging research is the ease with which the information gleaned can be generalized and applied to a wide range of species, and in particular to humans. To achieve this goal, a specific question may be explored in a wide variety of phylogenetically unrelated organisms. Alternate ways of addressing these issues include assessment of both phylogenetically distinct and closely related species that show disparate longevity, and/or in similar-sized organisms with markedly different life spans. Regardless of methodology, useful insights may be obtained from both data that converge and diverge.

PRINCIPLES OF USE OF ANIMAL MODELS

There are certain basic principles for use of animal models that should be adhered to for biogerontological research. These are briefly summarized here, but for an in depth review see Miller and Nadon.[8] Regardless of age, animals should be healthy, pathogen and disease free, and have no signs of tumors or lesions. It is imperative to carefully choose the age cohorts such that animals used are neither too young nor too old. Animals that are nearing the end of their lives may already be riddled with age-associated diseases, whereas those that are too young may still be undergoing the complex process of development and maturation. If a particular trait differs from young controls only in the oldest cohort, it is hard to ascertain if this is specifically due to aging, maturation of the young cohort, or age-associated pathologies (Figure 52–2). As such it is far better in initial surveys of novel model organisms to use more age cohorts and avoid the risk of misinterpreting data, or missing the important age-related changes in those variables (as highlighted in Figure 52–2).

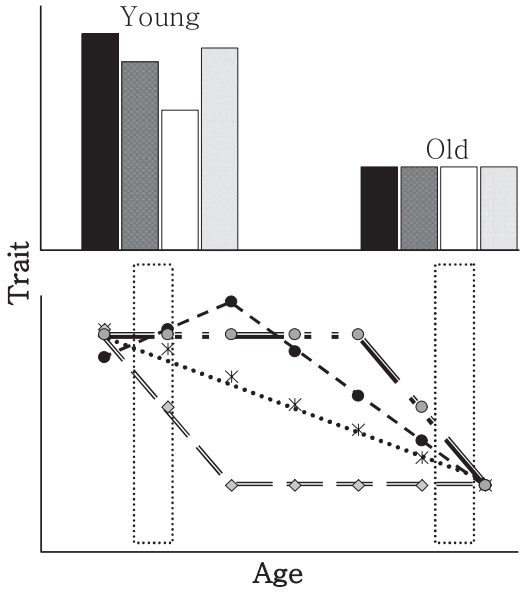

Figure 52–2. Age-related changes in four hypothetical species in which interspecies trait values are similar within each age cohort, although patterns of aging vary dramatically, and this cannot be duduced from the data provided in the two age cohorts.

STRAIN SPECIFICITY

When planning a study, the genetic background of the model organism is a critical design decision. In many cases, particular strains are used simply because they have been previously used by other scientists and are readily available.[18] Indeed, more than 70% of the mice requested from the U.S. National Institute of Aging are of the C57BL/6 strain.[19] This means that rodent aging research is primarily based upon a single genotype.

Inbred strains have the advantage of low genetic heterogeneity so that some traits show only slight intrastrain variation. Thus, statistical significance can be acquired using small sample sizes within a group. Use of highly inbred strains, however, is almost equivalent to repeated measures on a single individual, thereby limiting informed inferences about the generality of findings. For instance, C57BL/6 mice are extremely susceptible to atherosclerosis.[20] Any experimental intervention that reduces mortality from this strain-specific pathology may spuriously be assumed to affect normal aging and longevity. This is considered one of the main drawbacks of using any mouse strain as a model for human aging. F_1 hybrids, four way crosses, or outbred heterogeneous strains tend to be hardier and exhibit longer life spans than their parental stock.[13,21] While costs of experiments based upon genetically diverse populations are higher (since larger samples sizes are needed to overcome the greater variability in measured traits), the outcome is influenced less by any particular genotype, and there is more confidence in broadly applying the conclusions gleaned from these studies.

Aging studies should be undertaken in both genders, for differences in genotype may be evident. For example, old male CBA mice have a stronger likelihood of developing hepatocellular tumors than females.[13] Similarly, quantitative trait locus (QTL) mapping of *Drosophila* genes has identified gender specific loci that differentially alter longevity.[22]

ANIMAL HUSBANDRY

If studies are to be reproducible, animals ought to be housed under identical conditions and have standardized diets. Housing and dietary requirements for worms, flies, and mice have been well established to provide optimal living conditions in the laboratory. For this reason interlaboratory comparisons and experimental interventions can be undertaken facilitating greater confidence in data obtained.

In novel species, housing animals under simulated natural conditions and providing a varied diet may ameliorate captivity-associated stresses. For instance, naked mole-rats are highly social species that naturally live in underground burrows. In captivity these animals are housed communally in a series of interconnected plexiglass tubes. Animals housed in this way thrive, whereas those housed under standard rodent conditions do not, and develop dry skin and associated maladies (R. Buffenstein, personal observations). Thus, the health of the animal may outweigh the scientific desire for uniformity in diet and environment.

TRADITIONAL MODELS OF AGING

The three traditional multicellular model species for aging research (worms, flies, and mice) have been thoroughly studied. Breakdown in the maintenance of genomic stability, stochastic damage to DNA, and inadequate repair processes, as well as oxidative damage and impaired protein processing and folding have been widely implicated in their aging.[23,24] Caloric or dietary restriction (DR) appears to prolong life span in all classical models.[25] Similarly, single-gene mutations that alter life span have been identified in yeast,[26,27] worms,[28] flies,[29] and mice.[30] Furthermore, a similar genetic mechanism and a concomitant biochemical pathway have been found across the phyla.[31]

EXPERIMENTAL MANIPULATION DR without nutrient deficiency induces life span extension in all four evolutionary divergent traditional model species. In all cases metabolism is attenuated initially and reproduction is inhibited.[25] The ubiquity of this process in other organisms, however, is equivocal.[32–34] DR may exert its life-extending effects by acting as a low-level stressor, inducing reduced ROS formation and less oxidative damage accrual,[35] lowering glucose and insulin levels,[25] and/or decreasing insulin-like growth factor-1 (IGF-1).[36] DR appears to attenuate the rate of aging and extend longevity through a variety of mechanisms.[37] While the life-extending effects of DR on human longevity are unknown, a National Institute on Aging (NIA) study to address this was initiated in 2002.[38]

Although most studies of DR involve energy reduction without a concomitant nutrient deficit, it has been shown that limiting protein intake, or more specifically methionine, may lead to similar, though not as pronounced life-extending effects.[37] Methionine residues on proteins are readily prone to ROS attack and activity of a broad range of proteins is reportedly altered by its oxidation.[39] Limiting dietary methionine content lowers ROS production,[40] and also increases oxidative stress resistance.[17] In addition, methionine-restricted diets reduce glucose and insulin levels and lower IGF-1 concentrations in mice.[17] It therefore appears that methionine restriction may act on the same pathways as DR when exerting its longevity-extending effects.[37]

Kenyon[31] suggests that the conserved responses to DR provide further evidence that there are regulatory genes for longevity that may retard aging by delaying reproduction. She proposes that by linking reproduction and aging, these genes may be selected for; animals that do not show a decline in reproductive output when nutrients are scarce would become extinct.

GENETIC MANIPULATION Genetics has proved to be an incredibly powerful tool with which to probe proximate causes of aging. It substantiates the existence of genes that control life span.[4,31,41,42] Mutations in worms, flies, and mice that extend the life span are all associated with loss of function[42,43] and for the majority a concomitant decline in reproduction. This implies that genes enhancing reproductive fitness have been selected in the laboratory setting and possibly also from an evolutionarily standpoint. Research on guppies in the wild has shown that evolutionary tradeoffs between longevity and reproduction can manifest within as few as 60 generations, such that populations in predation-prone zones show earlier sexual maturity, greater reproductive fitness, and shorter life spans than those in areas with low predator density.[44] These genes, promoting early life reproductive fitness, appear to be detrimental later in life, and are a good example of selection by antagonistic pleiotropy.[45]

Many of the genetic manipulations that extend longevity reduce the size of the organism.[42] However, while IGFs have been implicated as life span determinants in all traditional models,[46] such that animals with low levels of IGF-1 live longer, small body size does not appear to be a requirement for this life span extension.[47,48] Heterozygous chico null/+ flies are normal in size yet live 36% longer than wild-type flies.[49] Similarly, the $p66^{shc}$ knockout mouse shows no reduction in size yet nevertheless shows a 30% increase in longevity,[50] an increment comparable to that of Snell dwarf mice.[51]

Genetic studies in invertebrates and mammals have elucidated mechanisms associated with prolonged longevity by either genetic or environmental manipulations. DR of dwarf mice (lacking pituitary functions) further extends longevity in an additive manner.[42] These data and the observation that DR is DAF-16/FOXO independent suggest that the longevity mechanisms are independent of each other.[52,53] Long-lived mutant *C. elegans*[53] and *Drosophila*[54] and $p66^{shc}$ mice[50] all show increased resistance to oxidative stressors. Similarly, oxidative stress studies using fibroblasts from dwarf mice also show that cell survival following exposure to oxidative insults correlates with life span.[55] Other studies, however, report contrary findings inconsistent with the mechanism of oxidative stress resistance causing longevity. Chico mutant flies show resistance to oxidative stressors similar to wild-type animals, despite being longer-lived.[49] In mice, Hauck *et al.*[56] reported that long-lived $GHR/BP^{-/-}$ mice are extremely susceptible to oxidative insults, while Harper *et al.*[17] observed extreme sensitivity to hepatotoxins in long-living dw/dw and GHR-KO mutant mice. Also, the increased oxidative stress and damage in Mn SOD-deficient mice are not accompanied by a concomitant decline in life span.[57] Thus these data suggest that while resistance to oxidative stress and other toxins is a common characteristic of experimental life span extension, it is not an essential determinant of longevity.

NONHUMAN PRIMATES AS MODELS FOR AGING RESEARCH

Although considerable information has been gleaned from traditional aging models, expanding the species under study to nonhuman primates is important given their phylogenetic (evolutionary) proximity to humans. Rhesus monkeys (*Macaca mulatta*), the most commonly used primate model in aging research,[13] share approximately 90% of their genome with humans[58] and have many more traits in common with humans than traditional aging models.[13] Rhesus monkeys have regular monthly menstrual cycles and show cessation thereof with aging with menopausal hormone profiles similar to that of humans.[59] Thus, they may be particularly useful for studies addressing reproductive senescence.[60] Age-

related changes in neurological function and memory of monkeys also parallel those of humans.[61,62]

While the advantages of primate use in aging biology are obvious, to date their use in aging research has been rather limited. This appears to be primarily due to relative costs compared to other animal models,[13] fear of disruption by animal rights groups, as well as logistical issues associated with their comparatively long life spans. These issues may be potentially overcome through the use of small, rat-sized primates (e.g., common marmoset or mouse lemur) that have both shorter maturation times and life spans than rhesus monkeys; their research potential has been only scantly (i.e., Zeng *et al.*[63]) exploited to date.

NONTRADITIONAL MODELS FOR AGING RESEARCH AND THE COMPARATIVE APPROACH

Experimental manipulation in traditional models has led to 20–400% increases in mean and maximum life span (MLS). A major enticement to employ a comparative method is the more than 40,000-fold natural difference in life span among animals. Just within mammals, maximum life span varies by at least two orders of magnitude (Figure 52–3). Generally MLS lengthens in a predictable manner (i.e., MLS is proportional to mass$^{0.2}$, see Speakman[64]) as species increase in size such that for every doubling of body mass in mammals, there is on average a 16% increase in MLS. Body mass, however, can explain only ~35% of the variation in MLS of mammals. For our size *Homo sapiens* is a very long-living mammal, with an MLS (122.5 years) greater than that of elephants (MLS 80 years) and even much larger blue whales (105 years),[3] and that is 5 times[65] to 10 times[66] longer than predicted by mass (Figure 52–4). To date we do not know why humans, and a few other long-living mammals, lie more than two standard deviations away from this allometric relationship, nor do we have a good understanding of the mechanisms that facilitate slow aging, even though this clearly is highly relevant to biogerontology.

ADVANTAGES AND DISADVANTAGES OF THE COMPARATIVE APPROACH Comparative differences among species with disparate longevity provide a powerful source of putative mechanistic traits that can be further explored in depth; however, uncritical application may lead to numerous erroneous generalizations. This is especially true when comparisons are made between organisms with different complexities of biological organization and where specialized functional adaptations have evolved.

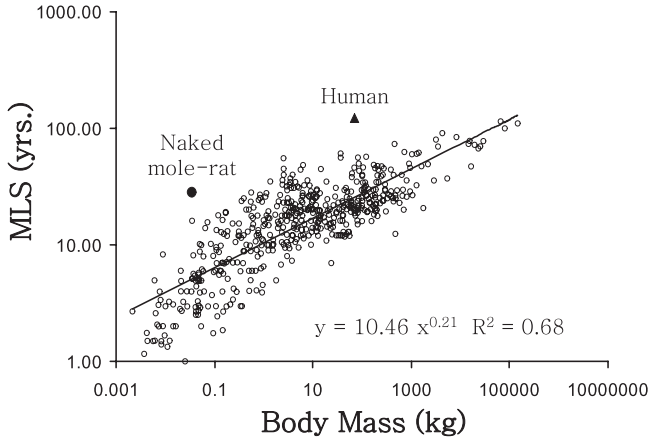

Figure 52–3. The allometric relationship between body size and maximum life span (MLS) for 500 nonvolant mammals. Data from the various orders generally fall close to the descriptor (MLS = $M^{0.21}$); notable exceptions are humans (triangles) and naked mole-rats (circles).

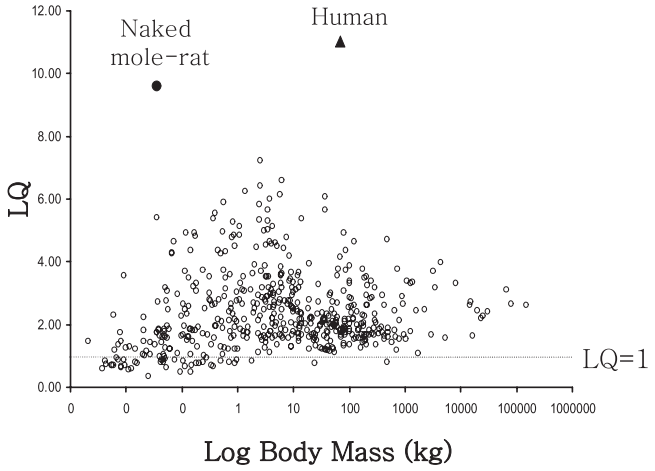

Figure 52–4. The longevity quotient (LQ; the ratio of observed maximum life span to that predicted by body mass using the equation of Prothero and Jurgens[66]; $y = 5.3 \times \text{mass}^{0.174}$). Both naked mole-rats and humans have exceptionally high LQs.

Two problems routinely plague comparative studies: first, the covariation of a specific trait with body mass is frequently ignored when interpreting findings, and second, phylogenetic relatedness between species may affect the statistical independence of data suites. Indeed, it is an axiom of comparative biology that species with a close evolutionary relationship share more traits than more distantly related species and comparative studies ignoring phylogeny may lead to spurious conclusions. Speakman[64] highlighted this problem in a hypothetical study outlined below (Figure 52–5) comparing a trait that appears to be well correlated with both maximum life span and body mass in nine species. Although data appear well correlated and even residual analyses show significant relationships, careful scrutiny reveals that data from species within the same order cluster together. In effect this hypothetical study pseudoreplicates data, such that although nine species were examined, in actuality it is only three orders with mutation events that clearly are not shared between orders. This problem of overestimating the number of degrees of freedom has long been recognized in comparative biology, and is overcome with sophisticated statistical methods (phylogenetically independent contrasts). There are, however, several situations in which it is more appropriate to use nonphylogenetic analyses such as when traits imply ancestral and nonevolved conditions.[67] While modern biological research occurs in an implicitly evolutionary context, it nevertheless is still possible to conduct comparative studies without taking the phylogeny into account, provided the aims of the question and the extrapolations thereof are carefully constrained. When traits are shared across taxa and classes, and these appear to be modified in tandem by some experimental intervention, with greater confidence it can be concluded that this is an important and conserved pathway, such as is evidenced with DR and reduced insulin/IGF-1 signaling in worms, flies, and mice.

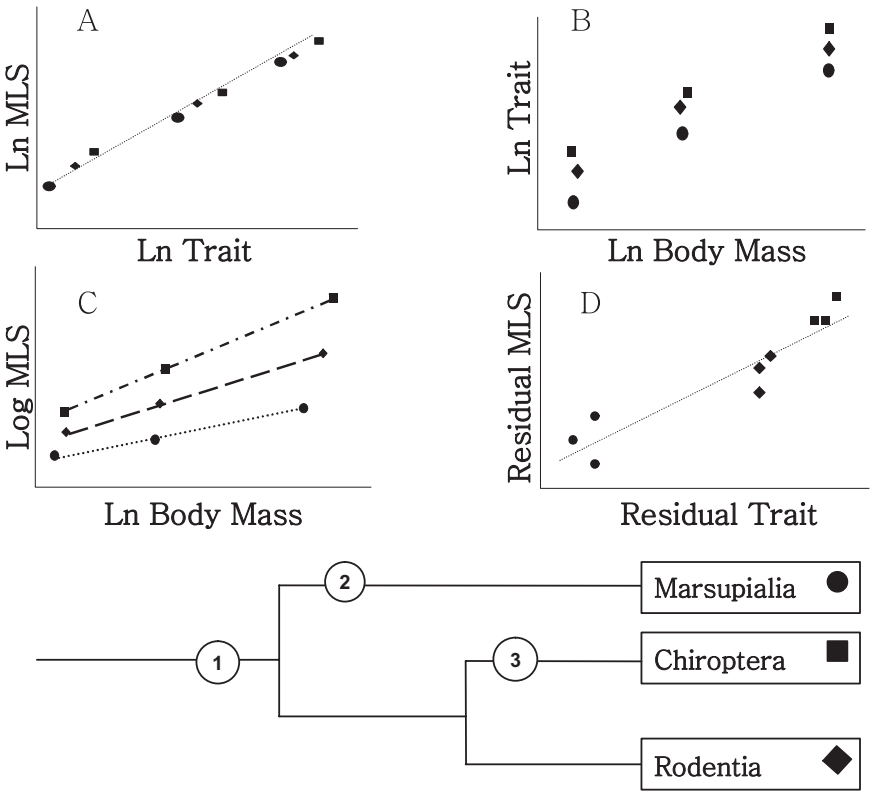

Figure 52–5. Hypothetical relationship based on nine species [three bats (squares), three rodents (diamonds), and three marsupials (circles)], modified from Speakman.[64] (A) The relationship between log MLS and log mass; (B) the relationship of a trait thought to be involved in aging as a function of body mass; (C) the relationship between log MLS and that trait, such that these raw data show a significant relationship between the trait and MLS. (D) The residual variation of the trait in (B) plotted against the residual MLS. This figure reveals a significant relationship between the trait and MLS; however, close scrutiny reveals that data are clustered by phylogeny. (E) The hypothetical phylogenetic tree of the nine species. Mutations (1, 2, and 3) affect all species downstream from that point; clearly sampling points downstream of the mutation points do not give phylogenetically independent samples and may lead to spurious conclusions.

WHICH ANIMALS TO STUDY? Organisms that live at least twice as long as expected from allometry (Figure 52–4), such as bats and mole-rats, as well as birds, fish, and social insects, are good candidates for discerning mechanisms employed in slow aging.[9] Less can be gleaned from animals with longevity quotients (the ratio of reported MLS to that predicted by mass) less than one, for it is extremely difficult to discriminate the effects due to accelerated aging from altered susceptibility to disease and inadequate husbandry of captive exotic species.

The evolutionary theory of aging posits that aging results from the declining power of natural selection to favor advantageous alleles, or eliminate deleterious ones at successive ages after sexual maturity.[43] Thus, animals that experience high extrinsic mortality due to living in challenging environments (e.g., climatic conditions and/or high predation risk) will evolve life history traits that facilitate early reproduction, often at the expense of somatic maintenance, and will have short life spans, and vice versa.[43] It can be predicted that animals that can avoid predation, such as volant species (e.g., birds and bats), or those living in protected areas (e.g., subterranean mole-rats, social insects) will have low extrinsic mortality and evolve mechanisms facilitating extended longevity. Captive animals provide an opportunity to observe intrinsic mortality away from confounding problems associated with extrinsic mortality. Studies based upon comparative differences among species with rapid and retarded rates of aging may elucidate mechanistic differences.

INTERESTING EXCEPTIONS TO FAVORED HYPOTHESES IN NONTRADITIONAL MODELS FOR AGING RESEARCH The disposable soma theory posits that aging is ultimately due to the tradeoff between partitioning energy into somatic maintenance and reproduction.[68] In favor of reproduction, somatic maintenance is compromised and random molecular damage is inadequately repaired and accrues, leading to a concomitant decline in organismic function. Surprisingly, both the eusocial insects[69] and rodents[12] do not support this theory. In both insect and naked mole-rat colonies, the breeding animals live at least as long, if not considerably longer, than their nonbreeding relatives.[12,69] Similarly, many fish, amphibians, and reptiles fail to show signs of aging and maintain reproductive potential throughout their long lives.[70,71]

The free radical theory asserts that oxidative damage results from an imbalance between endogenous ROS and their neutralization by antioxidants, as well as removal of any incurred damage by organismal repair systems.[72] Some comparative studies have shown that both the generation of oxidative damage[73] and accrual are negatively correlated with species longevity.[74,75] However, naked mole-rat data show similar rates of ROS generation and paradoxically higher levels of accrued oxidative damage even at a young age than shorter-living rodents.[76] Another exception is that in eusocial insects antioxidant defenses are not superior in "queens," compared to "workers," and oxidative damage may accrue at similar rates.[77,78] Honeybee queens produce greater amounts of vitellogenin, a yolk precursor protein that reportedly has strong antioxidative properties,[79] and this may be linked to queen longevity.[80] Finally, Hamilton and collaborators[81] have reported higher oxidative damage in long-living birds than in shorter-living rodents. Consequently, while the oxidative stress theory may play an important role in homeostatic imbalance with aging, there are likely other factors that modulate both it and rates of aging.

CONCLUSIONS

The use of animal models in aging research has advanced the field considerably and continues to hold great promise for further advancing our knowledge of the aging process, as well as finding mechanisms to retard aging. However, much more work is needed to identify novel model organisms for aging research that may provide new insights into successful aging and compare the ubiquity of findings thereof with traditional models. There is a critical need for appropriate use of the comparative method and the development of better cross-species databases that make it possible to test the ubiquity of theories, mechanisms, and their potential translation for human application.

53 Gene Targeting in Human Somatic Cells

ERIC A. HENDRICKSON

ABSTRACT

Somatic gene targeting in human cells has two general applications of importance and wide interest. One is the inactivation of genes ("knockouts"), a process utilized to delineate the loss-of-function phenotype(s) of a particular gene. The second application is the process of gene therapy, which involves correcting a preexisting mutated allele(s) of a gene back to wild-type in order to ameliorate some pathological phenotype associated with the mutation. Both of these processes require a form of DNA double-strand break repair known as homologous recombination. Although bacteria and lower eukaryotes utilize homologous recombination almost exclusively, a competing process, known as nonhomologous end joining, predominates in higher eukaryotes and was presumed to prevent the use of gene targeting in human somatic cells in culture. A series of molecular and technical advances developed in the 1990s disproved this notion, but still resulted in a process that was cumbersome, labor intensive, highly inefficient, and slow. Within the past 5 years, the use of new gene delivery vectors such as recombinant adeno-associated virus and the identification of cell lines such as Nalm-6 that appear to undergo high rates of gene targeting have significantly brightened the outlook for this field and resulted in a gene delivery system that facilitates both gene knockouts and gene therapy modifications at robust levels. Thus, gene targeting in human somatic cells in culture has become not only feasible, but also relatively facile, and it harbingers a golden age for directed mutagenesis.

Key Words: Gene targeting, Gene knockouts, Gene therapy, DNA double-strand breaks, Nonhomologous end joining, Homologous recombination, Recombinant adeno-associated virus, HCT116 cells, NALM-6 cells.

INTRODUCTION

Somatic gene targeting is the intentional modification of a genetic locus in a living cell.[1,2] This technology has two general applications of importance and wide interest. One is the inactivation of genes ("knockouts"), a process in which the two wild-type alleles of a gene are mutated in order to delineate the loss-of-function phenotype(s) of that particular gene.[3] The second application is the clinically more relevant process of gene therapy, which, in its strictest sense, involves correcting a preexisting mutated allele(s) of a gene back to wild-type in order to ameliorate some pathological phenotype associated with the mutation.[4] Importantly, although these applications are—at the DNA level—reciprocal opposites of one another, they are mechanistically identical and utilize the same four basic steps: (1) a search for homologous sequences between the incoming donor DNA and the chromosomal DNA, (2) breakage [usually in the form of double-stranded breaks (DSBs)] of the DNA at the site of targeting, (3) exchange of DNA/genetic information between the donor DNA and the chromosomal DNA, and (4) ligation of the broken chromosome to restore its structural integrity. Together, these four steps define a process referred to as homologous recombination (HR), which is absolutely required for gene targeting to occur.[5,6] Although HR was known to predominate in bacteria and lower eukaryotes, the competing process of nonhomologous end joining (NHEJ), in which the incoming donor DNA is randomly integrated within the genome, predominates in higher eukaryotes and was presumed to prevent the use of gene targeting in human somatic cells in culture.[7] A series of molecular and technical advances disproved this notion, but still resulted in a process that was cumbersome, labor intensive, highly inefficient, and slow.[8] Within the past 5 years, the use of new gene delivery vectors such as recombinant adeno-associated virus (rAAV)[9] and the identification of cell lines such as Nalm-6 that appear to undergo high rates of gene targeting[10] have significantly brightened the outlook for this field and resulted in a gene delivery system that facilitates both gene knockouts and gene therapy modifications at robust levels. Thus, gene targeting in human somatic cells in culture has become not only feasible, but relatively facile, and it harbingers a golden age for directed evolution.

BACKGROUND

NONHOMOLOGOUS END JOINING

A double-stranded piece of linear DNA introduced into a cell can be incorporated into that cell's genome by either HR or NHEJ.[11] Bacteria and lower eukaryotes almost exclusively utilize HR for the uptake of foreign DNA. In higher eukaryotes, however, integration proceeds more frequently by a process that does not require extended regions of homology. Specifically, mammalian cells—and humans in particular—have evolved a highly efficient ability to join nonhomologous DNA molecules together.[7,12,13] In their seminal work on gene targeting, Capecchi and co-workers showed that although somatic mammalian cells can integrate a linear duplex DNA into corresponding homologous chromosomal sequences using HR,

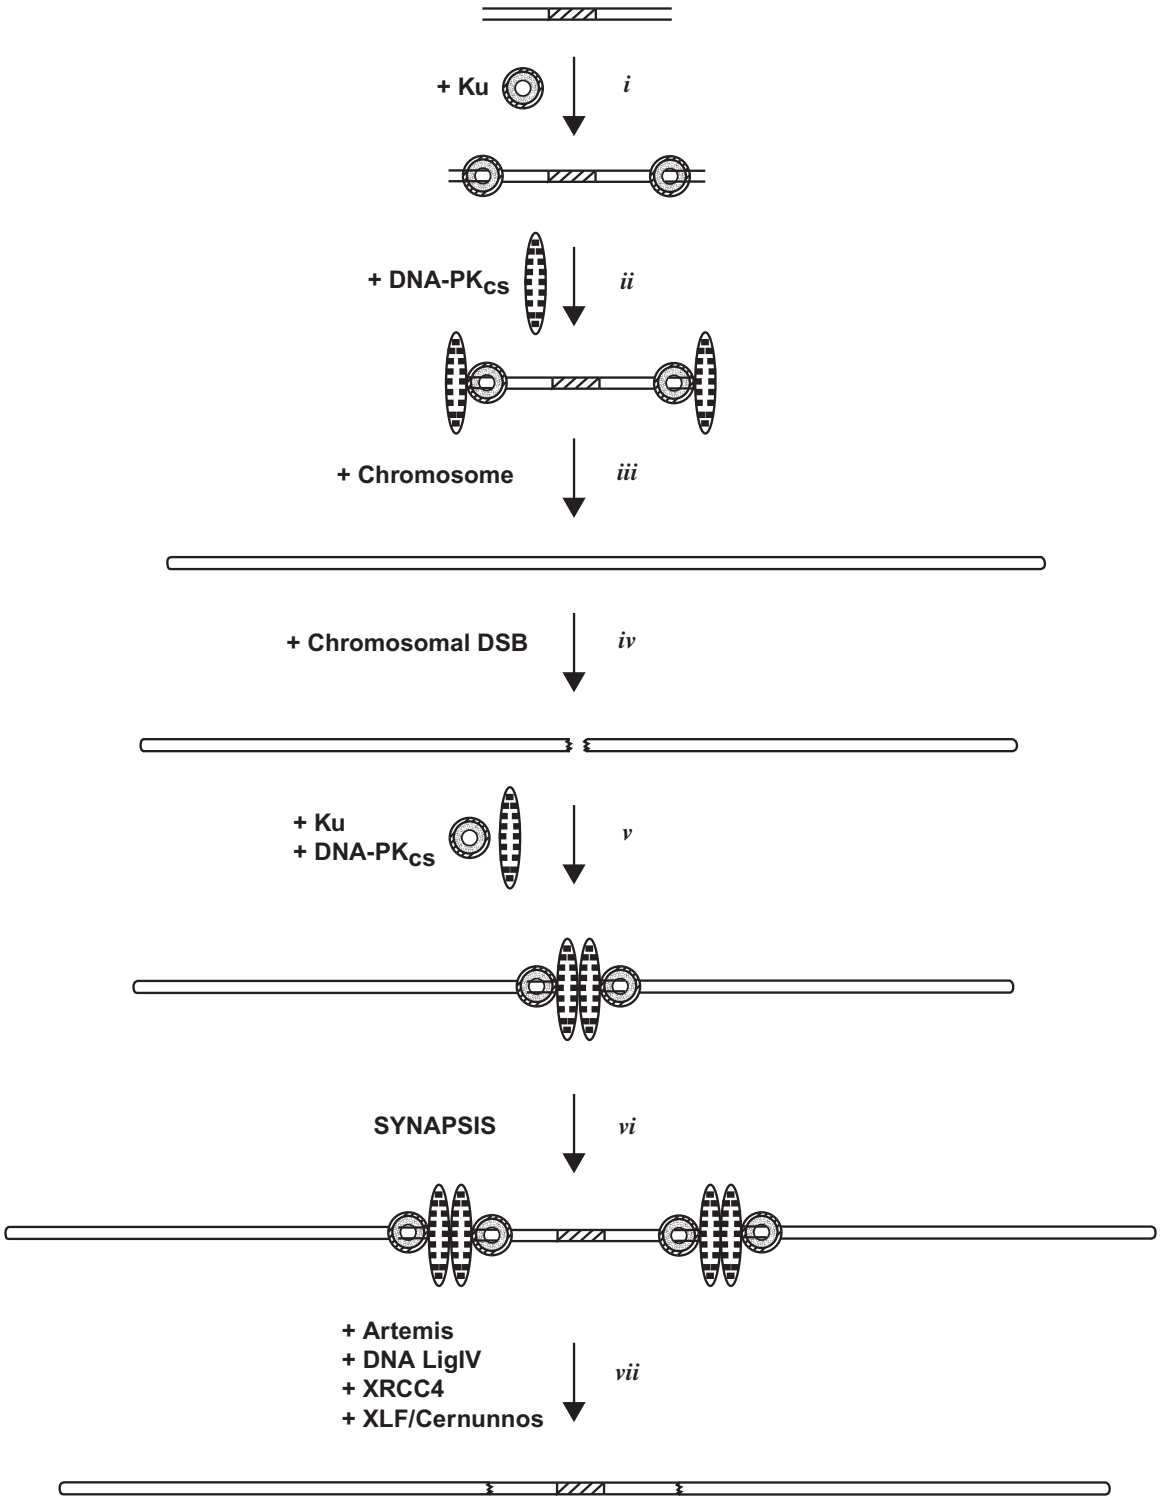

Figure 53–1. A hypothetical pathway for the role of NHEJ factors in random integration. The double line represents a transfected donor dsDNA that has homology to some location within the recipient cell's genome and the hatched box represents a positive drug selection marker. (*i*) The Ku heterodimer (stippled circle) binds onto the ends of the donor DNA. (*ii*) Ku recruits DNA-PK_{cs} (hatched oval) to the ends of the donor DNA. (*iii*) The donor DNA, complexed with DNA-PK, now interacts with a cellular chromosome (long double line with hairpinned ends). (*iv*) By an unknown process, a DSB is introduced into the chromosome (jagged slash). (*v*) DNA-PK complex components then assemble on the ends of the chromosomal DNA. (*vi*) The donor DNA, complexed with DNA-PK, synapses with the chromosomal DNA, also complexed with DNA-PK, in a process that probably involves DNA-PK_{cs} : DNA-PK_{cs} homotypic interactions. (*vii*) DNA-PK activates the downstream effectors Artemis, DNA LIGIV, XRCC4, and XLF/Cernunnos, which act in concert to repair the chromosomal DSB (jagged slashes), resulting in the random introduction of the donor DNA into the chromosome.

the frequency with which recombination into nonhomologous sequences occurred was at least 1000-fold greater.[14] This NHEJ pathway appears to be predominantly active during the G_1/early S phase of the cell cycle.[15,16] Given that NHEJ DSB repair is generally error prone, an attribute that bacteria and lower eukaryotes can ill afford, the increased percentage of noncoding DNA in higher eukaryotes may have facilitated the evolution of this pathway.

While the many details of NHEJ remain to be worked out, a reasonable model is that following the introduction of a linear double-stranded DNA (dsDNA) into a cell, the Ku86 : Ku70 heterodimer[17] binds to the broken DNA ends to prevent unnecessary DNA degradation[18–20] (Figure 53–1, *i)*. The binding of Ku to the free DNA ends recruits and activates the DNA-dependent protein kinase complex catalytic subunit[21,22] (DNA-PK_{cs}) (Figure 53–1, *ii*). This DNA is then brought into contact with a chromosome into which a DSB is introduced (Figure 53–1, *iii* and *iv*). This step(s) is poorly understood. The chromosomal DSB ends are almost certainly also occupied by Ku and DNA-PK_{cs} (Figure 53–1, *v*) and this probably facilitates the formation of a synaptic complex with the donor DNA (Figure 53–1, *vi*). DNA-PK_{cs} : DNA-PK_{cs} homotypic interactions are the critical feature required for synapsis.[23–25] Once DNA-PK_{cs} is properly assembled at the broken ends it, in turn, recruits and activates a nuclease, Artemis[26–28] (Figure 53–1, *vii*), to help trim the damaged DNA ends. The rejoining of the DNA DSB (Figure 53–1, *vii*) requires the recruitment[29] of DNA ligase IV[30,31] (DNA LigIV) and its two accessory factors: X-ray cross-complementing group 4[32,33] (XRCC4) and XRCC4-like factor (XLF)/Cernunnos.[34,35] In summary, mammals are different from bacteria and lower eukaryotes in that DSB repair proceeds primarily through an NHEJ recombinational pathway. Moreover, NHEJ must be overcome in order to facilitate gene targeting and this can occur when the incoming DNA is shunted into the HR pathway.

HOMOLOGOUS RECOMBINATION In HR,[6] the DNA ends of the incoming DNA are likely resected to yield 3′-single-stranded DNA overhangs (Figure 53–2, *i*). Despite intense inves-

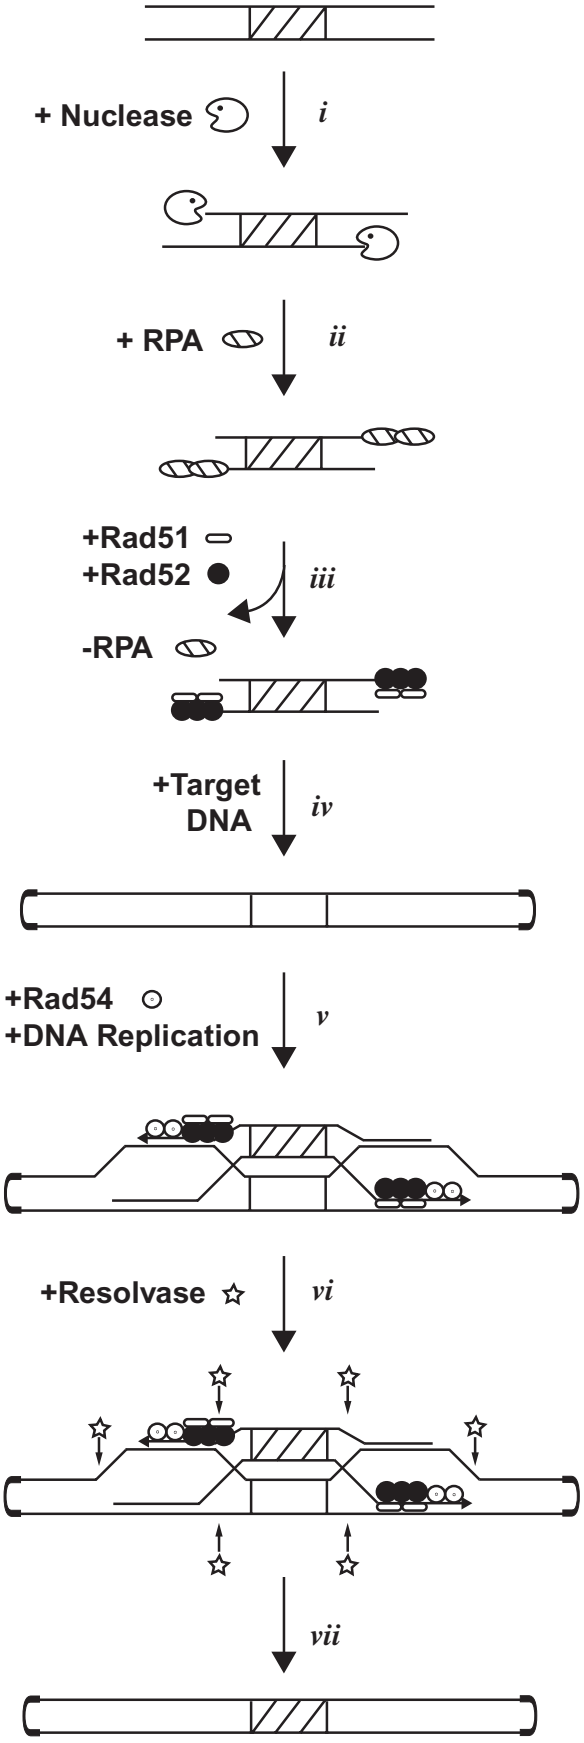

Figure 53–2. A hypothetical pathway for the role of HR factors in gene targeting. The double line represents a transfected donor dsDNA that has homology to some location within the recipient cell's genome and the hatched box represents a positive drug selection marker or a section of DNA containing the researcher's desired modification. (*i*) An unknown nuclease (PacMan™) resects the ends of the donor DNA. (*ii*) RPA (hatched oval circle) then coats the ssDNA ends. (*iii*) Rad51 (empty ellipse) and Rad52 (filled circle) then bind onto the ssDNA ends, displacing RPA in the process. (*iv*) The donor DNA complexed with Rad51 and Rad52 then associates with a chromosome (long double line with hairpinned ends) containing homologous sequences (open box). (*v*) With the assistance of Rad54 (open circle with dot) and DNA replication, the resected ends invade the donor DNA and set up a double Holliday junction. *Note:* The donor DNA shown in (*v*) is rotated with respect to the donor DNA shown in (*iv*) simply for the sake of presentation. (*vi*) The repeated action of a resolvase (star) is then required to complete the recombination process. (*vii*) At the end, the donor DNA has been precisely integrated into a homologous region on an endogenous chromosome. In all panels, the vertical arrows are drawn implying a temporal order to each process, although in many cases the precise sequence of events is not known. In all panels, the italicized Roman numerals refer to steps in each pathway that are described in the text.

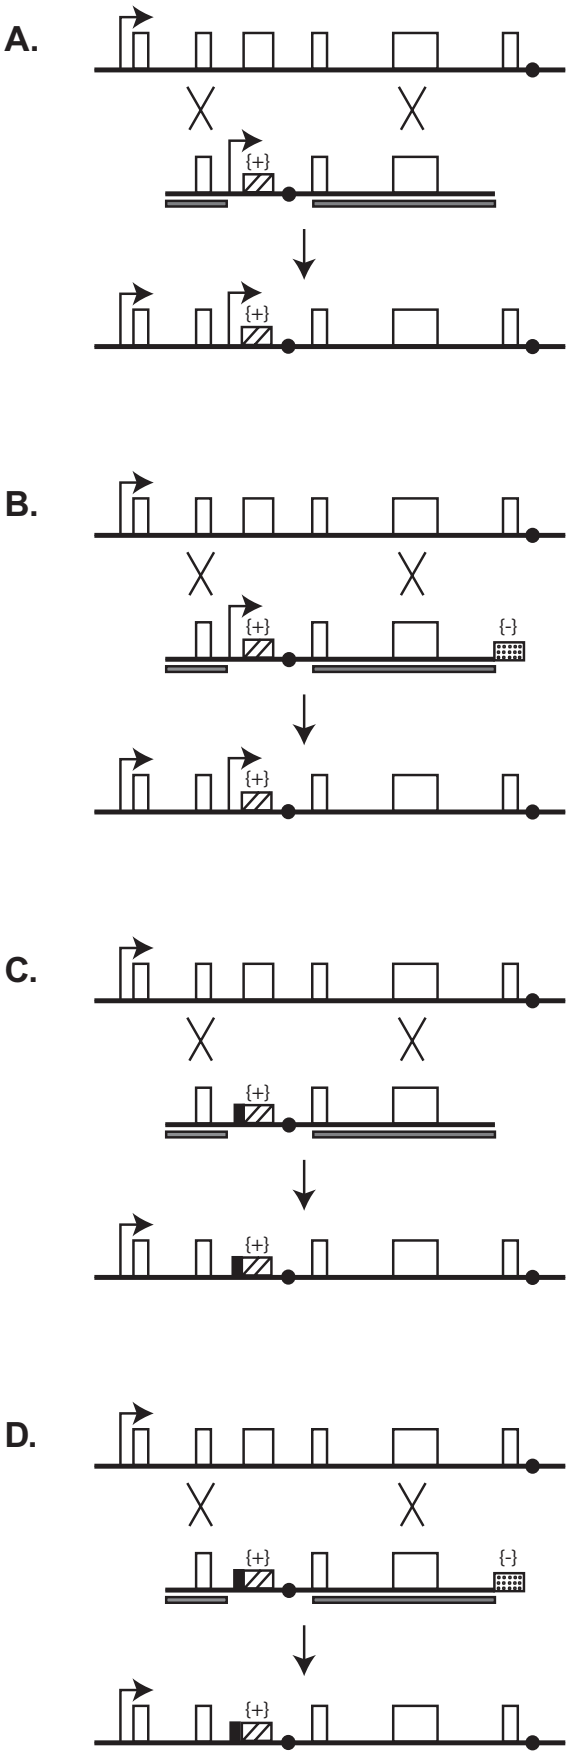
tigation, the identity of this nuclease(s) is still undetermined, although the MRN complex [Mre11/Rad50/Nbs1[36] and ExoI (exonuclease I)] has been repeatedly implicated as the likely culprit(s).[37] The resulting overhangs are then coated by replication protein A (RPA), a heterotrimeric single-stranded DNA-binding protein, which removes the secondary structures from the overhangs.[38] RPA subsequently helps to recruit radiation-sensitive 51 (Rad51) and radiation-sensitive 52 (Rad52) to the overhangs, although it is itself displaced in the process (Figure 53–2, *iii*). Rad51 is the key strand-exchange protein in homologous recombination.[39] It is essential for the homology searches on the target DNA, i.e., the entire human genome (Figure 53–2, *iv*), that are required to localize the incoming DNA to its specific, cognate chromosomal counterpart.[40] In humans, there are at least seven Rad51 family members and almost all of them have been implicated in some aspect of HR and also in human disease.[41] Rad52 is an essential accessory factor for Rad51 and it facilitates strand exchange, probably by overcoming the inhibitory role of RPA.[42] Strand invasion into the homologous chromosomal sequence requires radiation-sensitive 54 (Rad54) and DNA replication (Figure 53–2, *v*). Rad54 is a double-stranded DNA-dependent ATPase that can remodel chromatin, and it probably plays critical roles at several steps in the recombination process.[43] In particular, Rad54 is critical for stabilizing the Rad51-dependent joint molecule formation (Figure 53–2, *v*) as well as for promoting the disassembly of Rad51 following exchange.[44] Gene targeting generates a complex structure (Figure 53–2, *v*) that is essentially identical to the linearized plasmid "ends-out" recombination intermediates that have been extensively defined in yeast.[45] Ultimately, the resolution of this structure probably requires the participation of helicases of the recombination defective Q (RecQ) family[46] and certainly requires the action of a resolvase(s) to repeatedly nick the strands (Figure 53–2, *vi*). Although the identity of the human resolvase(s) is still debated, radiation-sensitive 51C (Rad51C) and X-ray cross-complementing 3 (XRCC3) have emerged as the most likely candidates.[47,48] The resolution of the cross-stranded intermediates with crossovers generates a modified chromosome in which the original chromosomal sequences have been precisely replaced by the sequences present on the incoming donor DNA (Figure 53–2, *vii*). In summary, human somatic cells express all of the gene products needed to carry out gene targeting. These events occur, however, at very low frequency due to the preferred usage of NHEJ.

METHODOLOGY

SELECTIONS AND VECTORS Since correct gene targeting is a rare event, strategies needed to be developed in order to detect them. Almost all of these rely on some form of selection.[1,2] Some of the earliest studies utilized naturally occurring loci and selections. Thus, the hypoxanthine phosphoribosyltransferase (HPRT) gene has been a popular choice for study since mutation of this gene can be negatively selected for by the acquisition of resistance to 6-thioguanine (6-TG), a nucleoside analogue that HPRT would otherwise metabolically activate to a toxic compound. Moreover, HPRT is an X-linked gene and male-derived hemizygous cell lines require only one round of targeting to generate the null (6-TG resistance) phenotype.[49–56] However, since most genes of interest do not provide such natural and accommodating selection strategies, the use of positive selection schemes was required. Some esoteric and specialized positive selections have been described, such as relying upon the gain of a cell surface epitope expression and fluorescence-activated cell sorting (FACS) analysis to obtain the correctly targeted cell line.[57] This and similar strategies,[58] however, were not widely applicable and thus they did not come into general use. Instead, the expression of antibiotic resistance genes that can be positively selected for have gained wide usage. One of the first—and by far still most popular and useful—marker selections is the neomycin resistance (NEO) gene. NEO encodes an enzyme that in bacteria confers resistance to the neomycin family of antibiotics, which kill by inhibiting protein translation. In mammals, the expression of NEO provides resistance to a similar compound called gentamycin 418 (G418). Thus, the inclusion of NEO on the donor DNA can be used to select for those cells that have stably taken up the DNA based upon their conversion to G418 resistance (Figure 53–3A). Similarly, other antibiotic resistance genes have been pirated for use in human gene targeting, including hygromycin (HYG), puromycin (PUR), histidinol (HIS), and blasticidin (BSD). Since two rounds of gene targeting are necessary to disrupt a diploid locus, investigators generally incorporate two of these markers into otherwise identical gene-targeting vectors to permit sequential selection for the modification of both alleles.[59–62]

Even with strong positive selection schemes, the majority of clones resulting from such an experiment are randomly targeted. This results in a time-consuming and laborious second step in which all of the drug-resistant colonies must be screened at the molecular level [usually either by polymerase chain reaction (PCR) or by Southern blotting analysis] in order to identify the rare correctly targeted clone. To enrich for the desired recombination reactions, gene targeting methodology was subsequently improved by the use of positive : negative selection (PNS) vectors.[1,2] These vectors provided the same positive selection schemes that the earlier vectors possessed, but they also incorporated a negative selection against nonhomologous integrations. This method consists of attaching a genetic element that can be selected against onto the 5′- and/or 3′-flank of the targeting vector. If this vector is randomly integrated into the host cell using NHEJ then the negative marker will be retained and this can be used to eliminate these cells from the analysis by a simple drug selection. If the vector integrates via HR, then the negative marker, being nonhomologous to the targeted locus, will be lost during the integration event (Figure 53–3B). The most commonly used negative marker is herpes simplex virus thymidine kinase (HSV TK). Although TK genes are widely conserved and ubiquitously expressed among all species, the viral TK genes have a slightly altered substrate specificity and this difference has been experimental exploited. Thus, the antiviral drug gangcyclovir (GANC) can be metabolized to a toxic analogue by the viral TK, but not by the cellular enzyme. Therefore, cells containing the viral TK gene (at randomly targeted sites) will be killed by GANC exposure, whereas cells expressing only the cellular TK gene (homologously targeted clones) will survive.[63,64] While HSV TK is still widely in use and appears to be adequate for most gene-targeting strategies, even stronger negative selections, such as using the diphtheria toxin (DT) gene, can significantly enhance the targeting frequency.[64]

Even with these improvements, the isolation of correctly targeted clones was a daunting affair and generally was accom-



plished only by the most obstinate of researchers. A huge improvement (by one to two orders of magnitude) came with the development of promoterless selection. These vectors are almost identical to the original positive selection with the important exception that the promoter driving the expression of the selectable marker has been deleted.[1,2] As a consequence of this, the selectable marker can be expressed only if it correctly integrates and/or if it is inserted randomly next to or within an actively transcribing gene. Since this requirement is not often met, the total number of drug-resistant clones obtained is significantly reduced and therefore so is the work required to characterize them. To facilitate the expression of the selectable marker, a slice acceptor sequence is often inserted 5′ of the marker gene (Figure 53–3C). This allows the selectable marker, if it is in frame, to be expressed as a fusion protein with the preceding endogenous exons (Figure 53–3C). Alternatively, an internal ribosome entry site (IRES) can be included 5′ to the splice acceptor to facilitate independent expression of the selectable marker. This is an important consideration, especially when exons at the 3'-end of a locus are being targeted.[65] Lastly, empirical observation suggests that it is probably most efficacious to combine the positive promoterless selection strategy with a negative selection (Figure 53–3D).[64,66] This is especially true for hard-to-transfect cells, such as human embryonic stem cell lines.[54]

SITE-SPECIFIC CRE : LOXP RECOMBINATION Although the promoterless vectors utilizing antibiotic drug resistance selections described above represent the current state of the art, they are still somewhat limited in their utility. For example, bold targeting schemes in which multiple loci are to be knocked out or modified would not be possible since the investigator would ultimately run out of selectable markers. In addition, essential genes cannot be directly knocked out since successful targeting would result in dead cells. These technical and biological difficulties, respectively, have been overcome through the use of the site-specific recombination system, cyclization recombination : locus of crossing over (x), P1 (Cre : LoxP).[67,68] Cre is a member of the integrase family of recombinases and it is required in its native state for a productive infection by the bacteriophage, P1.[69] Cre binds and recombines LoxP target sites, which are 34 bp long, that contain an asymmetric 8-bp core flanked by 13-bp inverted repeats. When the LoxP sites are artificially arranged in direct orientation on a chromosome, the ensuing Cre-mediated recombination results in two products: the chromosome with a single

Figure 53–3. Different selection strategies utilized during classical gene targeting. (A) Positive selection; (B) positive/negative selection; (C) promoterless positive selection; (D) promoterless positive/negative selection. The solid line represents chromosomal DNA. The open rectangles represent exons. The 90º bent arrow represents a promoter. The small, solid circle represents a polyadenylation sequence. The large Xs represent crossover recombination reactions. The hatched rectangle with a {+} over it represents a marker for which a positive selection exists. The shaded bars represent regions of homology between the donor DNA and the recipient chromosome. The stippled rectangle with a {−} over it represents a marker for which a negative selection exists. The solid rectangle represents a splice acceptor sequence. In all panels, the vertical arrows are drawn implying a temporal order to each process, although in many cases the precise sequence of events is not known.

residual LoxP site and a circle containing the other LoxP site plus all the genomic DNA that used to lie in between the two loxP sites (Figure 53–4A). This basic recombination reaction can be used to the researcher's advantage to remove the selection marker from an integrated knockout allele. Thus, if loxP sites are built onto the targeting vector within the flanking regions of both sides of the positive selection marker, the marker is said to be "flox"ed (flanking loxP sites). After the marker is used (positive selection) to identify the correct homologous recombination event, it can be removed by the expression of Cre (Figure 53–4B). Even after

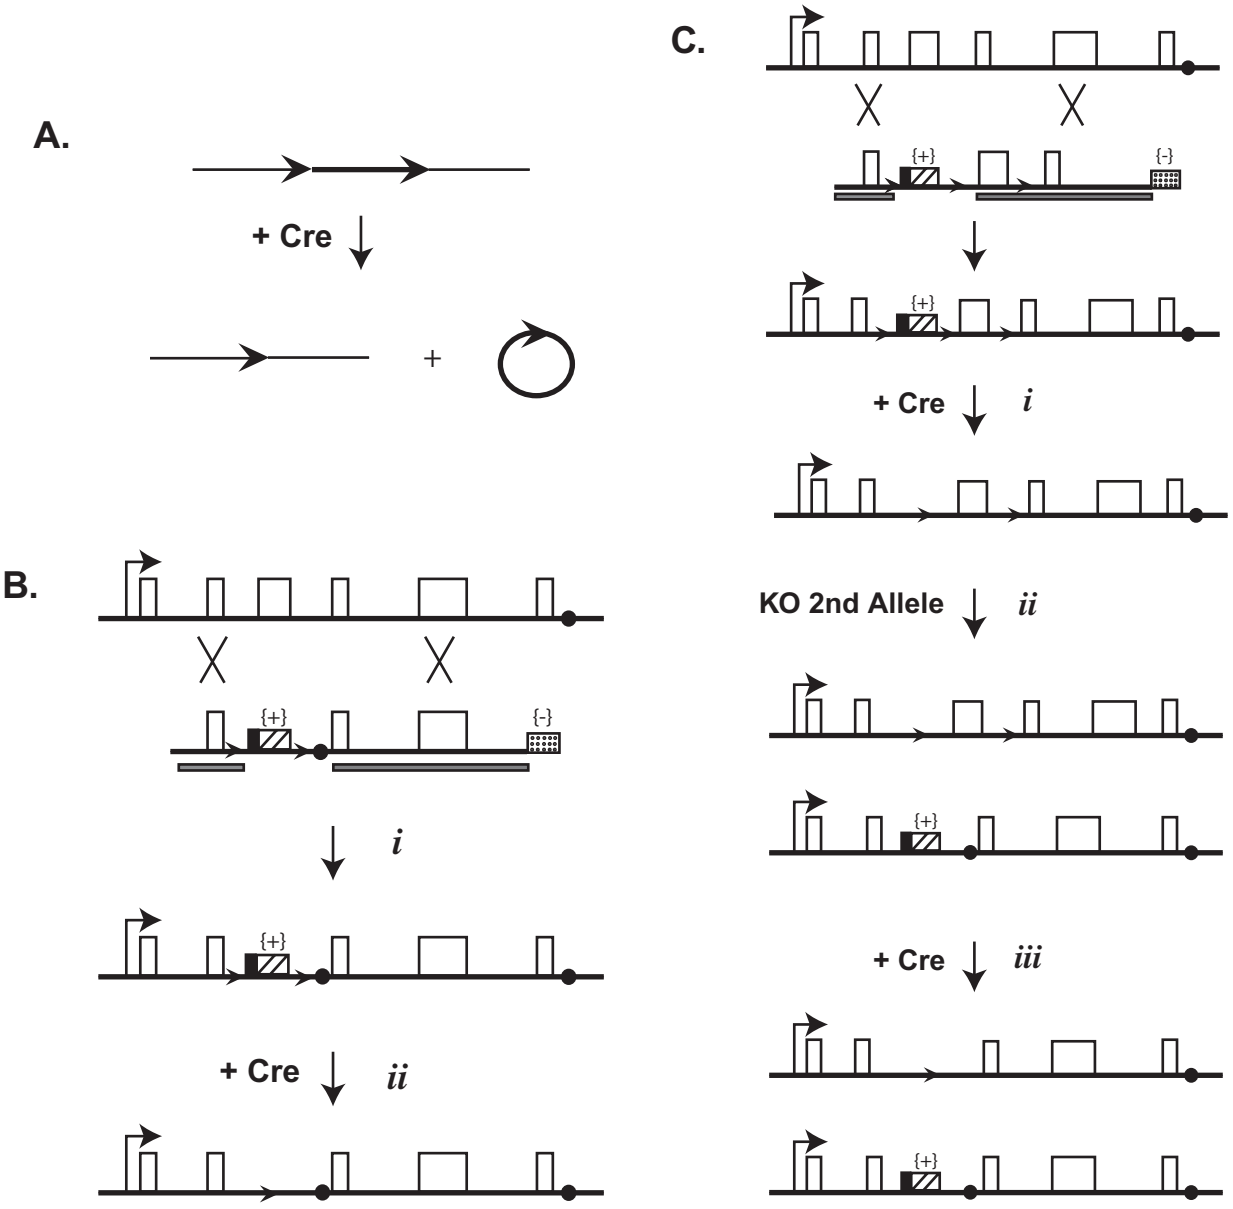


Figure 53–4. The basic Cre recombination reaction and its utility in gene targeting. (A) Cre deletional recombination. The line represents chromosomal DNA and the triangles represent loxP sites. Upon the addition of the Cre recombinase (+ Cre), recombination ensues resulting in a deleted chromosome containing a single loxP sequence and a circle, containing a single loxP sequence and all of the DNA (darker line) that used to exist between the two loxP sequences. (B) Selection marker removal. All symbols, with the exception of the triangles, which represent loxP sites, are as described in the legend to Figure 53–3. (*i*) A promoterless positive/negative gene-targeting event, in which the positive selection marker has been floxed, is shown. The cell harboring this construct is resistant to the drug specified by the marker. (*ii*) The addition of Cre (+ Cre) results in the deletional excision of the selectable marker. The cell harboring this construct is now sensitive to the drug specified by the marker. Note, however, that the allele is nonetheless still nonfunctional as an exon is missing and a polyadenylation sequence has been introduced into the locus. (C) Construction of a conditionally null allele. As in (B), a promoterless positive/negative selection-targeting event is shown. In this instance, the targeting vector contained three loxP sites, two flanking the positive selection marker and two flanking an exon to be deleted. The middle loxP site is shared by both pairs. (*i*) Upon the addition of Cre (+ Cre), deletional recombination between a pair of loxP sites can occur. Although three recombination events are possible, the indicated clone, in which the selection marker has been removed and the exon remains floxed, can be identified by molecular analysis. (*ii*) This cell line is subjected to a second round of gene targeting to create a heterozygous cell line in which the only functional allele is the floxed one. (*iii*) Upon a second exposure to Cre (+ Cre), deletion of the floxed exon occurs and results in a null cell line.

removal of the positive marker, the resulting allele is nonetheless inactive, since the exon(s) removed in the initial targeting event is still missing. Most importantly, however, the cell in which this event has occurred now becomes sensitive to G418. Thus, the original targeting vector and selection scheme can be reused to target the second allele. Using this approach, a positive selectable marker can be reused over and over again to permit a theoretically limitless number of gene targeting events within the same cell line.[64] Thus, in a fashion analogous to murine model systems, in which animal husbandry is utilized to construct strains of mice containing two or more knockout alleles,[70,71] human somatic cell lines can be constructed containing multiple gene disruptions.[10,52,61,62,72]

In a comparable and often utilized scheme, three loxP sites can be built into the targeting vector, such that both the positive selection marker and the exon that ultimately is to be deleted are floxed (Figure 53–4C). After the selection marker is used to identify the correctly targeted clone, the cells are transiently exposed to Cre. A screening step is then utilized to identify those cells in which the selectable marker, but not the exon, was excised by Cre.[63] The resulting cell line is again sensitive to the antibiotic utilized in the positive selection and contains a floxed exon (Figure 53–4C, *i*). These cells can then be subjected to a second round of gene targeting in which the remaining wild-type allele is inactivated in a direct knockout scheme (Figure 53–4C, *ii*), resulting in a "conditionally null" cell line. This cell line is hemizygous for and expresses the gene of interest from an allele that is floxed. Thus, at the researcher's discretion, Cre can be reintroduced into this cell line. This deletes the remaining functional allele and results in a cell line that is null for the gene of interest (Figure 53–4C, *iii*). In this manner, the mechanism of action of essential genes can be studied.[73]

In summary, the bacteriophage P1 Cre : LoxP recombination system has been conscripted by molecular biologists to provide experimental schemes for the reuse of selectable markers and as a means to study essential genes in human somatic cells. This system can also be used to introduce subtle, hypomorphic point mutations into genes[2] and to create complex chromosomal rearrangements[3] for the mouse, but the strategies are identical for human cells.

CELL LINES AND TARGETING FREQUENCIES The choice of cell line to use is of obvious importance when considering a gene targeting approach. Fortunately, a large number of researchers working in disparate fields have, due to the biological questions that interested them, attempted to functionally alter genes in a wide variety of cell lines. For the ease of discussion, these cell lines can be grouped into either (1) the HCT116 cell line, (2) the NALM-6 cell line, and (3) all other cell lines (non-HCT116, non-NALM-6 cell lines). Another important parameter to consider is the expected frequency of targeting. Here, the historical variability is great, ranging from multiple instances of total failure (0% efficiency[59,61,64,74,75]) to a recent report of achieving correct targeting in the only clone analyzed (100% efficiency[10]). These two issues, choice of cell line and targeting efficiency, are discussed in more depth below.

Non-HCT116, Non-NALM-6 Cell Lines The first published report of gene targeting in human cells occurred just over two decades ago. Smithies *et al.* attempted to disrupt the β-globin locus in the human EJ bladder carcinoma cell line.[74] No correctly targeted cell lines were obtained, but the same authors were subsequently able to successfully target the human β-globin locus in a human : mouse hybrid cell line (Table 53–1). Several years later, Jasin *et al.*[57] reported the first isogenic targeting of an endogenous locus (the CD4 gene) in a completely human (the T-lymphocyte JM) cell line.[57] Since that time, a total of 17 different genes (albeit some of them multiple times) have been disrupted, in what amounts to a rather pedestrian ~1 gene per year ratio (Table 53–1). The genes that have been disrupted represent rather diverse areas of biology and include transcription factors (p53), oncogenes (Ki-Ras), cell surface receptors (CD43), and checkpoint effectors (p21), in addition to genes with clear clinical relevance [e.g., Bloom's syndrome (BLM) and cystic fibrosis transmembrane receptor (CFTR)].

As importantly, these 17 genes were disrupted in 17 different cell lines (Table 53–1), reinforcing the belief that almost all human somatic cells adequately express the HR machinery required for this process. In theory, the most relevant cell line to use for gene targeting—such that it might be an appropriate model system for human health—would be a "normal," nonimmortalized, nontransformed cell line. This has, in fact, been accomplished, both for the inactivation of a single allele of the β_2-microglobulin[76] and p53[77] genes as well as for the technically impressive double knockout of the p21 gene.[78] Unfortunately, nonimmortalized cell lines usually have proliferative potential for only 30–40 population doublings before they undergo senescence. Since 30–40 population doublings are also required to successfully carry out two rounds of gene targeting, the resulting cell lines have limited research utility, unless the area of investigation is specifically senescence.[78] Consequently, most researchers have turned to immortalized (and often transformed) cell lines in a "damned if you do and damned if you don't" scenario, begrudgingly losing some clinical and/or general relevance for the sake of obtaining a cell line with which they can actually do experiments. The most popular cell line has been the HT1080 line, which has independently been used 11 different times (Table 53–1). This tumorigenic cell line was derived from a fibrosarcoma biopsy from a 35-year-old male[79] and it contains an activated Ras oncogene.[80] The popularity of this cell line probably has more to do with its practical attributes of a rapid doubling time, good cloning efficiency, and good transfectability than with its developmental origin. Other human cell lines, however, that are routinely found in the laboratory have also been used for gene-targeting study including fibroblastic, epithelial, adherent, and nonadherent lines representing many terminally differentiated states. Of special note was the successful use of human embryonic stem (ES) cells.[54] The ability to genetically modify genes in ES cells is an obligatory step for many gene therapy approaches.[4] While many of the moral and ethical issues of this subject still need to be resolved, this study clearly showed that technically, such experiments are possible.

Overall, 188 correctly targeted gene disruption events have been reported for the 8296 drug-resistant clones carefully examined (Table 53–1). This represents a relatively robust targeting frequency of 2.27%. At this frequency, the amount of work required to disrupt a gene is minimal and can easily be carried out even by a small, graduate student-driven laboratory. However, great variability in the targeting frequency clearly exists. Thus, reports of targeting frequencies of 30–50%[51,54] must be contrasted with reports in which the frequency was orders of magnitude lower.[81,82] Similarly, there is little consistency within a cell line,

[a]+: Number of correctly targeted clones identified.
[b]#: Total number of clones analyzed.
[c]Frequency: Number of correctly targeted clones (+) divided by the total number of clones (#) analyzed.
[d]Genotype: (+) designates wild type; (–) designates mutated; (–*) designates a preexisting mutated allele; (O) designates a hemizygous configuration.
[e]Miscellaneous: (+RAD51 o/e) designates that the experiment was performed in cells overexpressing hRAD51; (+oligos) designates a study done solely by oligonucleotide transfections without a targeting vector; (+CDC2 o/e) designates that the experiment was performed in cells overexpressing hCDC2; (±BLM RNAi) designates a study done in the presence and absence, respectively, of RNAi directed against hBLM1.

with targeting frequencies as high as 28%[51] and as low as 0.01%[53] having been reported for HT1080 cells. Parameters such as chromatin or accessibility differences, frequency of repetitive DNA within a given locus, variable expression of HR gene products between cell lines, use or nonuse of "isogenic" DNA,[8] choice of delivery for the vector, length of homology on the donor DNA, to mention just a few, have all been invoked to explain differences in targeting frequency. Unfortunately, it is not known how important any of these parameters really are. Thus, there currently does not exist an a priori method to determine whether a particular gene can be correctly targeted and, if so, at what frequency. A comprehensive investigation of why some genes "target better" than other genes would greatly benefit the field.

The HCT116 Cell Line In the early 1990s, Shirasawa *et al.* described successful gene targeting of the Ki-Ras gene in two human colon carcinoma cell lines, DLD-1 and HCT116.[83] The laboratories of Drs. Bert Vogelstein and Kenneth Kinzler, which already had an established record in the investigation of colon cancer and genetic instability,[84,85] apparently took this report to heart and initiated their own series of studies in which they disrupted genes thought to be involved in *DNA Repair*/chromosome stability in the HCT116 cell line.[59,77,86–89] The impressive success of these studies caught the attention of the *DNA Repair* community and many other laboratories have subsequently followed in their footsteps. Overall, 22 genes have been disrupted in this cell line in the intervening 13 years (Table 53–2). Some of these genes

[e]Miscellaneous: (In a BLM$^{-/-}$, p53$^{-/-}$, XRCC3$^{-/-}$, RAD54$^{+/+/+}$, RAD54$^{+/+/-}$, RAD54$^{+/-/-}$, RAD54$^{-/-/-}$, bkg) designates studies in which the gene targeting was done in the indicated respective backgrounds; (HSV TK selection) designates a study using herpes simplex virus thymidine kinase gene as the negative selection; (DT selection) designates a study using the diphtheria toxin gene as the negative selection; (Retargeting) designates events in which the targeting vector has integrated in the previously disrupted allele; (Promoter +) designates a study done with a vector using a selectable marker driven by a promoter; (Promoterless) designates a study done with a vector using a promoterless selectable marker.

are identical to those that have been disrupted in other cell lines (e.g., p21, p53, and HPRT; compare Table 53–1 with Table 53–2), but many of them are novel. In particular, the HCT116 studies are noteworthy because of the large number of times that two rounds of successful gene targeting have been carried out, allowing for an assessment of the null phenotype (Table 53–2). Moreover, HCT116 is the only cell line, with the recent exception of NALM-6 cells (see below), in which compound knockout strategies—in which two or more genes are disrupted to investigate their genetic interaction with one another— have succeeded.[52,61,62,72,90] Overall, 226 correctly targeted integrations have been reported for 85,119 drug-resistant clones analyzed (Table 53–2). This represents a rather pathetic targeting frequency of 0.27%, which is an order of magnitude lower than that reported for the non-HCT116, non-NALM-6 cell lines (Table 53–1). At this frequency, the work required to identify a correctly targeted clone becomes a significant issue and is thus usually undertaken only by laboratories with sufficient manpower. This frequency does, however, include a study in which the RAD54B gene was first disrupted in HCT116 cells and then (mostly unsuccessful) attempts were made to target the RAD51L2 and XRCC2 loci, thus validating the requirement for RAD54 in HR/gene targeting (Figure 53–2). Even if this large, negative study (two positive clones from 17,973 clones analyzed) and other studies in which the HCT116 genetic background was altered prior to use for gene targeting are omitted from analysis, the targeting frequency in a wild-type HCT116 background is still a paltry 0.39%. This frequency is low enough to daunt all but the most committed of researchers. Still, it should be noted that there is great variability in the targeting frequency in HCT116 between loci, with frequencies as high as 37% being reported for the p21 locus[59] and many instances of targeting frequencies ranging from 1 to 10% (Table 53–2). Again, unfortunately, there is no a priori way to know ahead of time how well a particular gene may or may not target.

In summary, for the past 5–10 years, the HCT116 cell line has been the gold standard for performing gene knockouts in human somatic cells. Although it is an immortalized, transformed colorectal carcinoma cell line, its utility stems from its relatively stable karyotype[91–93] and because it is diploid and wild-type for almost all of the relevant *DNA Repair*, DNA checkpoint, and chromosome stability genes[59,77,88] with the exception of meiotic recombination defective 11[94] (Mre11). Nonetheless, HCT116 is not a "normal" cell line. (1) It is mutated in the Mut L homolog 1 (MLH1) gene, which makes it a mismatch repair[95,96] as well as a transcription-coupled repair[97] defective cell line. As such, it has an overall microsatellite instability phenotype. In addition, genes that have homopolymeric tracts within them, such as Bax and Mre11, often spontaneously mutate one or both alleles.[94,98] (2) HCT116 cells have gains of parts of chromosomes 8q (accounting for the triploid nature of the RAD54B gene[61]), 10q, 16q, and 17q and also contain two derivative chromosomes carrying two translocations, der(16)t(8;16) and der(18)t(17;18).[91,92] (3) Finally,

[e]Miscellaneous: (±BLM RNAi) designates a study in which the gene targeting was carried out in the presence (+) and absence (–), respectively, of RNAi directed against the Bloom's syndrome helicase; (Rescue ± BLM RNAi) designates a study in which the correcting gene targeting a knockin experiment was carried out in the presence (+) and absence (–), respectively, of RNAi directed against the Bloom's syndrome helicase; (In a $BLM^{-/-}$ bkg and $LIGIV^{-/-}$ bkg) designates studies in which the gene targeting was done in the indicated respective genetic backgrounds.

HCT116 cells also contain a dominant gain-of-function mutation in the β-catenin gene, a potent transcription factor that drives c-myc expression.[99] As a word of caution, it should be noted that the aberrancies described above are the ones that are known and reported. It is quite likely that other genes are mutated or misexpressed relative to a normal, nonimmortalized, nontransformed cell in HCT116 cells and the impact of such differences on the phenotypes of a knockout of your favorite gene is hard to assess. In the same cautionary vein, recent reports of phenotypic differences between a knockout of the Ku86 gene in HCT116 cells[64,93] and NALM-6 cells[100] suggest that investigators need to take care in generalizing their results to other cell lines and other systems.

The NALM-6 Cell Line In 1998, Grawunder *et al.* described the successful targeting of both alleles of the DNA LIGIV gene in the human pre-B acute lymphoblastic leukemia (ALL) cell line, NALM-6.[60] A total of three correctly targeted clones were obtained from 144 analyzed for a relatively robust 2.08% targeting frequency. This cell line then lay (scientifically) dormant for the next 5 years until a report appeared in 2004 from the laboratory of Dr. Koyama describing the disruption of the BLM gene.[101] In the subsequent 2 years, the Koyama laboratory published a series of papers[10,56,66,100] describing the disruption of an additional eight genes in this cell line (Table 53–3). Impressively, 56 correct targeting events from a total of 1071 drug-resistant clones analyzed have been reported, for an overall frequency of 5.23% (Table 53–3). Thus, this cell line appears to carry out gene targeting at least twice as well as most other human cell lines (Table 53–1) and 20 times better than HCT116 cells (Table 53–2). If these frequencies can be reproduced in other laboratories, it is likely that the NALM-6 cell line will supplant HCT116 as a model system for human somatic cell knockouts.

It must be reiterated, however, that NALM-6, like HCT116, cells are not "normal." This line was established in culture some three decades ago from the peripheral blood of a 19-year-old man suffering from ALL.[102] Although the cell line is diploid, it carries at least one derivative chromosome containing a translocation [der t(5;12)(q33.2;p13.2)].[103] This translocation has fused the platelet-derived growth factor receptor-β (PDGFRB) gene (a tyrosine kinase involved in cell proliferation) to the translocation-ETS-leukemia (TEL) transcription factor gene,[104] resulting in a dominant gain-of-function chimeric kinase. Coincidentally, NALM-6, like HCT116, is also defective in mismatch repair. In the case of NALM-6 neither mutS homolog 2 (MSH2) nor mutS homolog 6 (MSH6) is expressed.[104] Thus, although it has not been directly demonstrated, it seems highly likely that NALM-6 cells will show microsatelite instability and high mutability of genes that have homopolymeric tracts within them. In addition, it can be anticipated that the more popular this cell line becomes, the greater is the likelihood that other genes that are mutated or misexpressed relative to a normal, nonimmortalized, nontransformed cell will be uncovered. Lastly, the same cautionary note concerning the recent reports of phenotypic differences between a knockout of the Ku86 gene in HCT116 cells[64,93] and NALM-6 cells[100] suggests that investigators utilizing NALM-6 cells—just like those utilizing HCT116 cells—need to take care in generalizing their results to other cell lines and other systems.

THE FUTURE OF GENE TARGETING: RECOMBINANT ADENO-ASSOCIATED VIRUS

Adeno-associated virus (AAV) is a human parvovirus that has both latent and lytic life cycles.[9,105,106] During the latent infection, AAV integrates stably into the human genome, preferentially, but

not exclusively, at a site on chromosome 19.[107,108] In an ironic twist, it was this characteristic of site-specific integration that first drew the attention of the gene therapy field to AAV, since the use of AAV as a gene delivery vector would not have the serious problem of random insertional mutagenesis attendant with almost every other viral vector delivery system. While this has turned out to be true[109] and clinical trials using rAAV are underway,[110] the use of AAV as a gene targeting vector has far outpaced its use as a gene therapy delivery vector. The ability to undergo a latent infection is a necessary part of the AAV life cycle since AAV requires the presence of a helper virus (generally adenovirus) for a productive lytic infection. Thus, AAV has been detected only in individuals undergoing the symptoms of an adenoviral[105,111] or herpes simplex virus[112] infection. Approximately 85% of the human population is seropositive for AAV, although there is no pathology or disease that has been attributed to an AAV infection.[106]

AAV is a single-stranded DNA virus of 4.68 kb. Either strand of the integrated AAV DNA can be packaged[113] and both are equally infectious.[114] Multiple serotypes of the virus are known, but only the AAV-2 serotype is routinely utilized in the laboratory. AAV encodes two genes, Rep (replication) and Cap (capsid). Rep is required for viral replication, needed for viral integration, and can potentiate viral gene expression.[106] Cap encodes the viral capsid proteins, of which three isoforms, VP1, VP2, and VP3, exist.[115,116] These genes are flanked by identical inverted terminal repeats (ITRs) of 145 bp that form T-shaped hairpins, due to three palindromic sequences residing within the ITRs.[117] The ITRs are essentially the only *cis*-acting sequences necessary for viral replication,[118] packaging, and integration.[119] This fact greatly facilitated the development of rAAV as a gene delivery and gene-targeting vector. Thus, if Rep and Cap are provided in *trans*, then the internal 4.39 kb of AAV can consist of recombinant DNA of the investigator's choosing.[120] Similarly, the adenoviral gene products E1A, E1B, E4, E2A, and VA are required for AAV replication.[106] Originally, these were provided by coinfecting with live adenovirus, which, of course, precluded the use of the resulting AAV stock for gene therapy experiments. This significant detriment was overcome once again simply by providing recombinant adenoviral functions in *trans*.[121] In summary, AAV has been known to the research community for some four decades and the life cycle of the virus is quite well understood. The virus was subsequently conscripted in the 1980s by investigators who were interested in viral vectors for use in gene therapy. Recombinant molecular biological methodologies were then used to develop an rAAV system for the production of virus stocks that could productively infect every human (and many other mammalian) cell line tested to date.

This story took a very unexpected and surprising turn in 1998, when Russell and Hirata demonstrated that rAAV vectors could be used for gene targeting.[122] Impressively, they used rAAV not just to inactivate genes, but to introduce defined modifications into homologous chromosomal sequences at very high frequency. They demonstrated this first with a Neo reporter construct, but also showed that they could modify an endogenous locus (HPRT) with similar efficiency.[122] In the intervening 8 years, the Russell laboratory and many others have confirmed and extended these original observations. Thus, 15 endogenous loci have been inactivated in a wide variety of human cell lines, ranging from investigator favorites such as HCT116 and NALM-6 to more biologically relevant normal diploid fibroblastic or stem cell lines (Table 53–4). The most spectacular use of rAAV to date was the correction of a dominant negative mutation in the COL1A1 gene in stem cells derived from patients afflicted with osteogenesis imperfecta.[123] Overall, 234 correctly targeted events have been recorded from a total of 6305 drug-resistant colonies examined (Table 53–4). This is an overall targeting frequency of 3.71%, which is much better than the traditional transfection-based approaches using HCT116 cells (compare Table 53–2 to Table 53–4) and comparable to the targeting frequencies reported for non-HCT116, non-NALM-6 (compare Table 53–1 to Table 53–4), and NALM-6 (Compare Table 53–3 to Table 53–4) cells.

Why rAAV works so well for gene targeting is not clear. A priori, the virus, because of its ITRs, has at least 145 nt of non-homology at either end of the donor DNA and this is generally a deterrent to homologous integration. Moreover, because the drug selection cassettes that are usually present on a targeting vector are 2 to 2.5 kb in length, this restricts the left and right homology arms to 0.9 to 1.0 kb each, such that the resulting recombinant virus can be packaged properly. This length of homology for the arms is extremely short in comparison to traditional approaches using transfection of linear dsDNA, where arms of 3–8 kb are standard. That rAAV gene targeting does work, however, is indisputable. Since invasion of a single-stranded donor DNA into the recipient chromosome is an essential feature of gene targeting (Figure 53–2), it is probable that rAAV—an ssDNA virus—readily becomes an HR intermediate.[9] Needless to say, other factors, such as the likely higher concentration of DNA in the nucleus provided by a viral infection as compared to DNA transfection, probably also work in its favor. Research into other parameters, such as multiplicity of infection, DNA sequence of the arms, cell cycle effects, and promoterless selection schemes, are currently all under investigation and it is likely that the rAAV gene targeting frequency can be substantially optimized.

What must be emphasized, however, is the ease of working with rAAV in comparison to the traditional methodology. Thus, historically, an investigator needed to spend 6 months or more assembling a targeting vector (although see Iiizumi *et al.*[66] for a faster alternative) and then spend another 6 months to a year laboriously transfecting their targeting construct into cells and screening the resulting drug-resistant clones by Southern blot analysis. With rAAV methodology, the entire experiment starting from the idea, "I'd like to knockout gene X," to having a cell line in hand can take as little as 2 months (B. Ruis, S. Oh, and E.A. Hendrickson, unpublished data). Importantly, Kohli *et al.* did the field a major service by developing a protocol, driven almost exclusively by PCR, for the development of targeting vectors and viral stocks.[124] Since the viral vectors and helper plasmids (expressing the necessary AAV and adenoviral gene products) are all commercially available (Stratagene), anyone can adopt this methodology into their laboratory. Additionally, in an ironic twist, because the rAAV targeting arms are so short, it becomes technically feasible to screen the resulting clones not by Southern blot analysis, but by PCR, thus once again expediting the targeting process.[124] It should be pointed out that almost all of the rAAV studies carried out to date have used a simple positive selection, in which the rAAV vector carries a drug selection marker constitutively expressed using a strong viral promoter. Recently, a promoterless version of an rAAV vector has been described and targeting frequencies of ~20% were reported.[65] If the use of this

vector becomes generally applicable, there will be few obstacles to targeting any gene of interest. Lastly, it should be noted that one obvious improvement might involve using rAAV methodology with the NALM-6 cell line, which appears to be so proficient in standard gene targeting. However, in our unpublished studies, rAAV seems to target no better in NALM-6 than in HCT116 cells (Table 53–4).[125–148]

CONCLUSIONS

In the 21 years that have elapsed since the first report of a gene-targeting study in human somatic cells,[74] a total 46 endogenous genes have been disrupted or modified. While modestly impressive in its own right, this number pales in comparison to the number of knockout mice strains that have been generated in the same time frame. Some of this difference is simply a reflection of the choice of model systems and the biological questions being addressed. Thus, for example, questions of development cannot be addressed in somatic cells in culture. Some of the difference, however, has been due to the fact that carrying out knockouts in human cells in culture is inherently more difficult than in murine ES cell lines. All in all, a total of 704 correctly targeted events in human somatic cells have been recorded from 100,791 clones examined, for a less than robust 0.7% success rate. Importantly, however, the identification of new cell lines such as NALM-6 and, most importantly, the development of the novel rAAV technology portend great improvements in this success rate in the foreseeable future. Moreover, since the rAAV methodology is still relatively in its infancy, we can expect that modifications will be developed to improve this already promising technique. While it is unlikely that gene targeting in human somatic cells will ever be as facile as gene replacement in yeast, it is clear that powerful methodology already exists to make such studies practical. Moreover, if the promise of the rAAV system comes to fruition, researchers working on human somatic cells in culture will have a powerful and facile weapon at their scientific disposal.

ACKNOWLEDGMENTS

I thank Dr. Anja-Katrin Bielinsky (University of Minnesota Medical School) for her comments and helpful discussions. I thank the past and current members of my laboratory who have contributed to the development of this methodology. This work has been supported in part by Grants HL079559 and GM069576 from the NIH to E.A.H.

54 Animal Models for Investigating the Causes and Mechanisms of Mammalian Germ Cell Aneuploidy

JOHN B. MAILHES AND MARY ANN HANDEL

ABSTRACT

Aneuploidy is a condition whereby the chromosome number of a cell or an organism is not an exact multiple of the haploid number for the species. It represents the most prevalent genetic abnormality of mankind and is associated with failed reproduction, mental and physical retardation, and cancer. Although research involving various organisms is providing information about the interactions between the biochemical pathways and the organelles responsible for chromosome segregation, we are still far removed from understanding the numerous potential molecular mechanisms of aneuploidy, especially in mammalian germ cells. Furthermore, the mechanisms of aneuploidy need to be studied in both male and female germ cells because of the inherent differences between male and female gametogenesis. The mouse aneuploid models presented here include those relevant to unique human disorders (Down syndrome) and those involving knockdown and knockout of genes needed for chromosome segregation. Also, models resulting from RNA interference technology and the exposure of cells to chemicals that specifically disrupt specific biochemical pathways or cellular organelles during gametogenesis are presented.

Key Words: Animal models, Aneuploidy, Female germ cells, Male germ cells, Molecular mechanisms.

SIGNIFICANCE OF ANEUPLOIDY FOR HUMAN HEALTH AND REPRODUCTION

Aneuploidy represents the greatest genetic affliction of humans. However, little is known about the causes and even less about the underlying molecular mechanisms of aneuploidy, especially in mammalian germ cells, where most aneuploidy is thought to arise. Human aneuploidy is linked with embryonic loss, mental and physical anomalies, and cancer. Approximately 10–30% of fertilized human eggs,[1] 10% of all human conceptuses,[2,3] 50% of spontaneous abortuses,[4,5] and 0.31% (204/64887) of human newborns[6] have an abnormal number of chromosomes. Even though numerous hypotheses have been proposed for the etiology of human aneuploidy, the only consistent findings are its positive correlation with maternal age[4,7,8] and its more frequent occurrence during female meiosis I for certain chromosomes.[9–12] Although the relationship between human aneuploidy and maternal age remains elusive, data suggest that such an association is linked to decreased frequencies of chiasmata formation,[13] abnormally placed chiasmata,[14] progressive losses of cohesion proteins,[15,16] and spindle checkpoint proteins.[17–19] It is now generally accepted that both nondisjunction and premature centromere separation (PCS) represent major events leading to human germ cell aneuploidy,[15,20,21] and that variation exists among chromosomes for the likelihood of missegregation.[22,23] Due the multitude of potential mechanisms, it is not surprising that a unique precept about the etiology of aneuploidy remains elusive. Recent information about the molecular mechanisms of chromosome segregation in various species is providing a foundation for research designed to investigate the causes and mechanisms of human aneuploidy.

While animal models for aneuploidy (e.g., trisomy models) have been useful for studying the consequences of aneuploidy, most animal models for the genesis of aneuploidy have not been specifically evaluated for their relevance to humans. Such comparisons are difficult because of ethical and sample size limitations and the biological variability inherent among human gametes. Thus, animal models are the only approach to obtain fundamental information about potential genetic hazards when humans are exposed to certain chemicals and other aneuploidy-inducing agents. It is important not only to identify those agents that significantly increase the incidence of aneuploidy in germ cells, but also to know if aneuploid germ cells are transmitted to progeny. However, the value of animal models goes far beyond the fact that they provide an experimentally malleable system for testing various agents. In fact, their greatest value to research on the etiology of aneuploidy may lie in the numerous genetic models that are available. These models enable determination of the roles of specific molecules in processes of meiotic chromosome dynamics and chromosome segregation that lead to gametic aneuploidy.

Here we review first, the basic processes of meiosis that, when they go awry, can lead to gametic aneuploidy, second, a sampling of the wealth of genetic models available for dissecting processes of meiosis and the genesis of gametic aneuploidy, and finally, what we have learned from analysis of environmental agents that cause aneuploidy. Our focus is on the laboratory mouse.

OVERVIEW OF MAMMALIAN GAMETOGENESIS

One interesting feature about human aneuploidy is its sexually dimorphic aspects, namely, it is highly correlated with maternal age and occurs more frequently in maternal meiosis for some chromosomes. Thus, much of the value of animal models lies in the exploitation of the sexual dimorphism of gametogenesis, which we highlight here in this overview of gametogenic processes and mechanisms, the context in which the origins of aneuploidy must be considered. Fundamental to the origins of aneuploidy is the process of meiosis. This specialized cell division process is defining of gametogenesis, as it occurs only in germ cells. In brief, the stages of meiosis include a premeiotic S-phase (often temporally longer than a mitotic S-phase), an extended prophase of meiosis I, during which chromosome pairing, synapsis, and recombination occur, and, finally, the two meiotic divisions that establish germ cell haploidy. For convenience, the extended meiosis I prophase is described in substages: during leptonema, chromosomes condense and begin to pair; during zygonema, chromosomes are paired and their intimate synapsis is initiated; during the pachytene stage, synapsis is completed and recombination (crossing over) occurs; and during the diplotene stage, desynapsis occurs. The intimate chromosome synapsis required for recombination is mediated by the synaptonemal complex (SC). The crossovers, visually apparent as chiasmata, serve to ensure the stable bipolar orientation of homologous pairs of chromosomes, a prerequisite to their correct segregation during the division process. Thus, although the primary defect leading to gametic aneuploidy may lie in prophase events, the nondisjunction that gives rise to incorrect chromosome segregation occurs in the meiotic division phases. The first meiotic division is a reductional one in which the homologous chromosomes are segregated into daughter cells; during the second, equational, division, sister chromatids are separated.

OOGENESIS Mammalian meiosis begins in the fetal ovary and is later arrested postpartum at the diplotene (dictyate) stage of meiosis I. Unless oocytes undergo atresia, they remain in diplotene until meiosis resumes in response to the luteinizing hormone (LH) surge prompting ovulation. Oocyte maturation (OM) is critical in setting up a correct meiotic division and encompasses the transition from diplotene to metaphase II (MII) and involves both nuclear and cytoplasmic remodeling.[24–27] In most mammals, metaphase II (MII) oocytes are ovulated and primed for fertilization, which initiates anaphase II.

Although differences in the biochemical pathways of OM exist among marine invertebrates, amphibians, fish, and mammals, the initiation and orderly temporal sequence of events during OM are influenced by species-dependent protein modifications by kinases and phosphatases.[28] In mammals, the intraoocyte titer of cyclic adenosine monophosphate (cAMP) plays a major role in initiating OM. Elevated levels of cAMP favor cAMP-dependent kinase activity and retention of oocytes in the diplotene stage of meiotic prophase. Conversely, low cAMP levels shift the equilibrium toward cAMP-dependent phosphatase activity, which is needed for activating maturation promoting factor (MPF).[24–27,29,30] MPF is composed of a 34-kDa catalytic subunit (CDC2A, sometimes referred to as $p34^{cdc2}$) that exhibits serine-threonine kinase activity and a 45-kDa cyclin B regulatory subunit (CCNB1). MPF is activated when CDC2A is dephosphorylated at the tyrosine 15 residue and coupled with cyclin B1, whereas, it becomes deactivated when tyrosine is phosphorylated.[31–33] MPF activity oscillates; it is highest during metaphase, but decreases at anaphase[34,35] and following fertilization[36–39] or parthenogenetic activation.[38,39]

Besides MPF, other kinases and phosphatases are also involved in the nuclear and cytoplasmic changes that occur during OM. Mitogen-activated protein kinases (MAPKs) are serine-threonine protein kinases that phosphorylate many of the same sites as active MPF.[40,41] These kinases mediate intracellular signal transmission in response to external stimuli, participate in assembling the first meiotic spindle, and prevent rodent oocytes from entering interphase during the interval between meiosis I and II.[42,43] Unlike MPF, MAPK activity remains high throughout OM.

Another kinase that has important functions during OM is the *Mos* protooncogene product MOS. This serine-threonine kinase is detected throughout OM[44–46] and exerts numerous species-dependent functions during OM including activation of the MAPK pathway.[47] MOS functions as a cytostatic factor by preventing premature exit from MII in mouse oocytes.[48,49] Oocytes from *Mos*-deficient mice are capable of completing OM, but fail to arrest at MII and subsequently undergo spontaneous parthenogenetic activation.[49–51] In addition to their roles during OM, the kinases MPF, MAPKs, and MOS also have important roles in the spindle assembly checkpoint (SAC), anaphase-promoting complex (APC) activation, and initiating the metaphase–anaphase transition (MAT).[40,47,52–54]

Upon completing OM, mouse oocytes remain in MII for a limited time period until fertilization, spontaneous activation, or atresia. Fertilization or parthenogenesis leads to elevated intraoocyte calcium levels that enable the formation of a calcium–calmodulin complex and calcium-dependent protein kinase II activation.[55] This kinase then initiates a cascade of kinase-phosphatase reactions that ultimately leads to unique dephosphorylation events, proteolysis of specific proteins, and inactivation of MPF, MAPKs, and MOS.

Considering that the synchronous interaction between unique kinases and phosphatases with their target compounds is needed for the normal temporal progression of OM and the MAT, it seems reasonable to suspect that alteration of their normal activities may lead to downstream effects manifested by chromosome missegregation. Based on their antagonistic effects relative to the degree of tyrosine CDC2A phosphorylation,[56] certain kinase and phosphatase inhibitors can alter the rate of OM and induce spindle abnormalities and aneuploidy in rodent oocytes. Okadaic acid (OA) specifically inhibits the protein phosphatases 1 (PPP1) and 2A (PPP2A) that dephosphorylate serine and threonine residues.[57,58] When mouse oocytes were treated with OA, MPF activation was inhibited[59] and abnormalities involving spindle fibers, multipolar spindles, kinetochores, and chromosome alignment were detected.[60–62] Furthermore, elevated frequencies of PCS and aneuploidy were found in mouse oocytes exposed to OA.[63] Some of the above observations may be related to the finding that OA treatment resulted in hyperphosphorylation of both microtubule-organizing centers and microtubule-associated proteins (MAPs)[59,60] and that hyperphosphorylated MAPs appear to have a reduced affinity for microtubules.[61]

The kinase inhibitor 6-dimethylaminopurine (6-DMAP) can disrupt CDC2A kinase and MAPK activities and reversibly block mouse oocytes at various stages during OM.[64–65] When mouse dictyate oocytes were exposed to 6-DMAP during *in vitro* culture, both protein phosphorylation and germinal vesicle breakdown

(GVBD) were inhibited, and when 6-DMAP was added after GVBD, first polar body formation was prevented.[64] Other data showed that 6-DMAP inhibited protein phosphorylation in activated mouse MII oocytes, which resulted in the premature disappearance of phosphorylated proteins and abnormalities involving polar body extrusion and pronuclei formation.[65] A relevant point about either *in vivo* or *in vitro* oocyte aging is that the pattern of protein dephosphorylation events appears to be correlated with increased frequencies of spontaneous oocyte activation and PCS.[15,66–71]

SPERMATOGENESIS The tempo and timetable of spermatogenesis differ markedly from that of oogenesis. Germ cells in fetal rodent testes enter into a period of mitotic arrest until shortly after birth. During the same period, the germ cells, positioned in the center of the seminiferous tubules, initiate ameboid activity and move between the Sertoli cells to establish themselves on the basal lamina of the tubules, a niche favorable for stem cell activity.[72] During the second week of life, large numbers of differentiated spermatogonia enter meiotic prophase, and by the end of the third week, the meiotic divisions occur and postmeiotic spermatid differentiation, or spermiogenesis, is initiated. Thus, the first wave of spermatogenesis is more or less synchronous, but subsequently, in adult life, these distinct processes of mitotic proliferation, meiosis, and spermiogenesis occur simultaneously in the testis and different generations of germ cells are present simultaneously. Because of the complexity of the adult testis, the first wave of spermatogenesis is frequently studied experimentally to determine temporal relationships and expression patterns, especially for meiotic events.

Unlike meiosis in the female germ cell, there is no meiotic arrest during spermatogenesis. After the extended prophase (more than a week long in mice), germ cells proceed through diplonema and the two meiotic divisions rapidly, in a period of 24 h or so. This rapid and uninterrupted timing has important consequences that may be informative about the relative incidence of gametic aneuploidy in males versus females. First, the recombination-based crossovers, manifest in chiasmata, are not "old" at the time of the meiotic division. Similarly, other "binder" proteins, such as chromosomal cohesins, are relatively "new" in spermatocytes at the time of the meiotic divisions. Together or separately, these could contribute to greater fidelity of metaphase chromosome alignment and subsequent segregation in male gametogenesis. In contrast, in females, both chiasmata and binder proteins are established during prophase, in fetal life, and thus they could be quite "old" at the time of the meiotic divisions, although nothing is known about the potential turnover and replacement of these proteins in oocytes.

Experimental analysis of chromosome segregation during male meiosis is hampered by the fact that very little is known about the regulation of the onset of the meiotic division phase in spermatocytes.[73,74] Although oocytes spontaneously enter the meiotic division phase upon removal from the follicle, removal of mid-prophase spermatocytes from their surrounding Sertoli cells does not prompt the onset of the division phase. Thus, the signal for the onset of the division phase is likely to be a positive one, either autonomous to the germ cell or emanating from the Sertoli cells. Although genetic evidence is lacking, the G_2/MI transition, as the progress from late meiosis I prophase to the first meiotic division is known, is likely to be mediated, as in oocytes, by the universal cell cycle regulator MPF.[75] Experimentally, the G_2/MI transition can be induced by treating pachytene spermatocytes with OA, but the exposed cells do not complete division, hampering analysis of chromosome segregation. Another experimental approach to the analysis of MI chromosome segregation is the injection of pachytene spermatocytes into oocytes, but in this case, chromosome segregation is not normal,[76] thus perhaps providing a model system for analysis of the genesis of gametic aneuploidy.

GENETIC MODELS FOR ANEUPLOIDY

The quintessential value of the mouse for the study of aneuploidy is the plethora of genetic models available. These include models of aneuploidy (e.g., mouse models for Down syndrome) for analysis of the consequences of aneuploidy, as well as single gene mutations that can be used to decipher the intricacies of chromosome segregation, contributing to the analysis of causes and mechanisms of aneuploidy. Prior to the development of such mutant gene models (mostly by genetic knockout technologies), studies on aneuploidy had been limited to various chemicals, mainly those that damage microtubules, that induce aneuploidy in mammalian germ cells,[77–79] which can be transmitted to progeny.[23,80–82] These studies are useful (and are covered in the section on Environmentally Induced Aneuploidy in Germ Cells), but lack the precision and power of genetic models. Gene knockout and knockdown models, RNA interference technology, and mutant genetic strains are now being employed for studying aneuploidy as summarized below. It should be noted that the gene models represent a selective list (Table 54–1) of those proving most useful for analysis of the genesis of aneuploidy, and also, almost by definition, involve only one event in a complex, and yet not completely understood, series of biochemical reactions and cellular organelles that orchestrate chromosome segregation. Most of these models directly relate to aneuploidy, but some involve events that predispose cells to aneuploidy. Importantly, the full potential of these models has not yet been realized; for example, they may provide "sensitized" models for testing of potential environmental disruptors of meiotic chromosome segregation.

Note: In the section below and in Table 54–1, standard gene and protein nomenclature, approved by international commissions on nomenclature, is used.

GENETIC MODELS FOR ANEUPLOID CONDITIONS The most studied human autosomal aneuploidy is trisomy 21 (Ts21) or Down syndrome. Several mouse models for Ts21 have become available.[83–88] The Ts(17^{16})65Dn, commonly known as Ts65Dn, mouse shows many features characteristic of Down syndrome[85,89] and has been particularly informative for teasing apart gene–phenotype relationships for the relevant chromosomal regions in attempts to understand the complexity of Down syndrome manifest in humans. In addition to these models for autosomal aneuploidy, models for sex chromosome aneuploidy have also been exploited to determine the consequences for physiology and meiotic pairing of extra (or deficient) sex chromosomes.[90–92]

ANEUPLOIDY IN MODELS FOR EVENTS OF CHROMOSOME PAIRING, SYNAPSIS, AND RECOMBINATION Chromosome pairing is mediated by cohesins, proteins that promote sister-chromatid cohesion, and by proteins of the SC. The synaptonemal complex protein 3, SYCP3 (encoded by the *Sycp3* gene in mice and by the *SYCP3* gene in humans), is a meiosis-specific structural protein needed for chromosomal structural integrity,

Table 54–1

chiasmata formation, and chromosome synapsis. Expression of SYCP3 protein is restricted to meiotic prophase I and disappears during diakinesis in mouse oocytes.[93] In meiotic prophase chromosome preparations, SYCP3 is found in the SC during meiotic prophase,[94] where it colocalizes with the RAD21 (also known as SCC1) cohesin subunit.[95] In meiosis division-phase spermatocytes, SYCP3 localizes to the centromeres by metaphase I and subsequently disappears by telophase I.[95] Spermatocytes in homozygous *Sycp3*$^{-/-}$ male mice exhibit synaptic failure and meiotic arrest during zygotene, and the male mice are infertile.[96] The females, however, are not infertile and oocytes from *Sycp3*$^{-/-}$ females display incomplete synapsis and alignment of homologs during pachytene and abnormal position and reduced frequency of chiasmata; chromosomes are found as univalents in oocytes and aneuploid zygotes are produced,[97] apparently by oocytes that evade checkpoint control.[98] This sexually dimorphic phenotype is not clear; it may in some way reflect the fact that SC proteins remain associated with centromeres until meiotic division phase in males, whereas they disappear prior to this in females.[93]

The "structural maintenance of chromosomes" (SMC) family of proteins includes both cohesins and condensins. SMC1B (also known as SMC1 beta, encoded by the mouse *Smc1b* gene) is a meiosis-specific isoform of a cohesin subunit.[99] Genetic knockout analysis reveals that SMC1B has a role in preserving chiasmata and maintaining chromosome cohesion until anaphase.[100,101] *Smc1b*-deficient mice also display sexual dimorphism; spermatocytes arrest during meiotic prophase, whereas oocytes progress to MII.[93,100] The pachytene arrest noted in males was attributed to incomplete synapsis of homologs. In oocytes, reduced recombination and premature loss of sister chromatid cohesion during meiotic prophase I suggest that SMC1B helps stabilize chiasmata until anaphase, and, interestingly, this may be a factor in the age-related increase in oocyte aneuploidy.[101]

The MLH1 DNA mismatch repair protein promotes meiotic recombination in yeast.[102] Mouse genetic models are available, as the mouse *Mlh1* gene has been knocked out.[103,104] In spermatocytes of *Mlh1*-null mice, chromosome pairs fall apart, presenting as univalents at metaphase I,[103] the condensed univalents do not assemble onto the spindle apparatus, and spermatocytes die, perhaps in response to a recombination or chiasmata checkpoint.[105] This was also found to be the case for female mutants,[106] where there is failure to exclude the second polar body and zygotic death.[104] These observations suggest that the MLH1 protein is essential for the maintenance of chiasmata. In a robust validation of the utility of such models for basic insights, it was subsequently found that MLH1 localizes to sites of crossing over that become the chiasmata.[107] Likewise, deficiency for the related MLH3 mismatch repair protein causes meiotic arrest and aneuploidy phenotypes.[108]

Other chromosomal proteins have also been found to play a role in chromosome dynamics that lead to correct meiotic chromosome segregation. ATRX (α-thalassemia/mental retardation syndrome X-linked homolog) is a centromeric-binding protein of the SNF2 family of helicase-ATPases. When ATRX activity was inhibited by antibody microinjection or RNA interference in mouse oocytes, chromosome alignment was disrupted during metaphase II.[109] TOP3B (DNA topoisomerase III beta) is a type IA DNA topoisomerase.[110] Targeted disruption of the *Top3b* gene in mice causes a homozygous phenotype of infertility with a high incidence of aneuploidy in male germ cells.[111] Topoisomerases are required for meiotic chromosome condensation and division in yeast and mammals,[112] but much remains to be learned about their precise role.

ANEUPLOIDY IN MODELS FOR CHECKPOINTS THAT MONITOR GENETIC INTEGRITY BUB1B (also known as BUB1R) comprises one of several spindle checkpoint proteins.[113]

Generation of *Bub1b* mutant mice resulted from a gene-targeting strategy creating a hypomorphic allele in mice embryonic stem cells.[114] Progressive reduction of BUB1B expression in mouse embryonic fibroblasts, spermatocytes, and oocytes resulted in aneuploidy. Also, a correlation between chronological aging of wild-type mice with diminished expression of BUB1B in somatic and germinal cells was noted. This relationship suggested a role for spindle checkpoint protein activity and the maternal age effect of aneuploidy.[114]

Another spindle checkpoint protein well studied in yeast is MAD2, known in the mouse as MAD2L1. Morpholino-based gene silencing of *Mad2l1* transcripts in mouse oocytes during meiosis I resulted in premature proteolysis of both cyclin B and securin, attenuating meiosis I and causing an elevated incidence of aneuploidy. Conversely, overexpression of a human *MAD2L1*-GFP construct in oocytes led to homolog nondisjunction.[19] Insufficiency of MAD2 L in mouse,[115] as well as partial knockout of *Mad2l1* in human and mouse mitotic cells,[116] has been shown to result in an accelerated rate of meiosis, PCS, and aneuploidy. Additional data from real-time polymerase chain reaction (PCR) experiments have demonstrated that *MAD2L1* transcripts in human oocytes decrease as a function of maternal age[17] as well as postovulatory age in mouse oocytes.[18] Together, these data indicate an important role for MAD2L1, a spindle checkpoint, in monitoring chromosome segregation.

OTHER GENETIC MODELS OF GAMETIC ANEUPLOIDY Meiosis-defective 1 (*Mei1*$^{-/-}$) mice were derived from chemically mutagenized embryonic stem cells.[117] The *Mei1* gene encodes a protein, MEI1, of unknown function.[118] Spermatocytes from homozygous *Mei1*$^{-/-}$ mice exhibited zygotene arrest with abnormal synapsis of homologs; but some oocytes progressed to metaphase I and displayed asynapsis and abnormal chromosome alignment.[117] Thus, when revealed, the function of the MEI1 protein may shed light on processes involved in setting up accurate meiotic chromosome segregation.

Males of the PL/J mouse strain are characterized by a high frequency of morphologically abnormal sperm, an elevated frequency of aneuploid sperm, as well as spermatocytes exhibiting chromosome asynapsis and other meiotic prophase abnormalities.[119] Genetic analysis revealed that these features are complex traits, and thus far the underlying genes have not yet been identified.[119] Also, senescence-accelerated mice (SAM) exhibit age-related defects in chromosome alignment during oocyte meiosis I and II.[120] This phenotype is reminiscent of that of the *Smc1b*-null mice, and it was speculated that cohesion defects in aged mice may be associated with misalignment and PCS.

ENVIRONMENTALLY INDUCED ANEUPLOIDY IN GERM CELLS

As mentioned previously, many studies have shown that various chemicals, mainly those that damage microtubules, can induce aneuploidy in mammalian germ cells.[77–79] Moreover, several studies have demonstrated that aneuploid germ cells can be transmitted to progeny.[23,80–82]

Animal models for aneuploidy have not been specifically evaluated for their relevance to human aneuploidy. Such comparisons are not possible due to ethical and sample size limitations plus the biological variability inherent among human oocytes. Because of this, animal models are the only experimental approach to obtain information about potential genetic hazards when humans are exposed to certain chemicals and other aneuploidy-inducing agents. As mentioned earlier, it is not only important to identify those agents that can significantly increase the incidence of aneuploidy in germ cells, but also to know if such aneuploid germ cells can be transmitted to offspring. Several relevant agents are described below and in Table 54–2.

FEMALE GERM CELLS Several review papers list compounds (aneugens) reported to induce aneuploidy in mammalian female germ cells.[23,78,79,121,122] Most of the chemicals reported in the earlier reviews dealt with spindle poisons such as colchicine, vinblastine sulfate, and benomyl, whereas, more recent articles have involved compounds that inhibit unique biochemical[63,123] or cellular organelle activities.[22,109] Thus, it is well-recognized that various types of compounds are capable of inducing aneuploidy in dividing cells. Based on the numerous unique cellular and biochemical reactions involved with chromosome segregation, the list of aneugens can be expected to increase. For example, it has recently been shown that exposure to bisphenol A can increase meiotic nondisjunction in mouse oocytes.[124] Furthermore, environmental agents can be expected to act not only on individual gametes, but also on the conceptus produced by their union. For example, conditions associated with fertilization *in vitro* may increase mitotic nondisjunction in early cleavage,[125] and the mouse is an excellent model for study of this phenomenon. Although identification of aneugens has merit, it is also of importance to describe their mode of action. Agents may act proximally, on mediators of cell division, but may also act distally and upstream, perhaps on endocrine receptors, to create a "susceptible" cellular environment. Thus, for each cell type, the molecular mechanisms of normal chromosome segregation need to be known as well as the effects of a particular perturbation during the chain of events comprising mitosis and meiosis. How such information

Table 54–2
Environmental agents affecting mammalian germ cell chromosome segregation

Agent	*Cell type*	*Cytogenetic event*	*Reference*
MG132[a]	Mouse oocytes	Meiotic arrest, aneuploidy, premature chromatid separation	167
Vanadate[b]	Mouse somatic cells	Aneuploidy, premature chromatid separation	168

[a]Proteasome inhibitor.
[b]Tyrosine phosphatase inhibitor.
[c]Protein phosphatase 1 and 2A inhibitor.
[d]Kinesin EG5 inhibitor.

can be utilized for reducing the incidence of human aneuploidy still remains the ultimate task.

MALE GERM CELLS Experimental analysis of the effect of environmental agents on genesis of germ cell aneuploidy is facilitated in the male by the relative accessibility of the critical germ cell stages. Two primary germ cell stages are used for analysis of environmental agent effects directly on male germ cells: primary spermatocytes, for assessment of impairment of the SC and/or pairing and recombination, and sperm, for assessment of effects on chromosome segregation. In spite of the availability of these germ cell stages, the effect of environmental agents on transmissible aneuploidy can be detected only at the level of the zygote or offspring.

A number of agents can affect the synaptonemal complex structure of mouse spermatocytes, introducing breaks or discontinuities, which are detected after silver staining or with immunofluorescent labeling of surface-spread chromatin. These include colchicine,[126,127] cyclophosphamide,[128,129] and etoposide. The latter is the most thoroughly studied agent with respect to both the full spectrum of effects and species, and is an excellent example of the power of combined genetic, cellular, and cytogenetic analyses. First found in 1998 to produce peak mutagenicity in primary spermatocytes of the mouse,[130] etoposide was subsequently found to reduce crossing over[131] and to produce heritable chromosome abnormalities and aneuploidy.[132,133] Together, these studies illustrate the spectrum of techniques that can be brought to bear on an analysis of germ cell effects of environmental agents. The first discovery of germ cell stage sensitivity came from analysis of the mutagenicity of etoposide in a genetic-specific locus test,[134] relying on detection of specific mutations in offspring. This was followed by careful analysis of SC and chromosome morphology in surface spread chromatin coupled with genetic recombination analysis (of offspring) to show abnormalities in meiotic protein localization and reduced recombination.[131] The discovery that etoposide causes nondisjunction and gametic aneuploidy required scoring of offspring and, especially, the use of sperm FISH. This technique, involving hybridization of chromosome-specific probes to denatured sperm DNA *in situ*,[135] is among the most useful for direct determination of gametic aneuploidy. FISH analysis of sperm from etoposide-treated mice revealed increases in aneuploid sperm.[133,136,137] Interestingly, FISH data on sperm from treated human males (undergoing chemotherapy) also revealed an increase in the frequency of aneuploid sperm.[138] Etoposide and diazepam[139] are the only chemicals known for which both mouse and human sperm aneuploidy data are available. Even with the knowledge that sperm are aneuploid, transmissible aneuploidy can be detected only by examination of offspring, which has been a limiting factor in these studies. However, the technique of PAINT/DAPI has facilitated rapid and accurate scoring of chromosomes in zygotic first-cleavage metaphase[140]; application of this to studies of environmental agents could provide new insights.[141] Nonetheless, although these studies highlight the potential utility of rodent models for environmental induction of gametic aneuploidy, we still do not know the exact mechanism(s) by which etoposide or other environmental agents act in promoting nondisjunction and heritable gametic aneuploidy.

ETIOLOGY OF ANEUPLOIDY

Although the incidence of aneuploidy has not been routinely studied in mammals other than humans and rodents, the available data show that it occurs more frequently in humans than in rodents, and more frequently in females than in males. Is there a unique aspect of human female reproduction that renders it more vulnerable to chromosome missegregation? One feature is the absence of a defined estrus period during the menstrual/estrous cycle. Most domestic mammals ovulate during or shortly after the estrus period of their estrous cycle in order to ensure that freshly ovulated oocytes are fertilized.[142] Since this situation does not occur in humans, the possibility exists that fertilization of postovulatory aged oocytes might occur. Indeed, it has been proposed that fertilization of postovulatory aged oocytes may contribute to the higher incidence of aneuploidy in humans relative to other species.[6,143–147] Furthermore, two epidemiological studies offered support for an association between fertilization of aged human oocytes and early embryonic failure[148] and trisomic offspring.[143]

Postovulatory and *in vitro* oocyte aging involves a progressive, functional deterioration of the biochemical and cellular organelles essential for accurate chromosome segregation, normal fertilization, and embryonic development.[120,148] During this aging process, a narrow window of time exists for the optimal expression of gamete physiology. The fertilizable life span of mammalian oocytes ranges from 12 to 24 h and only 6 to 8 h in mares.[142] Although the fertilizable mean life span for both induced and naturally ovulated mouse oocytes is approximately 15 h postovulation, their optimal time for fertilization ranges from 4 to 6 h postovulation.[149–151] After this period, time-dependent intraoocyte changes take place among certain cellular organelles and biochemical profiles that can lead to apoptosis.[152–155]

In addition to postovulatory aging, other hypotheses include reduced and abnormally positioned chiasmata,[13,14] biological aging that is associated with reduced oocyte pools and reproductive hormones as maternal age increases,[156] compromised gonadal environment,[91,157] and premature centromere separation.[15,16,20] Recent data suggest that maternal age is positively correlated with progressive deterioration of cohesion between bivalents,[21,97] progressive loss of cohesion proteins,[95,101] and spindle checkpoint proteins.[17] Experimental data have shown that chronological aging of female mice deficient for the SMC1B chiasmata-binding protein led to deterioration of both chiasmata and arm cohesion as well as elevated levels of univalents and single chromatids in oocytes.[101] Recognizing that many of the reported aneuploid hypotheses are not necessarily mutually exclusive, it now appears that both preovulatory (maternal aging) and postovulatory-related alterations in the biochemical pathway regulating chromosome segregation can predispose oocytes to aneuploidy. Furthermore, these same cellular features governing chromosome segregation may also contribute to male gametic aneuploidy. Considering the numerous intracellular biochemical and organelle changes that can alter normal chromosome segregation, it seems reasonable to state that various molecular approaches will be needed to better understand the intricate details of aneuploidy.

FUTURE DIRECTIONS AND CONCLUSIONS

Since many potential mechanisms may lead to aneuploidy, specific investigations into the molecular mechanisms of aneuploidy that alter one event, or even several events, of the chromosome segregation pathway represent only a small component of the overall format underlying chromosome segregation. It has been estimated that approximately 500 yeast genes directly or indirectly control chromosome segregation.[158] Accurate

chromosome segregation requires the temporally coordinated interaction among unique biochemical and cellular organelles. Some of these events include protein kinases and phosphatases, topoisomerases, microtubule kinetics, kinetochores and their proteins, centrosomes, motor proteins, passenger proteins, spindle checkpoint proteins, anaphase promoting complex, proteasomes, and securin, cohesin, and separin proteins. Abnormalities involving microtubule capture by kinetochores, removal of catenations between sister chromatids, chromosome condensation and biorientation, kinetochore–microtubule tension, and the spindle checkpoint have the potential for predisposing cells to aneuploidy.

Technologies such as DNA microarrays[159] and RNA-mediated interference of genes and protein kinases involved with cell cycle progression[160,161] offer avenues for deciphering cell cycle progression and chromosome segregation pathways. RNAi silencing and gene knockdown technologies have been used to alter the expression of the MAD2L1 protein in mouse oocytes[19,162] and BUB1B protein in mouse germ and somatic cells.[114] Reduced expression of these SAC proteins was associated with aneuploidy. Additionally, large-scale knockout strategies for genes upregulated during yeast meiosis found that deletion of specific genes required for maintaining centromeric cohesion during anaphase I resulted in chromosome missegregation.[163,164] Furthermore, data derived from genomic and proteomic analyses are expected to provide clues about the fundamental processes associated with cell division. Gene expression analyses of cancer cells showed that a subset of genes is universally activated in most cancers,[165] and that overexpression of cell division regulatory genes was linked with chromosome aberrations and neoplastic progression.[166] Continued research involving the chronological sequence of molecular events comprising chromosome segregation during mitosis and meiosis coupled with cytogenetic analyses is required to further our knowledge about the origin of gametic aneuploidy.[167,168]

55 Genetic Models of Alzheimer's Disease

YANN S. MINEUR

ABSTRACT

This chapter presents and discusses different strategies to dissect genetically the molecular mechanisms of Alzheimer's disease. First, a short preamble sketches the common phenotypical features of Alzheimer's disease. Second, a basic introduction defines the characteristics of a good animal model along with the different molecular strategies commonly used to develop transgenic animals. Third, an exclusive census of genetically modified mouse models describes some of the remarkable characteristics observed in these animals and tries to weigh the pros and cons of each of them. Finally, a brief note highlights gene–environment interactions relevant to the field of genetic mouse models and Alzheimer's disease. All sections are illustrated with examples focusing on behavioral phenotypes with a specific interest on learning and memory.

Key Words: Alzheimer's disease, Transgenic, Mouse models, Neuroanatomy, Behavior, Learning, Memory, Amyloid, Secretases, Tau.

INTRODUCTION

Alzheimer's disease (AD) is expected to affect 16 million individuals in the United States by the year 2050. While the onset of AD-associated dementia can be subtle, the inexorable evolution of this disease ultimately leads to global cognitive deficits including memory, orientation, reasoning, and judgment. Unfortunately, besides limited cholinergic therapies aimed at improving cognitive decline in patients, no effective therapies are currently available.

Extracellular neuritic plaques and intraneuronal fibrillary tangles (NFTs) are the two classical hallmarks of AD pathology in the brain.[1,2] Neuritic plaques are typically composed of β-amyloid oligomers (Aβ) surrounding dystrophic neurites. These plaques will precipitate and accumulate (primarily in the cortex and the limbic system),[3–5] leading to neuronal death, which is thought to be responsible for dementia observed in AD patients[6] (see Figure 55–1).

Tau, a microtubule-associated protein, is the primary component of NFTs.[7] In AD, tau is hyperphosphorylated, resulting in disruption of microtubule dynamics, impaired axonal transport, and intraneuronal polymerization of the cytoskeleton. These molecular events will also result in neuronal death.

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

For a pathological diagnosis of AD, neuritic plaques and NFTs are required.

It is now commonly believed that abnormal production and aggregation of Aβ (especially the more fibrillogenic and insoluble $A\beta_{42}$ isoform) are the primary cause of the plaques found in AD.

ANIMAL MODELS OF ALZHEIMER'S DISEASE?

Investigating the molecular mechanisms of AD in human subjects is particularly difficult because only postmortem tissue can be studied, once the disease has reached its most advanced stages. Neuronal tissue harvested from human brain is generally fragile and very sensitive, affected by aging, medications, and other possible neurological defects. In addition, the complexity is increased by broad individual variability due to genetic and environmental factors. Moreover, the availability of brain tissue is limited. Most of these difficulties can be overcome by using animal models.

Given the wealth of data available on models of AD, this chapter will principally focus on the mouse. Mice are the most popular animal models (for AD), primarily because their genome can be manipulated easily. This advantage has led to the generation of a variety of genetic mouse models, although rat models do exist as well (see, for instance, Hu *et al.*[8]).

Nevertheless, invertebrate models such as *Drosophila melanogaster* and *Caenorhabditis elegans* should not be thrust aside too hastily. In spite of their clear limitations—mainly the lack of mammalian brain structures and greater genetic distance from human than mice—these model organisms can aid in the study of AD. These "limitations" can also be an advantage: simpler organisms are generally easier for mapping of neuronal networks and for investigating molecular interactions. From a practical point of view, these animals are also smaller, cheaper to house and breed, and have shorter generation times than any mammal. Thus, many generations can be produced in a short time span. As a result, transgenic fly and worm AD models have been developed for both Aβ and tau expression.[9–11]

HOW DO WE DEFINE A "GOOD" MODEL OF ALZHEIMER'S DISEASE?

Modeling a disease in an animal can be challenging. A good AD model should, as much as feasible, present the following features:

- Reproducibility: a good model should yield consistent phenotypic features across generations and time, and

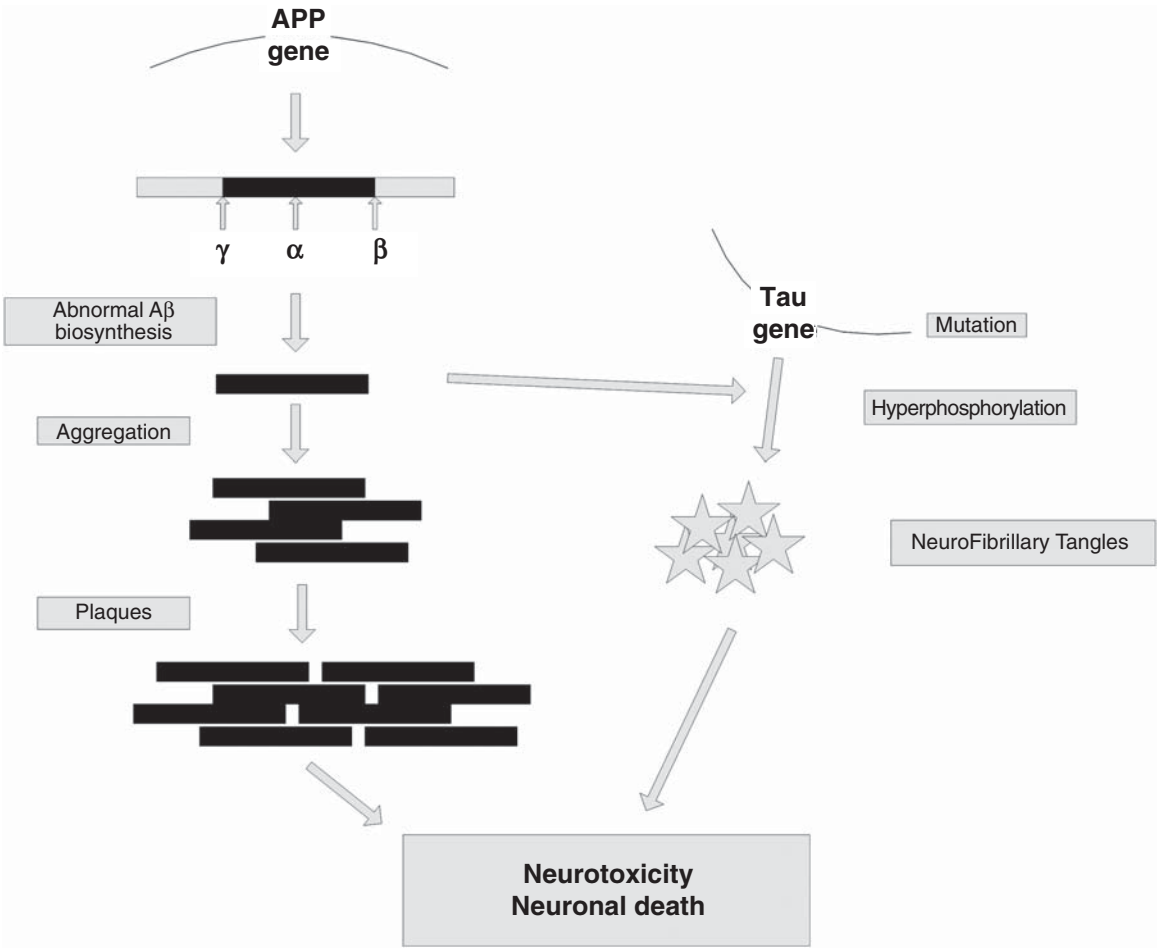

Figure 55–1. Simplified overview of the amyloid cascade hypothesis of Alzheimer's disease. See text for details.

possibly across investigators and laboratories. However, the latter can be quite difficult to achieve despite the best efforts to do so.[12]

- Face validity: the phenotypic features should "look" the same as those observed in the human disease. Of course, this can be problematic for phenotypic traits related to higher cognitive function and/or for human characteristics impossible to assess and model in mice. Nevertheless, a plethora of behavioral assays performed in mice permits evaluation of memory processing and cognitive functions, for instance. In addition, physiological and biochemical analyses allow the identification of amyloid plaques and subsequent neuronal damage similar to that observed in AD.
- Construct validity: the model either relies on, or reveals, the *same* basic *underlying mechanisms* as AD, including the accumulation of Aß peptides, hyperphosphorylation of tau, and subsequent neuronal death. By extension, genetic validity is part of this category when a disease or its risk factors engage genetic components similar to the ones in human subjects.
- Predictive validity: the observed effects of particular disease-triggering elements should be similar between the animal model and human subjects. For instance, β amyloid-induced plaques with neuronal losses would constitute good predictive validity of an animal model of AD. A good predictive validity can also help in defining how useful and/or safe a drug/treatment can be.

These three latter categories are not mutually exclusive one with another. Phenotypical factors can belong to one, two, or all of the categories.

GENETIC MOUSE MODELS OF ALZHEIMER'S DISEASE

It is crucial to realize that "natural" development of plaques and tangles does not occur in mice (or other species commonly used in scientific research). Thus, engineering a model for AD requires experimental manipulation, either genetic and/or pharmacological, the latter generally consisting of the exogenous administration of different Aβ peptides into the normal rodent brain. Both techniques have advantages and disadvantages, but are essentially complementary. This chapter will focus on genetic models of AD. For a review of mouse models of AD that use exogenous Aβ administration and their comparison to transgenic models, the reader is referred to Stephan and Phillips.[13]

Genes encoding proteins shown to play a role in the onset of AD pathology would be the prime candidates for manipulations. Consequently, a large number of genetically modified mouse lines

have been generated using several of the following common techniques:

- Gene deletion or knockout (KO): in these models, defined gene(s) expression is absent throughout the life of the animal, from the earliest stage of development. Refinements have been added to this techniques resulting in conditional KO mice, in which the expression of a gene is abolished but only in restricted brain area(s)/neuronal types, and/or at a specific time during development of the animal. The deletion of a gene can also be reversible.
- Transgenic overexpression: in this case, a foreign gene, e.g., human APP (hAPP), is introduced into the genome and its expression (level and region) is driven by specific promoters.
- Targeted mutation or knockin (KI): a specific region of a gene is mutated, leading to loss or alteration of the proteins encoded by the targeted gene.

Combinations of these genetic techniques are possible and are becoming common in mouse models of AD. The following section will describe and compare several AD mouse models generated to date.

APP TRANSGENICS The first successful genetically engineered mouse models of AD were transgenic mice, characterized by increased Aβ levels induced by overexpression of its precursor (APP). Commonly, hAPP—and usually a mutant form linked to the early-onset familial form of AD—is introduced into the mouse genome. In turn, this gene transfer leads to the expression of the transgene. To date, numerous hAPP models have been generated including PDAPP, Tg2567, APP23, TgCRNDN8, and J20. Each model uses either different APP mutations, different promoters, or a different genetic background of the host mouse strain (see Table 55–1 for more details and http://www.alzforum.org/res/com/tra/ for a comprehensive list of transgenic models). Not surprisingly, the phenotypes are therefore dissimilar between these strains, characterized by different qualitative and quantitative levels of neuroanatomical defects.

These strains have all been assessed behaviorally, some extensively. PDAPP and Tg2567 have been studied in great detail and high APP levels induced by the transgene were shown to be responsible for cognitive abnormalities in both lines. Both lines are considered to be reliable AD models, because they exhibit clear learning deficits over time and across laboratories. Moreover, the cognitive decline observed in these animals was observed in many cognitive tasks. For instance, Tg2576 mice, developed by Hsiao *et al.*,[14] show a progressive impairment in various forms of the water navigation task,[15] deficits in a version of the Barnes maze,[16] and poorer performance in a T-maze alternation task and contextual fear conditioning.[17]

SECRETASE TRANSGENICS The β- and γ-secretases catalyze the processing of APP into the various forms of Aβ, whereas α-secretase is part of the nonamyloidogenic pathway (see Figure 55–1). Thus, genes encoding these secretases are candidate genes of interest for AD.

β-Secretase BACE1 is the predominant neuronal β-secretase. Both transgenic mice overexpressing BACE1 and knockout mice lacking BACE1 have been generated and, intriguingly, at least one of their behavioral phenotypes is opposite: BACE1 KO mice exhibit more anxiety-like behaviors than controls, whereas transgenics showed less anxiety-like behaviors. However, cognitive deficits have not been observed.

The development of double transgenic mice generated by crossbreeding mice overexpressing hAPP with those either lacking or overexpressing BACE1 has also helped identify the role of BACE1 in AD. As expected, double transgenic mice (hBACE/Tg2576) have increased amyloid pathology, high concentrations of both total Aβ and $A\beta_{42}$, and greater numbers of plaques than hAPP mice alone. However, elimination of BACE1 in the presence of hAPP rescues specific cognitive deficits associated with Aβ deposits.[18]

γ-Secretase The secondary cleavage of APP leading to $A\beta_{42}$ involves the activity of γ-secretase. Functional γ-secretase is a complex holoenzyme made of several individual enzymes, including presenilin (PS)1, PS2, Nicastrin, Aph-1, and Pen-2.[19,20] The presenilins (PS1, PS2) have been thoroughly investigated since human subjects with mutations in PS1 show early-onset AD. Many genetically engineered mouse models have been developed including KOs, transgenics, and KIs, double and even triple transgenics. While PS1 KO mice are not viable,[21] the development of conditional KOs (cKOs), in which the loss of the gene was limited to the postnatal forebrain, circumvented this lethality. PS1 cKO mice show mild cognitive impairments in long-term spatial reference memory and retention.[22]

Overexpression of a human form of PS1 (hPS1) in mice, however, induced only slight behavioral perturbations. KIs generated by a targeted missense mutation in murine PS1 overproduce $A\beta_{42}$; however, this does not lead to the aggregation of amyloid plaques. Nonetheless, mice perform poorly in an object recognition task, but are similar to controls in a water navigation test. These results suggest that changes in PS1 activity could influence

Table 55–1
Examples of different APP transgenic mice

Common abbreviations	*Transgene*	*Promoter*	*Genetic background*
PDAPP	Human APP with Val-717 substituted by Phe (Indiana mutation)	Human platelet-derived growth factor β (PDGF- β) chain gene promoter	Swiss × C57BL/6 × DBA2
Tg2567	Human APP with mutations Lys-670 substituted to Asn and Met-671 to Leu (Swedish mutation)	Hamster prion promoter	C57BL/6 × SJL
APP23	Human APP751 with Swedish mutation	Murine Thy-1.2 gene	C57BL/6
TgCRNDN8	APP695 with Swedish and Indiana mutations	Hamster prion promoter	C3H/He × C57BL/6J
J20	APP695 with Swedish and Indiana mutations	Human platelet-derived growth factor β (PDGF- β) chain gene promoter	C57BL/6 × DBA2

hippocampus-dependent memory pathways.[23,24] Mice lacking PS2 do not exhibit obvious neurological or behavioral abnormalities, and can reproduce successfully. In contrast, PS2 overexpressing transgenic mice and KIs with mutations in PS1 exhibit poor performance in a water navigation task. cPS1/APP double transgenic mice have also been generated (cPS1 carries a neuron-specific conditional KO of the PS1 gene). In this line, accumulation of Aβ is faster and Aβ levels are higher. Behaviorally, cPS1/APP double transgenic mice performed poorly in several cognitive tasks (for details, see Kobayashi and Chen[18]). As was seen in hAPP/PS double transgenics, the cPS1/APP double transgenic mice do not develop amyloid plaque; behavioral abnormalities in an object recognition task were rescued in the double transgenic mice.[25] This reinforces the conclusion that inhibition of secretase could constitute a promising target for AD treatment or prevention.

α-Secretase α-secretase cleaves about 90% of APP. However, α-secretase induces production of the P3 peptide, which does not appear to be associated with amyloid neurotoxicity. Although P3 can be detected in amyloid plaques, very few reports suggest deleterious effects on neurons. Hence, the α-secretase-processing pathway is referred to as nonamyloidogenic.[26,27]

Numerous enzymes have α-secretase activity including the ADAM (a disintegrin and metalloproteinase) family. These proteins all have α-secretase cleavage activity, but differential patterns of expression.[28–30]

In "normal" mice, overexpression of ADAM10 does not appear harmful; however, in transgenic models of AD, neuronal function can be restored by ADAM10 overexpression. For instance, Postina *et al.*[31] demonstrated that increased α-secretase expression prevents plaque deposits in aged animals overexpressing hAPP.

In contrast, overexpression of inactivated ADAM10 (mADAM10) in APP mice worsens amyloid aggregation. In a water navigation task, mADAM10/APP double transgenic animals showed deficits in the acquisition phase of place learning and in the probe trial, whereas the ADAM10/APP double transgenics performed similarly to control animals. Long-term potentiation (LTP) was also improved in the double transgenic mice as compared to APP transgenics, suggesting a rescue of synaptic plasticity by increased α-secretase activity. Previous findings from Moechars *et al.*[32] corroborate these results: in transgenic animals carrying a modified hAPP in which the α-secretase cleavage site has been altered (APP/RK), similar results were observed. The APP/RK transgenic animals showed increased APP expression with a shift toward β-site cleavage amyloid peptides. Additionally, these animals had shorter life spans than control mice, were more aggressive and hyperactive, and displayed abnormalities in the amygdala, cortex, and hippocampus.[33]

TAU In addition to the "amyloid-related" transgenics, complementary mouse models have been developed that overexpress human tau in its normal and/or mutated forms (including a form associated with frontotemporal dementia and Parkinson's disease, FDPD).

Human tau proteins are encoded by a gene on chromosome 17. Six brains isoforms resulting from alternative splicing have been described and can be divided into two classes: proteins with three C-terminal repeat domains (3R) and proteins with four domains (4R). Most transgenic models have been generated with one of the mutated 4R forms, varying from "regular" 4R tau to mono-mutated forms (P301L, P301S, V337M) and multiple-mutated 4R forms.

Although tau-related pathologies have been detected in the brains of these transgenics,[9,10] few studies have characterized these animals behaviorally.

In the elevated plus-maze, 11-month-old transgenic mice overexpressing the V337 mutant tau gene displayed less anxiety-like behavior compared to their wild-type littermates. In contrast, no differences were detected in a water navigation test. These animals showed impaired habituation in an open-field exploration task. Additionally, these tau transgenic mice showed an irregular neuronal-shaped hippocampus and altered neuronal activity.

Another related line carries the R406W tau mutation (found in human subjects with a tauopathy resembling AD). Observations made in aged animals (ranging from 16 to 23 months of age) revealed a blunted fear response to cues, but not to context, after 2 days of conditioning. The same animals showed lower levels of contextual fear after 15 days of conditioning, suggesting that long-term memory loss may be more dramatic in aged R406W tau transgenic mice. These data suggest that there is a deficit in associative memory in mice overexpressing a mutated tau gene. Neuroanatomically, transgenic mice develop tau inclusions in the hippocampus, amygdala, and neocortex, structures known to be involved in memory formation.[34]

Subtle differences and specific impairments were also observed in transgenic mice overexpressing the P301L mutation of tau.[35] Aggregation and NFTs were observed in many brain areas, including the amygdala and the hippocampus, brain regions that are also severely affected by NFTs in AD patients. Because these mice show accelerated extinction in a conditioned taste aversion test, the authors evaluated their behaviors in tasks requiring an intact hippocampus, including the Morris Water maze and the Y maze. Differences were detected only in spatial working memory, with mice showing greater impairment with age, starting at 6 months. However, the transgenic mice were more active and slightly less prone to novelty-induced anxiety, which suggests that the impairment observed in these mice is not related to affective behavior unrelated to the hippocampus.

POLYTRANSGENICS Because Aβ and tau are two primary, and complementary, factors in the development of AD, and because the presenilins are clearly genetic susceptibility loci for the disease,[36] the interactions of these proteins were tested by engineering a triple-transgenic mouse model. To generate these mice, two transgenes (Tg2576, an APP mutant, and tau P301L) were transferred onto a PS1-heterozygous knockin mutation background. Triple-transgenic (3xTg) mice developed progressive age-dependent neuropathology, including plaques and tangles. Remarkably, the pattern of evolution of these abnormalities closely mimics some of those described in AD. In these mice, presynaptic dysfunction and LTP deficits precede the accumulation of extracellular Aβ. This suggests a significant role for intracellular Aβ in AD-dependent pathology, even in the absence of structural changes. Plaques first appeared in cortical regions, then in the hippocampus, and later in the amygdala, whereas tangles followed the reversed pattern, beginning in the amygdala. This sequence of events is in line with the amyloid cascade hypothesis of AD (cf. Figure 55–1). 3xTg mice also demonstrate age-dependent cognitive deficits.[37] The earliest cognitive impairments were recorded at 4 months of age, and were characterized by a deficit in long-term memory correlated with the intraneuronal accumulation of Aβ in the hippocampus and amygdala. No plaques or tangles could be detected at this age, suggesting that

they contribute to cognitive dysfunction only at older ages. Immunotherapy treatments eliminated intraneuronal Aβ deposits and, consequently, rescued the deficits observed in hippocampal-dependent cognitive tasks. The reemergence of Aβ pathology after immunotherapy led to the return of the cognitive deficits observed before treatment. Given these promising results and the very integrative nature of this model, triple transgenic mice have now been studied further and offer promising insights on the sequence of molecular and cellular events leading to AD.[38]

A NOTE ON EPIGENETIC AND ENVIRONMENTAL FACTORS IN ALZHEIMER'S DISEASE GENETICALLY MODIFIED MOUSE MODELS

Because familial cases of AD represent only 15% of AD and because genetic factors are essentially risk factors, an important field of research aims to determine the interaction between epigenetic factors and specific genetic alteration in an effort to identify gene–environment interactions. Two studies by Lazarov *et al.*[39] and Jankowsky *et al.*[40] have investigated the effect of long-term exposure to an enriched environment on double transgenic mice coexpressing APPswe and PS1 polypeptide variants. Although there are some discrepancies in the results (see Lazarov *et al.*[39] for discussion), the results unequivocally demonstrated that environmental factors can influence amyloid deposition in a gene-dependent fashion. Identifying other environmental factors that modulate disease progression could be very valuable in the treatment or prevention of AD.

CONCLUSIONS

Genetic mouse models have enhanced our understanding of the pathogenesis of AD and its underlying mechanisms. While inherent differences between mice and humans will always limit our ability to model this disease in animals, recent studies demonstrate that it is possible to generate plaques and tangles in a mouse, similar to human neuropathology. The evolution of both quantitative and qualitative genetic mouse models of AD has provided invaluable tools to better understand this pathology, along with the possibility of developing new therapeutics. When looking at the progress accomplished between the first transgenic models of AD and the current development of neuron-specific, conditional and polytransgenic models, it is clear that genetic models of AD will play an important role in finding a cure for this disease.

56 Rat Models of Experimental Autoimmune Encephalomyelitis

Erik Wallström and Tomas Olsson

ABSTRACT

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system (CNS) leading to neurological deficits. The relative inaccessibility of the CNS for sampling and the problems of experimental manipulations in humans make proper experimental models indispensable for progress in the basic understanding of the disease as well as for testing of therapy. There is no single experimental model mimicking all aspects of MS and a model should be chosen based on the scientific question being investigated. We describe our experience with antigen-induced models in the rat species. The clinical course of disease, monophasic versus relapsing/protracted, and the histopathological features depend on the strain of rats used, their MHC and non-MHC genes, as well as the myelin autoantigen used for immunization. Other factors such as age, weight, and gender also influence the outcome. Use of myelin oligodendrocyte glycoprotein in DA rats results in an MS-like relapsing disease with plaques of demyelination. Use of myelin basic protein in LEW rats results in an acute monophasic inflammatory disease with little demyelination. Several disease-determining factors and practical schemes for MS models in rats are presented.

Key Words: Multiple sclerosis, Autoimmunity, Myelin, Myelin basic protein, Myelin oligodendrocyte glycoprotein, Proteolipid protein, T cells, B cells, Antibodies, Major histocompatibility complex, Genetics, Demyelination, Inflammation, Axons, Neurons, Oligodendrocytes, Astrocytes, Macrophages, Microglia.

GENERAL CHARACTERISTICS

WHY MODEL MULTIPLE SCLEROSIS? Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS) with foci of inflammation, demyelination, and damage to axons. It is typically a disease of the Western world with prevalence there varying from 0.5 to 2 per thousand. This distribution most likely depends primarily on a higher genetic predisposition in these countries, but differences in environmental factors may also play a role. Despite its relatively low incidence and prevalence, it has a major impact on the afflicted individual and on society as a whole; its impact is also economic, since the disease starts early in life and persists for decades. In addition, drug companies have realized that MS is a valuable target, since currently approved drugs either have only modest effects or can result in rare but fatal adverse events.

Since there is a great medical need for better and safer treatments, in turn requiring better knowledge of disease mechanisms, MS continues to be a strong focus for research both in academia and in the pharmaceutical industry; disease-appropriate animal models are therefore indispensable for further progress. This is particularly so in MS, because the CNS is relatively inaccessible for sampling, observations in humans in most cases are descriptive, and experimental manipulation in humans is rarely possible.

In principle, a rodent model for MS can be used for studies of disease mechanisms, either by classical hypothesis-driven methods or by unbiased genetic tools, or for studies of new therapeutic strategies. There is no single model of experimental autoimmune encephalomyelitis (EAE) that covers all aspects of human MS, and the choice of a particular EAE variant should be carefully thought through depending on the scientific question.

To enable such a selection of a model, in depth knowledge of the natural course of the disease and its basic immunopathology is necessary. We refer the reader to several recent reviews on these topics, and give a summary of the most critical factors in the following.

MULTIPLE SCLEROSIS: COURSE AND SUBPHENOTYPES MS rarely starts before the age of 15 or later than 50 years. The average age of onset is 28 years, with a 2/1 female/male ratio. In about 85% of all cases of MS the disease follows a remitting relapsing course, with relapses of new neurological deficits on average every second year. Recovery can be complete or incomplete. Interestingly, the introduction of magnetic resonance imaging (MRI) into the study of MS has shown that there are up to 10 subclinical inflammatory events in the CNS on each clinical recognizable relapse. With time, most patients enter a secondary chronic progressive course with steadily increasing neurological defects. The mean time from onset to this phase is around 15 years. Current dogma suggests that the mechanisms during this progressive phase differ from those during the relapsing phase. None of the currently approved drugs for MS has had any effect on the progressive phase of the disease. Of MS patients, 10–15% start with a steady progression, categorized as primary progressive MS. Of note, few rodent MS models can mimic these very chronic aspects of MS.

The symptoms and signs of MS vary depending on where in the CNS the inflammatory lesions occur, and almost all

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

neurological functions can ultimately be affected. These are focal neurological disturbances. In addition, MS is accompanied by general symptoms and signs.

To enhance the understanding of the MS models described below we provide a short summary of common signs.

Afferent neurological functions are often affected. Patients may develop regional hypoesthesias/paresthesias and defects in deep sensation. Optic neuritis, with loss of vision in one eye, is common. In most cases vision recovers over weeks. Brainstem lesions may lead to signs such as dysfunction of ocular motility and central vertigo. Cerebellar lesions can lead to dystaxia. Motor tracts are often affected, resulting in monoparesis of an extremity, most often in legs, hemiparesis, or paraparesis. In the chronic progressive phase a slowly increasing paraparesis folowed by tetraparesis is common.

General signs include fatigue, which most patients refer to as their worst manifestation of MS. Depression is common. A mild or modest decrease of cognitive function occurs in up to 50% of MS patients. In quite rare instances full blown dementia may develop.

Just as there are scoring scales for the EAE models described below, there are rating scales for MS, used in clinical follow-up or during clinical drug trials. The best established is the expanded disability scale (EDSS), with which different neurological functions are assessed and rated in a neuroexamination. These are added together to produce a score from 0 to 10 : 0 is no neurological dysfunction, 6 reflects decreased motor function with the patient able to walk 100 m with unilateral support, and 10 is death due to MS. The multiple sclerosis functional composite (MSFC) is a more recently introduced scale in which performance on a simple cognitive test, motor function in the upper extremity, and walking ability are added together. There are numerous other scales, some based on patient self-report and some measuring quality of life.

MULTIPLE SCLEROSIS: HISTOPATHOLOGY MS histopathology is characterized by foci of inflammation, demyelination, and damage to neurons/axons. Initial periventricular lesions are composed of mononuclear cells, mainly macrophages, as well as an abundance of lymphocytes: $CD4^+$, $CD8^+$, T cells, and B cells. Demyelination ensues through macrophage attack. In addition, axons are damaged in this acute inflammatory attack.[1] Further damage to axons also occurs more chronically.

Classical demyelinated plaques varying in size from millimeters to centimeters ensue; these also contain astroglial scarring. To a variable extent demyelinated axons may become remyelinated by oligodendroglial precursors that are recruited.

PRESUMED IMMUNE PATHOGENESIS The formal proof for any autoimmune or alternative viral etiology is lacking. However, there is strong circumstantial evidence suggesting an autoimmune pathogenesis based on the following: (1) Increased numbers of myelin autoreactive T and B cells enriched to the cerebrospinal fluid can be detected in persons with MS. (2) Certain HLA class II alleles, gene products being restriction elements for $CD4^+$ T cells, dispose for MS. (3) Genomic regions disposing for MS overlap regions defined in rodent models known to be autoimmune.[2] (4) The organ specificity of the inflammatory attack in MS is most easily reconciled in the context of the immune system, perhaps the only system able to discriminate between such a broad variety of molecular targets. Finally, (5) some of the induced EAE models described in this chapter closely mimic both the clinical course and histopathological features of MS.

Based on immense numbers of studies in EAE and descriptive observations in human MS, a condensed sequential immunopathogenesis of MS can be described as follows.

For unknown reasons CNS autoantigen-reactive T cells become activated in the periphery (lymphoid organs/systemic circulation). Upon reaching the endothelium at the blood–brain barrier secretion of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ) cause endothelial upregulation of adhesion molecules such as intercellular adhesion molecule (ICAM) and vascular cell adhesion modules (VCAM). The latter seem of special importance as demonstrated in EAE.[3] The very late activation (VLA)-4–VCAM interaction allows activated T cells to pass into the CNS parenchyma, and upon rerecognition of a specific CNS autoantigen the T cells become reactivated with secretion of proinflammatory cytokines, inducing a further inflammatory cascade with recruitment of macrophages, chemokine secretion, etc. There is also a potential role for myelin-specific autoantibodies binding to myelin with destructive potential in the form of complement-mediated lysis or opsonization for macrophage attack. Most likely a series of downmodulatory events later takes place involving an endogenous steroid response and cytokines such as tumor growth factor-β (TGF-β) and interleukin 10 (IL-10).

One of the few experimental situations we have in human disease is during clinical trials against specific targets. The most effective treatment against MS hitherto demonstrated is blockade of VLA-4 with a humanized monoclonal antibody, reducing relapses by 68% and new MRI lesions by 90%. This is striking evidence in support of the idea that inflammation causes MS pathology, and not the opposite, which occasionally has been suggested. For this reason, experimental models built on induction of a systemic immune response attacking the CNS are relevant for MS pathogenesis.

Apart from a purely immunological pathogenesis, there is a growing interest in target-related factors. Thus, the CNS structures in the form of the blood–brain barrier, glial cells, and neuron axons take part in the pathogenesis of the disease, and there may well be genetically regulated differences in the function of these structures upon an inflammatory insult potentially explaining interindividual differences in outcome. For example, certain patients seem to do well despite intense inflammation in the CNS, while others suffer from severe sequelae after less intense inflammatory insults. It is likely that there is an important neurodegenerative aspect of MS in the chronic progressive forms of the disease.

THE GENETICS OF MULTIPLE SCLEROSIS Since the genetic background is well known to profoundly affect immune responses in general and also rodent MS models, we here provide a short note on what is known about the genetics of MS. Furthermore, if the particular genes disposing for MS can be found, they will denote primary causative pathogenic pathways, which will pave the way for therapy and prevention. As discussed below, rodent MS models may assist in the finding of such genes.

There is solid evidence for genes affecting the risk and course of MS, which is particularly clear from observations in twins, with an approximate concordance rate of 30% in monozygotic twins versus 2–4% in dizygotic twins.

The human leukocyte antigen (HLA) complex is the best established and proven genome region regulating MS. It contains around 200 genes, most of which are involved in immune

functions. Mapping of influences within the complex is difficult due to a strong linkage disequilibrium between genes in the complex. However, there is strong evidence that the class I and II genes are involved. Different alleles of HLA class II genes may either dispose for or protect against MS.[4] Class I genes also affect MS.[5] The basic reasons for these effects are not known, but current knowledge strongly suggests that the influence is related to the basic function of the HLA molecules, which is to bind antigenic peptides and present them to T cells. It can be argued that knowledge concerning those genes important for MS has been pivotal in the current focus on new therapies for MS directed toward interfering with T cell function.

The major histocompatibility complex (MHC; in humans equal to the HLA) molecules are among the most polymorphic genes existing in mammals, allowing a broad repertoire of peptides at the population level to be presented to the immune system; this in turn helps ensure that infectious agents do not develop strategies to escape host immunity. Thus, preferential or promiscuous binding of myelin autoantigen peptides is an explanation for the MHC regulation of MS. In this context it is worth noting that these phenomena have instrumental impact on the handling of the experimental models discussed below.

Non-MHC genes also regulate MS. However, several linkage screens have failed to demonstrate any genome regions apart from the HLA complex with major impact on MS. This in turn suggests that many genes are involved and each has a low or modest impact, which in turn has impeded their positioning. Present speculation suggests odds ratios in the range 1–2. Only a few non-MHC genes, such as the PRKCA and IL-7 receptor and a chemokine gene cluster,[6–9] have more definite evidence of support.

The outcome of human linkage screens discussed above as well as gene mappings in rodent models suggest that the number of genes with some degree of influence on MS may be around a hundred.[10] This non-MHC genetics may also have relevance for experimental modelling of MS, especially when MS genes are better defined. It also relates to the probable genetic heterogeneity of MS, that is, different genes may predispose for the same end phenotype in the form of MS, and thus potentially result in very different mechanisms. This may require different therapeutic strategies. In the future it may be possible to utilize genetic information for tailor-made therapy, in which individuals/families with particular sets of MS-disposing genes accordingly receive adapted therapies.

The non-MHC genetic background of different rodent strains is thus important to consider when evaluating the outcome of an experiment or experimental therapy. With time pharmacogenetically defined strains may be at hand (see more below).

EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS: HISTORICAL NOTES AND CURRENT DEBATE EAE historically emanated from research devoted to understanding the cause of neuroparalytic accidents of rabies vaccination. Some individuals developed an acute or subacute encephalomyelitis weeks after the rabies vaccination. The virus was grown in brains and the inoculum was contaminated with CNS material. Experiments by Rivers and Schwentker tested the brain material alone, which gave rise to encephalomyelitis in a proportion of monkeys. Later, introduction of Freund's adjuvant led to a much more reproducible disease induction. This experimental disease reflects acute disseminated encephalomyelitis (ADEM) rather than MS, which has a chronic relapsing course. As described below, there are now a series of chronic relapsing models that better mimic MS. For more than 50 years there has been continuous debate on EAE as a model for MS, relating to different views on the presumed etiology, the predictability of data in the models versus validity for MS, and the "spontaneous" occurrence of MS versus the need for active induction in rodents. John Alvord, Jr., one of the pioneers in research on EAE and myelin basic protein, in 1984 presented a graph charting the ups and downs in his belief in EAE as a model for MS[11]; this varied from close to 100% when myelin basic protein (MPB) was found to be a discrete encephalitogen to 0% when antimeasles antibodies were found in MS cerebrospinal fluid, suggesting measles as the cause of MS. In 1984 he was 80% convinced that EAE was a good model for MS.

Recently at least three studies have addressed these issues. First, a negative study argued that therapies developed in EAE do not work in MS.[12] An opposing view was presented by Steinman and Zamvil,[13] who argued that at least two therapies in MS, glatiramer acetate and anti-VLA-4 blockade, are completely based on EAE experiments and are of therapeutic use in MS. An intermediate view was presented by Ransohoff.[14]

It is often argued that EAE is not a good model for MS since it needs to be induced, whereas MS is spontaneous. However, twin data and epidemiological data strongly suggest that MS is also induced, or triggered by so far unknown events (infection is a common speculation). In particular, the 70% discordance rate in monozygotic twins suggests triggering by environmental factors.

PRINCIPAL MODELS OF EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS AND A NOTE ON THE SELECTION OF SPECIES

EAE can be induced in practically all species, and most commonly in the mouse or rat. For very select questions nonhuman primate models may be used, for example, when testing reagents that are specific only for primates including humans.

The mouse species has a number of advantages: it is small and therefore inexpensive to keep and breed, accessible for gene deletions, which is not yet possible in the rat, and transgenic expression of genes is easier. For genetics, the mouse displays a full genome sequence accessible on the internet, with single nucleotide polymorphism (SNP) and microsatellite maps. However, in our experience the models accessible in the mouse have been less reproducible and there is a paucity of chronic mouse models closely mimicking the course and histopathology of MS.

In this chapter we deal only with rat models, with which we have extensive experience. Here, a series of easily reproduced acute and chronic models are at hand. The rat genome sequence is now also available on the internet (ensemble.org), there is a microsatellite map, and SNP maps will appear. There is also access to a wide variety of EAE-susceptible and resistant inbred strains. Well-controlled acute monophasic as well as protracted relapsing EAE forms are at hand.

Many of these models are now routinely used by the pharmaceutical industry in evaluating new drug principles. A common problem in such experimentations is that drugs developed to fit human structures, irrespective of whether the drug is a monoclonal antibody, soluble receptor structure, or a low-molecular compound, often either have no or much lower binding affinities

to the rodent target. The solution to this is either parallel development of rodent-specific compounds or transgenic expression of the human target in the rodent.

The following induction methods can be discerned in principle.

Adoptive Transfer Experimental Autoimmune Encephalomyelitis That EAE had a central T cell-mediated pathogenesis was demonstrated in the early 1980s.[15,16] Myelin antigen reactive T cells were recovered from actively immunized mice or rats, cultured *in vitro* in the presence of stimulating antigen, and after several rounds of *in vitro* stimulation monospecific T cell lines and clones were obtained that upon transfer to naive syngeneic recipients caused EAE, in most cases with an acute monophasic disease course, with widespread inflammation in the CNS, but with little or no demyelination. This methodology has had enormous impact on the understanding of certain aspects of autoimmune disease, especially on questions such as T cell trafficking and the understanding of central features of T cell biology important for neuroinflammation. This form of EAE is therefore useful in studies of similar types of questions, but perhaps not in situations in which a disease course and pathology closely mimicking MS is required. We will not describe this form of EAE further.

Cotransfer Experimental Autoimmune Encephalomyelitis For studies of the additive or synergistic role of autoantibodies, research groups invented cotransfer models, in which autoimmune T cells were transferred along with myelin-specific antibodies. For example, in this way it was demonstrated that antibodies alone did not cause disease, but required the elicitation of CNS inflammation by the T cells.[17] Consequently this type of methodology can be used to address similar questions on the role of antibodies. We will not discuss this methodology further.

Actively Induced Experimental Autoimmune Encephalomyelitis The experimental animal is immunized with a CNS autoantigen, in most cases together with an adjuvant (mineral oil + mycobacteria, and sometimes also injection of pertussis toxin). This recruits an autoimmune T and B cell response causing EAE with either an acute monophasic or chronic relapsing course, depending on the autoantigen and/or the strain of rodent used. Detailed descriptions of this methodology will be provided below.

Certain viral infections in rodents, such as Theiler's murine encephalomyelitis, are accompanied by recruitment of an autoimmune response, where there is strong evidence to support the idea that this autoimmune response may be responsible for the chronic relapses that ensue.[18]

Transgenic Induction of Experimental Autoimmune Encephalomyelitis With recent still more fine-tuned, elaborate use of transgenic techniques, "spontaneous EAE" may occur. Thus mice are constructed in which a high proportion of the T cells expresses human T cell receptors for myelin autoantigens. The mice can be further manipulated to express human MHC molecules and T cell costimulatory molecules. In addition, they can transgenically express B cells producing myelin-specific antibodies. All these mouse variants, to a variable extent, display spontaneous EAE, which interestingly also varies depending on the laboratory environment in which they are kept. Naturally, these types of mice, although highly artificial, can be used for mechanistic studies.[19–21] It is a semantic question as to whether these forms of EAE should be regarded as spontaneous or induced. We think that the genetic manipulation represents a form of active induction. Potentially, these mice could also be interesting to explore with regard to environmental triggers that may precipitate disease in extremely susceptible rodents. We will not explore these EAE models further.

ACUTE MONOPHASIC OR CHRONIC RELAPSING EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

One of the oldest and best characterized EAE models is induced in LEW rats by subcutaneous immunization with MBP (derived from guinea pigs), or MBP_{gp} 63–88 peptide, emulsified in complete Freund´s adjuvant (mineral oil and heat-killed *Mycobacterium tuberculosis*). The first clinical signs of disease appear approximately day 9–10 postimmunization (pi) in the form of sudden weight loss. By approximately day 10–11 pi tail weakness is evident, progressing to hind leg weakness and eventually complete paralysis of the hind legs at day 12–13 pi A recovery phase follows, with complete (or nearly complete) gain of hind leg and tail function at day 16–17 pi. A small number (0–10%) of animals may have a second relapse around day 22–24 pi, but otherwise they stay healthy, and are resistant to further attempts to induce EAE.[22] Similar to MS, inflammatory infiltrates in the CNS are most common around small veins, but in the MBP-induced LEW rat model, lesions are found only in the spinal cord (they develop caudally to rostrally and parallel clinical signs of paresis) and not in the brain. At affected levels in the spinal cord, the whole parenchyma is infiltrated by $CD4^+$ α-β cells and activated macrophages. Some $CD8^+$ α-β cells, NK cells, γ-δ T cells, and B cells may also be present, and there are signs of activation of CNS resident cells (especially microglia).[23] Most other EAE models are "variations on the theme" described above, but may include features such as a high frequency of relapsing disease and/or demyelination.

In contrast to MBP-induced EAE in the LEW rat, rMOG (aa 1–125)-induced EAE (MOG-EAE) in DA rats displays both a high frequency of relapsing disease and focal inflammation with demyelination in the CNS.[24,25]

Clinically, relapsing-remitting signs of neurological dysfunction characterize MOG-EAE. However, there are also rats displaying chronic (nonremitting) signs of disease, acute lethal disease, or mild, very late clinical disease [occasionally DA rats have displayed no signs of clinical disease until day 50–60 postimmunization (unpublished observations)]. Therefore, MOG-EAE is similar to MS in its diversity in individual clinical courses. Rats may present with only one lesion in the optic nerves and one lesion in the spinal cord, mimicking the MS subtype Devic´s disease. Active demyelination is associated with the deposition of immunoglobulins and complement component 9 (C9), indicating antibody-dependent demyelination. Immunologically, there are signs of activation of both cellular and humoral anti-MOG-specific lymphocytes. This is again similar to MS, where both T and B cell responses to MOG and other myelin antigens are present.[26,27]

Due to the gradual release of antigen in actively induced disease, it is difficult to determine whether "chronic" EAE can be considered "truly chronic." If chronicity is defined as a "self-perpetuating" condition in which signs of disease continue indefinitely even after the removal of the initial trigger, then actively induced EAE is not proven to be chronic. Another problem with chronicity in EAE is the occurrence of irreversible neurological deficits. It is not difficult to devise a situation in which an acute inflammation causes irreversible neurological deficits due to

destructive lesions in the CNS. Signs of disease may then persist indefinitely after the disappearance of the acute inflammation.

PRACTICAL CONSIDERATIONS

CENTRAL NERVE SYSTEM AUTOANTIGEN Autoantigens for EAE-inductions may be purified (myelin) proteins, recombinant proteins, synthesized peptides, or even whole spinal cord and brain homogenates. There are pros and cons with all of these approaches. Purified myelin components may contain contaminations from other myelin proteins and a mixture of antigens is obviously also the case when whole spinal cord homogenates are utilized. Recombinant proteins circumvent the problem of contamination by other myelin proteins, but introduce potential immunologically active contaminations from the production system (often bacteria). Peptide-induced EAE may be complicated by the nonphysiological tertiary structure of peptides[28] and nonphysiological epitope selections.[29]

If a relapsing/remitting disease course is desired, rMOG seems to be the most consistent antigen to use, particularly with DA and LEW.AV1 rats. rMOG here denotes recombinant MOG aa 1–125 (the N-terminal Ig-like extracellular domain), since full-length MOG is difficult to express due to its low solubility. If disease is induced by MBP peptides, monophasic EAE usually ensues.[30,31] In adoptive transfer EAE, the antigen specificity of the transferred cells determines the topography of the CNS lesions and the extent of both parenchyma inflammation and macrophage activation.[32] Thus, the choice of antigen determines both clinical and histopathological disease expression.

DOSE OF ANTIGEN Although rarely discussed in studies on EAE, the dose of antigen may dramatically affect disease expression. Usually, titration experiments with three or four doses of antigen are necessary to set up experimental conditions before the actual experiment is started. In MOG–EAE, a reduction of the amount of antigen in the immunization may result in conversion of an acute lethal disease to a chronic disease, or to no disease.[24] Suggested immunization protocols are discussed in the section on Immunization below.

ADJUVANTS The minimum adjuvant utilized in most EAE studies is incomplete Freund´s adjuvant (IFA). IFA is a mixture of mineral oils, and it has by itself a complex impact on the immune system, including triggering of oil-induced arthritis in DA rats.[33,34] IFA protects the antigen from rapid degradation and thereby prolongs its exposure to the immune system. Macrophage phagocytosis may also be facilitated by a more particulate physical state of the antigen.[35]

Heat-killed *Mycobacterium tuberculosis* may be added to the IFA, resulting in complete Freund´s adjuvant (CFA).[36] CFA is a classical adjuvant, and has been utilized extensively to boost both cell-mediated and humoral immune responses to antigens with which it has been emulsified. The downside of using CFA as adjuvant is that it adds complexity; mycobacterial antigens interact with the immune system at several levels and responses to mycobacteria are genetically regulated.[37] In most EAE induction protocols, CFA is required to induce disease, while IFA induces protective immunity. The ability to induce EAE in DA rats with rMOG/IFA alone is therefore unique and reflects both the strong sensitivity to adjuvants in rats (especially DA rats)[38,39] and the potent encephalitogenic properties of MOG.

EMULSION The relation between encephalitogenicity and the size of the water/oil emulsion droplets in the inoculum has been studied by Maatta *et al.*[40] Increased encephalitogenicity was associated with the small size of the droplets (achieved by sonication instead of extrusion). A small droplet size corresponded to a large surface area, which preferentially contained antigen. In the extruded emulsion, the antigen was buried in the droplet interior. Even so, most EAE induction protocols do not favor sonication, and a proper emulsion is acquired by mixing the water/oil emulsion in a syringe, or rather two connected syringes. Glass syringes are preferable to plastic, since plastic syringes tend to "clog" from the emulsion. At the beginning of mixing, the emulsion is easily passed through the syringe, but after a while, the texture changes and it takes more force to compress the syringe. The emulsion is then ready to be used. However, before use, the emulsion may be tested by putting a drop in a beaker filled with water. The drop should not immediately dissolve in the water, but rather remain as a drop, or dissolve very slowly.

IMMUNIZATION In our hands, subcutaneous EAE induction is less effective than intradermal immunization. However, it is not always easy to achieve a completely intradermal location, especially with a volume of 200 µl, which is a common injection volume. If CFA adjuvant is utilized, rather than IFA, the immunization must always be subcutaneous, to avoid local inflammation and formation of a wound at the site of injection. A needle diameter of 0.6 mm is most often our choice. Thinner needles are difficult to use due to the consistency of the emulsion. It is advisable to make extra emulsion (for 5–10 extra animals) to avoid having to repeat the procedure if spills or other mistakes occur during the emulsification or immunization. It is also important to avoid self-injections, since it may trigger neuroinflammatory disease in certain individuals. We are aware of one such case in which the needle penetrated the skin of the hand with a minimal deposition of inoculum, and the person developed a subacute EAE-like disease. We therefore recommend a minimal surgical excision of the injection site if self-injection indeed occurs.

STRESS An old, but seldom systematically studied observation is that nonspecific stress may profoundly suppress EAE. When designing EAE experiments, care should be taken to avoid disturbances such as noise, changes in animal caretaker staff/routines, and experimental manipulations such as blood samples. Stress effects seem to be most pronounced before the appearance of clinical signs of EAE.[41,42] It has been suggested that differences in neuroendocrine function may constitute part of the non-MHC regulation of strain susceptibility/resistance in EAE.[43]

SEASONAL EFFECTS Seasonal effects are not well recognized in the EAE literature, but there are some reports. In 2004, Teuscher *et al.* reported increased susceptibility in mice immunized during the summer.[44,45] In contrast, our own experience is that EAE susceptibility (and fertility) in rats is reduced during the summer months (unpublished observation). It is unclear if the difference is due to the different types of animals or if the local environment is more important.

AGE AND WEIGHT Very young animals with immature immune systems differ in their response to EAE induction.[46] We avoid using rats weighing less than 150 g. In adult animals, age may be a factor of importance, in turn intimately linked to weight. Weight is important mainly with "mild" induction protocols, i.e., low doses of rMOG in IFA, while induction protocols with high doses of autoantigen and adjuvant are less sensitive to differences in animal weight. Since age-dependent weight increases differ in different rat strains, it is particularly important to consider weight

when comparing different strains. Among the common strains utilized in rat EAE experiments, LEW and PVG rats gain weight faster than DA and ACI rats. Also, male rats gain weight faster than female rats, so all gender comparisons need to consider this factor.

GENDER The impact of gender differs depending on the EAE model studied. In monophasic LEW rat EAE, induced by guinea pig spinal cord homogenate, males are usually more susceptible than females.[47] In SJL mice injected with PLP 139–151-specific T cells, female donor cells mediated more severe EAE than male donor cells.[48] In our own experience, monophasic MBP or MBP peptide-induced EAE is more severe and reliable in males, while MOG-EAE is more severe and reliable in females.[24,49,50] Mechanisms for gender influences in EAE may include direct hormonal effects on T cells and/or regulation by gender-specific non-MHC loci.[51,52] The Y-chromosome itself has been implicated as harboring such loci in mouse EAE.[53] In MS, the female-to-male ratio is 2 : 1.[54]

BREEDER AND SUBSTRAIN Inbred strains are, by definition, genetically homogeneous. However, if identical inbred strains are bred separately for several generations, accumulation of spontaneous mutations ("genetic drift"), residual heterozygosity, and/or accidental contamination by genetic material from other rat strains may well result in the establishment of "substrains."[55,56] Substrains are well known to differ in their susceptibility to EAE (and other autoimmune diseases).[57] Among the strains commonly utilized in EAE studies, LEW and BN rat substrains differ in their susceptibility to EAE, while there has been fewer problems regarding substrain differences in DA, PVG, and ACI rats.

MAJOR HISTOCOMPATIBILITY COMPLEX AND NON-MAJOR HISTOCOMPATIBILITY COMPLEX GENES Classically a series of different rat strains, differing in both their MHC and non-MHC genes has been divided into resistant or susceptible strains, mainly based on susceptibility to MBP or whole spinal cord-induced disease.

First, resistance or susceptibility should be used as relative terms since use of stronger immunization protocols can overcome genetic barriers.

Second, both features may reside in both the MHC complex and among non-MHC genes. As an example, the classical MBP EAE-resistant strain, the BN rat, is relatively resistant to EAE due to both non-MHC genes and an MBP nonresponder MHC haplotype.[58,59] However, the BN rat MHC (RT1N) is strikingly responsive to MOG, as demonstrated with RT1N on the EAE-susceptible Lewis non-MHC background.[24]

In the following section we discuss these matters in some detail.

WHY IS THE RAT STRAIN CRUCIAL IN SETTING UP AN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS MODEL?

MAJOR HISTOCOMPATIBILITY COMPLEX GENE IMPACT ON RAT EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS The influence of the MHC gene on EAE was recognized in the early 1970s,[60] as well as the influence of the HLA gene on MS.[61–63] The full genetic composition and distribution of rat genes are known in detail.[64] There are about 200 genes in the rat species, with the region divided into classical class I (Ia), class II, class III, and nonclassical class I (Ib) genes, situated in that order on rat chromosome 20. The nomenclature for the rat MHC is RT1, in which RT1A corresponds to classical class Ia genes, which corresponds to HLA A in humans. RT1B denotes class II genes corresponding to human HLA-DQ and mouse H2-A. The rat RT1D corresponds to HLA-DR and mouse H2-E.

Rat strains can be selected according to their MHC, based on their response to particular autoantigens (Table 56–1). Thus, there are different MHC restriction patterns depending on the particular autoantigen used for immunization. It is possible to select inbred rat strains with varying MHC on different genetic backgrounds, either with a relative non-MHC resistance or susceptibility.

In addition, there are strains with recombinations within the MHC providing options for a rough positioning of MHC regulation within the MHC complex. Use of such rats has positioned the major EAE regulation to the class II genes, with additional influences from other parts of the MHC.[24,5865] Mechanistically, the influence of class II is perhaps most easy to understand, especially with regard to peptide-induced EAE.

Starting with the most classical rat EAE, induced with MBP in the Lewis rat (RT1L), immunodominant stretches of the molecule have been defined. These comprise the MBP 63–88 region and the 89–101 region. Classically heterologous MBP of guinea pig origin has been most effective in inducing EAE in the Lewis rat. Interestingly, on the RT1U haplotype the rat sequence is as effective.[66] There is only a one amino acid difference in the core region of the peptide-binding site at position 79, by a single exchange of threonine (T) to serine (S). Despite the heterologous character of this guinea pig peptide, the fact that disease ensues must mean that recruited T cells recognize endogenous rat MBP. With these peptides, the use of intra-MHC recombinant strains between responder and nonresponder MHC has resulted in the mapping of major influences to the class II genes.[59] Use of peptide-binding assays has demonstrated that RT1B molecules restrict the response to the 63–88 peptide, while RT1D restricts the MBP 89–101 response.[67] Similar studies with MOG peptides on a series of rat MHC haplotypes have shown that MOG 91–108 is dominantly encephalitogenic.[68]

Since the basic function of class II genes is to present peptides to $CD4^+$ T cells, the regulation of class II MHC is likely to depend on differences in the peptide-binding abilities of the different class II variants. Peptide-binding studies with purified class II molecules from different MHC haplotypes have shown that dominantly immunogenic peptides in the rat bind with high or moderate affinity.[67] Peptides that bind poorly tend to be nonimmunogenic. This may be a difference compared to one example in the mouse in which the encephalitogenic MBP 1–10 is a poor class II binder. In addition, only a fraction of immunogenic peptides in the rat is encephalitogenic, suggesting that there are additional factors, perhaps in the quality of a class II-regulated immune response, that determine pathogenicity of the ensuing immune response, a topic that still is unresolved in autoimmunology.

Use of intra-MHC recombinant rats has also evidenced a function of the class I-$CD8^+$ T cell pathway in EAE, in which certain alleles may recruit a protective disease downregulatory immune response.[65]

Less well studied are influences from the class III region on EAE. However, there are indications that genes in this region may influence histopathological features of MOG EAE, such as the degree of axon loss and demyelination.[69]

Table 56–1
Selected EAE models: strains, MHC haplotypes, and autoantigens[a,b]

Strain	*MHC Haplotype*	*Autoantigen*	*Type of EAE*	*Comment*
DA	AV1	rMOG(1–125)	Relapsing	MS-like model
		MBP_{rat}69–87	Protracted in some rats	
		MBP 87–101	Protracted in some rats	Rat and gp sequence identical
		PLP_{bovine}	Severe EAE	
		Spinal cord homogenate	Prolonged, relapses	Simple, robust
LEW	L	MBP_{gp}63–88	Monophasic	Classic model, robust
		MBP_{rat}63–88	Monophasic	Less severe than with the gp peptide
		MBP 89–101	Monophasic	Rat and gp sequence identical
		rMOG(1–125)	Resistant	Resistance is relative in EAE; may be overcome
		PLP_{bovine}	<50% develop clinical signs	CNS pathology includes demyelination
LEW.AV1	AV1	rMOG(1–125)	Relapsing/chronic	
LEW.N	N	rMOG(1–125)	Severe, lethal	Chronic with low doses of autoantigen
		MBP_{gp}63–88	Resistant	
		MBP 89–101	Monophasic	
		MBP 87–110	Relatively resistant	$CD8^+$ cells involved in the relative resistance
LEW.W	U	rMOG(1–125)	Semiresistant	
		MBP_{gp}63–88	Monophasic	
		MBP_{rat}63–88	Monophasic	Similar severity as with the gp peptide
PVG	C	rMOG(1–125)	Resistant	
PVG.AV1	AV1	rMOG(1–125)	Semiresistant	
ACI	AV1	rMOG(1–125)	Resistant

[b]EAE, experimental autoimmune encephalomyelitis; MHC, major histocompatibility complex; MS, multiple sclerosis; CNS, central nervous system; r, recombinant; PLP, proteolipid protein; gp, guinea pig.

Finally, with the profound influences of the MHC on EAE induced with different myelin autoantigens, the selection of strain is of utmost importance when planning an experiment.

NON-MAJOR HISTOCOMPATIBILITY COMPLEX GENE REGULATION OF EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS The use of rat strains with differing non-MHC background genes but the same MHC enables demonstration of a non-MHC gene regulation of EAE. This has been demonstrated in the rat for both whole spinal cord-induced disease[70] and MOG-induced EAE.[49] Common rat strains that are relatively non-MHC gene EAE resistant include the BN, PVG ACI, and E3 strains. Susceptible strains include the LEW and DA strains. Naturally this has practical implications when selecting strains for experiments.

A long-term goal in EAE research, also extrapolated to human MS, has been to exactly position the non-MHC genes, both for the understanding of pathogenic pathways and for the selection of an appropriate model for mechanistic as well as therapeutic studies. Hypothetically, a particular experimental manipulation or drug treatment could have drastically different outcomes depending on the genetic makeup at the EAE regulating loci.

These gene mapping efforts have so far resulted in a number of quantitative trait loci (QTLs) with statistical probability for regulating disease. Typically F_2 crosses between resistant and susceptible strains are immunized and phenotype–genotype comparisons are made. In total, 19 whole-genome scans of rat or mouse crosses have been published resulting in a total of approximately 50 QTLs. Further experiments in advanced intercross lines have demonstrated that these may well be composed of several sub-QTLs, which contain more than one polymorphic gene.[71,72] Unfortunately, subsequent work to exactly position the responsible genes within the QTLs is much more laborious. At the moment, only a few examples of exact gene positioning have been achieved: in the rat the NCF1 gene regulating both arthritis[73] and EAE[74] and in the mouse IL-2.[75] Such gene positioning is achieved by creating congenic strains through selective backcrossing a selection of recombinants with phenotypic differences until very small fragments are achieved. Ideally overlapping congenics with only one gene ensues, thus providing formal proof. However, the positioning can be assisted by gene sequencing and expression analysis. The resulting congenic rats represent pharmacogenetically defined strains.

Studies of the type described represent a particular line of EAE research. For practical purposes in context with use of EAE as a model in general, it is important to know that the outcome of particular experiments can be profoundly influenced by non-MHC genes.

SCORING AND ETHICAL CONSIDERATIONS

EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS PHENOTYPES The most common phenotype in EAE is the "clinical score." Most studies use a scale in which Grade 0 equals an unaffected animal; Grade 1, tail weakness or tail paralysis; Grade 2, hindleg paraparesis or hemiparesis; Grade 3, hindleg paralysis or hemiparalysis; and Grade 4, paresis in three or more extremities (tetraparesis), a moribund state, or death. There are also more detailed scales, such as Grade 0 normal, 1 tail weakness, 2 tail paralysis, 3 tail paralysis and mild waddle, 4 tail paralysis and severe waddle, 5 tail paralysis and paralysis of one

limb, 6 tail paralysis and paralysis of a pair of limbs, 7 tetraparesis, and 8 premorbid or deceased.[76] Regardless of the number of grades, none of the scales is linear or parametric. Median values, percentiles, and nonparametric statistics are thus preferred. Sometimes, EAE grades are added for the entire observed disease period in a single animal, to create a "cumulative score." This is not correct since the scores are not linear; when it comes to disease severity Grade 1 for 3 days does not necessarily equal Grade 3 for 1 day. However, EAE rarely affects individual animals with higher scores for just single days, so in "real life" cumulative scores actually give a quite good overall approximation of how severe the disease has been throughout the experiment. An overall value for the clinical score for the whole experiment also avoids problems of multiple comparisons with associated loss of power, if scores are compared each day between experimental groups. Other obvious EAE phenotypes include incidence (usually Grade 1 is required for at least 2 days to score an animal as clinically EAE affected, to avoid "false positives") and maximum EAE score. Day of onset and the number of days with disease may be further phenotypes.

It is often simple to score animals with EAE during the initial bout of disease, when the disease often progresses from Grade 1 (tail paralysis) to Grade 2 (paraparesis, normally with tail paralysis), etc. In relapsing disease, it may be more complicated, because certain individuals, for instance, may recover from the tail paralysis, but still have a residual mild deficit in one hindleg. Usually such rats are scored as "2" (if the most common scoring scale is used), even if they have a normal tail.

There is, unfortunately, no common consensus on how to report EAE scores and several studies indeed report mean EAE scores, also with standard error bars! Regardless of how the EAE scores are reported, it is vital to remember that all scoring scales represent a gross simplification of the expression of the neuroimmunological disease. It is recommended that qualitative data (appearance, behavior) be added to EAE scoring sheets, when needed, to not overlook phenotypes not normally included in the classical EAE scoring scales.

Weight during the course of EAE may be a complementing phenotype. Usually, animals with EAE start to lose weight (compared to the normal slow weight increase) 1 day before the appearance of clinical signs of EAE. The weight loss during disease then roughly follows the disease course. However, weight is a complex phenotype and it may be affected by other factors besides the EAE itself. Thus, weight is not commonly reported in EAE papers, even if most centers indeed weigh animals daily during EAE experiments.

In addition to clinical scoring and weighing, there are a wide variety of histopathology, immunology, electrophysiology, and imaging techniques available to measure various aspects of EAE. It is beyond the scope of this chapter to list all available techniques.

All animal experiments should be guided by the three Rs: replace, reduce, and refine.[77] Most research animal departments and/or ethical review boards also have clear rules about when to euthanize animals, and they must of course be obeyed. As a general rule, animals reaching grade 4 EAE (tetraparesis) should be euthanized. However, it is important to also stress that reduction and refinement really need to be carefully thought through, since it is not ethical to perform underpowered experiments with too mild clinical disease expression. True replacement, refinement, and reduction, require careful planning of each experiment, to maximize the information obtained from every animal.

IMMUNIZATION PROTOCOLS

MBP_{GP}63–88 PEPTIDE-INDUCED EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS IN LEW RATS For each rat use 100 μg of peptide in 100 μl of phosphate-buffered saline (PBS) and 500 μg of *Mycobacterium tuberculosis* (MT) h57 (Sigma) in 100 μl of IFA. For 20 rats this equals 100 μl of stock peptide (20 mg/ml) in 1900 μl of PBS and 25 mg MT in 2000 μl of IFA. For immunization use 200 μl per rat subcutaneously at the tail base.

RMOG (AA 1–125)-INDUCED EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS IN DA RATS For each rat use 20 μg of rMOG in 100 μl of PBS and 100 μl of IFA. For 20 rats this equals 308 μl of stock rMOG (1.3 mg/ml) in 1692 μl of PBS and 2000 μl of IFA. For immunization use 200 μl per rat intradermally at the tail base.

57 Animal Models in Virology

JOSEPH L. BRYANT

ABSTRACT

The knowledge we have gained from the study of many diseases that affect humans comes from the study of disease processes in different animal species, and this has enhanced our understanding of the pathogenesis of the disease in humans. The American Medical Association says almost every advance in medical science in the twentieth century, from antibiotics and vaccines to antidepressant drugs and organ transplants, has been achieved either directly or indirectly through the use of animals as models of disease. In this chapter a brief overview of the uses of animal models for research on human viral diseases is presented.

Key Words: AIDS, Animal models, Cell biochemistry, Cell-based assays, Cervical cancer, Comparative medicine, Ebola virus, Genetic alterations, Genetic make-up, Hantavirus, Hepatitis C, Human papilloma virus, Influenza virus, Intracellular parasites, Mimicry, Nipah virus, Nonhuman primates, SARS, Transgenic mice.

INTRODUCTION

Animal models are used in almost every field of biomedical research. Almost all advances in medical knowledge and treatment, especially those in the past century, has involved work with laboratory animals. Two-thirds of the Nobel prizes awarded since 1901 have been for discoveries requiring the use of laboratory animals.

DEFINITION OF VIROLOGY Viruses are small infectious obligate intracellular molecular parasites. The most basic definition is that viruses are composed of a genome and one or more proteins coating that genome.

The simplest definition of virology is the study of viruses and viral diseases. What then is a virus? Viruses are small infectious obligate intracellular molecular parasites. Today the most basic definition is that viruses are composed of a genome and one or more proteins coating that genome. The virus genome is composed of either DNA or RNA. The genetic information for such a protein coat and other information required for replication are encoded in that genome. The HIV virus is a good example (human immunodeficiency virus/structure).[1,2] Virology is a work in progress. With much left to learn even about extensively studied viruses, we are also certain to be challenged by new, emerging viruses.[3,4] At first, virologists focused on the essential interactions of viruses with cultured cells in which they are grown. However, the strategies of viruses are often focused on interactions with systems of the host animal, notably the immune system. Present and future research in virology involves unraveling the many details of the virus–host relationship. We are likely to be frustrated over and over by the subtlety of the mechanisms that have evolved both to replicate viruses and to defend against host responses. In some cases we will see new examples of viral mimicry of cellular functions. Meanwhile, intracellular locations of viral activities and associations of viral proteins and nucleic acids with cellular counterparts will continue to illuminate details of cellular organization and regulation. Animal models of many human viral diseases are still needed to help elucidate the paths of viral dissemination and specific interactions of certain cells or organs with viruses.

SPECIFIC ROLES ANIMALS HAVE PLAYED IN RESEARCH IN HUMAN MEDICAL VIROLOGY There are several examples of specific roles animals have played in research in virology; one of the best examples is the virus that causes AIDS. The scientific literature is filled with numerous examples of the specific roles animals have played in viral research both in humans and animals.[5–8] Animal models are essential for investigating and studying diseases in humans and that includes viral diseases. In the very early 1980s, when reports of a lethal immunodeficiency disease began circulating, the news at first generated deep fears because no one knew what was causing the disease. The causative agent is a retrovirus, human immunodeficiency virus (HIV).[9] In fact, the reverse transcriptase in the viral particle provides the signal that was used to isolate the virus for the first time. Tremendous advances in our understanding of HIV have been made through the use of animal models.[9–13]

While there are several examples of specific roles animals have played in research in virology, one of the best examples is the virus that causes AIDS. However, there are limitations inherent in many of the current models, whether they are nonhuman primates or other models such as feline immunodeficiency virus (FIV). An exhausting review of the literature clearly shows that while there is no ideal model for HIV, the accumulating knowledge obtained from these models have made major contributions to understanding the pathogenesis of HIV.[14,15] As stated by Robert Gallo, "With animals, we may have a cure for AIDS, without animals we will never cure AIDS in my lifetime."[16]

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

Scientists are also using a number of different animal models to obtain information that can have application to HIV. FIV, transgenic mice, and rats that contain part of the HIV genome or coreceptors for viral entry, and severe combined immune deficiency (SCID) mice reconstituted with human immune system cells or tissues are some of the animal models being used to study the pathogenesis of HIV.[17–19]

Other examples of specific roles of animals in viral are the coronavirus, severe acute respiratory syndrome (SARS), in which the ferret and domesticated cat are susceptible to infection by SARS.[20,21] The scientific literature is filled with numerous examples of the specific roles animals have played in research in virology.[22–24]

HISTORICAL PROSPECTIVE OF ANIMAL MODELS IN VIROLOGY

Viruses have historically provided and continue to provide the basis for much of our knowledge and understanding of modern biology, genetics, and medicine. An understanding of viral genomes and viral replication provides basic information concerning cellular processes in general.

HISTORY OF RESEARCH ON SELECTIVE VIRAL DISEASES Virology's history began over a century ago; viruses, including bacteriophage, have been the source for much of today's molecular biology. In the past 40 years of research on animal virology, we have watched the field go from just growing and identifying animal viruses to a highly sophisticated branch of science. In fact, viruses, including bacteriophage, are the source for much of today's molecular biology. This personal and, of necessity, somewhat limited record reflects how far virology has come and where it still needs to go.

The early definition of a virus was any infectious agent that passed through a filter that caught bacteria. Nonetheless, as early as 1927, visionaries such as Hermann Muller recognized that the small size of viruses had profound implications. There simply was not enough room inside a virus for much more than its genetic material. Of course, no one then knew what genetic material was.

Most studies in virology until the 1950s focused on laboratory animals such as mice, chickens, and ferrets. A pathfinding exception was the work of John Enders and his colleagues at Harvard Medical School who, in 1949, adapted poliovirus to grow in cell culture. This achievement not only revolutionized the production of vaccines, but it set the path for the biochemical analysis of this and other viruses. Virology and immunology—those twins of offense and defense—are generally in a fine balance, but the story of HIV shows that the balance can be tipped against the immune system by a particularly cunning agent. Under the leadership of Dr. Robert Gallo, the Institute of Human Virology is dedicated to the discovery, research, treatment,and prevention of chronic viral diseases, including HIV/AIDS.[16]

The study of viruses has historically provided and continues to provide the basis for much of our most fundamental understanding of modern biology, genetics, and medicine. Virology has had an impact on the study of biological marcromolecules, processes of cellular gene expression, mechanisms for generating genetic diversity, processes involved in the control of cell growth and development, aspects of molecular evolution, the mechanism of disease and response of the host to it, and the spread of disease in populations. In essence, viruses are collections of genetic information directed toward one end: their own replication. The viral genome contains the "blueprints" for virus replication enciphered in the genetic code, and must be decoded by the molecular machinery of the cell that it infects to gain this end. Viruses are obligate intracellular parasites dependent on the metabolic and genetic functions of living cells. The replication and propagation of a given virus in a population are frequently (but not always) manifest with the occurrence of an infectious disease that spreads between individuals.

The historic reason for the discovery and characterization of viruses, and a continuing major reason for their detailed study, involves the desire to understand and control the diseases and attending degrees of economic and individual distress caused by them. As science progressed, it became clear that there were many other important reasons for the study of viruses and their replication. Since viruses are parasitic on the molecular processes of gene expression and its regulation in the host cell, an understanding of viral genomes and virus replication provides basic information concerning cellular processes in general (Table 57–1).

There is archeological evidence in Egyptian mummies and medical texts of readily identifiable viral infections, including genital papillomas (warts) and poliomyelitis. There are also somewhat imperfect historical records of viral disease affecting human populations in classical and medieval times. While the recent campaign to eradicate smallpox has been successful and it no longer exists in the human population (owing to the effectiveness of vaccines against it, the genetic stability of the virus, and a well-orchestrated political and social effort to carry out the eradication), the disease periodically wreaked havoc and had profound effects on human history over thousands of years. Smallpox epidemics during the Middle Ages and later in Europe resulted in significant population losses as well as changes in the economic, religious, political, and social life of individuals. The effectiveness of vaccination strategies gradually led to the decline of the disease in other parts of the world until after World War II. Recently fears have arisen that the high virulence of the virus and its mode of spread might make it an attractive agent for bioterrorism.[24]

Depending on the infection and the focus of study, other animals have proven to be useful in infectious disease research. These animals include the rabbit, rat, guinea pig, pig, dog, and monkey. The latter, in particular, has been utilized in the study of AIDS, as primates are the genetically closest relatives to humans. The advent of molecular techniques of genetic alteration has made the development of genetically tailored animal models possible. Thus, for example, mouse models exist in which the activity of certain genes has been curtailed. These are known as transgenic animals. The involvement of the gene product in the infectious process is possible on a scale not possible without the use of the animal.[25]

Table 57–1
Human diseases caused by viruses

Acute hemorrhagic conjunctivitis
Acute hemorrhagic cystic
AIDS/acquired immune deficiency syndrome—human immunodeficiency virus
Bronchiolitis—respiratory syncytial virus
California encephalitis—California encephalitis virus
Cervical cancer—human papilloma virus
Chickenpox—varicella zoster virus
Colorado tick fever—Colorado tick fever virus
Conjunctivitis—herpes simplex virus
Cowpox—vaccinia virus
Group, infections—parainfluenza viruses
Dengue—dengue virus
"Devil's Grip"—coxsackie B
Eastern equine encephalitis—EEE virus
Ebola hemorrhagic fever—Ebola virus
Gastroenteritis—Norwalk virus
Genital HSV—herpes simplex virus
Gingivostomatitis—HSV-1
Hantavirus hemorrhagic fever/Hantaan-Korean hemorrhagic fever—Hantavirus
Hepatitis
Hepatitis A—hepatitis A virus
Hepatitis B—hepatitis B virus
Hepatitis C—hepatitis C virus
Hepatitis D—hepatitis D virus
Hepatitis E—hepatitis E virus
Herpangina—coxsackie A
Herpes, genital—HSV-2
Herpes labialis—HSV-1
Infectious myocarditis—coxsackie B1–B5
Infectious pericarditis—coxsackie B1–B5
Influenza—influenza viruses A, B, and C
Keratoconjunctivitis—adenovirus
Lass hemorrhagic fever—Marburg virus
Measles—rubella virus
Meningitis, aseptic—coxsackie A and B (enterovirus), lymphocytic choriomeningitis virus
Mononucleosis—Epstein–Barr virus
Mumps—mumps virus
Pharyngitis
Respiratory syncytial virus
Influenza virus
Parainfluenza virus
Adenovirus
Epstein–Barr virus
Pleurodynia—coxsackie B
Pneumonia, viral—respiratory syncytial virus
Polio, poliomyelitis—Poliovirus
Progressive multifocal leukoencephalopathy—JC virus
Rabies—rabies virus
Roseola—HHV-6
Rubella—rubivirus
Severe acute respiratory syndrome (SARS)—a human coronavirus
Shingles (zoster)—varicella zoster virus
Urethritis—herpes simplex virus
West equine encephalitis—WEE virus
Yellow fever—Yellow fever virus
Zoster—varicella zoster virus

ASSESSMENT OF CURRENT AND POTENTIAL ANIMAL MODELS IN VIROLOGY

A number of potential useful models exist that may facilitate and improve the understanding of the pathogenesis and treatment of viral infection. A good example is HIV-1 disease.

Animal models have provided a controlled setting for the study of human immunodeficiency virus-1 (HIV-1) disease, the preclinical testing of novel antiviral compounds, and the evaluation of vaccines. Because the animals serve as models for humans they should be closely reflective of human physiology and pathophysiology. Moreover, their use must be complementary to, and not replaceable by, experimental approaches that do not require animals. For any given experiment, the critical question is which, if any, model is most useful—and why?

ADVANCES MADE IN BIOMEDICAL RESEARCH IN VIROLOGY USING ANIMALS

Viruses are collection of genetic information directed toward replication. The viral genome contains the blueprint for virus replication encoded in the genetic code and must be decoded by molecular biology. Exploitation of viral diseases of animals may ultimately provide a useful means of understanding human viral diseases.

The literature on the history of the use of animals in human medical virology is somewhat sketchy and not well organized. This clearly indicates that the study of viruses as a pathogen in animal models is a relative new field and in most cases, due to molecular biology and genomic research studies, is now coming into its own.

Most of the major advances in modern virology during the past 25 years have been due principally to the development of refined laboratory techniques and tools and have provided an array of new knowledge and information about the nature of viral infection and pathogenesis.

Changing their role from hunters of microbes to biochemists probing the nature of life, virologists are simultaneously reflecting and leading the revolution in biomedical research. By using the post-World War II tools of tissue culture, radioactive isotopes, chromatography, density gradient centrifugation, and the electron microscope, they have acquired vast knowledge about the way viruses infect cells and cause disease. Unexpectedly, the viruses themselves have emerged as powerful probes into the nature of cellular and life processes. Because of the necessarily close relationship between viruses and their host cells, the understanding and control of viral infections depend almost wholly on knowledge of the biochemistry of cells.

Vaccines and sera have been powerful aids in the prevention of viral diseases such as polio, measles, mumps, rubella, yellow fever, and hepatitis, but they are only extensions of the fundamental principles of Jenner's smallpox vaccine and Pasteur's rabies vaccine. Compared with the modern treatment of established diseases by means of specific chemotherapy, the management of viral diseases lags behind all other forms of chemotherapy.

ACHIEVEMENTS OF ANIMAL RESEARCH IN VIROLOGY

Several animal models, primarily rodents and monkeys, have been developed that recapitulate many aspects of the disease seen in humans. Studies reviewed here demonstrate how these models have played a vital role in understanding and developing therapeutics for these viral diseases.

HUMAN PAPILLOMAVIRUS AND CERVICAL CANCER As the scientific community continues to make new discoveries about factors contributing to the development of cancer, viral pathogens have been found to play an important role. In the development of cervical cancer, one specific type of abnormal cell growth (neoplasia), DNA from human papillomavirus (HPV), has been detected in 50–95% of lesions. It is estimated that women with HPV have 10–30 times the risk of developing cervical neoplasia than those not infected. Using this system as a model, many questions on how viral infections influence the development of cancer have been explored experimentally.[26]

INFLUENZA VIRUS The animal models presently available for the study of the pathogenesis of influenza virus disease have limitations.[27,28] Influenza A virus will experimentally infect a number of Old World and New World primates. The gibbon and baboon develop clinical illness with nasal application of the virus, and the squirrel, cynomolgus, and rhesus monkeys develop illness when the virus is inoculated intratracheally. Primate models suffer from a number of disadvantages, including the limited availability of expensive animals. In addition, these animals are outbred and the models lack many of the reagents necessary to characterize the host response in detail. Mammals such as horses and pigs that are natural hosts for influenza have also been used experimentally. However, their large size and the limited number of reagents available preclude their use in the laboratory.

Small-animal models that have been used to study influenza virus pathogenesis include the ferret, in which human influenza virus was originally isolated.[29] Adult ferrets become ill after infection with unadapted influenza A viruses, exhibiting fever, lethargy, and weight loss. The ferret model has been used in recent studies of H5N1 viruses, the transmission of influenza, and the development of resistance to antiviral therapy. Unfortunately, ferrets are outbred and reagents are not available for dissecting the correlates of protective immunity.

There has been one report, published in Polish and largely overlooked, of the use of outbred cotton rats (*Sigmodon hispidus*) for pathogenesis experiments with influenza viruses. Nasal administration of virus in lightly anesthetized cotton rats resulted in virus replication, the production of pulmonary lesions, and a strong immune response. Results suggest that the cotton rat may serve as a useful model for the study of influenza pathogenesis. The animals are small, inbred, easy to handle, and relatively inexpensive to purchase and maintain.[30]

Influenza virus strains that cause worldwide outbreaks (pandemics) are classic examples of emerging viruses that are maintained in other animal hosts before transmission to humans. Influenza viruses are isolated from a variety of animals, including humans, pigs, horses, wild and domestic birds, and even sea mammals.[31] The most devastating viral infection in this century was not caused by HIV, but by Spanish influenza, which killed more than 20 million people worldwide. Genetic studies suggest that the Spanish influenza virus originally was derived from birds. Furthermore, the causative viruses from the 1957 and 1968 influenza pandemics were hybrids between human and avian influenza viruses. Because humans did not have immunity to avian influenza viruses, the hybrid viruses produced devastating consequences (70,000 and 46,500 deaths globally in the 1957 and 1968 pandemics, respectively). Thus, it is critical to understand the

mechanisms by which new influenza strains capable of causing pandemics emerge. Animal models will play a critical role in understanding the mechanisms.

HANTAVIRUS Hantavirus is segmented RNA viruses belonging to the genus *Hantavirus* in the family Bunyaviridae. Hantaviruses are maintained in various rodent reservoirs, in which the hosts are persistently infected without disease symptoms. Specific hantaviruses transmitted from the contaminated urine and feces of infected rodents cause two important human diseases, hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS). Annually, hundreds of thousands of cases of HFRS are reported throughout Euro-Asia, whereas hundreds of cases of HPS are reported in countries in North and South America. Because rodents act as the natural reservoir for hantaviruses and human-to-human infections are rare, understanding the ecology of hantavirus within their natural reservoir is important for preventing and controlling the emergence of such diseases.[32]

The comparison of may hantavirus genomes form different rodent species has shown a clear correlation between the rodent species and the virus genotype, suggesting that hantavirus have coevolved with their natural hosts for >20 million years, since before the first humans evolved. It remains unclear how hantavirus exist within a rodent reservoir, particularly how they establish a persistent infection. In experiments with laboratory rats and mice, several groups have shown that an experimentally infected newborn animal readily develops a persistent infection, whereas an adult animal develops only a transient infection and recovers completely. On the other hand, epizootiological investigations have demonstrated that virus is transmitted between adult animals through wounds, and the adults develop a persistent infection.

EBOLA VIRUS Ebola virus is a nonsegmented RNA virus, which, together with Marburg virus, makes up the filovirus family. This now notorious group of viruses was discovered in 1967 when Marburg virus was identified as the etiological agent of a hemorrhagic fever outbreak in research facilities in Europe, which handled tissues from African green monkeys imported from Uganda. Subsequently, Ebola viruses were shown to be the cause of simultaneously occurring hemorrhagic fever outbreaks in 1976 in the Democratic Republic of Congo (DRC, formerly Zaire) and Sudan. These outbreaks were shown to be caused by two different subtypes of Ebola virus, which became known as the Zaire and Sudan subtypes. Mortality rates of up to 80% were recorded in these and more recent outbreaks in DRC and Gabon in 1995–1996. Epidemiological data from recent outbreaks indicate that close contact is necessary for efficient transmission of Ebola virus from one individual to another, and little evidence can be found for aerosol transmission of the virus. Despite considerable efforts to identify the natural reservoir for Ebola and Marburg viruses, the host species remains an enigma. Although nonhuman primates have been implicated as the source of the introduction of the virus into humans during several of the identified outbreaks, they are not considered likely to represent reservoir species because of their susceptibility to high-mortality hemorrhagic disease similar to that seen in humans.

NIPAH VIRUS Nipah virus is a newly discovered member of the paramyxovirus family of nonsegmented RNA viruses. This virus was responsible for a viral encephalitis outbreak in Malaysia that was first recognized in October 1998 and ended in midsummer 1999. This outbreak resulted in almost 300 confirmed infections, and the mortality rate for hospitalized cases was approximately 35%. Initially, Malaysian authorities thought the outbreak was caused by Japanese encephalitis (JE virus, a mosquito-borne RNA virus). However, JE vaccination and mosquito control efforts failed to halt the epidemic. The virus appeared to be first introduced into pigs, where close contact caused by intensive farming practices led to efficient pig-to-pig transmission, and subsequently pig-to-human transmission. Most human cases were in close proximity to the infected pigs. Genetic analysis showed Nipah virus to be closely related to Hendra virus, which recently was discovered in Australia as a cause of disease in horses and humans and also is maintained in *Pteropus* species fruit bats.

These examples highlight the subtle balance of environmental and genetic factors that can mold the diverse evolutionary patterns observed for RNA viruses and illustrate the complexity of these systems, which makes it difficult to predict future viral disease emergences. Much more research is needed and animal models will continue to be needed to ultimately understand and control these diseases.

RELEVANT ANIMAL MODELS

Use of animals as models for human disease has been indispensable in understanding the cause, biology, and prevention of disease. The Animal Model Division at the Institute of Human Virology has developed several relevant animal models, particularly for the study of AIDS and AIDS-associated cancers.

Animal models are required for the study of human diseases. However, the relevance of small animal models such as mice to natural human *in vivo* physiological and metabolic kinetics remains unclear. Large animal species may provide far more appropriate preclinical models that will more closely reflect human physiological characteristics and behavior. Among large animals, nonhuman primates may provide the best models because of their close phylogenetic relationship to humans It is essential to develop animal models for human diseases to reveal its mechanisms and to develop new therapeutic interventions.

Led by the author of this review at the Institute of Human Virology, the Animal Models Division is a unique feature of the Institute, enabling scientists to work with relatively inexpensive models to study AIDS and new drugs or therapies without risk to humans. Developing animal subjects for use in viral research is a science unto itself, and it is essential in taking a discovery from laboratory to clinic. The use of animals as models for human disease has been indispensable in understanding the causes, biology, and prevention of disease. “To my knowledge, almost all major scientific successes on unraveling and conquering human diseases have been with the use of animal models. AIDS and AIDS-associated diseases, will be no exception” (J.L. Bryant, personal communication).

VIRAL DISEASE IN SEARCH OF AN ANIMAL MODEL

Hepatitis viruses belong to different families and have in common a striking hepatotropism and restrictions of propagation in cell culture. Viral hepatitis represents a global public health problem. Over the past 20+ years, the chimpanzee model has served as the backbone for advancements in the hepatitis C virus (HCV) research field. Despite this remarkable progress, the chimpanzee model has some important disadvantages. Perhaps most

importantly, chimpanzees are rare, expensive, and difficult to handle. Limitations to the chimpanzee model have stimulated progress toward developing alternative animal modes for HCV research. Transgenic technology, coupled with the relative ease and low cost by which mice can be reared and maintained, along with the availability of inbred mouse strains, have made the laboratory mouse an attractive animal model for HCV research.

For some human viruses [e.g., hepatitis B (HBV) and HCV], no satisfactory cell culture or animal model exists, and in these cases, inhibition of an essential viral function or activity against related viruses can be used to indicate potential activity. When no satisfactory cell culture or animal model exists for the target human virus, it is particularly important to know whether a drug's active moiety enters cells, if it has a proposed intracellular site of action, and if the intracellular concentration is consistent with biochemical studies to identify an inhibitory concentration. Cell-based assays and host cell lines for studying viruses such as HBV and HCV replication may advance and improve, but at the present time are limited. For analysis of HCV replication, a replicon system has been developed that permits studies of viral replication and can be used to assess antiviral activity of some anti-HCV drugs.

More than 200 million people worldwide are now believed to be infected with HCV, including 4 million individuals within the United States. HCV accounts for the deaths of at least 8000 to 10,000 Americans each year and is now one of the most common indicators for adult liver transplants in developed countries. Before the introduction of anti-HCV screening in mid-1990, HCV accounted for 80–90% of new cases of posttransfusion hepatitis in the United States. Currently, injection drug use is probably the most common risk factor for HCV infection, with approximately 80% of this population seropositive for HCV. A high rate of HCV infection is also seen in individuals with bleeding disorders or chronic renal failure, groups that have had frequent exposure to blood and blood products.

HCV is a global public health problem, with approximately 3% of the world population now infected. The clinical course of HCV often involves chronic infection, which can lead to liver dysfunction and hepatocellular carcinoma. Because HCV cannot be efficiently propagated in cell culture, research has relied heavily on animal models to study the physical characteristics of HCV and the course of events associated with HCV infection. The chimpanzee is the only nonhuman primate actually proven to be susceptible to HCV infection and has commonly been used to study viral hepatitis induced by HCV. Molecular cloning of the HCV genome has now allowed HCV transmission studies in chimpanzees to progress from the early work of characterizing infectious serum to a current focus of characterizing infectious HCV molecular clones. Moreover, the cloned HCV genome has paved the way for the development of alternative animal models for HCV, most notably transgenic mouse models for the study of HCV pathogenesis.[33] The expression of specific viral protein products in these animal models will provide important insights into the structure–function relation that specific HCV genome sequences impart on virus replication and pathogenesis.

Despite this remarkable progress, the chimpanzee model has some important disadvantages. Perhaps most importantly, chimpanzees are rare, expensive, and difficult to handle, and must be housed and cared for in appropriate nonhuman primate research facilities. Such research facilities must possess proper surgical support and specialized veterinary care. Moreover, the chimpanzee has been listed as an endangered species since 1988, and appropriate safeguards must be considered whenever selecting such a model for research.

These and other limitations to the chimpanzee model have stimulated progress toward developing alternative animal models for HCV research. Transgenic technology, coupled with the relative ease and low cost by which mice can be reared and maintained, along with the availability of inbred mouse strains, have made the laboratory mouse an attractive animal model for HCV research.[34] An HCV infection cannot be propagated in mouse tissues, which obviously limits the research application of mouse models. However, expression of the HCV genome or subgenomic fragments of HCV within inbred strains of mice has demonstrated the utility of mouse models for research geared toward understanding mechanisms of HCV pathogenesis.

Transgenic mice expressing HCV proteins are only beginning to provide insights into the pathobiology of HCV infection. From the studies presented, it is clear that expression of HCV proteins per se is not directly cytopathic to hepatocytes, even when expression levels are greater than those observed in HCV-infected individuals. This evidence supports the notion that the host immune response to HCV may play a significant role in HCV pathogenesis. The use of conditional transgenic expression systems, such as the Cre/LoxP system, offers exciting prospects to study the immune-mediated mechanisms of HCV-related liver injury in transgenic mice. However, the recent development of mice immunocompetent for the HCV proteins using this system awaits full characterization. It is clear that in some transgenic mouse strains, expression of the HCV genome or the core protein alone results in the development of steatosis and HCC. How does the core protein induce these pathologies, and how may the other HCV proteins contribute to this phenotype? It is unclear whether this phenotype is a result of HCV protein expression directly or whether it occurs in combination with environmental or host-derived factors leading to chronic liver cell injury. Importantly, steatosis and HCC are relevant clinical manifestations seen in HCV-infected individuals. These transgenic mice should therefore play a pivotal role in elucidating the molecular mechanisms of HCV-related liver pathology.

CONCLUSIONS

There should be no doubt that the knowledge gained form the study of viral diseases in humans in different animal species has enhanced our knowledge and understanding of the pathogenesis of the diseases in humans. One important component of the value of using animals in viral research is that the pooling of knowledge of diseases in different animal species has led to more rapid progress in understanding the pathogenesis of diseases.

It was not the intent here to discuss comprehensively the contribution of animals in viral research but to historically acknowledge that they have played and will continue to play a major role in solving many health problems, including viral diseases in humans. A review of the literature clearly shows that depending on the training and background of the scientists concerning the use of animals in viral research, there are numerous differences of animal models in viral research. It is clear that the more knowledge the scientist has of diseases in animals the better the understanding of how a model can be used. For example, the direct application of knowledge of a disease in an animal, scrapie in sheep, has led to a better understanding of a human disease,

kuru. It was a veterinarian and pathologist, Dr. W. J. Hadlow, who through his experience with scrapie in sheep and goats noted the similarities of the histological lesions in the brains of kuru patients and those of sheep and goats. He suggested the inoculation of brain material from kuru patients into animals. Dr. Carlton Gajdusek, using chimpanzees, produced a fatal disease in these animals after a long inoculation period. This established a viral etiology for kuru and led to the prevention of the diseases. This is one of numerous examples of how applying the knowledge of veterinary medicine and human medicine can lead to the prevention and treatment of diseases caused by viruses.

Our understanding of emerging and reemerging viruses from an evolutionary perspective offers clear directions to follow. If we seriously plan to develop efficient and reasonable control strategies, an international concerted effort involving a thorough survey of the genetic diversity of viruses in time and space is a must. This will also help in understanding several processes that take place at the molecular level in a comparative context. More emphasis on multidisciplinary sciences is needed. Molecular biology and systematics, bioinformatics, data mining, and analysis are all becoming considerably sophisticated lately. Hepatitis C and HIV-1 are glaring proof that disease knows no national borders. The use of and development of animal models for studying viral diseases of humans will continue to be a necessary part of biomedical research in understanding the current viral diseases that affect humans and the new emerging viruses.

58 Nonhuman Primate Models for AIDS

NANCY L. HAIGWOOD, RAYMOND R. O'NEILL, AND VANESSA M. HIRSCH

ABSTRACT

Since the discovery of acquired immune deficiency syndrome (AIDS) and the human immunodeficiency viruses HIV-1 and HIV-2 in patients 25 years ago, efforts have been directed toward identifying or developing appropriate models for this disease. Several species of nonhuman primates can be productively infected with primate lentiviruses HIV-1, HIV-2, SIV, and genetic chimeras of HIV and SIV (SHIV), and the ensuing pathology has many elements in common with HIV infection of humans. This chapter summarizes the key features of the nonhuman primate models that have been developed for AIDS research as of 2006. It focuses on (1) the major contributions and limitations of these models to our understanding of HIV infection and pathogenesis and (2) uses of the models to test prophylactic and therapeutic approaches to prevent infection and/or limit disease. It is intended as a reference for investigators in the field as well as for those considering utilizing the models to address specific questions in AIDS research. In an overview of this type, comprehensive referencing of studies is not possible, and key examples are included in an effort to cite some of the many important studies performed to date. Many excellent comprehensive and focused reviews on the subject of nonhuman primate models for AIDS have been written in the past several years, and readers are encouraged to consult these reviews for details, examples, and additional references.

Key Words: HIV-1, HIV-2, SIV, SHIV, AIDS, Baboons, Chimpanzees, Macaques.

GENERAL CHARACTERISTICS

HISTORY OF AIDS MODELS Since the discovery of the etiological agent of AIDS, human immunodeficiency virus (HIV), efforts to combat the HIV/AIDS epidemic have been focused on the development of vaccines and drug treatment, as well as on behavioral interventions. Because the disease is known to be a caused by a blood-borne virus, some of the earliest efforts were directed to developing tests for screening the human blood supply. Recombinant viral antigens that were developed for diagnostic tests were also tested for their suitability as early vaccine candidates. The early vaccine work was bolstered with significant private and government-sponsored research funding commitments in the United States, Canada, the United Kingdom, and Europe, in part due to misplaced optimism about the ease of developing HIV vaccines. Much of this funding was directed toward the discovery and development of appropriate animal models to study antiviral immunity and to evaluate vaccine candidates and strategies. Although natural lentiviral infections in nonlaboratory animal species are known, none develops into an AIDS-like illness. Attempts to create transgenic mice or rats that develop AIDS have been unsuccessful to date.

Importantly, early research in academic laboratories and in industry did lead to anti-HIV, or antiretroviral (ARV) drug development in the absence of animal models. These early drugs targeted viral enzymes such as reverse transcriptase (RT) and protease (PR) with no human counterparts, and drugs could be screened for activity against the virus using *in vitro* enzymatic inhibition assays. Because this type of drug research did not require an animal model to demonstrate drug potency, nearly all of the ARVs in use at present were approved without animal model efficacy testing. With the development of PR inhibitors and their use in a cocktail of anti-RT inhibitors, patients could expect to experience significant, sustained control of virus replication and in many cases delay or prevention of opportunistic infections. These combination drug regimens were termed highly active antiretroviral treatment, or HAART.[1] Various improved formulations and combinations of HAART are the current standard of care in the developed world, and there are continuing efforts to find economic mechanisms to make these drugs available worldwide.

Despite success in developing HAART, the epidemic continues to spread worldwide through sexual transmission, primarily heterosexual, via mother-to-child transmission, and drug use via blood-contaminated needles. As with other epidemics, an important public health goal is to develop vaccines that can prevent the acquisition or limit the spread of a lethal or seriously debilitating infection. These vaccines, once discovered, can then be utilized in concert with campaigns to limit transmission via behavioral changes. AIDS vaccine research has been far more challenging than drug research due to a number of factors. First, HIV-1 is a lethal virus that persists in the host due to its integration into the genome. Therefore the use of human challenge models is prohibited, even after the development of relatively effective ARV drugs. Second, the virus targets many of the very immune cells that are needed to eliminate or control it, leading to death by

infection with opportunistic agents. Thus, vaccines will need to be provided prior to or early in infection to stimulate maximal immunity before the loss of key immune cells. Finally, animal models described to date are imperfect and do not recapitulate all aspects of the infection. This is a particular irony, as the viruses HIV-1 and HIV-2 certainly were endemic to nonhuman primates before bridging the gap to productive infection of humans.[2] Nonhuman primates were imported to the United States and other European countries from Africa and Asia during the 1960s continuing through the 1980s to provide animals for testing in cancer and other biomedical research. In the early 1980s, investigators observed that some of their Asian macaques that had been exposed to African sooty mangabey monkeys harboring their own lentivirus (SIVsm) were succumbing to a disease that had remarkable similarities to AIDS in humans. This disease was termed "simian AIDS." The etiological agent was a blood-borne virus that showed morphological similarities to HIV-1 in electron micrographs and was designated SIVmac to indicate its origin in macaque monkeys. This fortuitous observation was the genesis of today's models that are in wide use for vaccine,[3–5] microbicide, transmission,[6] pathogenesis and treatment,[7,8] and behavioral research.[9,10] As noted in the abstract, many fine reviews have been published to describe the models and their uses, and the reader is encouraged to pursue these for additional information.

COMPARISON OF HUMAN AND SIMIAN LENTIVIRUSES In addition to animal passage of infectious blood and tissues, molecular cloning was a key technology in the identification of virus isolates for use in nonhuman primate studies.[11,12] Fulfilling Koch's postulate, it was demonstrated directly that blood from simian immunodeficiency virus (SIV)-infected macaques[13] as well as cloned SIV was the causative agent of this nonhuman primate version of AIDS in Asian macaques.[12] Like HIV-1, this SIV is a member of the lentivirus group of retroviruses, characterized by the presence of regulatory genes in addition to the standard retroviral *gag*, *pol*, and *env* genes. These viruses cause a persistent infection and a relatively slow disease course. It was subsequently demonstrated through molecular cloning of viruses from various African species including chimpanzees, sooty mangabeys, and African green monkeys that the SIVs are endemic to many African primates[14,15] and are by definition well adapted, failing to cause disease in their natural host. While there are a variety of different SIVs that are classified based on their African primate of origin, this chapter focuses on the SIVmac/SIVsm strains that are most widely used in vaccine and pathogenesis research. This research to determine the etiology of the simian disease was performed in parallel with early work to establish an animal host for HIV-1 and HIV-2. Originally imported for research in other diseases, the macaque models arose by accidental exposure to other endemic viruses, as noted above. Some of these monkeys (sooty mangabeys) harbor an endemic nonpathogenic virus, SIVsm, which was transmitted to the Asian macaques.[16] More comprehensive searches have shown that this group of viruses is widespread in many species of African primates. Painstaking field work to obtain samples and detailed phylogenetic analyses of viruses found in these samples[17] have led to our current understanding of the sources of HIV-1 and HIV-2 in humans. HIV-1 arose by exposure of humans to a virus endemic in chimpanzees, and HIV-2 from similar exposure to macaques infected with SIV, most likely SIVsm.[18] Susceptibility of specific cell types to viral entry by the nonhuman primate lentiviruses is enabled by the envelope glycoprotein, which binds to the cellular receptor (CD4, found on monocytes, macrophages, and subpopulations of T cells) and one or more of the 7-transmembrane chemokine coreceptors (typically either CCR5 or CXCR4).[19] HIV-1 laboratory isolates that are adapted for growth in tissue culture utilize CD4 and the chemokine receptor CXCR4, while primary HIV-1 isolates utilize CCR5.[20] SIV is known to utilize CCR5 and potentially other coreceptors as yet uncharacterized.[21] Mutations in the gene encoding CCR5 can confer partial or full resistance to HIV-1 infection in humans who are heterozygous and homozygous, respectively, for a 32-base pair deletion in gene that prevents expression of functional CCR5.[22] Despite conservation of receptor and some coreceptor utilization, the primate lentivirus envelope proteins, while structurally similar, differ as much as 20% in sequence, limiting cross-protective immunity. Recent studies have identified two important restriction factors unique to different primate species that operate at a cellular level to inhibit HIV or SIV viral replication. These are APOBEC3G, which exerts a late block to retroviral replication,[23] and TRIM5α, which exerts a dominant block to infection immediately after entry.[24] Further studies of how these restriction factors limit the acquisition of the ancestors of our current human epidemic will no doubt cast light on changes that accrued during cross-species transmission and important adaptations of the current viruses to increase transmission to humans.[25]

SPECIES UTILIZED FOR AIDS RESEARCH Early work to develop an infectivity model focused on infection of chimpanzees (*Pan troglodytes*) with HIV-1,[26] since they are the closest genetic relative of *Homo sapiens*. Although this species is readily infected with HIV-1 and there is a robust antiviral immune response, there was a puzzling lack of evidence for disease progression. Evidence for disease was found only recently in captive chimpanzees infected with one or more HIV-1 isolates for 10 years or more.[27] In retrospect, this finding makes sense, as the viruses being used to infect the chimpanzees had been selected and adapted for growth and pathogenesis in humans. There was a significant effort in the 1980s to expand the number of captive chimpanzees available for AIDS research via breeding programs, since the U.S. laboratory population was severely limited in number, and additional importation from Africa was prohibited. However, even with increased breeding, the cost of performing experiments with even a small number of chimpanzees was prohibitive for all but a few groups. These studies were limited to testing approaches that could block infection, such as an early study that showed an envelope-specific monoclonal antibody directed to the third hypervariable region could block intravenous infection with HIV-IIIB.[28] Although baboons (*Papio* species) were not productively infected with HIV-1, they could be infected with HIV-2, and some efforts were directed at developing a pathogenic HIV-2 via passage *in vivo*.[29] Macaque (*Macaca nemestrina*)-passaged HIV-2 led to a model characterized by high peripheral and tissue virus and rapid, irreversible loss of $CD4^+$ T cells.[30] Species that are susceptible to infection with SIV include *Macaca fascicularis* (cynomolgus), *Macaca mulatta* (rhesus), and *M. nemestrina* (pigtailed). An excellent discussion of the merits and limitations of each of these species can be found in the review by Hu.[5]

PATHOGENESIS In humans, HIV infection with a single or small number of variants quickly expands with viral replication to a group of genetically[31] and biologically distinguishable viruses.[32] Different virus–host combinations lead to differing degrees of pathology, with some of the equation dependent upon the virus and some dependent upon the host. Typically, macaques

Table 58–1
Nonhuman primate models for human AIDS

Virus	*Animal*	*Comments*
HIV-1	Chimpanzee	Replicates but usually no disease, or disease in >10 years Chimps are limited in number, expensive, and require long-term care
	Pigtailed macaque	Very poor replication, not a useful model for disease
HIV-2	Baboon	Moderate replication, not a useful model for disease
	Pigtailed macaque	One pathogenic strain replicates to a high level and causes an acute $CD4^+$ T cell loss (HIV-2–287)
SIVsm/mac	Rhesus macaques	Various strains that induce AIDS in macaques (SIVmac251, SIVmac239mc, SIVsmB670, SIVsmE660, SIVsmE543mc, SIVsmm9, SIVsmPBj)
	Pigtailed macaques	
	Cynomolgus macaques	Rhesus macaques of Indian origin the most frequently used model
SHIV	Rhesus macaques	The majority of strains use the CXCR4 coreceptor expressed on naive T cells and cause an acute $CD4^+$ T cell loss (SHIV-SF33, SHIV-KU1, SHIV-89.6P, SHIV-DH12)
	Pigtailed macaques	One pathogenic strain uses the CCR5 coreceptor on memory T cells and causes more of an AIDS-like disease (SHIV-SF162)

experience high viral loads and loss of $CD4^+$ T cells within 6 months to 2 years of infection, a course that is significantly foreshortened compared with HIV-1 or HIV-2 in humans. In comparative infection studies with SIVsmE660, for example, the time to loss of $CD4^+$ T cells and disease from opportunistic infection is significantly shortened in *M. nemestrina* compared with *M. mulatta*. Experiments with a shorter duration using host and virus pairs with high pathogenicity are less expensive and can provide greater throughput at primate centers. Therefore these models are frequently favored. A number of AIDS-inducing SIV isolates and molecular clones have been derived as detailed in Table 58–1. These include the SIVmac239 and SIVmac251 viruses originally described by investigators at Harvard, SIVmne from the National Cancer Institute and University of Washington research groups, and related strains SIVsmm9, SIVsmB670, SIVsmE543, and SIVsmE660 isolated by investigators at the Yerkes Primate Center and Tulane University.[7,33] The pathogenesis of disease is similar between these viruses and is characterized by (1) an acute phase of high viremia in which rapid loss of mucosal $CD4^+$ memory T cells occurs, (2) the development of cellular and humoral immune responses and a long, relatively asymptomatic period in which a gradual decline in immune function and loss of $CD4^+$ T cells occurs, and (3) the development terminally of opportunistic infections. Most of these viruses also cause SIV encephalitis, which has provided a model for AIDS dementia.[34] Loss of gut-associated lymphoid tissue (GALT) in SIV-infected macaques is a hallmark of pathogenesis[35,36] and was shown prior to such studies in humans.[37,38] Two important findings were derived from nonhuman primate studies: (1) the pathogenic nature of live attenuated vaccines in newborn rhesus macaques, despite lack of pathogenesis in juveniles;[39,40] and (2) the reemergence of virus from vaccinated "protected" macaques after several years, underscoring the difficulty of detecting some infections[41] as well as the permanence of lentivirus infection and the potential for lethal outcomes after years of control despite years of viral control.[42–44]

TRANSMISSION One of the most useful applications of the nonhuman primate models has been to explore the routes of infection by various isolates and clones. Early research involved intravenous inoculation of chimpanzees, baboons, or macaques with blood or infected tissues, and later infectious molecular clones. Each of the known routes of transmission in humans has been demonstrated in the monkey for both SIV[45] and for SHIV[46]: oral,[47] vaginal,[48] rectal,[49] and perinatal.[6,50] The importance of hormonal changes in susceptibility of transmission could be explored in a controlled manner, demonstrating higher susceptibility during different stages of the menstrual cycle.[51] Using these models, it has been possible to quantify the difference in infectiousness of various stocks by different routes, thereby showing that SIV and SHIV are approximately 1000-fold more infectious by the intravenous route than by any mucosal route.[48] Mucosal transmission of HIV-1 in chimpanzees was shown to be relatively inefficient,[52,53] leading to loss of CD4 cells.[54] Viral divergence was seen with dual infection in chimpanzees,[55] foreshadowing findings in the clinic[56] that have shown intersubtype and even intrasubtype recombination to be an important outcome of infection. Importantly, the nonhuman primate models allow the comprehensive investigation of cells that are infected in the genital tract[57] as well as investigations as to how the virus spreads following infection.[58]

HUSBANDRY/AVAILABLE STOCKS OF NONHUMAN PRIMATES AND LENTIVIRUSES

LOCATIONS OF MAJOR RESEARCH CENTERS USING NONHUMAN PRIMATES FOR AIDS RESEARCH Scientists working in nonhuman primate models for AIDS perform this research in academic, nonprofit, industrial, and government-sponsored laboratories and centers. Numerous private concerns provide purchase, care, and infrastructure for nonhuman primate work for investigators throughout the world. In the United States, there are eight National Primate Research Centers (NPRCs) for

Table 58–2
National Primate Research Centers in the United States, 2006

Primate center name and website	*Academic affiliate*	*City and state*

Yerkes National Primate Research Center http://www.yerkes.emory.edu	Emory University	Atlanta, GA

which long-term core support is provided by center grants from the National Center for Research Resources (NCRR) of the United States National Institutes of Health. Their locations, academic affiliations, and websites are listed in Table 58–2. The mission of these centers is to provide nonhuman primate resources, relevant scientific expertise, and biological samples to the research community, and each of the centers has active research in AIDS pathogenesis, vaccines, and treatments. Because of their historical involvement in AIDS research, these centers remain important resources to the research community worldwide. A current list of contact information for the NPRC, and an overview of how outside investigators may access these resources, is maintained at www.ncrr.nih.gov/ncrrprog/cmpdir/PRIMATES.asp. For specific experiments, specific pathogen-free (SPF) rhesus and pigtailed monkeys initially free of SIV, simian retrovirus D, STLV-1, and monkey herpes B virus are available from the eight NPRCs and from the Caribbean primate center in Puerto Rico (http://rcmi.rcm.upr.edu/docs/primate.html). In addition to these centers, many academic institutions, pharmaceutical and biotechnology companies, and the U.S. National Institutes of Health maintain primate colonies for in-house research. In Europe, the German Primate Center and the Biomedical Primate Research Center in the Netherlands house primates and have historically been major centers for AIDS research. This is by no means an exhaustive list; rather its objective is to acquaint the investigator seeking possible research collaborations with the national centers in the United States as a starting point.

VIRAL STOCKS The HIV-1 stocks that have been tested in chimpanzees and subsequently in macaques were derived from the early, laboratory-passaged viruses such as HIV-IIIB or HIV-BRU, HIV-LAI, HIV-MN, or HIV-SF2. These viruses replicated to high titers *in vivo* and elicited robust antiviral antibodies, including neutralizing antibodies. Although attempts were made by several investigators to infect macaques with HIV, sustained replication and pathogenesis were not observed. Today, it is strongly suspected that restriction by TRIM5α in cells from most macaque species was responsible for prevention of cross-species transmission. HIV-2 isolates were serially passaged in baboons with some efficient replication, but little or no pathogenesis.[59] After the observation that SIV infection caused pathogenesis in the Asian macaques, a number of virus isolates were derived from the blood and tissues of serially infected macaques. These three major types of SIV are based on SIVsm (naturally found in sooty mangabeys), SIVmac (from an experimental infection of *M. mulatta*), and SIVmne (from an experimental infection of *M. nemestrina*). Members of these isolates were further characterized by obtaining full-length infectious molecular clones that could recapitulate the pathogenic capacity of the isolate. Subsequently other members of the SIV family have been identified from naturally infected African green monkeys (SIVagm), mandrills (SIVmnd), colobus monkeys (SIVcol), and almost all of the various African monkeys, but not baboons. For the most part, the SIV/macaque model has utilized SIVsm or SIVmac in *M. mulatta* or *M. fascicularis*; other groups have favored the use of SIVmne in *M. fascicularis* or *M. nemestrina*.

Hayami and colleagues made a seminal contribution to the field when they constructed the first viral chimera between HIV-1 and SIV.[60–62] This virus consisted of the SIV "backbone" with the *env* gene replaced by that from HIV-1. Since this first SHIV construct, several additional SHIVs have been described.[63] However, the development of chimeric viruses has not been a trivial pursuit, and only one virus to date, SHIV-SF162P3, bears an HIV-1 envelope that utilizes the CCR5 coreceptor.[64] This virus was shown to cause depletion of $CD4^+$ T cells in the GALT, unlike CXCR4-utilizing SHIVs.[65] These chimeras have been very useful for vaccine efforts that target the development of neutralizing antibodies, since the env genes of SIV and HIV-1 are poorly cross-neutralized, if at all. SHIVs may also be useful in the pursuit of live attenuated vaccines.[66] Other important constructs have included replacement of other SIV genes, such as the RT gene, with that from HIV-1, in order to test RT inhibitors *in vivo*.[67]

Many investigators have developed stocks of SIV and SHIV that are made widely available to researchers who wish to perform challenge studies. The expense of preparing and titering these

large scale (300 vials or greater) stocks *in vivo* in the relevant nonhuman primate host is quite high, certainly well above $100,000 (U.S.). Typically a full *in vivo* titration requires purchasing, infecting, and housing at least 6 and up to 10 animals for up to 1 year in BSL-2 or BSL-3 containment, in order to support statistically robust outcomes.[68] In part to defray this cost, several primate centers have prepared and titered stocks that are widely distributed, and the NIH Division of AIDS also has made several stocks available, including a recent stock of SHIV-SF162P3 grown in *M. mulatta*. Clearly the use of identical challenge stocks is a variable that can be controlled by this judicious sharing of resources. The U.S. NIH has developed a shared resource for qualified investigators that is entitled the AIDS Research Reference Reagent Repository (http://www.aidsreagent.org/ecommerce/). This resource provides a very comprehensive and well-referenced set of viral stocks, cell lines for growing virus, monoclonal antibodies, recombinant antigens, etc. to investigators who are registrants and can show that their laboratories have met any required biological and biosafety containment criteria.

ADVANTAGES/DISADVANTAGES

There are many advantages to the utilization of nonhuman primate models for AIDS research. Some examples include increased understanding of viral and host factors that affect pathogenic outcomes, infectiousness via diverse routes of entry, and the roles of specific factors in limiting infection. The use of these models allows investigators to compare outcomes of infection in multiple individuals using the identical, characterized—in many cases cloned—virus stock. By this type of study, it is apparent that there are host factors contributing to pathogenic outcomes. Conversely, viruses derived at different times of infection can themselves have differential pathogenic potential.[69] Direct inoculation of virus at various mucosal sites has allowed a clearer understanding of the differential infectivity of stocks given by different routes. Similarly, the ability to perform timed necropsies of primates infected with well-characterized and genetically identical stocks has facilitated the identification of specific cell types involved in the earliest stages of infection by SIV and SHIV, as well as the rates of mutation that accrue after infection. Information about neurovirulence has been much more approachable in the SIV model than in infected humans.[70] The contribution of regions of the genome to the pathogenic potential of a given virus has been demonstrated with viral chimeras, and more recently the study of changes in the viral envelope over time has yielded interesting information about the inherent ability of the HIV-1 envelope to tolerate mutations *in vivo*.[71] One of the key questions in vaccine research is how neutralizing antibodies are generated, particularly those with the ability to neutralize multiple viruses. Neutralizing antibodies with broad capacity can be generated by infection with the primate lentiviruses, but they are rare, as in humans.[72] These models may offer insights into the mechanisms of development of key immune responses, including innate, cellular, and humoral immunity. Laboratory nonhuman primate models for AIDS allow comprehensive studies of the events occurring in the days immediately following exposure and infection, and experiments with various combinations of competing microbes, which cannot be accomplished for exposed humans.

Another area that can be addressed much more easily in the nonhuman primate than in humans is the evaluation of vaccines and therapies to limit mother-to-child transmission. Some new models were developed in recent years to test active and passive approaches for vaccination in very young primates. These include breast milk transmission,[73] perinatal transmission,[74] and the oral inoculation of newborns with SIV[75] or SHIV.[76] Risky approaches that would be prohibited in humans, such as live attenuated vaccines[39] and passive antibody transfer,[77–79] have been important tools to understanding host immunity and protection. Even with less than fully effective vaccines, it is possible to test how well newborns and infants respond to vaccination. Newborn rhesus macaques have been vaccinated with live attenuated vaccines or recombinant viral vectors expressing SIV antigens in the first few weeks of life and they have been able to mount significant immune responses and control pathogenic viral challenge,[80] which is encouraging news for the future once more effective vaccines are developed. Important information about passive immunity[81] such as dosing and timing[82] and active vaccination of newborns[80] can be derived from these models without risking human infants.

These advantages are balanced by a number of disadvantages. Obviously, the absence of a model that uses HIV-1 as the infectious agent is the most glaring problem for the field. Although certain aspects of this problem can be overcome by the use of SHIV clones and isolates, there is as yet no substitute for clinical work to understand human immune responses to the virus and pathogenic sequelae of the resulting immune depletion. Most non-SPF adult macaques in captivity harbor a virus that is lethal to humans, herpes B. This problem has led to the development of safety regulations to prevent exposure, but there have still been rare infections of animal handlers. One approach is to develop SPF breeding colonies, and many of the centers are making great strides in this area, eliminating (as noted above) SIV, simian retrovirus (SRV), simian T-lymphotropic virus-1 (STLV-1), and herpes B. The lack of complete genotyping, specifically with a focus on MHC Class I, has made the use of nonhuman primates more challenging for both pathogenesis and vaccine studies. Certain alleles in macaques that allow responses to key epitopes in SIV Gag, for example, were very useful in understanding escape from cytotoxic T cell (CTL) control of SIV.[83] This problem is complicated by the use of multiple species of macaques by different investigators, at a time when genetic characterization of the different species is not well developed. To some degree, the use of certain species to the exclusion of others (e.g., *M. mulatta* of Indian origin) has created a shortage that can be alleviated only by expanded breeding or acceptance of other species and subspecies. Differential virus replication in rhesus macaques of Indian and Chinese origin calls into question the interchangeability of the two populations for research.[84] Certainly, another major disadvantage is the expense of purchase and maintenance of these valuable primates, which has limited the size of studies. Thus, analyses of subtle differences in immune parameters in immunogenicity studies, for examples, have been much easier to evaluate in clinical studies in humans. Some of the recent efforts from the HIV Vaccine Enterprise include infusing HIV vaccine research with funding that can support much larger nonhuman primate studies that may have sufficient statistical power to inform the choice of immunogens for clinical development. However, most of the primate facilities are not designed to handle multiple large (>100 animal) experiments at one time, which will require careful planning and shepherding of resources. Finally, research in nonhuman primates requires an appreciation of the model at many levels, and for the first time investigator there are many complex

issues to consider. This last problem is one of the easiest to address, as seasoned investigators can be found to collaborate, and the NPRCs have as their mandate to serve the research community. Diverse samples of blood, tissues, and organs are available to all research investigators. Pilot studies are available by competitive application, and these can serve to match an investigator with a primate modeler, facilitating the development of preliminary data for a larger study or grant. Although the NCRR provides core support for the eight NPRCs, scores of additional grants from other Institutes of NIH that are awarded to numerous academic and research institutions provide the majority of the funding for the NPRC work. An additional resource to consider is attendance of the yearly Nonhuman Primate Models for AIDS Symposium, presently having completed its 24th Annual conference (http://www.hivatlas.org/24th_Annual_Symposium_on_Nonhuman_Primate_Models_for_AIDS) where current results and future collaborative efforts and opportunities are discussed.

PREDICTIVE VALUE OF THE MODELS As noted above, the uses of the nonhuman primate models are diverse, thus making the careful choice of the appropriate model for a particular study absolutely key to understanding the outcome(s). In addition, frequently due to availability of species and particular virus stocks, the same experimental design has been tested in different laboratories with divergent outcomes. Thus, one of the major issues confounding AIDS research has been the interpretation of results obtained utilizing different virus–primate pairs. These differences have also been compounded by the unfortunate limitations in nonhuman primate funding during the first 10 years of the epidemic, which led to use of sizes of experimental arms that were very small (three or four animals per group), insufficient to provide statistical power unless there were all-or-none outcomes. Recent studies have utilized much larger groups (6–10), allowing the interrogation of more subtle questions and comparisons between groups receiving different vaccines, for example. The current primate models for AIDS, as well as future models, would be considerably less expensive, allow greater throughput at the primate centers, and reduce the number of monkeys used yearly, if surrogate markers of vaccine success could be assessed before, or instead of, live virus challenge. Surrogate markers currently include both T cell and antibody responses in blood and at mucosal sites.

The most compelling question for the nonhuman primate models is their predictive value for human studies. In cases in which direct comparison can be made such as drug development or transmission studies, it appears that the predictive value is strong.[85] A great deal of our understanding about the biology of infection and dissemination via mucosal routes has been obtained from nonhuman primate studies, where both qualitative and quantitative data are forthcoming. Three recent reviews have touched on this point of predictive value for vaccine studies: Staprans and Feinberg,[3] Haigwood,[85] and Hu[5]. Once there is an HIV vaccine in humans with some efficacy, it will be possible to validate one or more of the nonhuman primate animal–virus pairs and to proceed with some confidence to use this model for future development. Until that time, these models will continue to serve as important adjuncts to clinical studies to understand the issues in transmission, persistence, and pathogenesis,[86] to elucidate innate and adaptive parameters of viral control,[87] and to serve as testing grounds for vaccine strategies.

VI Models of Other Human Diseases

59 Use of Congenic Mouse Strains for Candidate Disease Gene Identification in Complex Traits

Ute Christine Rogner and Philip Avner

ABSTRACT

Genetic analysis aims to establish the relationship between a gene and a specific trait through the parallel study of phenotype and underlying genetic variation. Current tools for genetic analysis in the mouse extend from standard matings such as intercrosses and backcrosses to the use of more specialized resources such as recombinant inbred (RI) strains and recombinant congenic (RC) strains. Both RI and RC strains are characterized by the fixation of a genome-wide admixture of novel genetic combinations subsequent to meiotic recombination and segregation. Other resources of particular interest for the analysis of complex traits include consomic and congenic strains. In consomic or chromosome substitution strains, the genetic admixture is restricted to a single chromosome, and in congenic strains it is restricted to a single chromosomal region. Consomic and congenic mouse stocks have played a pivotal role in the genetic analysis of complex diseases that are often under the control of both environmental and multiple genetic factors and include type 1 diabetes, multiple sclerosis, obesity, and cancer. This chapter will provide an overview of the different tools available in the mouse for the genetic analysis of complex traits, with particular emphasis on different aspects of the use of congenic mouse strains.

Key Words: Consomic, Congenic, Inbred mice, Complex disease, Quantitative trait locus (QTL), Gene.

TOOLS AND SYSTEMS OF GENETIC ANALYSIS IN THE MOUSE

The mouse is the organism of choice for modeling human disease with not only many thousands of mutations already isolated and projects to inactivate all mouse genes well underway,[1] but also with 450 described inbred strains,[2] a wealth of genetic and phenotypic diversity.

It is this collection of inbred strains, rather than the collection of mutations, that has provided the raw material for studying phenotypes under complex genetic control. This has, in recent times, been facilitated by the Mouse Phenome project (see database links), which aims at garnering and curating, through a coordinated international effort, baseline phenotypic data on most of the common inbred strains.

The breeding systems underlying the development of key genetic resources are shown in Figure 59–1. Each recombinant inbred (RI) strain contains a unique admixture of genetic contributions—in approximately equal proportions—from its two original progenitor inbred strains. Traditionally, such RI strains are established by crossing animals of two inbred strains, followed by 20 or more consecutive generations of brother/sister matings.[3] Recombinant congenic (RC) strains are also established by an initial crossing between two inbred strains, but this is followed by a few, usually two, backcrosses of the resulting F_1 hybrids to one of the parental strains, called the "recipient" strain, with subsequent brother/sister intercrossing as for RI lines.[4] In both RI and RC strains the result is a mosaic genetic structure with blocks of genetic material from one parent interspersed with blocks of genetic material from the other parent. RI and RC strains differ, however, in the relative contribution of the two parents to the final strains. The Complex Trait Consortium[5] represents the largest community effort to date to generate and maintain collections of RI lines having sufficient analytical power to allow for systematic quantitative trait locus (QTL) analysis. The current project aims to generate some 1000 RIs from eight different parental strains to sort out the genes behind different complex disorders.

Consomics and congenics are special types of inbred strains in which part of the genome of one mouse strain is transferred to another by backcrossing the mouse strain acting as the donor to the recipient strain followed by intercrossing in later generations to ensure fixation and homozygosity. Selection is systematically practiced to ensure retention of the desired genetic material from the donor strain. The method was first introduced by Snell who produced histoincompatible congenic strains, which he originally called "congenic resistant" strains.[6] In the case of a consomic, a whole chromosome is transferred.[7,8] In the case of a congenic strain it is a defined chromosomal segment, also termed the differential segment that is transferred[9,10] (Figure 59–1). Such congenic strains will normally carry differential regions of 10–20 Mb in size[11] unless specific efforts are made to reduce the size of the differential segment. Several hundred congenic strains currently exist. Many of these can be retrieved directly from the Jackson Laboratories. Congenic strains need to be distinguished from coisogenic strains that differ at only a single locus from their parental strain.[12] Coisogenics can be derived by both gene targeting involving homologous recombination or mutagenesis

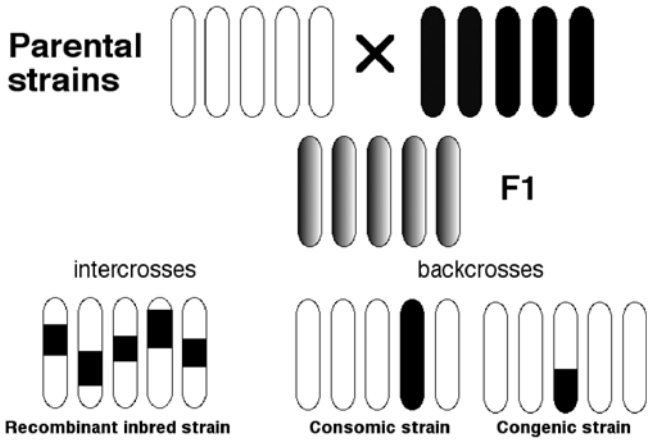

Figure 59–1. Genetic admixture in recombinant inbred strains, consomics, and congenics. Recombinant inbred strains are generated by intercrosses of F_1 mice and subsequent brother–sister interbreeding. Consomic strains are generated by repeated backcrossing of F_1 animals to the parental receiver strain, but only one chromosome is derived from the donor strain. In congenic strains only the differential chromosome segment is derived from the donor strain.

approaches. RI and RC consomic and congenic strains all have in common the advantage that they allow repeat phenotyping of large numbers of genetically homogeneous animals under defined environmental conditions.

APPROACHES TO THE IDENTIFICATION OF A GENETIC INTERVAL CONTROLLING A COMPLEX TRAIT

The starting point for the identification of a genetic locus controlling a complex trait, or QTL, is most often the generation of an F_1 intercross from two parental inbred strains differing in phenotype for the trait under study and the subsequent intercrossing of F_1 progeny to produce an F_2 generation that can be subject to genetic analysis. Alternative analytical schemes may involve the backcrossing of the F_1 progeny to either one or the other parental strains, to generate first-stage backcross generation animals (BC1) and/or eventually backcross 2 animals (BC2). The number of animals needed for the F_2, BC1, or BC2 analysis depends on the strength of the phenotypic effect conferred by each QTL under study and also on the size of the genetic interval(s) to be identified. Generally, experimental cohort sizes are in the range of several hundred animals. Most of the currently identified QTL genes are slightly atypical in presenting rather extreme phenotypes that confer above average contributions to the overall phenotype. Contributions of the average single QTL to the overall phenotype has been estimated to be 5% or less.[13] While increasing the number of F_2 or BC animals under study and using a higher marker density may increase statistical power and allow the candidate region to be better localized, the additional effort would sometimes be better directed elsewhere, for example, to fine mapping and use of congenic strains (see the discussion below).

Alternatives to the generation of *de novo* crosses involve the use of sets of RI lines and/or RC strains. The analytical power of an RI line set depends on the number of available sublines and the degree of genetic/phenotypic variation in the parental strains. While RI sets can deliver higher mapping resolution than F2 mice,[13] current RI sets will often have insufficient power to identify genes encoding small-effect QTLs. In contrast to RI sets, sets of RC strains have the property of limiting the amount of the genome that has to be searched for multiple genes involved in quantitative traits as long as they have been selected for the phenotype of interest. The genome of a standard RC strain comprises, on average, only 12.5% from the donor strain.[14]

Irrespective of the approach used in the initial QTL localization, moving on to subsequent candidate gene identification and characterization will often prove difficult with both genetic complexity and genetic background effects hampering progress. Consulting the Mouse Genome Informatics (MGI) database (see below) reveals, for example, that while an initial localization has been described for some 2000 quantitative trait loci, in less than 1% of the cases has the gene underlying the QTLs been identified. Recent advances have on occasion been linked to the use of innovative *in silico* "Hapmap" type strategies, but mostly to the exploitation of consomic and especially congenic strains, which are increasingly playing a pivotal role in the dissection of QTLs.

HAPLOTYPE MAPPING AS AN *IN SILICO* ALTERNATIVE AND COMPLEMENTATION

In silico mapping is a powerful computational-based method for predicting chromosomal regions regulating phenotypic traits.[15] The discovery based on the distribution of single nucleotide polymorphisms (SNPs) in different inbred mouse strains of an alternating mosaic pattern of relatively large, typically 1–2 Mb, genomic regions (blocks) of low or high polymorphic variation (SNPs)[16,17] is the foundation for this approach. Regions that are poor in polymorphic markers have been designated as regions of common ancestry. Haplotype blocks are conceptually defined as genomic segments harboring sets of coupled polymorphisms that reflect a common ancestral origin.[18,19] Genome-wide association studies involving the correlation of a phenotype, for instance, disease prone and disease resistant, over a wide selection of different inbred mouse strains to patterns of genetic variation in these same strains have provided powerful indications of potential candidate regions.[15] QTL genes are likely, although not necessarily, to be found in regions of different ancestry among pairs of differentially affected strains, while a given phenotype observed in common in different strains will likely be controlled by a region that is held in common between these strains.[20] The approach requires that well-standardized parental phenotype data are available for many inbred strains. The PHENOME project was established in part with this type of application in mind.

Applied to congenic strain analysis, knowledge of the haplotype block structure within a congenic interval may focus interest on a particular subregion within the congenic candidate region (Figure 59–2). There are several examples in the literature that have demonstrated the value of this type of combined approach.[21–23]

In whatever way *in silico* mapping is applied, the success of the strategy depends on the size of the underlying haplotype blocks and the panel of relevant mouse strains. The approach also depends on rates of mutation within regions of shared haplotype being sufficiently low as to not obscure the underlying patterns of haplotype variation. Recent work indicates that the definition of haplotype blocks is not that robust and that methods for QTL mapping may fail if they assume a simple block-like structure.[19]

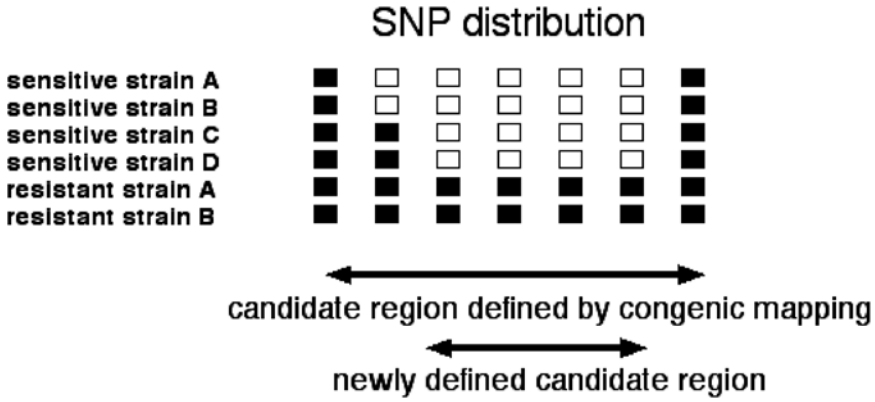

Figure 59–2. Haplotype mapping. Comparison of the SNP distribution within the candidate interval between disease-sensitive and -resistant strains may allow a candidate region to be further reduced.

USING CONSOMICS AND CONGENICS FOR DISSECTING QUANTITATIVE TRAIT LOCI INTO GENES

Consomic and especially congenic strains are proving to be key resources for the dissection of QTLs whose genetic control is very distant from the simplicity of characters showing single-gene dominant or single-gene recessive Mendelian inheritance. Understanding the role of an individual QTL is often hampered by the complexity of its genetic and phenotypic interactions with other participating QTLs. As an example, consider susceptibility to type 1 diabetes and the well-known disease model for type 1 diabetes, the nondiabetes (NOD) mouse.[24,25] It turns out that diabetes-sensitive strains such as NOD carry not only diabetes sensitivity loci but also QTL loci conferring diabetes resistance. Conversely, diabetes-resistant strains such as C57BL/6 carry loci conferring diabetes susceptibility as well as diabetes resistance genes. It is the overall balance and interactions that determine the final phenotype.[26] Some idea of the overall complexity is given by the 30 or more murine insulin-dependent diabetes loci (*Idd*) that have been genetically identified. In this complex situation, congenic strains often carrying segments derived from the diabetes-resistant C57BL/6 mouse strain have been of critical importance for breaking down the overall genetic complexity, for ensuring reproducibility of the detailed phenotyping studies, and for the comparative transcriptional profiling approaches used to narrow down the candidate region. Among non-major histocompatibility complex (MHC) *Idd* genes that have been cloned using a congenic strategy are *Idd3*, where *Il2* has been implicated,[22] *Idd5.1*, where *Ctla4* and *Icos* were suggested,[27] and *Idd5.2*, where *Nramp* is a likely candidate.[28]

The second reason to generate congenic strains is to study the effects of a gene mutation, knockout, knockin, or transgene on one or several different genetic backgrounds. This approach is of particular interest for studies on genetic modifiers.[29,30] The use of congenics, although often onerous, remains less time consuming than introducing the same modification in parallel onto different genetic backgrounds by gene targeting or transgenesis. Indeed, in many cases the latter approach may be impossible as the appropriate ES cell lines may not be available. When congenic construction is used, it should, however, be borne in mind, as already pointed out, that it is not a single gene that is being transferred but a gene and its surrounding genetic region. There have been examples showing that such genomic fragments can contribute to the phenotype or in a worst-case scenario even confer a new phenotype. Different breeding strategies to minimize such problems have been discussed.[31]

CLASSICAL AND SPEED BREEDING STRATEGIES FOR CONGENIC STRAINS

Congenic strains are derived by repeated backcrossing of the desired donor strain to the recipient strain with selection for the differential segment. This breeding is then followed by sister/brother interbreeding of the backcrossed progeny. In practice, female F_1 animals are mated with recipient strain males to establish the BC1 generation. Males heterozygous for the selected chromosome region are then repeatedly backcrossed to recipient females during congenic strain derivation. Congenic strains are then rendered homozygous for the genetic intervals under study by intercrossing heterozygous males and females of the same genotype and subsequently maintained by brother and sister mating. When repeated backcrossing is used to establish a congenic strain a minimum of nine generations of backcrossing is normally recommended to remove 99.9% of the unlinked and unwanted donor material,[32] though the exact number of required backcross generations appears somewhat arbitrary.[33] A genome scan, minimally, for other known loci relevant to the disease under study should be carried out before fixing the congenic interval so that if further backcrossing is necessary to remove a contaminating genomic fragment this can be carried out before the congenic strain is rendered homozygous.

Alternative congenic breeding schemes have been established that involve both positive selection for the desired differential segment and selection against the rest of the donor genome during early backcross generations. In such breeding schemes, called "speed congenics," the genetically "best" animals, i.e., those carrying the differential segment and minimal detectable donor strain material elsewhere in the genome, are selected. Theoretically the process can lead to the creation of a congenic strain with less than 0.5% contaminating donor genome unlinked to the differential segment within a total of five generations or four backcrosses.[34] Simulations suggest that screening between 16 and 20 male progeny per generation with markers spaced every 25 cM most efficiently reduces unlinked contaminating donor genome and represents an effective organizational strategy. Use of larger progeny cohorts and higher marker density seems of little advantage in reducing the contaminating donor genome until later back-

cross generations. High-density genotyping of the differential segment in later generations is, however, necessary to reduce the size of the target region below the 20–30 cM otherwise obtained at the N4 generation.[10] Experience suggests that both "best" and "second best" males should routinely be kept for breeding, in particular when intersubspecies congenic strains are being constructed and poor breeding performance may occur.

Recent simulation studies have suggested that marker-assisted breeding strategies can lead to increased background heterogeneity, or "gaps," in the recipient genetic background as compared to standard breeding procedures. This suggests that additional backcrossing may still be required in order to reduce the number and length of such gaps.[35] On the assumption of putative remaining gaps, it may be of interest to derive a given set of congenic strains from a single breeding pair and to generate at least one congenic strain carrying no differential fragment as an internal control for phenotyping.

When choosing recombinants to fix genetic intervals we recommend ensuring the highest possible density of markers within the differential fragment (1–2 cM) to avoid partial heterozygosity.

While the genetic interval conferring a particular phenotype in a given congenic strain can often be reduced and refined by identification of new recombinants during further backcrossing, it becomes increasingly difficult to obtain the necessary recombinants as the genetic distance under study is reduced and much larger breeding populations are needed. Several studies have shown the existence of sex-specific differences in recombination frequency[36–38] and it can, therefore, on occasion, be of use to change the direction of the cross and use heterozygous females instead of males or vice versa. It should be noted that recombination does not occur with random efficiency throughout the genome and is often higher at so-called hotspots. Certain theories predict that recombination will occur more often in regions in which gene density is higher and less often in "gene deserts," an expectation borne out for the human genome, where recombination rates are found to be higher in regions of the genome with higher gene density.[39] The informative polymorphic markers necessary to characterize the recombinants can be normally identified from the MGI database. Current densities of available markers ensure that only rarely will additional comparative sequencing efforts be required to identify additional SNPs.

When analyzing congenic strains, it has been observed that the phenotypic effects often get smaller as the genetic interval is reduced and subcongenics are generated. This most often occurs when the original effect was due to the combination of several genes and may reflect the relatively frequent occurrence of QTLs as haplotype blocks. In other cases, genetic interactions may lead to the suppression of phenotypes when intervals are combined and in such cases the generation of subcongenics is accompanied by an increase in the penetrance of the trait.[40] In theses cases, complexity within the genetic interval can normally still be successfully addressed, although it may require larger numbers of animals to be phenotyped and studied.

The benefit that can be obtained from a panel of congenic strains is critically dependent on the quality of the phenotyping available, which, in turn, is obviously dependent on the disease under study. The availability of subphenotypes for characterization is often critical to the fine dissection of the trait. Analysis often starts with the most robust and basic phenotype before proceeding to more subtle analysis of subphenotypes. Phenotyping methods often employed range from histology, behavioral studies, and the evaluation of physiological parameters to metabolomics and transcriptional profiling. At this stage of the project, the efforts employed in the construction of the congenic strains are usually rewarded.

CANDIDATE GENE IDENTIFICATION AND VALIDATION

Once a candidate region has been defined and characterized, the crucial difficulty of identifying and validating the causative gene(s) arises. It is important to realize that there is rarely one single approach, but rather a spectrum of complementary approaches that can be used to identify without ambiguity the gene(s) underlying a QTL.

The identification of changes in the primary nucleotide sequence, which is powerfully diagnostic in the case of mutations in monogenic disorders, is of much less certain value in the case of QTL characterization. First, because nonsense or stop codons that completely abolish gene function are much less likely to underlie QTL variation than in mutations affecting monogenic traits. Second, because the investigator cannot, a priori, know whether to expect changes in coding sequences or in noncoding regulatory sequences. And third, because extensive nucleotide variation may occur outside of the exon sequences of some genes, which renders the identification of causal polymorphisms in such regions potentially perilous. This indeterminacy may moreover be compounded if the causal gene lies within a region that shows a high degree of polymorphism between the parental strains. In such cases the polymorphism within the genomic sequence of the causal gene will likely be no more marked than that of the surrounding genes. Such regions of elevated polymorphism are to be found throughout the mouse genome and reflect the breeding history of mouse inbred strains (see above). Such caveats suggest that resequencing of entire regions in the donor and recipient strains is an approach that can help to exclude a certain proportion of candidate genes rather than lead to the unambiguous identification of the responsible gene.

The use of expression profiling for candidate gene identification is based on the idea that in many cases the QTL will reflect quantitative changes in the expression of the underlying gene(s). This approach has proven to be particularly fruitful in cases in which the phenotype of the disease under study has provided clues as to the class(es) of genes or to the tissues in which the candidate gene is likely to be expressed. Annotated lists of genes for the region under study obtained from Ensembl, MGI, or NCBI databases, including *in silico* expression profiling approaches based on exploiting data from sources such as Serial Analysis of Gene Expression (SAGE) libraries, microarray analysis-based datasets, and cumulative data on expressed sequence tags (ESTs) (see Table 59–1), allow the tissue expression profiles of the genes to be established. Where necessary these data are then validated for the most promising candidates by comparative expression profiling of the discriminatory congenic strains using techniques such as quantitative real-time polymerase chain reaction (PCR). A complementary variant of this approach uses genome-wide microarray-based expression profiling to identify possible genetic pathways.[41] The efficiency of both strategies depends on the completeness of the gene annotations and the exhaustiveness of

the gene representation that is being exploited and is influenced by both the cellular complexity of the target tissue and relative transcript expression levels. In the case of complex tissues sensitivity may be increased by analyzing cellular subpopulations of the tissue in question.[42,43]

Neither the identification of sequence variation nor of altered expression profiles is of itself sufficient to establish causality. For this, techniques of gene inactivation, gene overexpression, and the gold standard, replacement of the allele of one strain by that of the other strain—referred to here as "allele shuffling"—are required. Ongoing programs for inactivation or mutating all mouse genes will increasingly provide "off the shelf" ES cells carrying a knockout for the candidate genes under study. Database links that provide information about existing knockouts and mutants are listed in Table 59–1. Exploiting such resources for QTL validation may in many cases be complicated by the need to cross the knockout onto the relevant genetic background. Interestingly, some of the constructs used in these global knockout programs may facilitate application of a knockin strategy, which would enable the integration of alternative functional allelic forms of the gene at the disabled locus to be undertaken.[44]

An alternative and potentially very efficient strategy for gene disabling is the use of small interfering RNA (siRNA) to inhibit/knock down gene expression. RNA interference (RNAi) is a highly evolutionary conserved process of posttranscriptional gene silencing (PTGS) in which double-stranded RNA (dsRNA), when introduced into a cell, causes sequence-specific degradation of homologous mRNA sequences.[45] Double-stranded RNAs of around 21 nucleotides in length inhibit the expression of specific genes and can work effectively both *ex vivo* and *in vivo*.[46–48] The RNAi WEB database provides a good summary of such studies and excellent practical advice. The long-term and stable inhibition of gene function normally necessary for assessing the effect of a QTL implies that delivery systems capable of supporting stable and persistent expression *in vivo* are necessary. Cloning of stable interfering short hairpin (sh) RNA molecules and use of several viral vectors and transposon-based nonviral vectors have been reported that fulfill this requirement.[49,50] Interestingly, such RNAi approaches can be used with embryos circumventing the strain restriction bottleneck associated with ES cell use. Although there are problems associated with off target non-specificity of RNAi that require stringent control, RNAi can be engineered to be specific for particular allelic forms of a given gene. Providing technical problems can be overcome, experiments aimed at targeting RNAi to alleles of a candidate gene in F_1 animals from two discriminatory congenic strains should prove particularly informative.

Overexpression studies provide an alternative if less stringent way to either further reduce the size of the candidate region or to validate formally candidate genes, when the trait under consideration is dominantly or codominantly expressed.[51,52] Such approaches are often carried out using BAC clones, which may be one to several hundred kilobases in size and therefore allow the gene to be tested along with many of the *cis*-acting sequences necessary for its regulated expression. Such studies are being facilitated by the construction of BAC libraries for many mouse strains other than C57BL/6 and 129/Sv.[53] The fingerprinting of these libraries and the ready availability of both mouse genomic draft and finished sequences[54] and of strain resequencing programs allow the DNA hybridization probes necessary for BAC isolation to be easily designed. Although BAC transgenesis is an

efficient process, it should be noted that both copy number variation and variation in the site of integration in the genome leading to position effects may lead to modifications in gene expression profiles that might hamper or obscure the identification of the gene when subtle phenotypes are concerned.

COMPARATIVE GENOMICS BETWEEN MOUSE AND HUMAN

Humans and mouse have both evolved from an ancestral small mammal that split into two species toward the end of the dinosaur era. Despite 75 million years of separate evolution, only about 300 genes—1% of the 25,000–30,000 genes in the mouse genome—were found to be without an obvious counterpart in the human genome and vice versa,[55,56] leading to the idea that in the majority of cases the underlying biology and physiology of processes occurring in humans and mouse will be similar or identical. Most studies of mouse models of human disease are predicated on this. Diseases under monogenic control most often, although not necessarily always, provide support for the assumption.[57] Where the assumption fails to hold, because mutations in a given gene fail to produce the same phenotype in both species, the differences are mainly imputable to differences in physiology, to subtle differences in the gene regulation, and or/to differences in the specific mutation itself rather than to the absence of the gene. The predictive value of QTLs identified in one species for the other is generally considerably weaker. This is almost certainly due to the genetic heterogeneity underlying most complex traits, to differences in penetrance even when the same gene may be concerned, and to differences in the spectrum of naturally occurring variation at a given locus in humans and mouse. This, however, does not imply that the underlying genetic networks are highly divergent and if we take the case of type 1 diabetes this is clearly not the case. Indeed, the identification of causative genes for the autoimmune disease type 1 diabetes (T1D) in humans and candidate genes in the NOD mouse has shown that susceptibility or resistance to type 1 diabetes, involving genes and pathways contributing to autoimmune pathogenesis, are primarily held in common by the two species. To cite but one example, gene variants for the interacting molecules IL2 and CD25, members of a pathway that is essential for immune homeostasis, are present in mice and humans.[58] In this context, identifying the mouse genes involved in type1 diabetes by consolidating our knowledge of the pathway underlying the pathogenesis will both indirectly and directly identify novel targets, which can be studied for their possible role in the human pathogenic process.

Congenic strains have and will continue to play a central role in the panoply of genetic tools available to the research scientist. Indeed, their importance and pivotal role are likely to rise as the tools necessary for high-throughput systematic functional testing of candidate genes lying within the candidate regions defined by using congenic strains become more widely available.

ACKNOWLEDGMENTS

We thank Richard Harvey and Christophe Rachez for critical reading of the manuscript. 60 Animal Models of Sudden Infant Death Syndrome

JANE BLOOD-SIEGFRIED

ABSTRACT

Sudden infant death syndrome (SIDS) is the most common cause of postneonatal infant mortality in the developed world. It is a diagnosis of exclusion, defined as the sudden and unexplained death of an infant between 1 month and 1 year of life. Examination of specific pathology may be possible only in an animal model. The three animal models most commonly used in SIDS research to examine risk factors are the piglet, neonatal rabbit, and neonatal rat. We also describe a developmental rat model of sudden unexplained death in response to viral and bacterial infections. This model offers a unique way to evaluate the role of immune development and its relationship to potential risk factors believed to be important in the etiology of SIDS.

Key Words: Animal model, Cytokine, Endotoxin, Inflammation, Influenza virus, Neonatal rabbit, Neonatal rat, Piglet, SIDS.

INTRODUCTION

Sudden infant death syndrome (SIDS) is the most common cause of postneonatal infant mortality in the developed world.[1,2] It is a diagnosis of exclusion, often defined as the sudden death of an infant not explained by a thorough autopsy, review of the clinical history, and examination of the death scene.[2,3] SIDS occurs from 1 month to 1 year with the peak incidence between 2 and 6 months of age. Although infants dying of SIDS appear normal and healthy, there is often a history of a mild viral illness that is not thought to be the cause of death.[1,2]

Epidemiological research has helped establish risk factors for SIDS including ethnicity, maternal smoking and drug use during pregnancy, environmental tobacco smoke exposure, concurrent viral illness, overheating, and sleep position; in addition, the incidence is highest in the winter months.[4] Before 1990, prone sleeping was considered the greatest risk factor for SIDS. With the decrease in SIDS due to the campaign to put infants to sleep on their backs, the most significant risk factor has become maternal smoking. Although passive smoke exposure can cause respiratory problems in infants, maternal smoking during gestation is the most important risk for SIDS.[5–7]

The etiology of SIDS is thought to be multifactorial, and it is quite likely that many different means can cause the unexplained death. Several theories of causation are prevalent in the animal model literature, in particular, pathology related to respiration. Changes, both central and systemic, that can affect oxygenation, rebreathing of carbon dioxide, and recurrent apnea are a prime focus of animal research.[8–11]

Other animal studies have focused on damage to the fetal neurological system. Autopsy evaluation of many SIDS cases reveals histological and chemical changes that indicate abnormal development in the brain.[12,13] These abnormalities are located primarily in the brainstem but are found throughout the brain as well. They reflect possible damage from anoxia, but are not limited to that particular insult. For example, prenatal nicotine exposure without hypoxia may cause structural and neurochemical changes in the brain.[14–18] An animal model offers a way to examine the developing nervous system and damage from possible insults.

A more recent area of animal research focuses on mechanisms that challenge cardiovascular responsiveness through overheating, hypoglycemia, infection, and toxins. Risk factors such as the increased incidence of SIDS in winter months parallel closely those associated with these cardiovascular challenges.[19]

Prone sleeping position is thought to play a significant role in risk because of changes in gas exchange; however, elevated body temperature may also be a factor. It is believed that the fatal event involves the inability to compensate for a vital physiological challenge to a compromised infant during sleep. Compensatory mechanisms of gasping ability, arousal, and efforts to overcome lowered blood pressure and heart rate are currently being examined.[13,20]

Some autopsy findings observed in SIDS infants have been difficult to explain. Many SIDS infants have characteristic intrathoracic petechiae and liquid blood in the heart.[21,22] These could be associated with efforts to overcome hypoxia, respiratory distress, suffocation, or resuscitation; however, they could also be due to coagulation problems associated with infection and inflammation.[23,24] Autopsy findings are varied, but there are often signs of inflammation and response to infection that are out of proportion to preexisting symptoms. Thymic involution, a sign that the infant has been responding to excessive stress, is observed in more than half of SIDS cases.[25]

A good animal model must reflect the characteristics of an uneventful history without a clear cause for death. Careful consideration must be given to associations between the human condition and the findings in the model. Insults should be plausible and compatible with daily living, and they cannot be so severe that they are obviously the cause of the death.

ANIMAL MODELS OF SUDDEN INFANT DEATH SYNDROME

Many animals have been used to study sudden unexplained death in cats,[26,27] chick embryo,[28–31] dogs,[8] ferrets,[32,33] guinea pigs,[34] mice,[35–37] and several primates.[38,39] Although primates are more like humans than the other species, they present difficulties for researchers. Primates have fewer offspring and much longer gestations than other laboratory animals. In addition, many species of primates are endangered, adding moral and legal reasons not to subject them to science that involves the death of offspring. Therefore the majority of research on sudden unexplained death has been done using the piglet, neonatal rabbit, and neonatal rat (Table 60–1). This chapter therefore focuses on models developed in these three species.

PIGLET The piglet is commonly used in neonatal research, in part because it is a large animal, which allows easy manipulation of equipment and procedures. The piglet also has a tracheal morphology that is very similar to a newborn infant.[40] Many processes have been well characterized in perinatal swine models. Piglets have been used primarily for respiratory research in SIDS, but they have also been used to examine the effects of heat and heat stress, reflux, and cardiac development.

A large study published in 1994 evaluated the natural history of a group of 1921 piglets, examining all animals that died for cause of death. Eight animals died suddenly or unexpectedly; however, only one animal represented a "SIDS-like" death. It was concluded that although there was a high incidence of mortality, the incidence of sudden unexplained death in the piglet was very low, and thus it would be pointless to study the piglet in the natural state.[41]

Nevertheless, studies in piglet models have been very productive in focusing on specific systems. Galland and colleagues,[42,43] for example, in an early study, looked at the effects of hyperthermia and oxygen consumption and tested the hypothesis that a cold face and hot body might increase hyperthermia and drop O_2 consumption in a cold climate. They found that face cooling could also increase rapid eye movement (REM) sleep, a time of risk for SIDS.[42] Additionally, this study supported the idea that head covering does not increase CO_2 or decrease O_2 but has its primary effect by increasing body temperature.[44]

In another study, heated piglets developed tachycardia, hypotension, and metabolic acidosis. They also became tachypneic, with hypocapneic alkalosis and neutrophil leukocytosis. Interestingly, these animals had excessive hemorrhage in the lungs and alveolar edema, similar to that seen in SIDS cases.[45] In addition, piglets have been shown to have a delayed response to airway obstruction while they are recovering from fever.[46]

Xia and colleagues used decerebrated, vagotomized piglets to evaluate the combined effects of hyperthermia and apnea in sudden death. They found that respiratory inhibition associated with chemoreflex was prolonged when body temperature was elevated,[47] and these changes were probably mediated by the central nervous system (CNS).[48]

It has been proposed that reflux during sleep has a negative effect on the ability of the human infant to autoresuscitate.[49] The piglet model allows for manipulation of the gastrointestinal (GI) tract and artificial instillation of a mildly acidic compound to stimulate airway protective responses in naturally sleeping and sedated animals.[49,50] Richardson and Adams examined lung changes postmortem following laryngeal chemoreflux and found that these piglets had petechiae in their lungs.[51] Togari and colleagues examined the compensatory role of cerebral circulation in respiratory control in a high CO_2 environment and found that reduction of cerebral blood flow caused respiratory suppression in hypercarbic piglets.[52]

The piglet model has also been used to examine hypoxic responses to infection and smoking. Pretreatment with nicotine

Table 60–1
Animal models examining risk factors for sudden infant death syndrome in the piglet, neonatal rabbit, and neonatal rat

Risk factors	*Animal*	*Conclusion*	*Reference*
Hyperthermia	Piglet	Head covering does not decrease O_2 or increase CO_2 but has its primary effect by increasing body temperature	42–44
	Piglet	Piglets have a delayed response to airway obstruction while recovering from fever	46
	Piglet	Respiratory inhibition in response to chemoreflex was prolonged with elevated body temperature; these changes are probably mediated by the central nervous system (CNS)	47, 48
CNS	Piglet	The reduction of cerebral blood flow caused respiratory suppression in hypercarbic piglets	52
	Rabbit	Maternal cocaine exposure alters the maturation of centers in the brain important for autonomic and respiratory function	58–60
Autonomic tone	Piglet	Imbalance in autonomic tone favoring parasympathetic tone could cause a problem in the developing piglet	55–57
Nicotine	Piglet	Nicotine and infection interfere with autoresuscitation from chemoreflex or hypoxia	53, 54
	Rat	Prenatal nicotine exposure decreases autoresuscitation in response to apnea; this appears to be related to the affect on autonomic nervous system development	72–79
Toxins and infection	Rabbit	Intravenous administration of different bacterial toxins increased catecholamine levels, and induced bradycardia, hypotension, and apnea in neonatal rabbits	62, 65
	Rat	Combinations of bacterial isolates were lethal to rat pups	66, 83, 84
Development	Rat	There is a transitory period of imbalance in brainstem respiratory control in the 12-day-old rat	86–88
	Rat	Lethal response to influenza A and endotoxin challenge in the 12-day-old rat pup	83, 84

and endotoxin has been shown to interfere with autoresuscitation and produce prolonged apnea in experimental piglets exposed to a subglottic acidified saline solution.[53] Nicotine and interleukin (IL)-1β had synergistic effects, decreasing the animal's ability to respond to apnea.[53] This response was also stimulated by intermittent hypoxia down to 6% O_2, then reoxygenation. Nicotine and inflammatory mediators appear to act as cofactors in hypoxic–ischemic neurological injury.[54] Froen and colleagues did not examine the synergy between endotoxin and nicotine; however, their work suggests a relationship between either nicotine or an inflammatory response to infection and lethal apnea.[53]

SIDS infants may succumb to a fatal cardiac arrhythmia that is not detectable on autopsy, and researchers have used the piglet to examine the development of cardiac sympathetic innervation and evaluate arrhythmia.[55] These studies have established that an imbalance in the maturation of autonomic function favoring a parasympathetic response could pose a problem to the developing piglet.[56] They have also shown that the piglet can be used to evaluate prolonged QT syndrome in swine.[55,57] This syndrome can cause lethal arrhythmias in all age groups and may possibly be a mechanism of SIDS.

RABBIT The rabbit allows researchers to do larger scale manipulations than are possible in rodents. In SIDS research, rabbits have been used primarily to examine the effects of respiratory insults, infectious agents, and gastric reflux.

In an early study, a series of experiments examined the effect of maternal cocaine use in pregnancy on respiratory response in neonatal rabbits.[58,59] The researchers exposed rabbit pups to different levels of FiO_2 and found that prenatal cocaine changed the maturational response of respiratory control.[60] This supported the basic hypothesis that cocaine use alters the maturation of centers in the brain important for autonomic and respiratory function.

Gastrointestinal pathogens are known to be a leading cause of morbidity and mortality in children under the age of 5 years.[61] Siarakas and colleagues examined the effects of intravenous administration of six common bacterial toxins on the cardiorespiratory system in 1–3 kg rabbits. They observed bradycardia, hypotension, and apnea with sudden death and concluded that under the right conditions, bacteria could produce toxins that cause inflammatory responses similar to those associated with endotoxin-induced shock.[62]

The rabbit has also been used to evaluate the response to acid reflux by instilling an acid solution in the larynx of neonatal rabbits, inducing obstructive, central, and mixed apnea.[63] Similarities between the gastrointestinal tract of the young rabbit and the human infant provide a good model for evaluating potential effects of toxigenic bacteria.[64] A study using this model measured catecholamine responses to intravenous and intraluminary exposure in the gastrointestinal tract to bacterial toxins. With increasing intravenous doses, the study found a dose-related increase in catecholamine levels and sudden death. However, intraluminal doses did not increase sudden death. It appears that a healthy gut provides a good protective barrier.[65]

RAT The rat is a wonderful research animal because it is large enough to allow manipulation using standard equipment and it has the added advantage of large litters and fast turnover of progeny. A drawback to rat research is that there are fewer antibodies available for immune studies, and knockout strains are much less developed than with mice. In spite of this, the rat has often been used in SIDS research. Rat models have been developed to examine both infectious and respiratory insults, and current work is focusing on neurological changes in the brain following prenatal nicotine exposure.

Building on a body of work showing that infectious insults could cause unexplained death, Lee and colleagues showed that following subcutaneous injection of nasopharyngeal bacterial isolates cultured from human SIDS infants, 21-day-old weanling rats died rapidly without terminal signs of illness and with minimal inflammatory changes in lungs, liver, and heart.[66] When pathogen samples were paired (*Escherichia coli* and *Staphylococcus aureus*) mortality occurred much more abruptly, demonstrating the synergy between pathogens.

The identification of *Helicobacter pylori* DNA in postmortem tissues of SIDS infants led to the use of a rat model to examine fatal apnea as a response to gastroesophageal reflux in infants.[67,68] There is little evidence that *H. pylori* is the primary cause of SIDS; however, this model is consistent with the infectious challenge theories of SIDS.[69,70]

Maternal smoking is an independent risk factor for SIDS.[71] Passive exposure to environmental tobacco smoke increases risk,[5,6] but the risk of SIDS doubles with maternal smoking and is three to four times higher if the mother smokes more than 10 cigarettes per day.[7] Nicotine is currently considered a neuroteratogen and thus it is possible that maternal smoking during pregnancy is more harmful than postnatal exposure to environmental tobacco smoke.[5,72]

Prenatal exposure to nicotine has been shown to cause a decreased response to apnea and respiratory insult; in addition, it is believed that nicotine affects the development of autonomic responsiveness and delays maturity in the newborn, increasing the risk of SIDS.[73] The rat offers an excellent model in which to evaluate the effects of nicotine on development of the respiratory and central nervous systems.

Perinatal nicotine has been shown to impair respiratory function and response to hypoxia in neonatal rats during the first week of life.[73–75] More recently, investigators have used the rat model to evaluate changes in autonomic function as a result of perinatal nicotine exposure, as well as its effects on the heart,[76] brain,[77] and respiration.[78,79] The changes appear to last well into adulthood.[15,80]

A DEVELOPMENTAL MODEL OF SUDDEN UNEXPLAINED DEATH

The studies reviewed above did not always address the consistent observation that the peak incidence of SIDS occurs between 2 and 4 months in all countries for which accurate data are available.[1] The factors underlying the increased susceptibility of this particular age range need to be examined. Developmental responses to infectious challenges may be crucial in this regard.

Animal models have been important for developing and testing ideas about the physiological events leading to SIDS; however, it is difficult to show a direct connection to human immune development. We think that rat immune development may provide a useful model for human infants. The rapid development of the immune and neurological systems in the rat makes each day a significant time point for comparison to human infants.

There may be changes in the development of immune responses that turn a minor illness into a lethal event.[81] We have addressed this issue by assessing an age-dependent model of susceptibility in rats to a nonlethal strain of influenza A virus and a sublethal dose of endotoxin.

Initial experiments were done on postnatal day (PND) 10 to ascertain mortality, timing between doses, and dose response. Pups were treated with 25 µl of a rat-adapted influenza virus (RAIV) given intranasally.[82] One to 5 days post-RAIV treatment, five pups per day, per dose, were given an intraperitoneal dose of endotoxin (2 mg/kg, 0.5 mg/kg, 0.2 mg/kg, or 0.05 mg/kg). A second control group of RAIV-naive pups were given the same dose of endotoxin at each time point. RAIV controls received virus only on PND 10. Pups were examined every 4 h postendotoxin for morbidity and mortality.[83]

The animals died quietly without significant symptoms 8–10 h postendotoxin. This model produced 20% mortality on PND 10, 70–80% mortality on PND 12, but no mortality after PND 14.[83,84] This narrow window of susceptibility on PND 12 is similar to the narrow window of susceptibility to SIDS in human infants between 2 and 4 months of age.

Additional studies were conducted to establish the critical age at which the dual challenge resulted in unexplained death. Pups were treated intranasally with RAIV on day 8, 10, or 14 of life and then given endotoxin (0.5 mg/kg, 0.2 mg/kg, 0.1 mg/kg, or 0.05 mg/kg) intraperitoneally 2 days later. RAIV-naive pups were given endotoxin in the same doses and time interval as the first group. Additional controls were treated with RAIV only on PND 8, 10, or 14. Pups were examined every 4 h for morbidity and mortality, and deceased animals were removed for necropsy.[83]

Adult (8-week-old) rats were similarly challenged with the established adult dose of 100 µl of RAIV intranasally and endotoxin (2 mg/kg, 0.5 mg/kg, 0.2 mg/kg, 0.1 mg/kg) intraperitoneally 2 days post-RAIV treatment.[85] There was no morbidity or mortality in the adult animals.[83]

Interestingly, Liu and Wong-Riley showed developmental changes in the respiratory center in the brainstem of rats in the susceptible period.[86–88] On PND 12 rat pups had an abrupt switch in the expression of $GABA_A$ receptor subunits in the pre-Botzinger complex in the rat brain, the key area for respiratory control in the brainstem. The transitory period of imbalance between inhibitory and excitatory drives may leave the respiratory system vulnerable to respiratory insults, including an immune response to a significant infectious stimulus.[86–88]

These experiments have helped us to establish a model of sudden unexplained death in neonatal rats. Influenza administration on PND 10 followed by an endotoxin challenge of 0.2 mg/kg on PND 12 caused the highest mortality and the lowest morbidity in these animals. The model was used in all subsequent experiments, described below.

MATERIALS AND METHODS

ANIMALS Fischer-344 rat dams were obtained from Charles River Laboratories (Raleigh, NC).

Procedure

1. Animal cages were placed in Illinois isolation cubicles for all of the studies.
2. Dams were housed in individual flat bottom plastic cages at 72ºF ± 2, humidity 50% ± 10, in with 12-h light–dark cycles.
3. All animals received food and water *ad libitum*.
4. Within 48 h of birth, rat pups were randomly cross-fostered and litters standardized to eight pups per dam.
5. A vigorous sentinel animal program was in place to evaluate viral spread. However, it has been shown that there is no between-cage contamination and little within-cage cross-infection using RAIV.[89]
6. In developmental studies each litter is considered a single group ($n = 1$); therefore for the experiments, only one pup was removed from each cage for each treatment group.

INFLUENZA We developed our model based on work done by Burleson, who showed that an influenza strain could be adapted to induce an immune response in rats without causing signs of illness.[89] RAIV was developed from Influenza A/Port-Chalmers/1/73 (H3N2) virus. It had been initially purchased from American Type Culture Collection and adapted by 10 successive passages in allantoic fluid of chicken eggs.[89,90] A detailed description of this model and methods can be found in *Methods in Immunotoxicology*.[89]

For our studies, the virus was a gift from Gary Burleson (Burleson Research Technologies, Raleigh, NC). The virus was passaged in adult male F-344 rats using isoflurane anesthesia, as described by Burleson.[89] One day after infection the lung tissues were removed and homogenized in Eagle's minimal essential medium (EMEM) solution diluted to a 10% weight/volume suspension. The virus was washed and frozen in 0.5-ml aliquots at –70ºC.[89] Viral content was analyzed using the Madin–Darby canine kidney plaque assay.[89] Prior to use, the virus was deemed clear of mycoplasma, bacterial, viral, and fungal contaminants.

Procedure

1. On PND 10, stock virus was mixed with phosphate-buffered saline (PBS) in a 1:100 dilution and held on ice until used. The viral content of the 1:100 diluted solution was 1.9×10^4 plaque-forming units (PFU)/ml.
2. Pups were removed from the dam and given 25 µl of RAIV intranasally using a pipetteman. The viral solution was dripped on the nare and inspired by the pup.
3. Pups were allowed to recover before they were placed back with the dam.
4. All pups in five cages were RAIV treated and those in another five cages were treated with PBS. This was done to ensure five subjects in each treatment group.

ENDOTOXIN *E. coli* endotoxin 0127:B8 was obtained from Sigma (St Louis, MO).

Procedure

1. On PND 12, endotoxin was diluted with PBS to a concentration of 0.02 mg/ml.
2. Individual pups were weighed, and the average weight for these studies was 20 ± 2 g.
3. Endotoxin dilution was given in a single intraperitoneal dose of 0.2 ml.
4. At 2, 4, 6, or 8 h postendotoxin administration, five pups were removed from five dams in each treatment group and sedated using a 2:10 dilution of Nembutal 50 mg/ml mixed in PBS (0.2 ml intraperitoneally = 0.01 ml/g).
5. Dams were kept in cages with the pups until the end of the experiment for pup warmth and feeding.

COLLECTION OF SERUM FROM A CARDIAC PUNCTURE

Procedure

1. After establishing that the animal was adequately sedated, a 25-gauge needle and syringe were used to collect blood

from the heart. Prior to starting, the plunger of the syringe was pulled to the 0.05 ml position.
2. Placing the needle at the zyphoid process, the needle was inserted, then angled at 15–20º and advanced slowly toward the left axillae until blood appeared in the syringe.
3. Blood was slowly removed and placed in a serum separator collection tube.
4. The tubes were spun according to the package directions.
5. The serum was collected, placed in a cryotube, and frozen at −70ºC.

HARVESTING OF ORGANS FROM EACH PUP

Procedure

1. The spleen was removed and placed in RPMI to be processed for cell phenotyping.
2. One kidney with adrenal gland, one lobe of lung, one lobe of liver, one half thymus, one half heart, and a small piece of spleen were placed in cassettes for histology.
3. The other half of each organ was placed in a cryotube, flash frozen in liquid nitrogen, then stored at −70ºC to be used for reverse transcriptase polymerase chain reaction (RT-PCR) assay.
4. All remaining animal tissues were placed in biohazard bags and treated as infectious waste.

CHARACTERISTICS OF THE MODEL

Characteristic findings reflected increased inflammation and the release of nitric oxide, stimulated by the dual infectious challenge. At each time point following endotoxin, the RAIV-treated animals were more severely affected than the RAIV-untreated animals. At 6 h postendotoxin, the pups were mildly cyanotic and cool, and adequate cardiac blood samples were difficult to obtain. These animals have been shown to be hypotensive and bradycardic using a tail cuff measuring device (Hatteras Instruments, Inc., Raleigh, NC). Following cardiac puncture at 6 h, RAIV-treated pups continued to bleed without clotting, suggesting disorder of the clotting mechanisms, often seen with severe infection.

Gross examination revealed petechiae in the lungs, subendocardial hemorrhage, lymphoid cell necrosis of the thymic cortex, and pale kidneys in endotoxin-treated RAIV-treated animals. All pups still had milk in their stomachs, suggesting a rapid progression to death. The RAIV-treated animals died between 8 and 10 h postendotoxin. No other animals died.

HISTOLOGY Tissues (liver, spleen, thymus, heart, lung, kidney) were processed, embedded in paraffin, sectioned at 5–6 μm, and stained with hematoxylin and eosin (H&E) for microscopic examination, as described by Blood-Siegfried.[83,91] All RAIV-treated animals at 6 and 8 h postendotoxin injection had signs of inflammation and oxidative stress. The inflammatory component was minor compared to the prominent necrotic process. In addition, there were signs of altered clotting processes.[83]

CELL PHENOTYPING (FLUORESCENCE-ACTIVATED CELL SORTER) Cells were double stained for surface antigen expression, as described in Blood-Siegfried.[83,92] The macrophage cell population started migrating out of the spleen by 2 h after endotoxin administration in the RAIV-treated animals. This occurred in RAIV-untreated animals between 2 and 4 h postendotoxin administration. A similar change also occurred in T-lymphocyte populations, both CD4 and CD8. Migration out of the spleen started at 2 h postendotoxin administration in the RAIV-treated animals, which responded 2 h before the RAIV-untreated animals.[83]

BRONCHEOALVEOLAR LAVAGE FLUID Alveolar cells and fluid were harvested by lavaging the lungs of five animals per group *in situ* at least five times with 2 ml of ice-cold Ca^{2+}, Mg^{2+}-free PBS as described in Blood-Siegfried.[83,85] Cell populations identified on Wright stain from broncheoalveolar fluid (BALF) showed a predominance of alveolar macrophages with little fluctuation in cell numbers across time or between groups. RAIV treatment did not appear to increase inflammatory changes in the lungs of these animals.[83]

ENZYME-LINKED IMMUNOASSAY Commercial rat cytokine enzyme-linked immunosorbent assay (ELISA) kits (Biosource, Camarillo, CA) were used to measure tumor necrosis factor (TNF)-α, interferon (IFN)-γ, and interleukin (IL)-12 in serum, BALF samples, and liver homogenates.[83,84] The only cytokine showing a statistically significance change was IFN-γ with RAIV-untreated pups demonstrating a 2-fold greater increase at 6 h than RAIV-treated animals. There was no significant difference in TNF- α, IL-12, and IFN-γ in BALF or liver tissue cytokines across time or between groups; however, there was an increase in inflammatory cytokines in all endotoxin-exposed animals.[83,84]

REVERSE TRANSCRIPTASE POLYMERASE CHAIN REACTION ASSAYS Total RNA was isolated from flash frozen liver and lung samples according to the methods described by the manufacturer for the RNeasy kit (Quiagen, Valencia, CA).[84] Endotoxin administration stimulated a brisk upregulation of inflammatory cytokine mRNA in RAIV-treated animals and this occurred several hours earlier than in the animals not exposed to RAIV. The same pattern occurred with nitric oxide synthase mRNA. RAIV treatment thus appears to prime the immune system in these animals to respond very quickly to the endotoxin challenge.[84]

IMMUNOHISTOCHEMISTRY Tissues were fixed in 10% neutral buffered formalin, processed routinely, and embedded in paraffin. Serial sections (6 μm) of liver were stained for NF-κB, COX-2, or inducible nitric acid synthase (iNOS).[84,93] The same pattern of rapid response of iNOS was verified by immunohistochemical staining at 6 h postendotoxin; higher levels of iNOS staining were found in liver samples in animals not treated with RAIV, substantiating the PCR findings. No differences in immunostaining for NF-κB or COX-2 were noted between liver sections from RAIV-treated or untreated animals at any time points examined.[84]

CONCLUSIONS

Animal models provide a useful tool for evaluating potential mechanisms of sudden unexplained death in infants. Indeed, examination of specific pathology may be possible only in an animal model. Comparisons between species may be difficult, but some characteristics of SIDS can be evaluated in these systems.

In our model, RAIV treatment appears to prime the immune response in 12-day-old rat pups, and the response is specific to this age group. Our model thus offers a unique way to evaluate the role of immune development and its relationship to potential pathogens in the etiology of SIDS.

61 Animal Models of Posttraumatic Stress Disorder

HAGIT COHEN, MICHAEL A. MATAR, AND JOSEPH ZOHAR

ABSTRACT

Posttraumatic stress disorder (PTSD) affects about 20–30% of exposed individuals. Clinical studies of PTSD generally employ stringent criteria for inclusion in study populations, and yet in animal studies the data collection and analysis are generally expressed as a function of "exposed" versus "nonexposed" populations, regardless of individual variation in response. There is a need for a better parallel between the approach to understanding animal behavioral models and the contemporary understanding of the clinical conditions. We conceived an approach to understanding the consequences of stress exposure in a manner that would enable us to segregate the study animals into groups according to the degree of their response to a stressor, i.e., the degree to which their behavior is altered or disrupted. The idea was to set apart the most clearly affected, i.e., "extreme behavioral response" group from the "minimal behavioral response" at the extremes, and to establish a middle group of partial responders, groups that better reflect behavioral criteria akin to clinical symptoms already defined. This chapter presents an overview of a series of studies, examining the contribution, validity, and practicality of this animal model.

Key Words: Posttraumatic stress disorder, Animal model, Hypothalamic–pituitary–adrenal axis, Early-life stress, Juvenile stress, Corticosterone, Brain-derived neurotrophic factor.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) is an incapacitating chronic syndrome reflecting a disorder of cognitive, emotional, and physiological processing and/or recovery from the initial reaction to exposure to a potentially traumatic experience (PTE).[1]

In the first hours to days following the experience the majority of individuals exposed to an extreme event will demonstrate, to a varying degree, symptoms such as intense fear, helplessness, or horror followed by anxiety, depression, agitation, shock, or dissociation, and may have trouble functioning in their usual manner for a while.[2–7]

Retrospective and prospective epidemiological studies indicate that most individuals affected by a PTE will adapt within a period of 1–4 weeks following exposure,[2,6] and only a small proportion will develop long-term psychopathology.[2,6] In the United States, studies report that the rate of lifetime exposure to at least one "serious" traumatic event (excluding grief and mourning) is quite high; a conservative estimate reported 61% among men and 51% among women.[8] Other studies have found similar rates.[9–14] The lifetime prevalence of PTSD in the general population reaches about 7% overall,[15] suggesting that about 20–30% of individuals exposed to severe stressors will develop PTSD.[9] This figure varies depending on the type of trauma studied, where male rape victims suffer very high rates and populations exposed to natural disasters significantly less.[16] The discrepancy between the proportion of the general population exposed to PTE and those who eventually fulfill criteria for the disorder suggests qualitative differences in vulnerability and/or resilience.

After extensive study over the past two decades, PTSD was established as a disorder and listed in the *Diagnostic and Statistic Manual* (*DSM*). A diagnosis of PTSD is made if the required symptoms are present 1 month or more after exposure to a triggering event: (1) intrusive reexperiencing of the traumatic event in the form of nightmares and flashbacks, with an exaggerated response to trauma-related reminders/cues; (2) persistent avoidance of stimuli associated with the trauma and emotional numbing; and (3) persistent symptoms of exaggerated startle response, increased physiological arousal, and sustained preparedness for an instant alarm response.[1]

PTSD has severe effects on widespread areas of the individual's functioning, severely compromising their quality of life and affecting their workplace, family, and social life. Moreover, PTSD is also often comorbid with other disorders such as depressive and anxiety disorders, drug and alcohol abuse, cognitive and memory impairments, and sexual dysfunction.[1] The development of PTSD is often a gradual process and extends over time through a series of stages ranging from relatively contained distress to severe disability.[17] As the disorder evolves over time, pathological changes and debilitating comorbidity may become fixed and irreversible. Unlike processes in which exposure to repeated stimuli induces a process of learning or conditioning, implying an increased efficiency in processing of data to produce the required response, the psychopathology underlying PTSD produces a paradoxical vulnerability to negative sequelae upon subsequent exposure to stress.[17]

The sequelae of exposure to a traumatizing stressor are subject to extensive clinical study. Clinical research often gives rise to important questions or hypotheses as to the pathogenesis, clinical course, and outcomes of such events. Among the issues raised are

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.),

those relating to factors that may confer risk or resilience for the development of more severe stress-induced clinical outcomes, such as PTSD. By their nature, clinical studies raise issues concerning premorbid factors largely by means of extrapolating retrospectively. Prospective studies are almost impossible to conceive and would most probably be prohibitively expensive to put into practice.

An animal model can give a good approximation of certain aspects of the complex clinical disorder at best, enabling the study of questions raised in clinical research in a prospective study design and under far more controllable conditions. To maximize its validity as an extension of clinical research, the design of the animal model must strive to conform as closely as possible to the clinical entity and the contemporary conception of the disorder.

ANIMAL MODELS OF POSTTRAUMATIC STRESS DISORDER

The basis of PTSD as a clinical entity rests upon etiology and requires exposure to a severely stressful experience or traumatic event. Thus, exposure to a stressogenic/traumatic experience has formed the basis for animal models of PTSD.

There are as yet no uniformly accepted animal models for PTSD. A number of animal models have been developed in which intense stressful experiences, aversive challenges, and situational reminders of a traumatic stressor have been shown to have long-term effects on psychological/behavioral and physiological functioning, reflected in biobehavioral paradigms and biophysiological tests, e.g., hypothalamic–pituitary–adrenal (HPA) axis assays and electrophysiological studies.[18–30] Irrespective of the study design or of the stress paradigm, animal studies have generally included the entire stress-exposed population as the study population and the results discussed and conceptualized as involving this population versus "others." However, in practice there is considerable heterogeneity in the degree of behavioral disruption or response to the stressor and animals tend to demonstrate considerable individual differences, certainly in the degree to which their behavior is disrupted.

THE CUT-OFF BEHAVIORAL CRITERIA MODEL

One way to reconcile this disparity is to regard the heterogeneity of animal responses to stress paradigms as modeling the heterogeneity of human responses to traumatic stress, and to develop means by which the degree of the individual's behavioral response forms the basis for a system of classification, akin to the inclusion and exclusion criteria employed in clinical studies.

Since the scope of animal models is limited to observable and measurable parameters, the behavioral criteria for the model of stress-induced conditions developed by this study group are based on two well-established paradigms that measure anxiety-like, fearful, avoidant and hypervigilant/hyperalert behaviors, paralleling aspects of traumatic stress-induced human behaviors.[25,31] Exploratory behavior on the elevated plus maze (EPM) serves as the main platform for the assessment of these behaviors and the acoustic startle response (ASR) paradigm allows for a precise quantification of hyperalertness, in terms of magnitude of response and habituation to the stimulus.

In our model, we exposed adult rats to a predator scent (cat urine) stressor (PSS) for 10 min as previously described by Adamec *et al.*[23,25,26] and others.[28–30,32–35] Regarding the conceptual validity of the model itself, "predator exposure trauma" is a potentially life-threatening situation (criteria A) and it may represent a more ''natural'' setting than other types of stressors on a teleological level,[23,24] such as electrical tail shocks and restraint which might possibly be related to extreme conditions like torture.

Seven days after a single 10-min PSS exposure, the exposed rats showed significantly decreased time spent in the open arms of the maze and increased levels of avoidance and anxiety-like behavior in the EPM, and higher mean startle responses as compared to control rats. However, the animals' behavior was not uniformly disturbed, but rather demonstrated a broad range of variation in severity of anxiety-like behaviors (Figure 61–1).

Quantitative and qualitative assessment of individual animal behavioral responses to stress exposure provides a degree of standardization that enables a greater degree of resolution. For instance, groups of subjects can be defined by their response pattern or magnitude and selectively focused on for study or followed up over time; the prevalence of defined patterns of response may be assessed and compared, allowing the "potency" of different stressors to be compared, behaviors to be correlated to physiological parameters, and so on. Since partial responses are far more difficult to quantify and interpret, in animal models more so than in human subjects, the studies carried out according to this approach to date have preferred specificity to sensitivity, and have sought to create clearly defined groups of behaviors for comparison. By means of well-defined cut-off behavioral criteria (CBCs), the studies have focused on animals displaying an extreme behavioral response (EBR) on both the EPM and the ASR paradigms performed consecutively, compared to those displaying a minimal

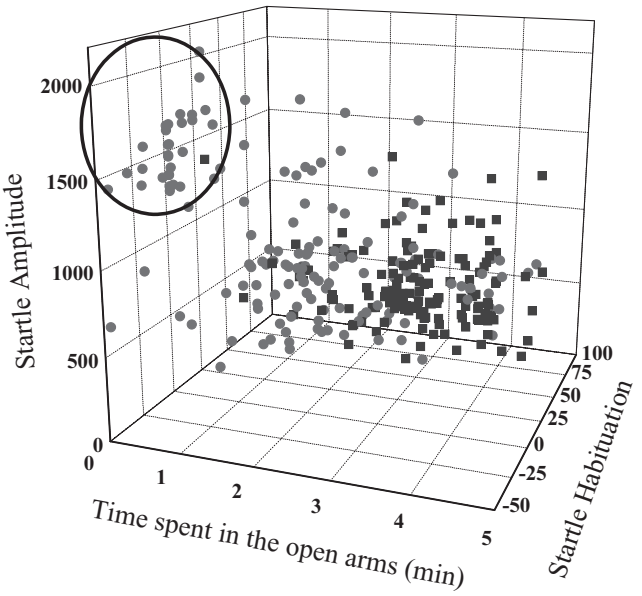

Figure 61–1. The effect of single PSS exposure versus unexposed control on rat anxiety-like behavior and acoustic startle response and habituation. The representation of the data from both paradigms (EPM and ASR) shows two obvious and rather distinct features. First, it is clear that PSS exposure alters the response of the majority of individuals to at least some degree. Second, the cluster of individuals that forms in the upper left hand corner of the graph (i.e., had the more extreme responses to exposure) is quite distinct from the majority of individuals.[36,48] (See color insert.)

behavioral response (MBR) to both, and compared to controls. "Maladaptive" responses to both of these serial CBCs were required for "inclusion" into the EBR group, whereas the reverse was required for inclusion in the MBR group.[36]

The criteria for each behavioral paradigm were as follows:

1. Extreme behavioral response: 5 min (entire session) spent in the closed arms and no entries into the open arms on the EPM; the mean amplitude of the startle response (at 110 dB) exceeds 800 units and the startle response shows no habituation over time.
2. Minimal behavioral response: 0–1 min spent in the closed arms and eight or more open arm entries on the EPM; the mean amplitude of the startle response (at 110 dB) does not exceed 700 units and habituation is demonstrated.
3. Partial behavioral response: animals neither EBR nor MBR are termed "partial behavioral responders" (PBR).

When behavioral data for the entire exposed population were examined in this way, based on the segregation of animals according to the CBCs, it was demonstrated that only about 25% develop significant extreme behavioral disruptions as the result of exposure to the stressor (Figure 61–2A), as compared to 1.3% in controls (Figure 61–2B). Similarly, the prevalence of MBR rats in the exposed groups was 24.7% (Figure 61–2A) and in the control group was 80.0% (Figure 61–2B).[36]

These results are in agreement with trends in the literature on human studies,[9] mentioned above, in which about 15–35% fulfill criteria and another 20–30% are considered as PTSD spectrum disorders.[9,10,13] It was therefore suggested that application of CBCs is both feasible and valid.

The above-mentioned approach to the analysis of animal data is conceptually equivalent to *DSM* criteria for PTSD and the criteria proposed by Yehuda and Antelman.[37]

The demonstrated reduction in the time spent by rats in the open arms of the plus maze may parallel avoidance behavior seen in human PTSD (Criteria C). Since the total number of entries into any arms of the plus maze is the same, except that the EBR rats keep to the closed arms only, the results are consistent with anxiety, and not with nonspecific impairment of locomotion. *DSM-IV* defines this symptom as a persistent avoidance of reminders of the trauma and numbing of responsiveness. Since the exposure took place in an open space it is in keeping with the described definition.

The assessment of rats after 7 days has previously been established by Adamec *et al.*,[25] and is taken to refer to PTSD and not to acute stress reaction. Our results have since shown repeatedly that as of day 7, the prevalence rate remains constant at about 25% until day 30. The *DSM-IV* defines PTSD as lasting more than a month after the exposure. So the persistence of anxiety symptoms on day 7 after the exposure fulfills the time element of PTSD.[25]

In the next step, we examined the validity of applying the CBC concept in animal studies, using dynamic unsupervised fuzzy clustering.

Unsupervised fuzzy clustering (UFC) analysis is a mathematical tool that attempts to assess the relationships among patterns of a data set by organizing the patterns into groups or clusters, such that patterns within one cluster are more similar to each other than patterns belonging to different clusters.[38–42] The main goal of most clustering methods is to supply useful information by grouping data in clusters, where within each cluster the data exhibit similarity. Similarity is defined by a distance measure, and global objective functional or regional graph theoretical criteria are optimized to find the optimal partition of data. The partition approach defines the cluster to which each data element belongs by using the elements of the membership matrix.[38–42]

The full range of the dataset was classified into three ($C = 3$) clusters. The data in the clusters that the model yielded corresponded to the data for the animals designated behaviorally by means of the CBCs as clearly affected, partially affected (including some unexposed animals), and clearly unaffected (Figure 61–3).

The UFC analysis yielded, in addition to the "anxious" and the "baseline" clusters, a third group corresponding to an extreme pathological response (see Figure 61–3). According to this analysis, about 22% develop extreme behavioral disruptions as the result of exposure to the stressor, as compared to 0.7% of the unexposed control group. This extreme response group (i.e., maladapted rats) exhibits significantly higher startle response and significantly more avoidance behavior in the EPM than other animals. Again, these proportions are in agreement with current trends in the literature on PTSD studies in human subjects.[9] Taken together, the UFC analysis supports the conceptual contention of the CBCs and thus lends validity to our previous studies. Moreover, the clustering process may help us to find and define the characteristics of the subgroup of the unexposed population that has a higher risk of developing PTSD.[43]

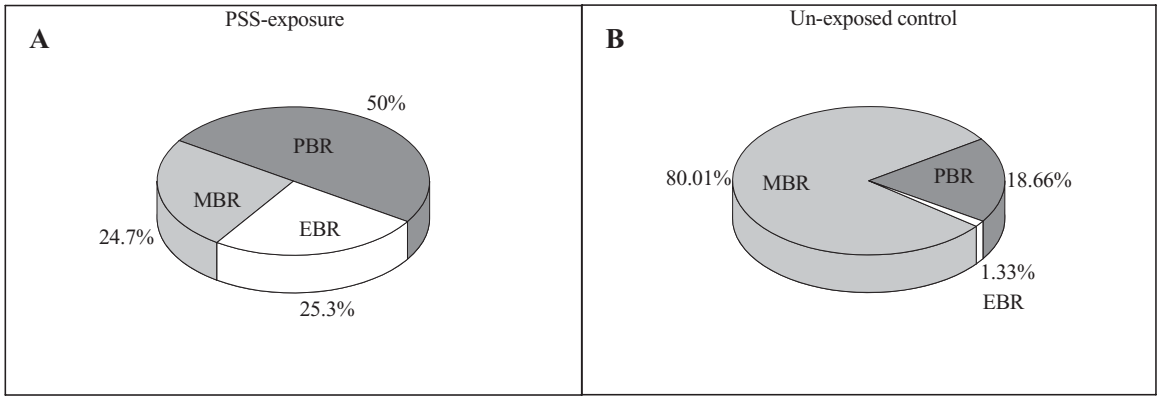

Figure 61–2. Reanalysis of data applying cut-off behavioral criteria. (A) PSS exposure. (B) Unexposed control.

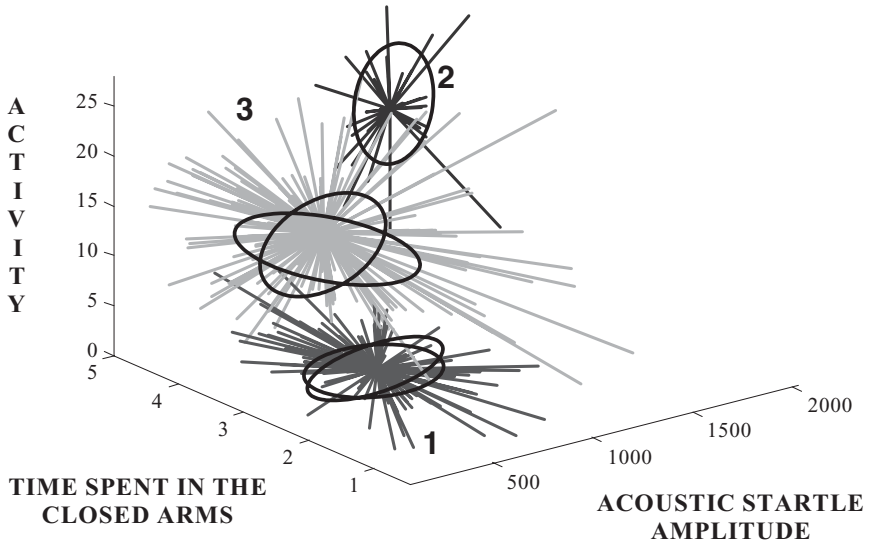

Figure 61–3. Unsupervised fuzzy clustering: Partition of four behavioral parameters into three clusters. The ellipses represent the standard error of each characteristic in each cluster. The first cluster (C1) is related to baseline behavior associated with unstressed animals and is characterized by very low levels of anxiety (MBR). The middle cluster (cluster C3) represents the subclinical or partially affected animals and is characterized by some degree of anxiety and stress levels (PBR). Cluster C2 corresponds to the exposed animals and is characterized by higher levels of anxiety and stress, namely the extremely affected animals (EBR).[43] The behavioral parameters were acoustic startle response amplitude, time spent in the closed arms on the EPM, number of entries to the closed arms, and the total number of entries to the open and the closed arms of the EMP (total activity).[43]

In the next section, we present a series of studies that were constructed to examine the prevalence of EBR and MBR responses over time, in an attempt to map the transition from the immediate reaction, concomitant with an acute stress response, to more enduring and chronic changes, representing PTSD, under different conditions.[44]

By means of singling out the clearly affected individuals labeled as EBR from among the entire population of rats exposed to the stress paradigms, and focusing on them, a time curve could be constructed to reflect the prevalence of clearly "symptomatic" behavior over time (Figure 61–4).

Immediately following the traumatic stimulus, most of the animals (90%) manifested a pattern of behaviors that fulfills criteria for EBR status for the first few hours. This can be regarded as being equivalent to the initial response observed in human subjects in the first hours or days after an extreme event. The prevalence of rats fulfilling the CBC criteria for EBR decreased rapidly, and subsequent sampling revealed that at the end of a week only 25% of the total exposed population had PTSD-like symptoms. The time curve appears to indicate that the rats responded initially with a ubiquitous, probably normative, acute response, but only about 15% went on to suffer from enduring behavioral effects.

The curve representing these responses, although gleaned from different groups of rats, very clearly resembles, both in term of time and of prevalence, the curve of human responses to exposure to a significant stressor and the proportions affected.[45] This pattern of symptoms has been demonstrated across the different kinds of traumatic events, both in human PTSD and in the different models in this study. We submit that the distinction between the acute phase of the stress response seen in most subjects immediately after exposure and the chronic enduring effects associated with stress found after several days or weeks is important in the study of animal models dealing with the behavioral and physiological consequences of stress.[44]

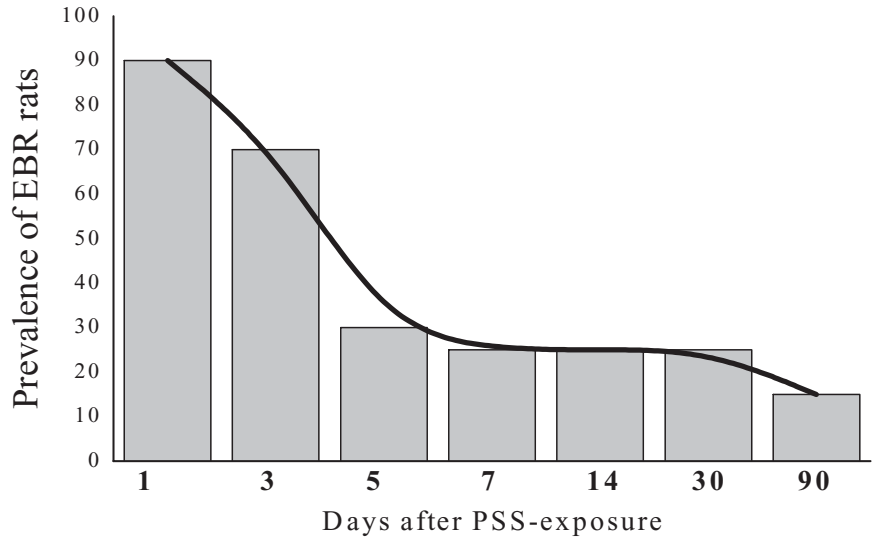

Figure 61–4. The prevalence of EBR rats after single exposure to a predator stimulus along the time axis. A steady drop in prevalence of EBR rats from 90% on day 1 to 15% by day 90 is shown. As of day 7, this rate remains constant until day 30. Our results have shown a progressive, time-dependent decline in the prevalence of EBR rats during the first few weeks that follow a trauma.[44]

BIOLOGICAL STRESS RESPONSE

It is well known that the biological stress response is key to understanding the pathophysiology of PTSD and its associated symptoms. Thus, the primary aim of the following study was to analyze separately various biobehavioral parameters of the animals that responded in a more marked manner to exposure to a stressful, potentially traumatic, event and to compare these to the parameters of rats that demonstrated no such response. We submit that this approach would better approximate the individual variance seen in posttraumatic stress responses in humans (i.e., the clinical syndrome) in a more valid manner.

In a series of studies this approach has elicited highly significant overlap between animals showing EBR and those with extreme biophysiological measures, i.e., HPA axis assays (corticosterone and neuroactive steroids), heart rate variability (reflecting autonomic nervous system activity), and BDNF mRNA and protein levels much more clearly than when the exposed group was analyzed as a whole.

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Exposure to stress or a threat to homeostasis triggers activation of the parvicellular neurons of the paraventricular nucleus in the hypothalamus to release corticotropin-releasing factor and vasopressin. These hormones stimulate synthesis of polypeptide precursor proopiomelanocortin products, which include adrenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone cells, and β-endorphin, that have been shown to interact with the immune system.[46,47] In the adrenal gland ACTH stimulates the release of glucocorticoids, typically cortisol in man and corticosterone in rodents. The responses of the HPA axis are regulated by an efficient negative feedback system, exerted by glucocorticoids. Taken together, the HPA stress hormones play a major role in mediating both adaptive and maladaptive responses.

We evaluated plasma corticosterone and ACTH levels 7 days after PSS exposure. Throughout the study data were analyzed for exposed versus unexposed populations as a whole, and then reanalyzed according to the CBC classification separately for EBR, MBR, and PBR versus unexposed controls, and finally these groups were compared to each other (Figure 61–5).

Our results have shown that a single 10-min exposure to a PSS significantly increased plasma corticosterone (Figure 61–5A) and plasma ACTH concentrations (Figure 61–5B) only in EBR rats, but not in MBR individuals or in nonexposed controls.[36,48] The fact that there is a clear-cut involvement of the HPA axis in the physiological component of the syndrome has been quite firmly established by studies in PTSD patients and animals, despite conflicting data reported by different groups.[49–52] The results of the present study are in keeping with those of certain groups of investigators.[53] Moreover, Adamec and colleagues[24–26] have found evidence of differential dysregulation of the HPA axis in certain strains of rats exposed to cats. One week after cat exposure, Hooded rats show elevations in basal plasma corticosterone, whereas Wistar rats do not. This difference in strain reactivity was proposed to be related to the higher basal anxiety in Hooded rats. We may speculate that greater basal anxiety could even stem from factors such as response to the blood sampling procedure, or possibly that different strains possess different vulnerability factors.

The fact that EBR rats show a dysfunction of the HPA axis, whereas MBR rats do not, indicates quite clearly that the population of exposed animals is not a homogeneous cohort, and that it is important to distinguish between affected and unaffected subjects in the analysis and interpretation of data from animal studies.[36,48]

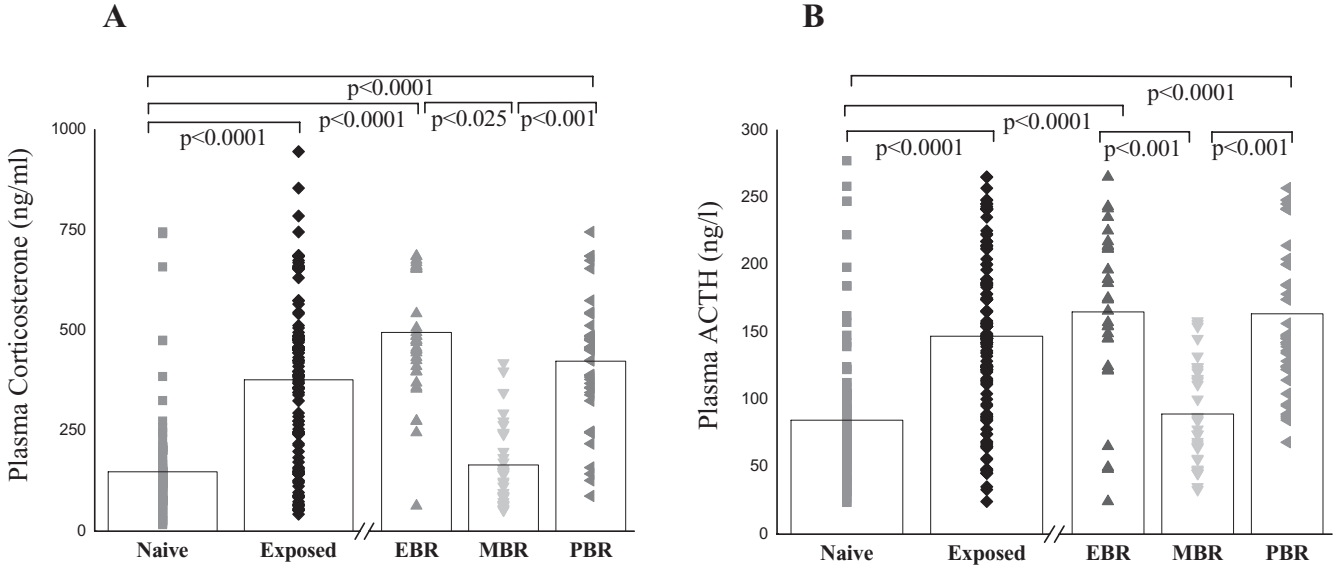

Figure 61–5. Circulating levels of (A) corticosterone and (B) ACTH at day 7 post-PSS exposure. Seven days after exposure, the PSS-exposed population demonstrated significantly increased plasma corticosterone (A) and ACTH levels (B) compared to controls [$F(1,260) = 116.2$, $p < 0.00001$; $F(1,260) = 83.8$, $p < 0.00001$, respectively].[36] Reanalysis of data according to CBCs: significant differences in plasma corticosterone and ACTH levels were demonstrated between the subgroups of exposed animals [$F(3,296) = 133.3$, $p < 0.0001$; $F(3,296) = 74.6$, $p < 0.0001$]. The post hoc Bonferroni test revealed that plasma corticosterone and ACTH levels of EBR individuals were significantly higher than in MBR individuals ($p < 0.0001$ for both) or in controls ($p < 0.0001$). The levels of PBR animals also varied significantly from those of MBR ($p < 0.001$) (and controls).[36]

Other adrenal steroids, such as the neuroactive steroids, may be involved in the development of long-term behavioral changes after exposure to a PTE, and hence in vulnerability and resilience. Dehydroepiandrosterone (DHEA) and its corresponding sulfate ester dehydroepiandrosterone sulfate (DHEA-S) are neuroactive steroids that are synthesized *in situ* within the brain and in peripheral steroidogenic organs.[54–56] DHEA and DHEA-S appear to possess a number of physiological roles and are known to act as allosteric agonists of the γ-aminobutyric acid ($GABA_A$) receptor—DHEA-S being the more potent of the two.[55] This activity may imply an effect on behavior, cognition, mood, and sleep.[57] In addition, they are reported to exert an effect on neural plasticity and to possess neuroprotective qualities. Indeed, both DHEA and DHEA-S protect rat hippocampus neurons against *N*-methyl-D-aspartate (NMDA)-induced excitotoxicity, glucocorticoid-induced neurotoxicity, and oxidative stress-induced damage induced by the $H_2O_2/FeSO_4$ complex.[58] Changes in the levels of neuroactive steroids may thus be involved in the pathophysiology of adaptive and maladaptive stress responses.

This study assessed the relationship between peripheral DHEA, DHEA-S levels, and magnitude of behavioral change, i.e., EBR and MBR individuals[59] (Figure 61–6).

Whereas both extreme and minimal behavioral response groups of exposed rats displayed decreased levels of DHEA-S compared to controls (Figure 61–6B), DHEA levels were selectively reduced to a statistically significant degree only in EBR rats, compared to both MBR rats and controls (Figure 61–6A). Assuming that grossly disrupted behavior (EBR) is maladaptive, the implication is that DHEA may be involved in mediating adaptive responses to a stressful event (resilience). Conversely, an impaired neuroactive steroid response to a stressogenic experience may be associated with an increased susceptibility to PTSD-like responses. DHEA-S levels are normally two to five times higher than those of DHEA, whereas in the exposed groups this ratio is inverted. Since DHEA-S is a more potent negative modulator of the GABAergic receptor than DHEA, this inverted ratio implies a decrease in negative modulation. This may represent an adaptive factor while stressful conditions prevail, yet may also mediate (or characterize) long-term EBR. It is of note that DHEA possesses antiglucocorticoid activity[60] and decreases corticosterone levels.[61] Thus the reduced DHEA levels in EBR rats may cause the increased levels of corticosterone.[59]

Taken together, the results suggest that concomitantly decreased circulatory levels of DHEA and elevated corticosterone levels may be associated with a pathological response to stress, while maintenance of normal levels of both steroids may be associated with resilience or a "buffering" of the negative effects of stress. It remains to be established whether changes in the synthesis or release of neurosteroids are a cause of, a risk factor for, or a consequence of stress-related disorders.[59]

The neurobiological mechanisms involved in PTSD thus presumably include changes in synaptic efficacy and plasticity in various brain areas, which, rather than improving, in fact impair the ability of the brain to respond adequately to subsequent stress responses.[62] Were it possible to correct or to induce mechanisms that would reinstate adaptive neural plasticity and remodeling, this dysfunction might be overcome.

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin (NT) family of survival-promoting molecules, plays an important role in the growth, development, maintenance, and function of several neuronal systems.[63] It is known to modulate synaptic plasticity and neurotransmitter release in a variety of neurotransmitter systems, as well as intracellular signal-transduction pathways.[63] It regulates axonal and dendritic branching and remodeling,[64–67] synaptogenesis in arborizing axon terminals, efficacy of synaptic transmission, and the functional maturation of excitatory and inhibitory synapses.[68–70]

Growing evidence suggests important roles for BDNF in the pathogenesis of mood disorders and in the mechanism of action of therapeutic agents, such as mood stabilizers and antidepressants.[71–73] BDNF may also be involved in the pathophysiology of anxiety disorders. Data derived from animal studies have

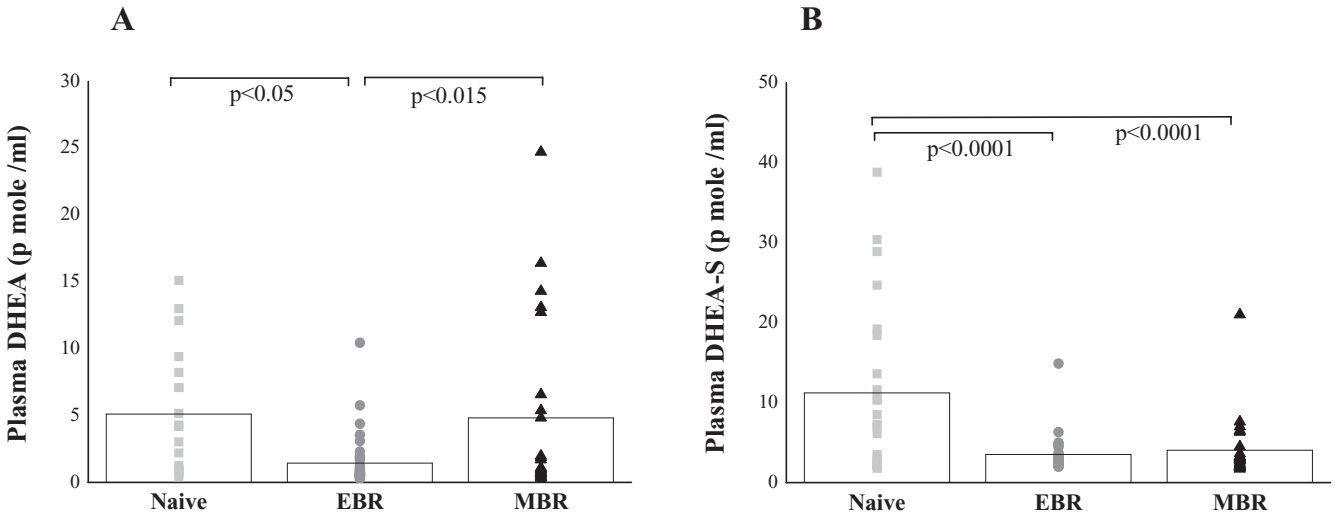

Figure 61–6. Circulating levels of (A) DHEA and (B) DHEA-S at day 7 post- PSS exposure. The plasma DHEA levels of EBR rats were significantly lower than in the MBR group (Bonferroni test $p < 0.02$) and in unexposed controls (Bonferroni test $p < 0.016$). There was no significant difference between the MBR and control groups (A). Plasma levels of DHEA-S in exposed animals, both EBR and MBR, were significantly lower than in controls (Bonferroni test $p < 0.0001$, $p < 0.0001$, respectively) (B). There was no significant difference between the DHEA-S levels of the EBR and MBR groups.

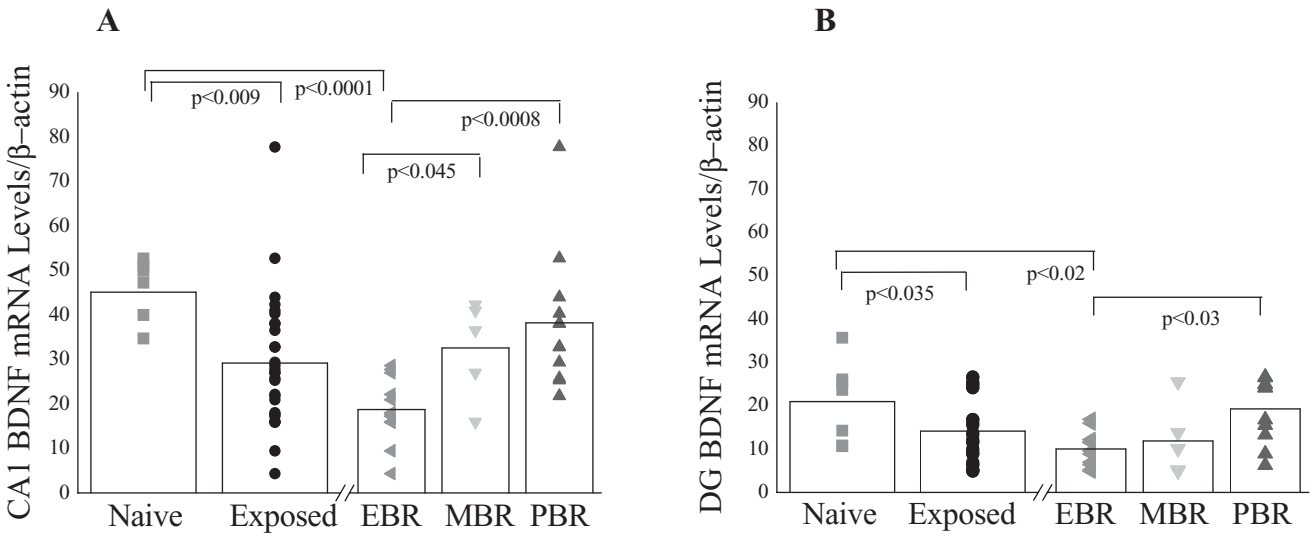

Figure 61–7. Hippocampal BDNF mRNA levels at day 7 post-PSS exposure. Exposed versus unexposed populations: the PSS-exposed population demonstrated significantly decreased CA1 (A) and DG (B) mRNA BDNF levels compared to controls [$F(1,34) = 7.8$, $p < 0.009$, and $F(1,34) = 4.1$, $p < 0.05$, respectively]. Reanalysis of data according to CBCs: in the hippocampal subregions CA1 (A) and DG (B), there were significant differences between groups [$F(3,32) = 10.35$, $p < 0.0001$, and $F(3,32) = 5.0$, $p < 0.007$, respectively]. The post hoc Bonferroni test revealed that stress exposure significantly decreased CA1 BDNF mRNA levels in EBR individuals as compared to controls ($p < 0.0001$) and as compared to MBR ($p < 0.045$) and to PBR animals ($p < 0.0008$). In the DG area the Bonferroni test revealed that PSS exposure significantly decreased BDNF mRNA levels in EBR individuals as compared to controls ($p < 0.02$) and to PBR animals ($p < 0.03$). There were no significant differences between EBR and MBR individuals in the DG subregion.[76]

demonstrated that compared with wild-type mice, BDNF conditional mutants (in which BDNF has been eliminated from the brain after birth through the use of the cre-loxP recombination system) were hyperactive after exposure to stressors and had higher anxiety levels when evaluated using the light–dark exploration paradigm.[74] On the other hand, single intrahippocampal administration of BDNF improved performance in a spatial memory task and had enduring anxiolytic effects.[75]

This experiment set out to examine the relationship between prevalence rates of distinct patterns of behavioral responses to predator stress, local levels of mRNA for BDNF, TrkB, and two other neurotrophic factors in selected brain areas (Figures 61–7 and 61–8).

The EBR animals exhibited significantly lower BDNF mRNA levels and higher TrkB mRNA in the CA1 and DG hippocampal subregions at day 7 as compared to naive unexposed rats and to the PBR group. In the CA1 subregion the EBR individuals exhibited significantly lower BDNF mRNA levels as compared to MBR or PBR animals. In other words, long-term downregulation of BDNF mRNA in the rat hippocampal CA1 subregion correlates with a PTSD-like behavioral stress response. This may represent a physiological marker characteristic of animals whose behavior is most severely affected by exposure to the stressor.[76]

Going beyond the mRNA expression, BDNF protein levels were assessed in the affected brain regions of behaviorally EBR individuals. The EBR animals exhibited significantly lower BDNF protein levels in the CA1 and DG hippocampal subregions at day 7 as compared to naive unexposed rats, concomitant with BDNF mRNA levels.[76]

Long-term BDNF deficiency in the hippocampus could have physiological consequences, inducing damage to hippocampal neurons. Neurotrophins, and particularly BDNF, are known to modulate many aspects of neuronal plasticity[77,78] and the selection of functional neuronal connections in the CNS.[79–81] Decreased expression of BDNF mRNA in the EBR group may decrease synaptic plasticity and the stabilization of synaptic connectivity, causing vulnerability to psychopathology. Interestingly, endogenous BDNF is required for the memory consolidation process through dual effects on postsynaptic gene expression (Arc) and local protein synthesis. Lower levels of BDNF after stress exposure may be involved in the anomalous traumatic memory consolidation process thought to occur in PTSD patients.[82] Because the exact mechanism of stress-induced BDNF downregulation is unclear and the expression of BDNF is regulated by various neurotransmitters, further studies would be necessary to unambiguously establish such a relationship.[76]

The consistent association between downregulation of BDNF in selected subregions of the hippocampus (CA1 and DG) and extreme behavioral responses to stress exposure may imply either a pathogenic role for BDNF and/or a physiological marker.

At 7 days the downregulation was found in both the CA1 and DG subregions and remained consistent over the entire 30-day trial period, specifically in the CA1 subregion and specifically in EBR animals. It thus extends beyond the scope of a transient change, which might be associated with maintenance of homeostasis, to represent a physiological characteristic of animals displaying severe chronic behavioral stress responses.

Taken together, a single 10-min exposure to PSS caused increased levels of "anxiety/PTSD"-related behaviors in EBR rats in the EPM and ASR paradigms 7 days later. However, the prevalence of EBR individuals in the exposed group was only 25.0%. These EBR rats exhibited significantly higher plasma corticosterone, and ACTH concentrations, lower plasma DHEA levels, lower hippocampal CA1 and DG BDNF mRNA, and higher

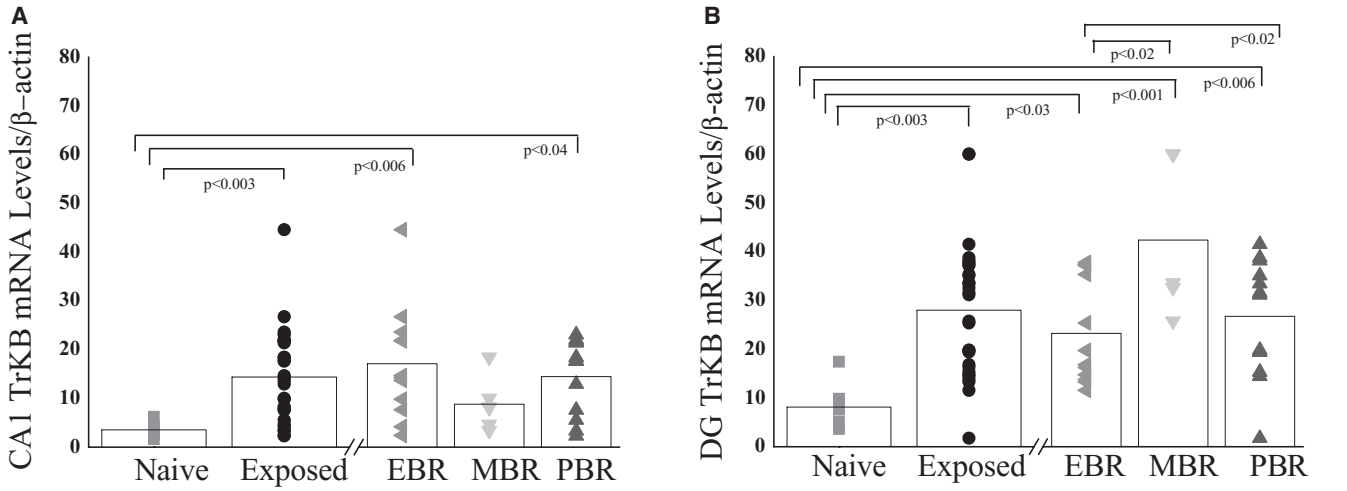

Figure 61–8. Hippocampal TrkB mRNA levels at day 7 post-PSS exposure. Exposed versus unexposed populations: the exposed population demonstrated significantly increased TrkB mRNA levels in CA1 (A) and DG (B) as compared to controls [$F(1,36) = 10.3$, $p < 0.003$, and $F(1,35) = 15.87$, $p < 0.0003$, respectively). Reanalysis of data according to CBCs: in the hippocampal CA1 (A) and DG (B) subregions, there were significant differences in TrkB mRNA levels between groups [$F(3,34) = 4.99$, $p < 0.006$, and $F(3,33) = 10.11$, $p < 0.0001$, respectively]. The post hoc Bonferroni test revealed that stress exposure significantly increased TrkB mRNA levels in the EBR groups as compared to controls ($p < 0.006$) in CA1. Moreover, TrkB mRNA levels were significantly higher in the PBR group as compared to controls ($p < 0.04$). The CA1 TrkB mRNA levels were not significantly different in the MBR group compared to controls. In the DG, the post hoc Bonferroni test revealed that stress exposure significantly increased TrkB mRNA levels in all the exposed groups as compared to controls (EBR: $p < 0.03$; MBR: $p < 0.001$; SC: $p < 0.006$). The TrkB mRNA levels were significantly higher in the MBR group as compared to the EBR group ($p < 0.02$).

hippocampal CA1 and DG TrkB mRNA. These changes were not found in MBR rats or in controls (not exposed), and therefore emphasize the importance of applying CBC (as an equivalent to the human "diagnostic criteria") in animal studies of PTSD.

The significant difference between accurate physiological parameters from EBR-exposed rats as compared to both MBR-exposed rats and controls is evidence for the construct validity of this proposed modification of animal models of stress and its sequelae.[76]

RISK FACTORS FOR DEVELOPING POSTTRAUMATIC STRESS DISORDER

Clinical studies of PTSD have elicited proposed risk factors for developing PTSD in the aftermath of stress exposure. Generally, these risk factors have arisen from retrospective analysis of premorbid characteristics of study populations. A valid animal model of PTSD can complement clinical studies and help to elucidate issues, such as the contribution of proposed risk factors, in ways that are not practical in the clinical arena.

EARLY LIFE STRESS AND SUBSEQUENT PSYCHOPATHOLOGY

Evidence suggests that early life stress is a major risk factor for the development and persistence of mental disorders such as mood disorders and PTSD.[83–87] Numerous studies in rodents have demonstrated substantial long-term biophysiological consequences of environmental manipulations in immature (preweaning) animals, in which the formation of neuroendocrine regulatory mechanisms has not been completed and associative neuronal circuits are not yet fully elaborated.[88–93] Juvenile (postweaning but prepubertal) animals have also been shown to demonstrate long-term behavioral consequences subsequent to early exposure to PTE's.[94]

Although most previous studies of early life trauma in animal models have focused on suckling pups, we focused on juvenile animals (postweaning, prepubertal), taken to represent "childhood" versus "infancy," i.e., a period in which a significant degree of plasticity in a rapidly maturing brain (and stress response system) might be found. Exposure to marked stress at this critical developmental phase in all likelihood has significant effects on later functioning, and possibly on the development of brain structures and their interactions.

ANIMAL MODEL FOR TRAUMA IN CHILDHOOD/YOUTH

Male Sprague–Dawley rats were randomly assigned to five groups: (1) unexposed control: not exposed to any adverse conditions at any time; (2) juvenile stress (JS): exposure to a predator scent (cat urine) at 28 days of age; (3) adulthood stress (AS): exposure to a predator scent in adulthood (9 weeks of age); (4) juvenile and adulthood stress (JS + AS): exposure to a predator scent both at 28 days and at 9 weeks; and (5) adulthood and adulthood stress (AS + AS): recurrent exposure to a predator scent at 9 weeks and again 30 days later.

The stress paradigm consisted of placing the rats on well-soiled cat litter for 15 min and the controls on unsoiled litter. Behavioral responses were assessed in the elevated plus maze and the acoustic startle response paradigm.[95,96]

The results demonstrate that juvenile trauma increases the vulnerability for developing subsequent long-term behavioral

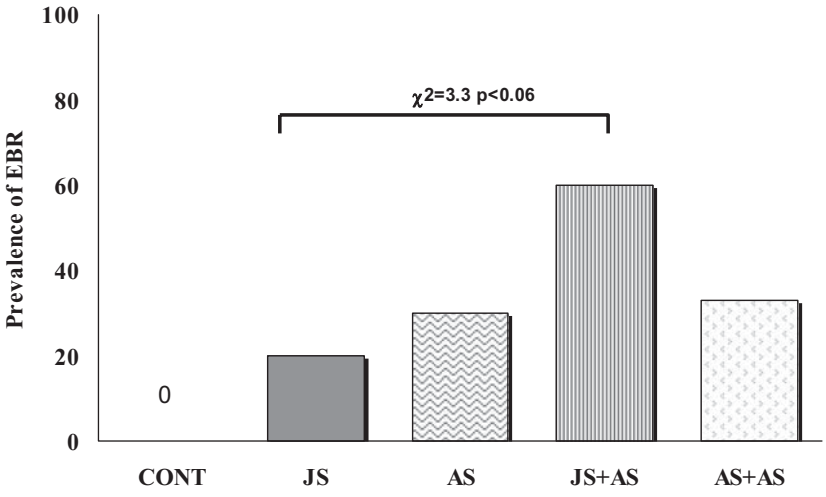

Figure 61–9. Effect of single exposure to predator scent early in life on the prevalence of extreme behavioral response. Juvenile exposure to predator scent stress significantly affected the response to reexposure in adulthood: 60% of the rats exposed to predator scent both at 28 days and at 9 weeks (JS + AS) demonstrated extreme behavioral responses, compared with 20–25% of those exposed only once either as juveniles (JS) or as adults (AS), and none in the control-unexposed group. Within the unexposed control group all rats were categorized as "unaffected" (MBR), and no rats displayed anxiety-like or depressive-like behaviors.[96]

disruptions, taken to represent posttraumatic stress symptom equivalents, after a second exposure to the same stressor in adulthood in a prospective study design (Figure 61–9). They thus serve to reassert retrospective findings from clinical studies.[84,85] This model may thus serve as a valid platform for further studies of childhood trauma.[95,96]

CONCLUSIONS

Animal models can help to elucidate certain aspects of the pathogenesis of a complex psychophysiological disorder such as PTSD in a prospective study design. Individual variability in pattern or degree of response to the stressor can be utilized to achieve greater validity of the model to the disorder it is intended to represent.

It could also help to address the debate as to whether PTSD is a disorder that reflects the upper end of a continuum of normal reactions to stress, as proposed by Ruscio *et al.*,[97] or whether it is a distinct entity intimately related to, but not on a direct continuum, with normal responses to stress.[37] So far, the distribution of the data is clustered at either end of the slope, suggesting a biphasic tendency of distribution. Results from studies of large populations will be needed to better address a qualitative or a quantitative linear approach to PTSD. However, the data presented suggest that it is important to perform a separate analysis for EBR- and MBR-exposed rats, since by means of this approach it is possible to highlight the range of individual differences in response to stress, whether they are qualitative or quantitative.

This animal model approach goes beyond accepting individual variability as an "unavoidable fact," but rather regards it with respect and focuses on individual variability as a useful source of knowledge. In this sense it may well represent an example of a more generalizable principle: individual variability in responses of participants in animal studies should be reexamined as a potential source for valuable information, and not disregarded or viewed merely as a source of unavoidable bias, throughout the scientific community.

62 Animal Models for Studying Fetal Alcohol Syndrome, Alcohol-Related Birth Defects, and Alcohol-Related Neurodevelopmental Disorder

TIMOTHY A. CUDD

ABSTRACT

Maternal alcohol abuse during gestation can result in a collection of fetal injuries, the most common of which can be broadly categorized as (1) intrauterine growth retardation, (2) craniofacial dysmorphology, and (3) central nervous system damage. These injuries are referred to by the terms (depending on specific conditions and manifestations) fetal alcohol syndrome, alcohol-related birth defects, alcohol-related neurodevelopmental disorder, and others. While the manifestations of injuries from maternal alcohol abuse during gestation have been described, there remain many unanswered questions: what are the specific mechanisms by which alcohol mediates these injuries, which women are at greatest risk, how can we identify affected children at an early age, and how might we intervene to prevent or mitigate the damage? Because of the inherent limitations of studies conducted in humans, the use of animal models is important in addressing these unanswered questions. However, no one animal species can be utilized to model all aspects of human prenatal alcohol exposure injury as no species is identical to the human with respect to development, structure, and function. Therefore, performing studies modeling human prenatal alcohol injury in animals requires careful consideration of the particular animal model and whether or not this species, studied under these specific experimental conditions, does model what occurs in humans. This chapter summarizes some of the important considerations in choosing an animal model, in general and in the context of animal models that have been utilized to study human prenatal alcohol exposure.

Key Words: Fetal alcohol syndrome, Alcohol-related neurodevelopment disorder, Alcohol-related birth defects, Teratogen, Ethanol.

INTRODUCTION

Three decades have passed since fetal alcohol syndrome (FAS) was first identified as a clinical syndrome,[1] and yet we still know surprisingly little about the range of long-term damage resulting from variations in gestational alcohol abuse and we know even less about the exact causes of or how to treat these deficits. Notwithstanding the documented clinical literature, much of the knowledge about the specific effects of gestational alcohol exposure on fetal brain, body, organ, and behavioral development has been derived from the effective use of animal models.

Human studies are handicapped in their ability to address some of the key issues related to FAS and other fetal alcohol exposure-induced damage because of variable consumption patterns of alcohol, unreliable self-estimates of alcohol intake by pregnant women, and because many women who abuse alcohol also abuse other drugs.[2] Furthermore, ethical considerations place considerable constraints on the use of human subjects to study the teratogenic impact of alcohol. The use of animal models circumvents many of the problems inherent in human studies. One major advantage of using animal models is that they make it possible to control important maternal and environmental variables such as genetic background, nutritional status of the mother, and dose and timing of the alcohol exposure, and also allow for questions to be addressed at a more mechanistic level.[3,4]

Fortunately, there is good correspondence between findings in human and animal studies,[5] which helps to validate the use of animals in FAS research. Animal studies have demonstrated that heavy alcohol exposure during development can produce deleterious effects in most of the same brain regions and organ systems that have been reported in humans with FAS. In addition, animal studies have expanded upon the gross morphological studies of humans with FAS by identifying deficits at the cellular (neuronal numbers) level in specific brain regions and alterations in the cellular morphology[6–11] and function[12] of neurons that survive the alcohol insult, as well as alterations in glia and myelin.[13–17]

ATTENTION TO DEFINITIONS

In this chapter, we will limit the discussion to *in vivo* whole animal models used to investigate the cardinal features that define FAS. The definition of FAS has remained essentially unchanged since it was originally defined in the 1970s: a characteristic pattern of facial anomalies, growth retardation, and various neurodevelopmental abnormalities.[1] A study by a special Institute of Medicine committee[18] added to that definition the criterion of a

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

confirmed history of drinking during pregnancy. Over the years since the adaptation of the term FAS, a variety of other terms have emerged. Fortunately, an excellent review of these terms appeared recently.[19] One of the earliest was fetal alcohol effects (FAE), which was used to identify children damaged by prenatal alcohol exposure but who did not exhibit all of the FAS criteria.[20] A more encompassing term, alcohol-related birth defects (ARBD), was coined for individuals (and animals) with other less common organ anomalies who had been exposed to alcohol prenatally, but who did not have the characteristic FAS face. The FAS face, as defined by the Institute of Medicine**,** is a specific pattern of facial anomalies, including short palpebral fissures and abnormalities of the premaxillary zone (e.g., flat upper lip, flattened philtrum, flat midface).[18] A term that has gained popularity within the past decade to categorize behavioral and cognitive deficits, which constitute the most severe consequences of fetal alcohol exposure, is alcohol-related neurodevelopmental disorder (ARND).[18] Finally, there are terms such as "partial FAS" (which includes some but not all of the facial features and a confirmed maternal drinking history) and fetal alcohol spectrum disorder (FASD), which has been used to designate the complete spectrum of deficits attributed to *in utero* alcohol exposure.[21]

It is important to appreciate that the cardinal features of FAS (collectively) are not the result of alcohol exposure during a restricted temporal period and that it is unlikely that a single mechanism is involved. Therefore, it would be inappropriate to make an unqualified claim that an intervention prevents FAS in an animal model when the model exhibits only some of the features of FAS and when the alcohol exposure occurred over a restricted portion of gestation. Researchers using animal models must be very clear about the conclusions they draw from studies on components of FAS or parts of gestation. To be accurate, investigators should refrain from claiming to have conducted an investigation of FAS unless the particular animal model exhibits all of the features used in the definition of FAS in humans, including the facial dysmorphology. By definition, this would exclude most animal studies.

ESSENTIAL ISSUES IN THE USE OF ANIMAL MODELS

All animal models that have been used to study prenatal alcohol exposure have specific advantages (and disadvantages). The advantages of a particular animal model must result in answering the research question at hand. A desirable quality of any study using an animal model includes the ease of extrapolating the results to the human condition. On the other hand, some model systems may be chosen because they are very dissimilar to the human condition, but when used in combination with other model systems, can be used to answer important questions. However, at some point there must be some verification that findings from experiments using an animal model that is very dissimilar are relevant to humans.

Ideally, an animal model should be one in which alcohol is imbibed voluntarily and preferentially, as in humans, and where the model expresses all of the features of FAS and where development is similar to that in humans. No such model has been found. Animal models that require forcibly exposing animals to alcohol create some level of stress in the subjects. In animal models that utilize an alcohol-containing liquid diet, the subjects have only one source of nutrition and thus do not voluntarily and preferentially consume alcohol. Thus, researchers must design experiments that control for stress. When it is necessary to utilize a route of alcohol administration other than oral, it is important to appreciate that faster or slower rise time might induce different mechanistic cascades to result in the cellular damage, thus confounding the interpretation of the mechanism of induction for the developmental defect.

It is very important to consider the timing of brain development relative to birth (i.e., how "developed" are the offspring when they are born compared with human babies) and how closely the animal model brain anatomy and functional capabilities match those of the human.[22] When the object is to develop a therapy, intervention, or treatment for alcohol-induced fetal brain injury, it will be crucial to know that the animal model is a functional homologue of human brain anatomy and function.

In studying fetal damage from prenatal alcohol, the real possibility of maternal and placental roles or interactions must be considered. On the other hand, important contributions have been made by using nonmammalian animal models to study the direct actions of alcohol on fetal development that do not involve the placenta and mother as factors.[23–26] These studies suggest that the placenta and mother are not required to create the specific damage being measured other than acting as the source of alcohol to the fetus. Nonmammalian animal models can be of considerable value in addressing specific research questions that cannot be addressed in mammals and in separating out maternal–placental and nonmaternal–placental contributions to the damage. However, it is important to remember that the human condition does involve maternal–placental involvement and these components may create interactions that cannot be appreciated in simple animal models. Furthermore, the questions being addressed in these simple models are specific to certain stages of development, patterns, and concentrations of alcohol exposure and it is necessary to remember that the full spectrum of fetal alcohol damage involves many different stages of development, patterns of exposure, and mechanisms of action.

There is no single "best" animal model for addressing all FAS, ARBD, and ARND questions. However, the key issues related to the research questions at hand must be addressed. For instance, if the focus is on questions associated with drinking patterns, then a model system that enables considerable control of the administration of the parameter of alcohol exposure is crucial. Sometimes this is simply a choice of technique (e.g., intragastric gavage versus liquid diet). At other times, it may be intrinsic to the model system (e.g., intravenous for the sheep; voluntary drinking for the miniature swine).

And finally, it should be emphatically stated that some studies are best performed in human subjects. For example, several large cohorts of children have been identified around the world who can be tested directly for specific kinds of cognitive and other functional impairments resulting from moderate to heavy *in utero* alcohol exposure. It can be argued that it makes little sense to perform an animal study and then try to extrapolate the results to humans if the question can be addressed more directly in humans in the first place, since it avoids the extremely problematic issues of extrapolating results from one species to another. Therefore, we argue that the most effective use of animal studies today will be to model important questions that for various reasons still cannot be conducted efficaciously in humans.

HISTORICAL PERSPECTIVES AND CURRENT STATUS

The initial animal studies that were designed after FAS was first identified and defined understandably had goals that were broad and relatively unfocused. For instance, substantial effort was made to determine whether alcohol was actually teratogenic in the absence of other factors such as polydrug use or undernutrition, and to catalog the spectrum of effects caused by *in utero* exposure to alcohol. It is important to remember that those studies were conducted in an environment in which few children with FAS had been identified and that many investigators in the teratology field were publicly skeptical that alcohol was really teratogenic. Therefore, those early animal studies were critically important in that they provided legitimacy to the claim of alcohol teratogenicity and helped to identify the ways that alcohol could adversely influence development. Because few affected children were available for experimental purposes, and then only on a limited basis, clinicians had to be especially prudent in their selection of studies. Early animal studies played an important role in helping to drive clinical research in the field. For instance, animal studies identified problems in learning and memory[27,28] and suggested that short-term memory might be particularly vulnerable to developmental alcohol exposure,[29] which in turn stimulated clinical researchers to ask whether short-term memory is compromised in children with FAS.[30,31]

The cardinal features of FAS that have been studied using animal models are (1) intrauterine growth retardation, (2) craniofacial dysmorphology, and (3) central nervous system (CNS) deficits. Intrauterine growth retardation (IUGR) has an identifiable endpoint: low birth weight, impaired intrauterine and early postnatal growth, or stunted growth. Much of the research on alcohol-induced IUGR has been performed in rats[32] and mice.[33] Yet body growth is affected by parturition,[34] and parturition in rats and mice occurs at roughly the brain growth velocity equivalent of the end of the second trimester in humans.[22] As such, the third trimester equivalent of fetal brain growth in rats and mice occurs after parturition. For that reason, it is necessary to be cautious about using these animal models to explore the interactions of alcohol and somatic growth if the primary goal is to use such information to prevent or treat alcohol-induced IUGR in humans.

The examination of alcohol-induced craniofacial dysmorphology is a good example of progress made in one area of fetal alcohol research primarily through the use of an animal model (see Mice below).

CNS deficits are by far the most diffusely defined of the three cardinal features of FAS and range from neuropathology to behavioral alterations. While considerable progress has been made in human studies, there is still a need for animal models. Animal models have been useful in answering questions about not only what deficits are created but also how alcohol produces CNS deficits. It is still difficult to generate reliable data about the amount and timing of alcohol consumption during pregnancy from women who gave birth to affected babies. It is unreasonable to expect women to remember precise details about their alcohol consumption over a year or more prior to delivery. Furthermore, many FAS children are given up for adoption or end up in foster homes. Thus, any pertinent information about the biological mother's drinking habits prior to or during her pregnancy is no longer available. The first animal model evidence that alcohol could kill developing neurons[35] was extremely important. Additional studies showed that neurons in other brain areas and at different times of development were (third trimester,[36,37] various trimesters[38]) or were not vulnerable (locus coeruleus,[39] neocortex,[40] ventrolateral nucleus of the thalamus[38]). CNS deficits have been measured in the following ways using animal models: deficits in neuron physiology,[12] neurotransmitter levels,[41,42] neurosteroid levels,[43] and neuroendocrine function,[44,45] alterations in DNA,[46] RNA,[47] and protein expression pattern,[48] small volume of brain for body size (microencephaly[49]), holoprosencephaly,[50] hyperactivity,[51] deficits in olfactory behavior[52] as well as in spatial learning and behavior,[53] deficits in operant learning,[54] and deficits in electroencephalogram (EEG) recordings,[55] a list that is not exhaustive.

These studies have brought the field to a point at which the further documentation of cell loss under slightly different experimental conditions is providing diminishing returns. That does not mean that these types of studies lack any importance, but they may provide little additional predictive value**.** On the other hand, there are studies of neuron loss that could make some substantial contribution beyond identifying yet just another case of cell loss. For instance, even 30 years after the first report of alcohol-induce Purkinje cell death,[35] little progress has been made in terms of which mode of cell death is involved.[56] Furthermore, because the animal models chosen to examine alcohol-induced Purkinje cell death (loss) were mostly early postnatal (when Purkinje cells are postmitotic) or *in vitro* explant cultures, it is not clear whether the modes of alcohol-induced cell death would be the same in an *in utero* third trimester model (guinea pig or sheep, for example) or earlier in development, prior to the third trimester equivalent. An interesting and important question is whether cell death of a particular neuron type (Purkinje cells, for instance) following *in utero* alcohol exposure[11] occurs via the same mechanism as occurs with early postnatal exposure. If the answer to this question reveals differences in the modes of cell death when comparing *in utero* and postnatal exposure then it would be much more important to pursue questions of how to prevent or reduce the damage using animal models where the exposure to alcohol occurs *in utero* as in humans. If instead, the mechanisms of cell death are found to be the same, then it would be an obvious advantage to pursue the questions using animal models that are smaller, cheaper, or have other advantages that would expedite the results (e.g., neonatal rats). Again, this example highlights the importance of choosing the correct animal model to address specific relevant questions that will generate specific answers rather than simply describing yet another feature of the effect of alcohol on brain development.

In summary, there is now a relatively broad understanding of the effects of alcohol on the developing conceptus. However, there is still a need for further development of behavioral dysfunction models to serve as specific tests for intervention and treatment. It is also important to determine the specific behaviors that are spared. Better knowledge of what is damaged and what is not can help our understanding of how the damage occurs. We are now positioned to utilize animal models to address questions concerning how alcohol damages the developing conceptus at the molecular level. Knowledge of the molecular and genetic basis of alcohol damage to the CNS will be crucial in developing effective strategies for intervention, treatment, and prevention.

MAMMALIAN ANIMAL MODELS

MICE (*MUS MUSCULUS*) The usefulness of the mouse as a model for alcohol research is a function of several factors, including its relatively short gestation time (19 days), the wealth of background information available on anatomy, physiology, and pharmacokinetics, and its established use in behavioral studies where there is information about brain function and certain behaviors. In addition to these advantages, genetic manipulations are well established, including transgenic mice, mouse lineages for high and low alcohol consumption and other alcohol-related behaviors, and reverse genetics. The potential usefulness of the mouse became even greater with the completion of the sequencing of the mouse genome. And already in existence are a large variety of inbred and knockout/in strains available for specific uses.

Some of the earliest studies using the mouse to examine the effects of alcohol on brain development found deficits in fetal and offspring growth[57] and offspring behavior following gestational alcohol exposure[58] and were interpreted as consistent with those found in fetal alcohol-exposed children. One important set of studies demonstrated that the craniofacial dysmorphology observed in children diagnosed with FAS could be induced in the mouse by alcohol administration at gastrulation.[59] In these studies, Sulik's research group[50,60] and that of Webster[61,62] showed that the C57BL/6J mouse was susceptible to facial dysmorphology only if the alcohol was given at gastrulation. The critical relationship between the timing of alcohol exposure and offspring deficit was one of the important issues addressed by the experiments using the fetal C57BL/6J mouse, in addition to the notable implication that a single binge-like exposure to alcohol during a narrow window of nervous system development could result in the induction of a definitive characteristic of fetal alcohol syndrome. These findings were important in establishing the mouse as a useful model system.

However, it is also important to appreciate the shortcomings of the mouse model. Not every pregnant mouse treated with a high dose of alcohol will have severely affected fetuses or, if treated with alcohol at gastrulation, will have fetuses with any discernible craniofacial dysmorphology. Furthermore, there is no evidence that the fetuses displaying a craniofacial dysmorphology at GD14 would survive past birth and no evidence that these fetuses would continue to display this deficit as development proceeded through adulthood. In addition, the brain development of the mouse is both prenatal and postnatal, meaning that in order to study the effects of alcohol during all three trimesters (equivalent to that of humans), the mouse mother must be treated from conception to parturition and the mouse offspring must be treated from birth to about postnatal day 10–12; that much of the third trimester equivalent of brain development is postnatal and that third trimester equivalent dosing does not involve the placenta and mother make relating these data back to humans problematic.

RATS (*RATTUS NORVEGICUS*) The laboratory rat is a popular choice of animal model in fetal alcohol research. Rats were used to provide descriptive data on the effects of alcohol before pregnancy,[63] before and during pregnancy,[64,65] and during pregnancy and lactation[66] on offspring development. More recently, rats have been used to link genes with alcohol-induced behavioral changes. There is a large amount of information available on the rat including basic anatomy, physiology, pharmacokinetics, and reproduction, including the significant availability of phenotypic data. The rat is also very useful for behavioral experiments due to its large size, relatively short gestation (22 days), unique intelligence, relatively long life span, and abundant amount of historical data from behavior studies.

Some of the earliest fetal alcohol studies using the rat showed both physical[7,67] and behavioral[68] alterations in the offspring of alcohol-exposed pregnant rats. These early descriptive studies were important because they showed a very strong correlation in findings between the rat and humans with FAS, and this helped to establish the rat as a suitable animal model for many basic research questions. As the FAS field progressed, however, it became clear that the rat was not the best model system for addressing all questions. While problems with alcohol administration methods[69,70] and issues related to timing of alcohol dosing[71] were overcome, others have persisted. One of the most obvious disadvantages is that brain development (relative to that of the human fetus) occurs both *in utero* and in the early postnatal period, much like the mouse. This means that although FAS is a consequence of heavy maternal drinking throughout pregnancy, most rat studies in the literature have modeled the equivalent of alcohol exposure only during the first two trimesters in humans. Thus, studies of temporal vulnerability[49] suffer from problems of extrapolation of the results to the human condition. Furthermore, the mouse is more often a better model than the rat when genetic manipulations and the creation of transgenic and gene knockin/out lines are needed (with some exceptions). Most rat strains lack genetic homogeneity, which does not allow alcohol–gene interactions to be suitably controlled. Even though efforts to create gene knockin and gene overexpression models in rats have suffered from problems associated with embryonic stem cell stages, naturally occurring mutations, gene-specific deletions, and breeding programs to create high and low alcohol-consuming rat strains[72,73] have been explored systematically. These alcohol-preferring strains have been useful in identifying specific deficits associated with gestational alcohol exposure.[74,75]

GUINEA PIG (*CAVIA PORCELLUS*) The guinea pig has a number of important advantages including its long gestation period, larger body size compared to rats or mice, and primarily the fact that the brain development of the fetal guinea pig is more advanced at birth than that of rodents. Therefore, the brain growth spurt, which occurs *in utero* in humans, also occurs *in utero* in the guinea pig, making it a favorable choice for fetal alcohol studies of temporal vulnerability. In a series of studies, researchers have discovered several interesting changes in brain development as a result of prenatal alcohol exposure in the guinea pig model system. For example, exposure of pregnant guinea pigs to oral alcohol throughout gestation results in offspring with reduced brain and body weights,[76] increased incidence of hyperactivity,[77] altered dendritic arborization of layer V somatosensory cortex pyramidal cells,[78] decreased numbers of hippocampal CA1 pyramidal neurons,[77] altered cortical γ-aminobutyric acid [GABA(A)] receptor expression,[79] and changes in the subunit composition of *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors in the cortex of adult offspring.[80] Of particular interest is that a recent study found that the hyperactivity induced by prenatal alcohol exposure was not related to alcohol exposure during the brain growth spurt[81] since offspring exposed to alcohol only during the brain growth spurt exhibited no behavioral changes and no changes in

hippocampal CA1, CA3, or dentate granule cell or cerebellum Purkinje cell density[82] but did exhibit brain growth deficits in the cortex, hippocampus, and cerebellum. Thus, the guinea pig has been used successfully to address questions about the temporal vulnerability of the brain to alcohol-induced injury without the confounding variable of prenatal versus postnatal alcohol exposure, which is always a concern with rat and mouse models. While the size of the guinea pig and the timing of its brain development relative to parturition are clear advantages over the mouse and rat for some aspects of fetal alcohol research, the current usefulness of the guinea pig animal model is limited due to several factors, including the greater expense of housing the animals compared to rats and mice and the absence of the genomic tools available in rats and mice.

SHEEP (*OVIS ARIES*) Sheep possess a number of major advantages for the study of FAS when compared to other species both large and small. First, the adult ewe and fetus are extremely tolerant of handling, surgery, and chronic instrumentation, features that facilitate long-term treatment and blood sampling at multiple time points within the same subject. Surgically placed indwelling vascular catheters can easily be maintained for many months in adult sheep, while extraordinary measures must be employed to maintain catheters chronically in most other animal models. Because of the robustness of the sheep fetus preparation, many basic physiology questions have been addressed using this model system. As a result, a large literature exists on the normal physiology of the fetal sheep, which precludes the need for exhaustive preliminary studies simply to determine normal values and to establish the animal preparation. A second major advantage of the sheep is its large body mass. The sheep fetus weighs between 0.85 and 4.50 kg during the third trimester equivalent (this wide weight range is due to the rapid growth during this period of gestation), while the adults will weigh between 50 and 75 kg, comparable with that of a human fetus and an adult woman, respectively. When the measurement of multiple dependent variables must be performed simultaneously and at multiple time points, thus requiring the collection of relatively large volumes of blood, an animal of significant body mass is required. Such experiments simply cannot be performed in small laboratory animals. A third major advantage of sheep is that this species has a much longer length of gestation with brain development, relative to humans, occurring entirely *in utero*, which allows the investigator more opportunity to intervene or perform experiments at specific times during gestation than when using most other species. However, maintaining research sheep is expensive and requires special housing and veterinary care, and the sheep model is less well established in terms of two of the three FAS characteristics, the facial dysmorphology and central nervous system function (brain–behavior relationships). Thus the research questions that are addressed using this animal model must be sufficiently important and focused and the sheep must possess great advantages compared to some other models in order to justify the resources expended.

While sheep were used even earlier to study basic physiological issues in the fetus and the effects of ethanol on the fetal cardiovascular system pertaining to the practice during the 1970s of using alcohol as a tocolytic, Potter and co-workers[83] reported the first use of sheep in FAS research. This was one of the first to use a large animal model to demonstrate reduced organ size, including brain, in alcohol-imbibing sheep. Not long afterward, Rose and co-workers[84] utilized a sheep model system to address ethanol actions on fetal endocrine function. Cumming and co-workers[85] reported on ethanol pharmacokinetics and cardiovascular responses in fetal sheep. The most prolific investigations to date of those utilizing a sheep animal model were conducted by James Brien's group who reported on fetal brain metabolism,[86] alcohol disposition in the fetomaternal compartments,[87] actions on cardiovascular and brain activity,[88] and other issues. Falconer[89] addressed actions of alcohol on placental blood flow and glucose metabolism utilizing a sheep model system. In addition to Brien, Richardson, and co-workers,[86] Gleason and Hotchkiss[90] have also investigated alcohol actions on cerebral blood flow and metabolism in fetal sheep. Reynolds, Brien, and co-workers investigated neurotransmitter responses to alcohol in fetal sheep[91] and the actions of *in utero* alcohol exposure on behavior in neonatal lambs.[92] We have now reported the establishment of the eye blink classical condition as a functional dependent variable in this species.[93] We also have utilized this model system to address issues related to FAS and hypoxemia[94] and disturbances in the hypothalamic–pituitary–adrenal axis[95] and the hypothalamic–pituitary–thyroid axis.[96] Additionally, we have further validated the usefulness of this model system by demonstrating that fetal alcohol exposure results in Purkinje cell loss like that reported in the well-established rodent model system at similar doses and patterns of exposure.[11] While this is not an exhaustive cataloging of all FAS-related work performed in sheep, it represents the breadth of application and the efficacy of this model system for use in investigating FAS-related issues. Drawbacks of the sheep model are expense and lack of genomic tools.

MINIATURE SWINE The pig, especially the miniature swine (due to its smaller size), possesses a number of important advantages over other species for use in fetal alcohol research. A major advantage over almost all other species is that the pig will voluntarily consume alcohol, to the point of intoxication, in the presence or absence of food or water,[97] especially if it is beer (Dr. Thomas Badger, personal communication). This attribute makes the pig behaviorally more like humans than other species in that no other mammalian species will voluntarily consume such large quantities of alcohol, even with special training (e.g., rats) or conditions (e.g., physical restraint). A second advantage involves the timing of brain development relative to humans. The pig fetal brain growth velocity profile is the most like the human, in both cases peaking at the time of parturition.[22] This attribute would allow for studies of trimester-based vulnerabilities without the need of modifying the timing of alcohol administration with respect to the timing of parturition. A third advantage of the miniature swine is that alcohol metabolism and clearance are very similar to humans,[97] whereas alcohol metabolism in rats and mice is quite different. Fourth, alcohol consumption by pigs during pregnancy increases embryonic and fetal loss and reduces birth weight as in humans.[98] These similarities between the pig and humans have been utilized recently to explore the hypothesis that alcohol mediates these actions by effects on the uterine environment.[99] Others have exploited the strengths of the pig model system to investigate the actions of alcohol on the maternal and fetal liver.[100] To our knowledge, no other groups of investigators have employed the pig model system to investigate the actions of alcohol on the developing fetus, suggesting that this species may pose opportunities for other areas of investigation. However, as with other large animal species, the expense and resources needed

to maintain a colony for research necessitate a clear justification of the questions addressed. Adult female miniature swine weigh over 100 pounds and they require substantial space, which restricts where they can be used. Furthermore, since the pig has been used infrequently as an animal model for FAS, the generalizability of the results for specific dependent measures must be examined carefully.

NONHUMAN PRIMATES (*MACACA MULATTA; MACACA NEMISTRINA*) Theoretically, nonhuman primates should be the best animal model of the human condition since they are most closely related to humans in terms of cognition and behavior. Additionally, nonhuman primates exhibit a similar pattern of fetal development compared to humans (with the exception that nonhuman primates are born slightly advanced of human infants with respect to motor function). Nonhuman primates possess a relatively large face and brain, and well-defined cortical regions like those of humans, in addition to intelligence that is surpassed only by humans. Much of their anatomy, physiology, pharmacokinetics, and reproductive behavior have been documented, and fetal development progresses similarly to that of the human. They exhibit advanced behaviors that have parallels to human behavior.[101] The nonhuman primate model clearly has an important role in the examination of complex human behaviors, such as executive function. These behaviors are more reliably examined in the nonhuman primate than in rodent models. Another important advantage is that not only can the same behaviors be examined in nonhuman primates as in humans, but also often the same testing apparatus and conditions of testing prevail. Consequently, the findings can be extrapolated more easily to the human condition.

Altshuler and Shippenberg[102] were the first to report FAS studies utilizing a primate model system (rhesus monkeys) instrumented with intragastric cannulas. However, their report was preliminary and contained no live births. Also around this time, Mukherjee and Hodgen[103] utilized rhesus monkeys and cynomolgus monkeys to address cardiovascular actions of alcohol on the fetus. However, these studies were performed acutely on anesthetized monkeys, an important drawback as anesthesia may have altered cardiovascular function and potentially protective reflex responses to alcohol. Fisher and co-workers[104] utilized cynomolgus monkeys to address effects of prenatal alcohol on placental nutrient transport. Hill and co-workers[105] utilized cynomolgus monkeys to address alcohol pharmacokinetics. These endeavors have in common that they each resulted in a single publication suggesting that employing a monkey model system was useful for addressing only very specific questions or that further efforts were unfruitful. Clarren and co-workers are the only group who have utilized a nonhuman primate model to produce more than a single report. Subjects (pigtailed macaques) in their studies exhibited neuroanatomical, cognitive, motor, developmental, and facial anomalies like those seen in children exposed to alcohol *in utero*.[106–110] This group has also reported neurochemical and immunological actions of prenatal alcohol exposure.[111,112]

However, this model system, like all others, possesses disadvantages as well as advantages. Among the primary disadvantages is the nearly absolute requirement of specific methods of restraint for both acute treatments and to maintain instrumentation in chronically instrumented animals; restraint thus becomes a major confounding experimental factor and a potential cause of high pregnancy losses. The high rates of reproductive losses reported in primates used in FAS research raise the distinct possibility that a selection process might confound results. A high stress level associated with restraint is a recognized problem in studies using nonhuman primates, more so than in other large (sheep, pig) animal models.[113] Schneider *et al.*[114] utilized a voluntary drinking method in a rhesus monkey animal model, which is a strength insofar as restraint for alcohol administration was avoided, but equally important, the voluntary drinking method can be used only to explore the effects of low and variable (within and between individual subjects) doses of alcohol, since primates are not fond of drinking alcohol (compared to, for example, miniature swine). As a consequence of the great expense and legitimate ethical concerns, as well as other significant practical problems (including health risks to investigators and animal care technicians), the nonhuman primate model is useful for addressing questions only when other animal models are inappropriate.

NONMAMMALIAN ANIMAL MODELS

Nonmammalian animal models have made significant contributions to many research fields, including toxicology, development, and environmental chemical, preclinical safety, and efficacy testing for new drugs under development by industry. A significant amount of information about embryonic development has been derived from nonmammalian species due to the rapid extrauterine development and embryo translucency. In addition, nonmammalian models can be used in experiments that require synchronized embryo subjects. This has been an issue in some mammalian animal models because the timing of specific developmental events within each fetus is not synchronized. For example, not all mouse embryos will be at the identical developmental stage when a treatment is administered to the pregnant mouse.[115] Synchronizing the embryos would be an exploitable advantage in order to assess the extent to which all embryos are, or are not, equally affected by the same alcohol exposure. In addition, the use of a lower organism for biomedical research is one positive step toward the goals of reduction, refinement, and replacement of the use of animals in research. Thus nonmammalian animal models may offer some distinct advantages for use in the FAS research field.

CHICKEN/CHICK EMBRYO (*GALLUS GALLUS*) The chick embryo has a long history of use in developmental research. The chick animal model offers obvious advantages such as small size, rapid embryonic development, and lack of a placenta, which may reveal the extent of maternal protective factors. This animal model has been used to study craniofacial development and its perturbation by developmental alcohol exposure. Cartwright and Smith[23] showed that increasing doses of alcohol injected into the chick embryo at the gastrulation stage resulted in increasing craniofacial and other developmental deficits (hindbrain segmentation and neural tube defects), as well as increasing mortality. While the threshold for mortality appeared to be at about 250 µl (10% ethanol solution), this dose still resulted in a significant incidence of craniofacial anomalies that correlated with extensive cell death in the neural crest cell population.[23] Further research in this area revealed that alcohol stimulates cartilage differentiation in mesenchymal cells from various facial primordia, suggesting a potential mechanistic explanation for the craniofacial dysmorphologies in the chicken with respect to the competition between bone and other tissues forming within the face.[116] In addition, the important role played by neural crest cells in the etiology of

alcohol-induced craniofacial dysmorphology has been confirmed[117] and this deficit can be rescued by injection with sonic hedgehog.[118] These studies demonstrate important advances in our understanding of how neural crest cells respond to alcohol at specific stages of their dynamic development into the face. However, it is important to recognize that the alcohol-induced craniofacial dysmorphology (which is only one of the triad of FAS characteristics) in the chick, like the mouse, may not be observable in posthatching subjects, which would render this animal model suitable for only specific research questions. Thus, the utility of this model for addressing the full spectrum of FAS is limited.

One of the most serious limitations of the chick animal model is the scarcity of information on genetic mutations and the lack of knowledge about the chicken genome. At least one study has determined that various strains of chick embryo are more or less susceptible to alcohol-induced neural crest cell apoptosis,[119] and this in an important step in the FAS field. However, little work is being done on direct genetic manipulations in the chicken that would assist in determining the relative importance of alcohol-induced changes in gene expression as a risk factor for the craniofacial deficit, which is the most common utilization of the chick animal model in the FAS field. Nonetheless, experiments using the chick embryo have resulted in major advances in knowledge about many aspects of embryonic development, such as neurogenesis, axis and limb development, and somatogenesis.

FROG EMBRYOS (*XENOPUS*) The *Xenopus* embryo model has been used extensively to study basic embryological processes and the effects of environmental and other toxicants on development.[120–122] The use of the *Xenopus* embryo model in developmental toxicology stems from its external development, large size, and identifiable blastomeres, its ability to withstand extensive surgical intervention, and the fact that it can be cultured *in vitro*. The wealth of information about early embryonic patterning events has been gleaned from *Xenopus* embryos, especially the maternal contributions to embryonic development that occur prior to transcription of the embryonic genome. The *Xenopus* embryo model has the potential for exploitation in the study of alcohol-induced defects, especially resulting from perturbations in very early developmental events. The results of one such study by Nakatsuji[123] support this statement. The tadpoles (exposed to alcohol from the stages of morula through neurulation) showed alterations in physical morphology resulting from the alcohol treatment; the width of the mouth and the length of the head were consistently smaller in the alcohol-exposed compared to the control embryos. In addition, these researchers found that the changes in neural organization occurred at gastrulation and neurulation, and involved alterations in cell migration to the affected region.

Using the bullfrog, Uray and Sexton[124] examined the effect of high levels of alcohol exposure on the development of the cerebellum and reported that the timing of alcohol exposure was critical with respect to disrupting cerebellar development.[26] The usefulness of the bullfrog model for studying the effects of alcohol may be limited since the alcohol levels required were at the extreme end of the physiological relevant range for humans.[124] The *Xenopus* embryo model may be best suited for fetal alcohol research questions concerning very early (embryonic) development due to the wealth of information available about normal *Xenopus* development. Furthermore, the role of genetic manipulations and gene interactions in controlling the well-studied developmental events is not well documented compared to other nonmammalian organisms.

ZEBRAFISH (*DANIO RERIO*) The zebrafish is a powerful animal model for the examination of early embryonic development that has been utilized surprisingly little within the fetal alcohol field. The zebrafish has many advantages, especially as a genetic and developmental model, due to embryo transparency (mutant phenotypes are easily identified in whole, living embryos), fecundity (females may lay 75–120 eggs per cycle), the ease of manipulation, and the durability of the embryos to withstand various culture conditions. For the fetal alcohol field, perhaps the most important feature of the zebrafish embryo as an animal model is the ease of genetic manipulations, including forward and reverse genetics, insertional mutagenesis (morpholino knockdown/knockout), and positional cloning.[125] The zebrafish animal model has been exploited in a wide range of related fields, including development,[126,127] teratogy,[128] environmental pollution assessments,[24,129] and behavioral studies with,[130] or without, the presence of alcohol.[131] Currently, there are very few journal articles documenting zebrafish teratogenesis from exposure to alcohol per se, but the field is growing. In one study, Blader and Strahle[132] found cyclopia in alcohol zebrafish embryos exposed to 2.4% alcohol, in addition to altered migration of the prechordal plate. Some researchers have used the zebrafish to study alcohol's effects on visual development by giving alcohol (1.5%) to zebrafish embryos at various developmental time points and testing them on visual function and physiology.[133] They found that the embryos treated with alcohol during the period of eye development had significantly smaller eyes and impaired visual function relative to control embryos. Although these findings are potentially relevant for the FAS field (since both eye/facial development and function are affected by embryonic alcohol exposure), one question that remains unanswered involves the concentration of alcohol to which the embryos were exposed (1.5–2.4%). These values clearly exceed the physiological tolerance of humans and it is important to reconcile that fact with information about exactly how much alcohol the embryo receives. If the embryo absorbs only a portion of the concentration of alcohol in the media and still manifests the defect, then this animal model has great potential. On the other hand, if the embryos achieve equilibrium with the media alcohol concentration, then the utility of the model may be severely limited because the effects may be the result of toxicity rather than teratogenicity. There is some indication that the alcohol level within the chorion is the same as that within the media and zebrafish do possess the enzymes responsible for the conversion of alcohol to its primary (and toxic) metabolite, acetaldehyde,[126] but to date, no one has determined the level of alcohol *within the embryo*. In addition to its other positive attributes, the zebrafish has the potential to be a very powerful tool for the understanding of the role of genes in alcohol-induced deficits due to the recent cloning of the zebrafish genome and extensive catalog of known mutations. Some of the genes screened to date have been linked to specific human disease states.[134] The zebrafish is being actively used by one institution (Institute of Neuroscience, University of Oregon) and the publication of a guide to zebrafish[135] and an information sharing website (http://zfin.org) are available. Therefore the zebrafish is likely to be increasingly more popular in addressing basic questions associated with the relationship of gene expression and the deleterious effects of alcohol exposure during early embryonic development.

FRUIT FLY (*DROSOPHILA*) The most powerful advantage of the fruit fly for alcohol research is the abundance of genetic mutations and the potential for manipulation of the fruit fly genome to explore gene–alcohol interactions. In addition, the fruit fly is well suited to exploring multigenerational effects due to its rapid development from embryo through reproductive age adult. The effect of alcohol on multiple generations has received little attention in the fetal alcohol research field, but likely will receive further investigation as the number of children diagnosed with FAS reaching adulthood and bearing children increases. Since the entire genome of *D. melanogaster* has now been sequenced and cloned, the probability of using it to address genomic questions and multigenerational issues related to fetal alcohol-induced damage has increased. This advantage has been exploited extensively to study genetic perturbations associated with behavioral sensitivity and resistance to alcohol.[136] One other interesting attribute of the fruit fly is that it can metabolize alcohol directly to acetate, bypassing acetaldehyde formation, which has interesting implications for the study of mechanisms of alcohol teratogenicity. Although the development of the fruit fly from fertilization to adulthood has been well characterized,[137] to date little research has been performed on the teratogenesis of alcohol per se,[138] although other chemicals have been tested for teratogenicity.[139] Obviously the small size and rapid development of the fruit fly make it a suitable model for environmental and chemical teratogenesis screening, but these factors become an obstacle to some specific research questions in the fetal alcohol field, such as mechanisms of craniofacial development.

ROUNDWORM (*CAENORHABDITIS ELEGANS*) Although the roundworm, *C. elegans*, has rarely been used to attempt to study questions related to developmental alcohol exposure, it has an enduring history in the toxicology and neuroscience fields, principally due to its small size, external development, simplicity of neural organization (302 neurons and 5000 synapses), and complete genome mapping. Specifically, C. *elegans* has been used to study the molecular basis of specific behaviors such as circadian rhythms[140] and habituation.[141] Some studies have shown a dose-dependent reduction in reproductive activity[142] and the existence of an alcohol-sensitive genetic mutation.[143] This nematode has the potential to be used to address specific fetal alcohol research questions, particularly simple behavior. However, its genetic differences from humans impede its overall usefulness. Currently, there are other nonmammalian models that share genes with humans that would be more suitable to the study of the role of genes in alcohol's effects on development. Nonetheless, when dealing with behavior questions, starting with a relatively simple system and moving forward has proven effective in other areas and may provide a useful approach to stimulate ideas with respect to more complex neuronal systems. At this point, it remains to be seen whether the advantages of the *C. elegans* model can be exploited to address important, specific fetal alcohol questions.

USE OF ANIMAL MODELS IN THE FUTURE

Enduring challenges that face the fetal alcohol field include finding ways to identify the women at greatest risk of abusing alcohol during pregnancy with the hopes of preventing prenatal alcohol exposure and identifying children at birth who have been exposed to alcohol *in utero*. More elusive may be identifying effective treatments for those diagnosed with FAS. In addition to simply providing data that can be used to support the argument for the reduction or cessation of drinking during pregnancy, there are still at least three areas in which animal studies can have a significant impact on the fetal alcohol field. The first of those areas involves evidence of conditions that increase fetal risk when associated with maternal alcohol abuse. Research in this area offers to help explain much of the variation that occurs in human offspring with histories of similar amounts of alcohol exposure and may help to improve the predictability of the likelihood and extent of damage to the developing fetus.

The second area is the identification of the mechanisms of alcohol-induced fetal damage. Mechanistic studies offer the best hope for insights into developing pharmacological strategies for intervention. Research is now beginning to focus on developing therapies to prevent the induction of fetal injury. For instance, Spong and her colleagues[144] recently demonstrated that the pretreatment of pregnant mice with two novel peptides resulted in a significant reduction in fetal demise following an acute dose of alcohol early in gestation. However, it will be important in the future to better define the role played by the peptides in mediating this action and to demonstrate these protective actions in other animal models.

Another approach to therapeutic intervention that is showing considerable promise is the employment of behavioral, environmental, or cognition stimulating conditions to improve specific fetal alcohol-induced behavioral deficits. Klintsova *et al.*[145] found that 20 days of forced complex motor tasks was sufficient to partially ameliorate the effects of postnatal binge alcohol exposure in a rat model system. However, the rat is a postnatal model for what occurs prenatally in humans. And in fact, the results suggest that the complex motor training actually increases plasticity in the brain, rather than ameliorating the brain damage itself. Nonetheless, if similar results could be found using other animal models of FAS and perhaps in FAS children, it would make a compelling case for this type of intervention at a much later developmental stage.

Third, some of the best opportunities for advancing the fetal alcohol field are likely to come from behavioral studies that will promote the bidirectional flow of information between animal and human studies. Two examples illustrate this point. The first is the use of eye blink conditioning as a tool to study FAS and other alcohol-related injury. This technique is especially powerful for three important reasons. First, unlike most other tests, it can be used effectively at different stages of development and even in the same subjects over time. Second, it can be used in both animals and humans. Third, much is known about the neuronal pathways involved in this type of learning. Eye blink conditioning has been studied in humans for many years, including the assessment of cognitive development in infants.[146] Because the neural substrates of classical conditioning at different developmental ages have been mostly worked out in animals,[147] researchers have begun to realize its potential for evaluating the effects of neurotoxic/teratogenic agents,[148] including alcohol exposure in developing rats.[149] These efforts have led to the correlation of specific deficits in conditioning with altered electrical activity[150] and neuronal loss[151] in the deep cerebellar nuclei. This powerful interaction between human and animal studies will allow specific types of learning deficits to be detected in human infants and then better understood by an animal model where the relevant functional neural pathways can be dissected.

Another creative example of how studies with animals can be extended to humans is the use of the principles of the Morris water maze. This type of learning task has been shown to require an intact hippocampus, and it is an effective tool for evaluating deficits in spatial learning in rodents that have been affected by developmental alcohol exposure.[152] On the surface, the behavioral requirements of the Morris maze hardly seem applicable to humans, especially those with substantial cognitive or motor impairments. However, the wealth of neurobiological information related to place learning stimulated investigators at the University of New Mexico to develop an innovative virtual water maze that can be used to assess learning differences in adolescents with FAS.[153] Again, with this application, deficits in humans can be understood in the context of neural systems that can be manipulated experimentally in animals.

These examples illustrate how future animal and human studies can interact and drive the field forward more rapidly than would otherwise be possible. The careful choice of questions that will have the most impact on the human condition**,** coupled with selecting the animal models that are best suited for addressing those questions, will undoubtedly have important implications in the development of detection, intervention, and treatment strategies for FAS, FASD, and ARND.

63 Modeling Drug and Alcohol Abuse

Experimental Examples of the Utility of Zebrafish

ROBERT T. GERLAI

ABSTRACT

This chapter will discuss the utility of zebrafish (*Danio rerio*) in the analysis of the biological and genetic mechanisms of acute and chronic alcohol (ethanol, ethyl alcohol, or ETOH) consumption on human brain function and it will also present examples on how zebrafish can be used as a model organism to study mechanisms of addiction to this and other drugs of abuse. The chapter's focus is biased toward behavior genetic approaches, i.e., it is not intended to provide a comprehensive overview of all possibilities with zebrafish. This bias represents a subjective view, but we also argue that genetic applications and a focus on behavioral function are perhaps particularly appropriate for modeling human alcohol and drug abuse, and we also argue that zebrafish will provide unprecedented insights into these diseases.

Key Words: Alcohol addiction, Alcoholism, Behavioral phenotyping, Drug abuse, Forward genetics, Zebrafish.

ZEBRAFISH, A FAVORITE OF DEVELOPMENTAL BIOLOGISTS AND GENETICISTS

Zebrafish has been a popular subject of developmental biology and genetics for the past three decades.[1] This popularity is mainly due to the pioneering work of Streisinger *et al*.,[2] who realized that certain characteristics of this vertebrate organism make it particularly useful for the investigation of biological processes involved in the ontogenesis of vertebrates (see Chapters 13 and 14 of this volume for a more general discussion of the use of zebrafish in biomedical research). Most importantly, zebrafish has an externally developing embryo that is transparent and thus its tissues and organs can be directly observed under the microscope. Another important advantage of this vertebrate over other model organisms, including the mouse or the rat, is that it is small (adult zebrafish reach a length of 4 cm) and is highly social, and thus can be housed in large groups in small fish tanks. Finally, a definite advantage of this species over many other laboratory vertebrate model organisms is its prolific nature. A single female can lay 200 eggs once every 2–3 days under ideal conditions.[3] After realizing these advantages, developmental biologists and geneticists started to develop genetic tools for this species[2,4–7] and as a result by now we have an impressive arsenal of genetic techniques available for zebrafish. For example, genetic markers crucial for the localization and identification of randomly induced mutations have been established. Rapid amplification of polymorphic DNA (RAPD) and amplified fragment length polymorphism (AFLP) have been utilized for positional cloning.[8–10] A genetic linkage map comprising more than 4000 polymorphic microsatellite markers [11] and radiation hybrid maps composed of both microsatellite markers and expressed sequence tags (ESTs)[12,13] are now available. Single nucleotide polymorphisms (SNPs) and oligonucleotide microarrays have been utilized for mapping of zebrafish mutations.[14] A viral infection-based insertional mutagenesis technique has also been established for the generation of insertional mutations that could be rapidly cloned due to the presence of the viral tag in the genome.[15] In addition to forward genetic approaches, reverse genetic methods have been developed. Morpholino antisense knockdown allows the inactivation of known genes in early embryos.[16] Targeted-induced local lesions in genomes (TILLING)[17] has also been successfully adapted to zebrafish.[18] Thus, now complete loss-of-function (null), gain-of-function, or partial loss-of-function (hypomorphic) mutations can be isolated and analyzed. Finally, the genome of zebrafish has been sequenced at the Sanger Center. All these tools and pieces of information are in the public domain (e.g., GenBank, Sanger Center website, and ZFIN).[19] In summary, the genetics of zebrafish is highly developed and places this species on par with the mouse and the fruit fly.[1,4,20,21] It is also important to note that genes discovered in this species have been found evolutionarily conserved and have homologs in mammals including our own species.[22] For example, such genes include genes whose products play roles in alcohol metabolism.[23,24] Furthermore, syntenic relationships between chromosomal regions of zebrafish and mammalian species have been determined.[25,26] It is thus expected that there is a good chance that genetic information discovered using zebrafish will translate well to mammalian systems. Thus could zebrafish be utilized in the mechanistic analysis of human alcoholism? Before we discuss this question, let us consider why we

would like to study the biology and genetics of alcohol effects and the abuse of this substance.

ALCOHOLISM IS AN ENORMOUS PROBLEM, YET A CLEAR PICTURE OF ITS MECHANISMS HAS NOT EMERGED

Alcohol abuse and alcoholism are frequent and debilitating diseases. Their direct effects on the individual can be devastating. Alcohol abuse may lead to behavioral and psychiatric problems with severe consequences for the patient as well as for the family and society in general. The direct and indirect costs of alcohol abuse are enormous. In the United States alcohol abuse was estimated to cost more than $150 billion yearly and resulted in 40,000 deaths (National Institute on Alcohol Abuse and Alcoholism, 1990), and these figures are becoming worse.[27,28] Prevalence estimates for alcohol abuse and dependence range between 11% and 16%, amounting to a staggering number of approximately 30 million people afflicted by this disease only in the United States.[29,30]

Treatment of alcohol-related problems includes detoxification (a short-term solution) and long-term rehabilitation programs, e.g., cognitive–behavioral therapy, motivational enhancement therapy, and Alcoholics Anonymous or related 12-step programs.[31] Although detoxification may be achieved, long-term rehabilitation programs have had only limited success, as the percentage of relapse at 3 months after the start of the program approaches 50%.[32] Briefly, there is an enormous unmet medical need for pharmacological intervention. Based on clinical and preclinical findings, several pharmacotherapies have been attempted, e.g., serotonin (5-HT) receptor partial agonists, γ-aminobutyric acid A ($GABA_A$) receptor agonists, dopamine receptor agonists and antagonists, and opioid antagonists[32] have been tried. However, most drugs have failed. Notable exceptions are disulfiram, a compound converted into diethyldithiocarbamate in the body, which then chelates copper and other metals important for metalloenzymes including alcohol dehydrogenase. Efficacy has been shown[33] for naltrexone (an opioid receptor antagonist) and for acamprosate (a drug that has some structural homology to GABA itself).

Efficacious pharmacotherapies have been difficult to develop because of the fact that the mechanisms of alcohol abuse and alcoholism are not understood. Alcohol is a nonspecific and low potency drug that affects numerous molecular targets and biochemical pathways and does it in a rather complex dose-dependent manner. Alcohol is known to impair the *N*-methyl-D-aspartate receptor (NMDA-R)[34] and enhance $GABA_A$-R function[35] via allosteric modulation of these receptors. The anxiolytic and sedative effects of alcohol may be mediated by $GABA_A$-R.[36] Inhibition of NMDA-R may underlie the memory-impairing effects of alcohol.[37] The reinforcing effects of alcohol are thought to be mediated by the dopaminergic system and serotonin (e.g., $5\text{-}HT_3$-R) receptors[36] and endogenous opioids.[32] Neuropeptides, e.g., neurotensin and corticotrophin-releasing factor (CRF), have also been implicated.[38] Adenosine (an inhibitory neuromodulator) has also been shown to interact with alcohol.[39] Voltage-gated ion channels (e.g., L-type, N-type, and T-type calcium channels, and the M-type K^+ channel) are inhibited by alcohol.[40–42] Alcohol may indirectly or directly influence second messenger systems or other intracellular signaling cascades[43] leading to modulation of transcription and/or translation processes. In summary, the number of molecular targets with which alcohol interacts is large and the mode of interaction is complex. A clear picture has not emerged as to the key molecular and neurobiological mechanisms that could explain the acute and chronic effects of alcohol. Consequently, development of appropriate pharmacological intervention has been difficult. A possible research route toward the understanding of the mechanisms of the effects of alcohol is to use model organisms. In the following we discuss some notable studies in this area of research.

DEVELOPMENTAL EFFECTS OF ALCOHOL IN ZEBRAFISH

The effects of alcohol on zebrafish have been extensively studied from a developmental biology perspective. For over three decades it has been clear that alcohol is deleterious for the developing zebrafish embryo: notochord and spinal cord duplications arose in the embryo after alcohol exposure.[44] Numerous recent studies have investigated the teratogenic and toxicological properties of alcohol in zebrafish and found that exposure to this substance during embryogenesis significantly affects the visual system leading to cyclopia, delayed, and abnormal lamination of the neural retina and to abnormalities in the pattern of tectal lamination as well.[45] Hallare *et al.*[46] showed that posthatching exposure leads to significantly increased mortality at higher alcohol doses (1.5% and higher) and it also induces numerous abnormalities including edema, reduced heartbeat, diminished pigmentation, and other major developmental defects such as disrupted axial body formation. In fact, among the three solvents studied [alcohol, acetone, and dimethyl sulfoxide (DMSO)], alcohol had the most deleterious effects. Zebrafish has also been proposed as a model of fetal alcohol syndrome.[47] In this study several of the above-mentioned abnormalities were found and the degree of severity of these abnormalities correlated with both the concentration of alcohol and the age at which the embryos were exposed to the substance. Strain differences in the developmental abnormalities induced by early alcohol exposure have also been demonstrated,[48,49] suggesting the involvement of genetic factors. The behavioral effects of acute alcohol exposure on the zebrafish embryo have been studied in detail by Lockwood *et al.*[50] who found a dose-dependent alcohol effect on locomotion closely corresponding to a previously described inverted U-shaped dose–response curve in adults[51] with intermediate doses resulting in the highest increase in activity. In addition, similar to what has been described in the adult,[51] the embryo also exhibited alcohol-induced melanocyte responses, i.e., an apparent darkening of skin pigmentation in response to alcohol.

Apart from the results presented in the latter study,[51] however, little is known about the effects of alcohol on the brain function and behavior of adult zebrafish. Given that in the human society alcoholism affects a large number of adults[30] and the mechanisms of alcohol's action and of alcohol addiction are not well understood,[52] analysis and modeling of the effects of alcohol on the adult vertebrate brain continue to be an important goal.[53] Classical laboratory model species including the rat and the mouse have been utilized to study this question. Many of these studies employed genetic approaches[53] and some of these studies are reviewed below.

RODENT MODELS OF THE HUMAN DISEASE: THE ADVANTAGE OF GENETIC APPROACHES AND THEIR COMPARISON

There is no a priori reason why genetics should be more powerful than any other approaches, and thus by focusing on genetic approaches in this chapter we do not imply that factors other than genes are unimportant in the development of alcoholism and in the abuse of alcohol and of other drugs. However, genetics provides an important experimental tool with which to probe the biological mechanisms of human diseases. Even when a larger proportion of human disease cases is due to nongenetic factors, genetic methodology has significantly contributed to the understanding of disease mechanism. For example, in Alzheimer's disease the familial cases account for only less than 5% of the patient population, yet the identification of the amyloid precursor protein, and the discovery of the role of its abnormal processing leading to the accumulation of A-β peptide fragments in neurons, has been significantly facilitated by genetics[54] (also see Chapter 22 of this volume). The point of genetic approaches is thus that they provide a window to the biological mechanisms irrespective of whether the cause of the disease is primarily genetic or environmental in nature. Besides, alcoholism and alcohol addiction as well as addiction to other drugs of abuse have been found to have a significant heritable component.[52,55,56]

To address the complexities of alcohol effects and the use and abuse of this substance in the adult, numerous genetic approaches have been employed using animal models. These include quantitative genetic (e.g., inbred strains and their crosses, selective breeding, recombinant inbred and recombinant inbred congeneic lines) and molecular genetic approaches (e.g., transgenic/knockout models). Gene expression analysis, e.g., gene chips, has also been employed. One of the first genetic approaches in alcohol research was the long-sleep (LS) and short-sleep (SS) selected mouse lines. LS mice bred for increased sensitivity to the sedative effects of alcohol showed enhanced response to the $GABA_A$ agonist muscimol compared to SS mice, suggesting involvement of GABA receptors in alcoholism.[57] Bidirectional selection was also conducted for seizure susceptibility associated with alcohol withdrawal and the withdrawal-seizure-prone (WSP) and withdrawal-seizure-resistant (WSR) mouse lines were generated.[58] Analysis of these selected lines revealed that seizure proneness is associated with increased NMDA-elicited convulsions and elevated expression of Ca^{2+} channels and $GABA_A$ receptor subunits. The disadvantage of all quantitative genetic studies including selection experiments is that only genes showing variability in the studied population may be investigated.

Quantitative trait locus (or QTL) mapping is also limited to the study of genes that show variability in the experimental population. Nevertheless, QTL mapping has identified chromosomes 1, 4, and 11 as the locus of genes associated with alcohol withdrawal in the mouse,[58] and finer mapping with recombinant congeneic mouse strains has been narrowing the regions of interest[59] leading to potential identification of the actual genes. Despite the widespread use of QTL analysis, however, success has been slow[58,60] (but see Tabakoff *et al.*[37]).

The effect of overexpression and underexpression of a candidate gene may be investigated *in vivo* in transgenic mice. "Candidate" genes tested for alcohol-related questions in this manner include, e.g., those encoding $GABA_A$ receptor subunits or the 5-HT_{1B} receptor, PKCγ2, dopamine receptors (e.g., D_2 and D_4), and neuropeptide Y as well as the *fyn* intracellular tyrosine kinase.[58] The pros and cons of transgenic techniques have been extensively discussed.[61,62] Briefly, the greatest disadvantage of these approaches is that they only allow the investigation of known genes but not the discovery of the involvement of novel ones.

Discovery of novel genes may be achieved by forward genetic approaches (see, e.g., the identification of the "Clock" gene in the mouse reviewed by Pinto and Takahashi[63]). Here the mutation is induced randomly, the mutation effects are tested at the phenotypical level, and the animal carrying the mutation is identified and then bred. In case of dominant or semidominant, i.e., not completely recessive, mutation the heritable change is observed at the F_1 generation and recessive mutations are detected at the F_3 generation. Localization and subsequent identification of the mutant gene are based on genetic marker-aided linkage analysis followed by positional cloning and or gene expression analysis.[63] Forward genetic approaches are now being utilized in zebrafish. For example, Guo *et al.*[64] have been using this strategy to identify genes involved in substance abuse with particular focus on the dopaminergic system. Darland and Dowling[65] and colleagues also focus on substance abuse (cocaine)-related behavioral mutants as well as visual system-related mutants.[66] The advantage of the mutagenesis approach is several-fold. First, compared to quantitative genetic studies, forward genetics is not limited to the discovery of genes that show variability. Second, unlike transgenic approaches, forward genetics allows the discovery of novel genes. Third, several mutations may be isolated for the same gene and from these mutants it is possible to make inferences about the function of the gene product. Fourth, both loss and gain of function mutations may be identified. In the following, therefore, we mainly focus on forward genetic applications and present a few examples of how these studies contributed to, or are expected to contribute to, the understanding of the mechanisms of alcohol and other drug abuse-related human diseases with the use of zebrafish.

NOVEL GENES POTENTIALLY RELEVANT IN DRUG USE AND ABUSE: THE FIRST SUCCESS STORIES USING FORWARD GENETICS IN ZEBRAFISH

The characteristics of zebrafish make this species particularly amenable to high-throughput screening, and indeed, forward genetic approaches, which are screening intensive, have already yielded successfully results with this organism. For example, Guo *et al.*[64] have been using this strategy to identify genes involved in substance abuse with particular focus on the dopaminergic system. They implemented a mutation screen based not on behavioral phenotypes but on the histological analysis of dopaminergic neurons. Based on alterations using tyrosine hydroxylase (TH) immunohistochemistry, they detected mutants whose catecholaminergic systems were affected. For example, the "too few" mutant exhibited a reduced number of dopaminergic neurons in the hypothalamus during embryonic stages.[64] Later, Rink and Guo[67] discovered that the "too few" mutation also affected the development of serotonergic neurons, and identified that this mutation disrupted a zinc-finger-containing protein,[68] a probable transcription regulator. Another mutation they identified was "foggy." [64]

This mutant exhibited abnormalities (reduced or lack of TH staining) in diencephalic, telencephalic, and retinal DA neurons, as well as in the locus coeruleus and in peripheral sympathetic neurons. Guo *et al.*[9] identified the gene carrying the "foggy" mutation using positional cloning and found that it is a phosphorylation-dependent dual regulator of transcription elongation, a finding that provided the first key evidence that negative regulators of transcription elongation may control key aspects of neuronal development. Why is this all relevant for addiction research? It is, as Guo[69] argues, because the dopaminergic system plays crucial roles in reward and is known to be a key player in drug abuse.

Behavioral characteristics have also been utilized as criteria for the identification of mutants in forward genetic studies. Darland and Dowling have shown development of preference for cocaine in zebrafish after a single trial in a place preference paradigm[65] demonstrating that a drug abused by humans also has rewarding properties in zebrafish. In their forward genetic screen using the conditioned place preference paradigm Darland and Dowling identified three distinct mutations selectively affecting cocaine-dependent behaviors.[65]

THE BOTTLENECK: PHENOTYPICAL SCREENING PARADIGMS

Up to now, we have not discussed an important disadvantage associated with the use of zebrafish. Although this species is excellent for high-throughput screening due to the ease with which random genetic mutations may be induced and propagated in a large number of offspring, a major disadvantage of zebrafish is that appropriate phenotypical screening techniques are available mainly for the developmental biologist but not when it comes to the question of what behavioral alteration or brain dysfunction may be elicited by the mutation. Briefly, the foundation of forward genetics, the phenotypical screening methodology, is mainly missing. This critical comment, of course, does not concern the already successful forward genetic studies discussed above, but it must be noted that these studies represent the exception rather than the rule: compared to what we know about the behavior and brain function of other model organisms, zebrafish may be regarded as an uncharted species.[70,71] Given that the success of gene identification and thus the discovery of how genes may contribute to particular phenotypes rest on our ability to identify mutants and given that alterations of brain function may be best detected using behavioral testing, appropriate and sensitive behavioral screening applications are an absolute must when it comes to the question of how genes contribute to drug use and abuse. In the following, we present our first few attempts to develop behavioral screening applications for the detection of mutations affecting alcohol use and abuse.

CHARACTERIZATION OF ZEBRAFISH BEHAVIOR AND THE DEVELOPMENT OF HIGH-THROUGHPUT TEST METHODS

First let us consider an important point that is sometimes confused in the literature, the definition of an "animal model." According to our view, an animal model can be regarded as a model if it has at least some construct, face, and predictive validity. That is, if the model resembles some mechanistic aspects of the human disease, if it is similar to it in its phenotypical manifestation (appearance), and if it can reliably predict the outcome of some manipulation that is expected to influence aspects of the human disease. Why are we discussing these points here? Because we want to emphasize that the following discussion will not be about an animal model in this strict sense. It will include our latest results concerning the development of behavioral testing methodology that will be useful for the identification of mutations affecting alcohol-induced behavioral responses. That is, it will include the foundation of forward genetics.

We already mentioned that we[51] investigated the acute effects of alcohol in adult zebrafish. The tests we developed were designed to be deliberately simplistic so that automation and fast speed could be achieved in future mutagenesis studies. The results we obtained showed that alcohol-induced behavioral changes closely resembled those seen in humans. For example, locomotory activity of adult zebrafish showed a characteristic inverted U-shaped dose–response curve with intermediate doses eliciting hyperactivity and the highest applied dose eliciting a sedative effect (Figure 63–1). Similarly, intermediate doses elicited increased aggression as measured by how close a fish swam to his mirror image (Figure 63–2) or how much aggressive posture it showed toward it (Figure 63–3). The shortcoming of this study was that all behavioral responses were manually quantified, i.e., a human observer blind to the experimental conditions scored the previously recorded videotapes. While this method is very precise and is unbiased,[72] it is rather time consuming. To investigate the feasibility of automated computer-based behavioral quantification in the analysis of zebrafish behavior two manual quantification methods were

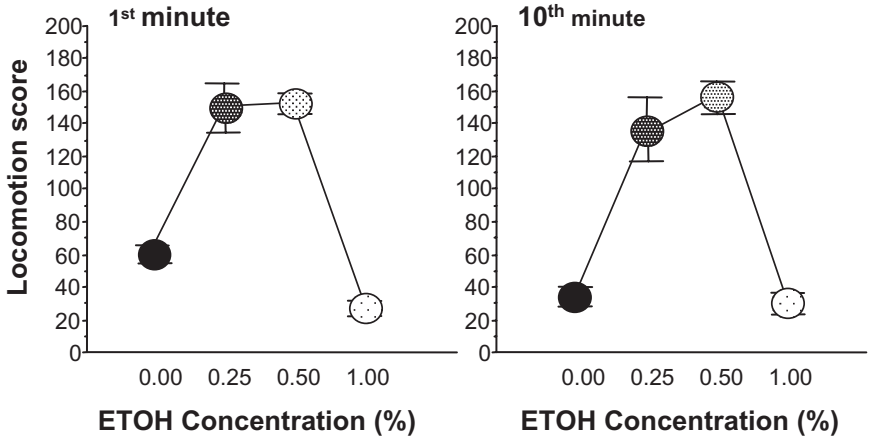

Figure 63–1. Locomotory activity of zebrafish (outbred wild-type population) after acute (1-h-long) alcohol treatment is increased by intermediate doses of alcohol. The locomotion score was manually recorded and is calculated as the number of crossings between segments of the observation tank during a 1-min observation session at the beginning (first minute) and at the end (tenth minute) of the test. Mean ± SE are shown. Sample sizes: ETOH 0.00% = 13, ETOH 0.25% = 15, ETOH 0.50% = 13, ETOH 1.00% = 16. Note that ETOH 1.00% fish exhibited depression of activity while the other two alcohol-treated groups showed a robust increase. For further details and statistical analyses see Gerlai.[70]

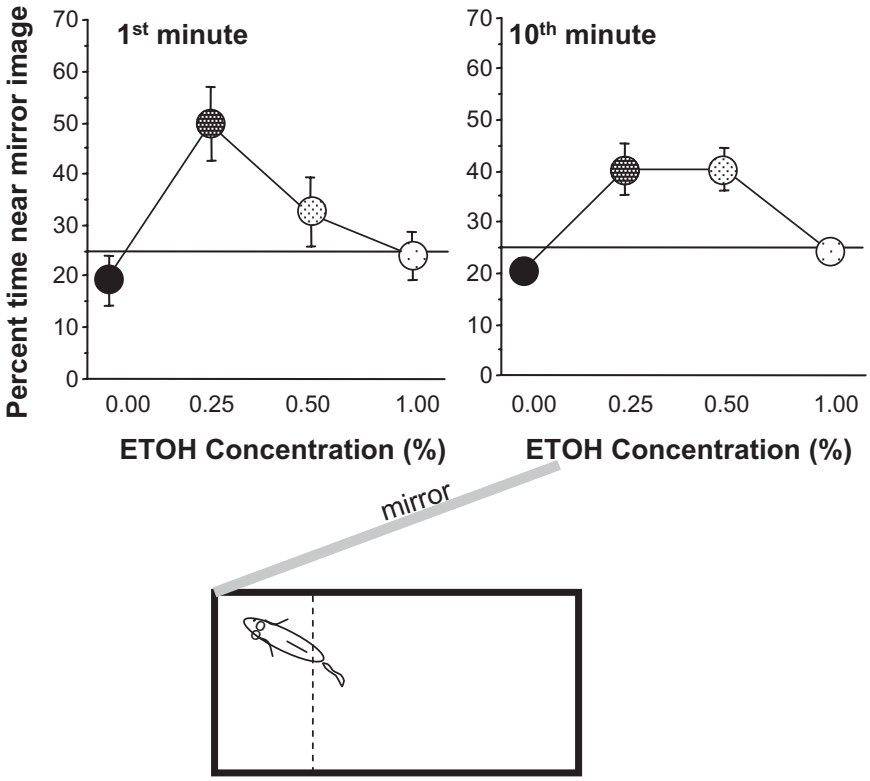

Figure 63–2. Intermediate alcohol concentrations (acute 1-h-long treatment) enhance preference for staying close to the mirror image, a "conspecific opponent," indicating enhanced aggression. Mean ± SE are shown. Sample sizes: ETOH 0.00% = 15, ETOH 0.25% = 16, ETOH 0.50% = 16, ETOH 1.00% = 18. Similar to locomotor activity, performance was quantified for the first and the tenth minute of the session. Note the inclined mirror making the mirror image appear larger when viewed by the subject from the left side of the tank. Note the inverted U-shaped dose–response curve. The solid horizontal line represents the chance level. For further details and statistical analyses see Gerlai.[70]

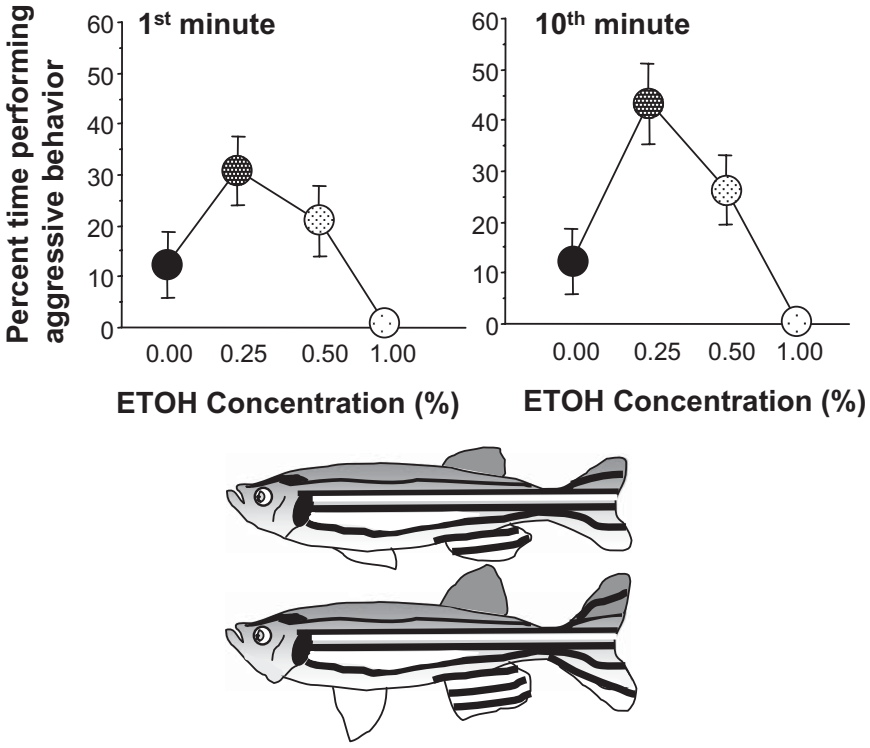

Figure 63–3. Intermediate doses of alcohol (1-h acute treatment) enhance aggressive behavioral responses elicited by the sight of an opponent (mirror image) as measured by quantifying the amount of time the fish spent with agonistic motor and posture patterns. Mean ± SE are shown. Sample sizes: ETOH 0.00% = 15, ETOH 0.25% = 16, ETOH 0.50% = 16, ETOH 1.00% = 18. Note that data are obtained by quantifying videorecordings of the same fish as in Figure 63–2 and sample sizes are identical to those shown in that figure. Also note that the lower one of the two zebrafish is displaying (showing an aggressive posture). For further details and statistical analyses see Gerlai.[70]

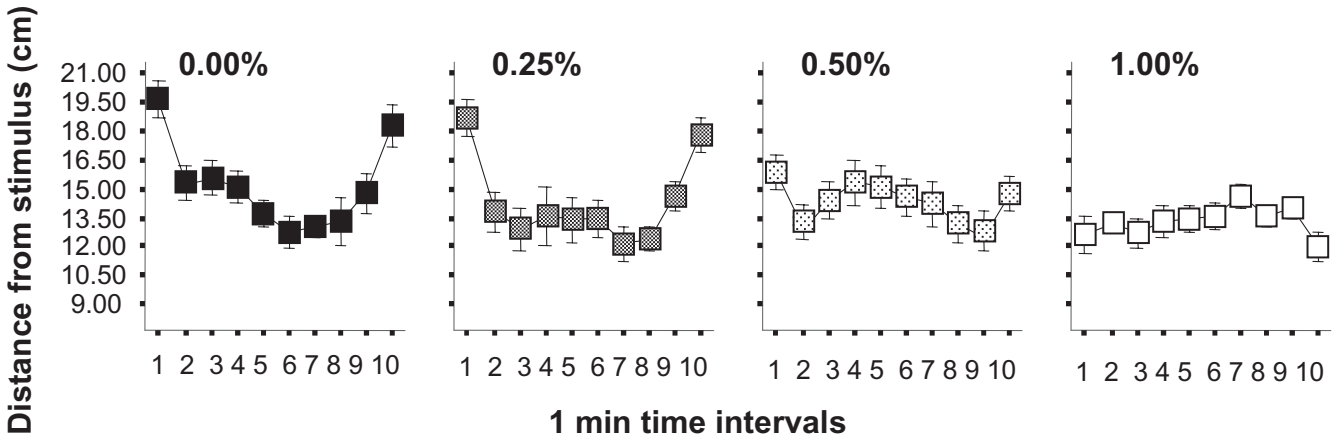

Figure 63–4. Acute (1-h-long) alcohol treatment reduces the distance of zebrafish from a predator model stimulus in a dose-dependent manner. The acute dose is indicated above the graphs. Mean ± SE are shown. Sample size (*n*) for each dose group equaled 14. Note the U-shaped time trajectories, which are due to the fact that the predator model was presented only during the first and during the last minute of the test. Also note that the predator model is very effective and elicits increased distance at 0.00% and at 0.25% alcohol doses but at higher doses its effect diminishes. For further details and statistical analyses see Gerlai *et al*.[73]

compared with a more sophisticated video-tracking-based automated technique. A very good correlation was found among the results obtained by the different methods and this suggested that automated behavioral quantification, and thus high-throughput behavioral screening, will be possible. Utilizing video-tracking and the previously developed test paradigms, we are now investigating the acute and the chronic effects of alcohol exposure in adult zebrafish. Our preliminary findings suggest that alcohol has fear-reducing properties at the doses employed (interpreted as an anxiolytic effect in the human literature) that manifest, for example, as reduced distance from a predator model (Figure 63–4). Importantly, this effect was detected without the need for a human observer to be present. Chronic alcohol exposure effects have also been successfully quantified using the automated video-tracking method. We have also found that after a 2-week-long exposure to 0.25% ethanol, fish exhibit significant adaptation to the substance and when exposed to the same concentration during a test they do not increase their activity level (Figure 63–5), i.e., we have obtained evidence for adaptation to alcohol in zebrafish.[73] Signs of withdrawal symptoms were also detected in that fish that received chronic alcohol treatment showed hyperactivity when exposed to fresh water (Figure 63–5). Briefly, these results suggest that acute and chronic exposure to alcohol has significant behavior-altering effects in zebrafish analogous in appearance to those

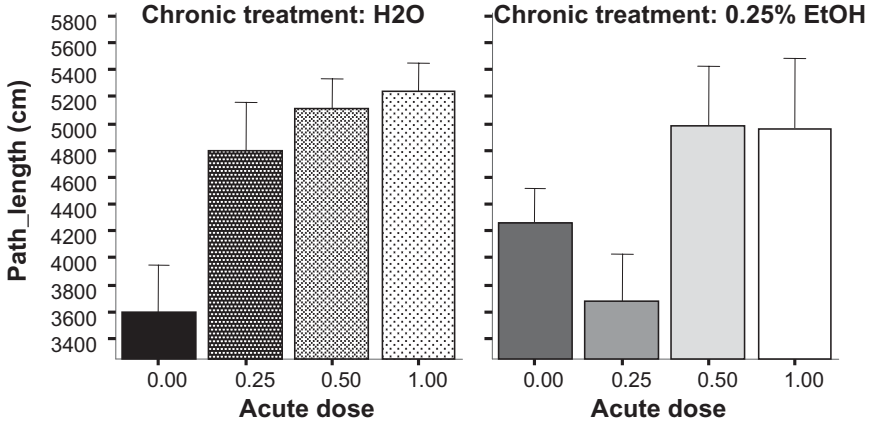

Figure 63–5. The effects of acute and chronic alcohol treatment on the locomotor activity of zebrafish: the total path length (centimeters) traveled during the 10-min recording session shows adaptation to alcohol. The left panel shows the results for fish that were not exposed to alcohol during chronic treatment (chronic treatment H_2O). The right panel shows the results for fish that received chronic ethanol (0.25% concentration) for 2 weeks (chronic treatment ETOH). Mean + SEM are shown. Sample sizes are as follows. Chronic treatment freshwater groups, $n = 14$ for each group. For chronic treatment ETOH, $n = 13$, 12, 12, and 13, respectively; for acute treatment ETOH, dose = 0.00%, 0.25%, 0.50%, and 1.00%, respectively. Note that the first bar on the left panel (fish that received no alcohol acutely or chronically) is not different from the second bar on the right panel (fish that received 0.25% ethanol both chronically before and acutely during the experiment), suggesting adaptation to alcohol in response to chronic treatment. Also note the somewhat elevated path length value of the first bar on the right panel (fish that received the 0.25% chronic ethanol treatment but were withdrawn from it 1 h before and during the behavioral recording session), suggesting withdrawal-induced hyperactivity. For further details and statistical analyses see Gerlai *et al*.[73]

seen in humans. Also it is important to note that these changes can be quantified using automated methods. Automated computerized behavioral quantification is an important requirement for high-throughput screening. It allows the application of a large number of test apparatuses running in parallel. The limiting factor in such a setup is no longer the amount of time an experimenter has but rather the physical space available and the cost of the equipment. Given that the test tanks are small and the equipment is also inexpensive (commercially available video equipment and computer hardware and software), high-throughput screening is now thus feasible.

In summary, the above results demonstrate that high-throughput behavioral screens are feasible with zebrafish. Given the strength of the genetics of this species and the increasing number of laboratories that utilize zebrafish as a model system, we forecast that zebrafish will be a promising animal model with which the acute and the chronic effects of drugs of abuse, including alcohol, may be investigated both in the embryo and in the adult. These investigations will undoubtedly lead to discoveries of novel genes and biochemical mechanisms involved in alcohol and drug abuse-related abnormalities and thus will allow the development of biologically sound animal models of these diseases.

64 Mouse Models for Experimental Cancer Therapy

Sara Rockwell and Karen R. Rockwell

ABSTRACT

Tumors in laboratory rats and mice have long been the major model systems used in experiments intended to improve the diagnosis and treatment of cancer. A wide variety of rodent models are used in experimental cancer therapy; all have strengths and weaknesses as models for human cancer and as models for developing improved therapies for cancer. The strengths and the limitations of the various models are discussed in this chapter. These should be considered carefully by researchers as they select systems for use in their projects in experimental cancer therapy, as they design and perform their experiments, and as they analyze their data and translate their studies to improve the care of cancer patients.

Key Words: Mouse, Inbred strains, Experimental cancer therapy, Tumor models, Toxicities of anticancer agents, History of laboratory mouse.

INTRODUCTION

ORIGINS OF LABORATORY MICE Popular culture associates white mice with biomedical research, but most people (including many scientists) do not realize that laboratory mice are very special creatures, with unique characteristics and pedigrees that trace back over 30 centuries.[1–4] Humans and mice have lived together since ancient times. The English word *mouse* traces back through the Latin *mus* and Greek *mys* to the Sanskrit *mush*, a name derived from the verb meaning "to steal," showing that the habits of these little rodents were familiar to Indo-Europeans at least 6000 years ago. Greek history ascribed a major victory of the Greek army to the intervention of the god Apollo, who sent mice into the enemy camp the night before the battle to chew through the leather thongs of the shields and render them useless. The Greeks celebrated this divine intervention by building temples to *Apollo Smintheus* (Apollo the god of mice) and by raising under the alters of these temples white mice, which were credited with powers of prophecy and healing. Domesticated mice with unusual coat colors, color patterns, appearance, and behavioral characteristics have been raised and studied in Asia for more that 3000 years. The Chinese character meaning "white mouse" is ancient. The symbol for "spotted mouse" was present in the first Chinese lexicon, compiled in 1100 BCE. Because mice gathered and stored food and other objects, they were considered prudent and wise. In Japan, mice were considered to be the messengers of Diakoku, the god of wealth, and the activities of mice raised in his temples were analyzed to predict the success or failure of business ventures.

People have continued to raise domesticated mice since these ancient times. Domesticated house mice and "fancy mice" with unusual characteristics appear frequently in art and literature throughout the world. By the eighteenth century, breeding of fancy mice had become a global commercial enterprise as well as a common hobby. Mouse farms, which bred and sold mice of European, Asian, and mixed origins, were common in the United States as well as Europe and Asia. Mice were bred for unusual coat colors, including white, black, yellow, and chocolate, and to have patterns that included spots, stripes, and markings like Siamese cats. Strains of dwarf mice, hairless mice, mice with curled or kinked tails, "waltzing" mice, and other unusual mice were also developed.

THE RISE OF EXPERIMENTAL BIOLOGY The emergence of biology as an experimental science in seventeenth and eighteenth century Europe saw the use of mice as laboratory models.[1,2] Harvey's studies of anatomy and circulation and Priestley's and Levoisier's studies of respiration used domesticated mice. Some historians believe that Mendel's studies of the inheritance of specific traits included studies with mice as well as pea plants. The discussions of Darwin's theory of evolution in the late 1800s and the rediscovery of Mendel's work in 1900 enhanced interest in heredity and led to experiments involving the deliberate breeding of organisms with divergent traits. Mice rapidly became important models in this research. The mouse's short gestation time (21 days), short time to sexual maturity (3 months), and relatively large litter size facilitated genetic studies. The commercially available lines of mice with readily distinguishable physical and behavioral traits provided ideal starting materials for geneticists who wished to study inheritance and assess whether specific traits could be fixed by inbreeding in animals, as they were known to be in plants. By the early 1900s, William Castel, Clarence Little, Hasely Bagg, Leonell Strong, Leo Loeb, and many other American geneticists were studying inheritance in mice.[1,2]

THE DEVELOPMENT OF INBRED MOUSE STRAINS In the early 1900s Abbie E.C. Lathrop, who owned the Grandby Mouse Farm in Grandby, CT, noticed that the different "families" of fancy mice she was raising differed dramatically in their incidences of cancer.[1,2] She sent mice from her cancer-prone mouse

From: *Sourcebook of Models for Biomedical Research* (P. M. Conn, ed.),

family to the geneticist Leo Loeb. This led to a series of collaborative studies examining the role of genetic and endocrine factors in the development of mammary tumors. About the same time, Ernest Tyzzer published a series of papers describing studies in which tumors were implanted from mice of one "race" into mice of related and unrelated lineages. Little began studying the hereditary factors that determined sensitivity or resistance to tumor transplantation, and decided that there was a need for mouse models with a "homogeneity of genetic constitution" that allowed this problem and other complex, non-Mendelian problems in genetics to be studied rigorously. By the early 1900s a number of researchers were systematically inbreeding mice, often with founding stock obtained from the mouse lines sold by Grandby Mouse Farm, to produce different strains of uniform, genetically defined animals that provided the foundation stock for modern laboratory mice.

INBRED STRAINS

The inbred mouse strains that result after ~50 generations of brother–sister mating and selection for uniformity and desired traits are unique biological models (see Chapter 20, this volume).[2–6] First, all of the animals within an inbred strain are genetically identical, except for the inevitable differences in the male and female karyotypes. Moreover, the mice are homozygous at all genetic loci; all recessive alleles are therefore expressed. The resulting animal-to-animal homogeneity in physiology, behavior, development of strain-specific disease, and response to treatments or manipulations has profound implications for the design and performance of biological experiments. In addition, because the strains have been bred to homozygosity, the first generation (F_1) hybrids resulting from a cross of two inbred strains are also uniform and genetically defined. Inbred strains of mice therefore provide powerful model systems for studying genetic diseases and for studying the effects of genetic factors on the development of injuries and diseases produced by exogenous agents, as described in detail in other chapters in this volume. The characteristics of most inbred strains of mice are well described on the mouse genome informatics website at http://www.informatics.jax.org/.[6]

The development of inbred mouse strains was intrinsically linked to their use in studying the implications of heredity factors in the development of cancer.[1,2] Their critical role in this area has continued and has expanded with the development of genetically engineered mice (GEM) that allow studies of the effects of the presence, absence, mutation, or altered expression of specific genes or combinations of genes (see Chapter 41, this volume).[6,7] These models have also found wide use in preclinical studies of the potential benefits and toxicities of agents being developed for the prevention and treatment of cancer.[3,4,8–10] They have also been used to study the mechanisms of action of these agents and to develop regimens for use in initial clinical trials of novel anticancer agents.[3]

MODEL SYSTEMS FOR STUDYING THE TOXICITIES OF ANTICANCER AGENTS

Most anticancer agents produce their beneficial effects by killing or preventing the growth of the malignant cells. Unfortunately, cancer cells develop from the normal tissues of the same patient, and although their evolution through precancerous lesions to cancer results in the acquisition of the cellular phenotypes associated with malignancy, cancer cells seldom develop absolutely unique physiological signatures that can be used to target cancer therapy with complete specificity. Instead, the targets generally appear at low levels or in slight variations on some cells in normal tissues, and the agents therefore have effects on normal tissues as well as tumor. The development and testing of new cancer therapies therefore must always involve studies of the toxic side effects of the agents, as well as studies of their antineoplastic efficacies.

Inbred strains of laboratory mice have proven invaluable for studying the response to therapy of the critical tissues that limit the intensity of cancer therapy. The value of these models results from several factors. First, the genetic homogeneity of the mice within an inbred strain minimizes animal-to-animal variations in the delivery of treatment related to factors such as size, percent body fat, or uptake from the injection site or the gastrointestinal track. Similarly, for drugs that are enzymatically activated or metabolized, the uniformity in the enzymes and enzyme levels within an inbred strain produces greater uniformity in pharmacokinetics than would be seen in outbred mice with enzyme polymorphisms. The physiological differences in different inbred strains of mice[4–6] can result in very different effects from the same agent. This is illustrated by a comparison of the duration of anesthesia produced when the same intraperitoneal dose of the same barbiturate is injected into mice of similar sex and age, but from different strains: the reported "sleeptimes" vary by a factor of about 3.[5]

Other genetic differences between inbred strains also influence the response of mice to treatment, through mechanisms that reflect both cellular and tissue level effects. Inbred strains differ in their ability to repair the DNA damage that produces the effects of many anticancer drugs. As an extreme example, *scid* mice, often used as hosts for human tumor xenografts because of their profound immunodeficiency, are immunodeficient because the *scid* mutation produces a deficiency in the repair of DNA double-strand breaks. Because of this cellular repair deficit, radiation injuries to the normal tissues of *scid* mice develop at extremely low radiation doses, one-third to one-half the dose needed to produce the same effect in normal mice.[11] Less obvious differences in DNA repair exist among inbred strains.[12] For example, studies of radiosensitive BALB/c mice, radioresistant C57BL/6 mice, and their hybrid progeny relate the different radiosensitivities of these mice to differences in DNA-PKcs expression that result in variations in nonhomologous end joining. Physiological differences at the tissue or whole animal level also affect the development of treatment-induced injuries. Susceptibility to the development of lung fibrosis after treatment with radiation or bleomycin, for example, is a heritable trait in mice. Different inbred strains and their crosses, as well as GEM, show striking variations in lung injury after irradiation that reflect the influences of multiple genetic loci.[13] The use of mouse strains with differing susceptibilities to naturally occurring diseases of specific organ systems, described elsewhere in this book, offers opportunities to determine how the development of injuries from cancer therapeutic agents mimics and how it differs from the development of the genetically induced diseases and the functional declines associated with aging.

The use of inbred strains to study the effects of anticancer agents has some significant implications for experimental design. The uniformity of the mice within a strain has statistical implica-

tions: it reduces the number of animals needed in experiments and allows detection of smaller effects than could be seen with more variable models. It has been possible, for example, to detect age- and sex-dependent differences in the toxicity of some agents that would be masked in experiments using animals from a more variable population. In fact, it should be noted that some of the toxicities commonly ascribed to therapeutic agents have been definitively identified *only* from studies of mice and other model organisms. We know from Muller's studies in fruit flies and Russell's studies in mice that irradiation of the gonads causes germ line mutations that can lead to mutations or genetic disease in the progeny.[14,15] The potential for this deleterious effect in humans is assumed and is considered when planning cancer therapy for patients who may have children in the future, but a significant increase in genetic diseases or polymorphisms above the background rate has never been demonstrated in any human populations studied, including the large, heavily irradiated populations of Hiroshima and Nagasaki.[3] Uniform, genetically defined mouse models therefore provide extremely powerful experimental systems for defining and studying the potential toxicities of anticancer drugs and allow researchers to address questions that cannot be answered either using *in vitro* systems or by studies of human populations.

There are also potential problems and pitfalls in the use of inbred mice as model systems. The breeding of inbred lines must be closely monitored to ensure that the expected genotype, phenotype, and uniformity are maintained. Breeding errors that result in the introduction of foreign genes can be disastrous for the experiments. It is important for researchers to realize that the inbred mice they purchase or acquire from different sources may not be identical, despite the fact that they have the same strain designation.[4–6] Some mouse strains were not actually fully inbred at the time the founder stock was separated to establish the different sublines now available.[2,4] Genetic drift, resulting from random spontaneous mutations, has also introduced genetic changes into the sublines.[4,6] The slow accumulation of genetic differences becomes important when comparing sublines that have been separated for many decades (i.e., dozens of generations). Moreover, some natural mutations (such as the *nude* mutation) have occurred several times and some transgenics and knockouts have been produced multiple times; these mutations are therefore available in mice of different outbred and inbred backgrounds. Investigators should consider the substrain designations, as well as strain designations, and should research the origins and characteristics of the substrains if they change vendors or sources. They should also consider the microbiological status [including the presence/absence of strain-associated viruses such as mouse mammary tumor virus (MMTV)] of the mice from different sources. The parental genotypes of some GEM, especially those produced using the genetically diverse strain 129 mice or their crosses,[6] are not well defined. Thus, although the gene of interest may be the same in the different genetically altered mice, there may be very significant differences elsewhere in the genomes.

Additional thought must be given when using hybrids between inbred strains (see Chapter 20, this volume).[5,6] Although F_1 hybrids are uniform and genetically defined, they are heterozygous, rather than homozygous, and recessive genes will therefore be hidden. Moreover, the two possible crosses will not be the same. For example, a C3H × C57BL mouse would differ from a C57BL × C3H mouse in its X and Y chromosomes, in its imprinting, in its mitochondrial DNA, and in intrauterine and postnatal exposures that reflect the mother's genetics or epigenetics (classically including exposure to MMTV in the milk).

Certain caveats must always be remembered when using any mouse model system. Disney's cartoons notwithstanding, mice are not furry little people. Researchers must always be aware that there are differences between mice and humans that can complicate or even preclude the use of mice as models for specific projects. An obvious example in cancer therapy is that mice do not vomit: they are therefore useless as models for predicting the nausea associated with cancer therapy or for developing approaches to ameliorate this toxicity. The pharmacological and pharmacokinetic differences between mice and humans must also be considered. Uptake, distribution, and elimination of drugs are often much more rapid in mice than in people. In studies of hypoxic cell radiosensitizers, such as misonidazole, where radiosensitization increased with the drug levels in the tumor at the time of irradiation and toxicity increased with the cumulative drug exposure, the mouse models showed much greater efficacy than could be obtained in patients and failed to predict the peripheral neuropathies seen in clinical trials.[16] The differences in the rates of cell proliferation in mice and people[10] must also be considered in designing studies of anticancer agents. Many antineoplastic drugs and radiation are "cycle-active" agents, which have effects that differ for cells in different phases of the cell cycle. Because mouse cells generally have much shorter cell cycle times than human cells, the effects of changing the duration of treatment or the timing of multifraction or multiagent regimens in mice will be different from those in people. Similarly, the late tissue injuries (e.g. lung fibrosis, kidney damage) that limit the delivery of many anticancer regimens will develop more rapidly in the mouse (with a lifespan of 2–3 years) than in people.

MODEL SYSTEMS FOR STUDIES OF THE EFFICACY OF ANTICANCER THERAPIES

Studies of the efficacy of potential anticancer agents require the use of model tumor systems, because even the most sophisticated cell culture systems cannot replicate the complex environments within solid tumors or the interactions between the tumors, stroma, and hosts. A wide variety of mouse tumor models exist. Each has value for addressing specific questions, but each has potential limitations, as discussed below. Researchers using any of these model tumors should also consider the strengths and limitations of mouse models discussed above, as most of those discussions are equally germane to studies of tumors.

MODEL RODENT TUMORS

Spontaneous Tumors Outbred and inbred mice develop spontaneous tumors (i.e., tumors developing from an unknown etiology) over their life spans.[4,5,8–10,17] These are seldom used in experimental cancer therapy because they develop in many organs and locations and have a wide spectrum of histologies and characteristics. Moreover, any specific type of spontaneous tumor will occur with a relatively low frequency. Because the incidence of spontaneous tumors increases with age, such tumors become common only in colonies of animals being held for life span studies: they are rarely found in experiments using young mice or even in production colonies, because breeders are culled as their production rate declines in midlife. These factors preclude the accumulation of large numbers of similar spontaneous tumors for study. Their use has therefore been limited primarily to the

initiation of transplanted tumor lines, the common models described below.

Autochthonous Tumors Many inbred strains of mice develop strain-specific tumors at a high frequency or have high incidences of specific tumors if given specific treatments.[4–6] These are not true "spontaneous" tumors, because they result from the effects of specific oncogenes and/or endogenous viruses. They are called "autochthonous tumors" when they are studied in the mice in which they arose. Examples of autochthonous tumors include mammary tumors in C3H mice, which transmit the MMTV in their milk and have a genotype conferring sensitivity to the carcinogenic effects of this virus; radiation-induced lymphoma in C57BL mice, reflecting the presence and induction of the radiation-induced leukemia virus; or the characteristic tumors developing in GEM carrying activated oncogenes or harboring specific deficits in tumor suppressor genes. While most work with these tumor models has focused on studying the etiology of the cancer and the molecular pathways leading to malignancy, a few projects have examined the responses of these tumors to therapy. C3H mouse mammary tumors have been used, for example, to study the effects of hormonal manipulations, as well as effects of radiation and drugs.[16]

Autochthonous tumors are true primary tumors, growing in the site where they arose. The tumor/stroma relationship therefore bears a closer resemblance to primary human tumors than does that of tumors arising from cells transplanted into healthy mouse tissue. The limitations arise from the costs and difficulty of working with these tumors. To obtain sufficient tumors for study, large colonies of mice at risk must be maintained and monitored for tumor development over periods of months or years. Because the initial evolution of tumors from precancerous lesions is recapitulated in these models, the tumors will be quite variable. They may have different histologies, variable growth rates, and variable metastatic and invasive potentials. Tumors will develop in different locations (e.g., different mammary glands or different lymph nodes) and some may be in locations that rapidly lead to morbidity or death. Some animals will develop multiple primary tumors simultaneously or during an experiment, complicating studies of therapeutic responses. Some tumors will become detectable at an earlier stage than others. The age and health of the hosts will vary. Tumors will develop in the colony at different times spanning months or years; one or only a few tumors will be available for treatment at any one time. Each treated and control group will therefore include tumors discovered, treated, and observed separately. All of these factors introduce experimental variability and raise technical and statistical problems for the use of these model systems in studying the response of established malignancies to therapy. They are therefore used primarily in studies testing interventions that might delay the development of malignancies by preventing development of premalignant lesions, ablating such lesions, or preventing their progression to malignancy.

Transplanted Tumors

Tumor Lines Mice from the same inbred substrain are essentially identical twins, and, like identical twins, they will accept reciprocal transplants of tissues without rejection. They will also accept transplants of tumors developing in mice of the same substrain. Transplanted tumors in inbred mice are the most common mouse model systems used in experimental cancer therapy.[8–10] Use of these tumors offers notable advantages in experimental design. All tumors within an experiment can be inoculated in the same anatomical site, with the same pool of tumor cells, during the same session. Tumors within an experiment can be treated as a cohort, with treated and control tumors examined and assayed simultaneously by the same observer. The use of transplanted tumors therefore offers numerous advantages in terms of simplifying the experimental design and reducing the numbers of tumors (and therefore mice) needed to perform experiments with adequate statistical power to compare the effects of different treatments.

There are many things the researcher needs to consider before beginning a project examining the response of transplanted tumors to therapy. First is the choice of tumor model. A wide variety of experimental tumor lines are available from researchers and from institutional and commercial cell and tissue repositories. The investigator should ensure that the characteristics of the tumor line to be studied are appropriate to address the question being asked. Early passage tumors generally grow more slowly and are better differentiated than are tumor lines that have been serially transplanted in mice or passaged repeatedly in cell culture. This reflects the fact that serial passage (*in vivo* or *in vitro*) selects for the cells with the most rapid growth rate.[12] Over the first dozen serial passages the tumor cell population evolves to have shorter cell cycle times and a higher fraction of proliferating cells. Early passage tumors may offer better models for well-differentiated human tumors. However, this comes at a price: more cells or tissue must be implanted to produce a tumor and some recipient mice may not develop tumors; the tumors grow more slowly; and tumors show greater tumor-to-tumor variability in histology, behavior, and response to therapy. Late passage tumors are better characterized, are more uniform, and are rapidly growing and easy to handle. Established tumor lines vary in their invasiveness and metastatic potential. Some lines metastasize early (perhaps even before the primary tumor becomes palpable) either to specific tissues or widely; others rarely produce metastasis. Studies of metastasis will require the use of model systems different from those studies using local control as an endpoint, in which long-term observation of the site of the treated primary tumor is essential and the presence of metastasis would preclude observations long enough to use this assay meaningfully.

Selection of Hosts The host mice should be uniform in origin, age, sex, weight, and/or any other critical characteristics. Age is a critical factor. Many vendors sell very young mice (4–5 weeks of age), which are too small to carry the tumor burden needed for the studies. Moreover, the pharmacology and effects of anticancer drugs often differ in immature and adult mice, even when drug doses are given on a per gram basis. Animals should be held until they reach 2–2.5 months of age before inoculating tumors. The researcher should ensure that the substrain chosen as the host is appropriate and syngeneic with the tumor line—noting that some substrains of common inbred lines have been separate long enough that they will reject tumors (and skin grafts) from other substrains. Some long-passaged tumors (e.g., Harding-Passey melanoma, S180, and Ehrlich ascites carcinoma) arose in outbred mice or mouse strains that no longer exist, and have been carried in mice of many different strains.[17] In addition, some tumor lines exhibit tumor-specific or viral antigens that render them immunogenic even in "syngeneic" mice.[8,17] The possibility that the hosts will mount immune responses to transplanted tumors must therefore be considered when designing experiments and interpreting data.[8,17]

Care should be taken to ensure that experiments begin with mice of the best possible microbiological status. The purchase price of specific pathogen-free mice may be higher than that of "conventional" mice and the per diem charges for maintaining the mice under stringent microbiological conditions may likewise be higher. However, any loss of animals or experiments due to intercurrent infections can soon make this difference in cost disappear. Almost all cancer therapies are immunosuppressive; treated mice will therefore be at increased risk of illness and morbidity from both pathogens and "nonpathogenic" organisms. In addition, it has been shown repeatedly that both active infection and past infections alter the physiology and immune function of mice in ways that perturb tumor growth and alter the responses of tumors and normal tissues to therapeutic agents.[8] Stress from other sources (noise, handling, recaging of aggressive adult males) has also been shown to affect tumor growth, and even minor changes in husbandry can alter drug effects (e.g., changing from pine shavings to corn cob bedding alters liver microsomes and therefore changes the pharmacokinetics of some drugs).[8] Care should therefore be taken to select appropriate animals and to house and handle them appropriately throughout the experiments.

Inoculation of Tumors Many other technical factors must be considered in designing experiments with transplanted tumors. The site of tumor implantation is important. While older studies often used tumor cells injected into the peritoneal cavity, this implantation site is now used infrequently. Intraperitoneal injection produces ascites, in which tumor cells and host immune cells exist as single cell suspensions in the ascites fluid. However, ascites models mimic the growth of only a few natural tumors, such as ovarian carcinomas and leukemic infiltrates. As appreciation of the interactions between the malignant cells of solid tumors and the stroma and vasculature has improved, the limitations of ascites tumor models and the importance of studying solid tumor cells in a more realistic association with stroma have become clear. Most solid malignancies are now implanted subcutaneously, intradermally, or into tissues such as muscle, lung, brain, spleen, or mammary fat pad. Orthotopic implantation of tumors into the tissue of origin or into a common site of metastasis has theoretical advantages and in some cases provides tumors that better model invasion and/or metastasis from primary tumors of the same histology.[18] However, orthotopic implants generally require surgery to expose and visualize an internal organ for inoculation. The wound-healing responses and immunosuppression resulting from surgery can complicate interpretation of the results, and the internal location of the developing tumors precludes the sequential tumor observations needed to monitor tumor growth, to deliver treatment at a specific predetermined volume, or to follow the effects of treatment on tumor growth and cure. Single terminal observations of tumors treated at a prespecified time after treatment have often been used to assay responses with such tumors; this compromise presents many experimental design problems. Sequential imaging of tumors using X-rays, computed tomography (CT), magnetic resonance imaging (MRI), or assays of light from green fluorescent protein (GFP)-expressing tumor cells offers the potential for more rigorous delivery of treatment and sequential monitoring of tumor growth, but is labor intensive and subjects the mice to multiple anesthetizations and immobilizations for imaging. Subcutaneous, intradermal, and intramuscular injections allow better visualization and measurement of the tumors, but at the price of an artificial location.

The site of inoculation should be chosen to allow the tumor to grow to the desired experimental size without interfering with movement and without invading, metastasizing, or ulcerating to produce painful disease. For example, injecting tumors in the loose skin of the flank is preferable to injection into the very constricted skin of the foot. The study should also be designed with endpoints that allow the hosts to be euthanized at a humane point in time. One of the hallmarks of cancer is that tumors in many sites can grow to relatively large sizes without causing pain and discomfort. This, in fact, is one of the factors which makes early detection of cancer difficult and necessitates the use of screening tools such as mammography, pap smears, prostate-specific antigen (PSA), and colonoscopy to detect early asymptomatic cancer in human populations. Investigators should design experiments that use this window of opportunity as effectively as possible and thereby perform their experiments with as little pain or distress to the animals as possible.

Tumor cells for inoculation can come from several sources. Small pieces of minced tumor can be inoculated using a trocar. This technique transplants intact tumor tissue including stroma and may allow transplantation of fragile tumor cells that do not survive the procedures needed to prepare cell suspensions. Many tumors are inoculated using single-cell suspensions prepared from tumors or cell cultures.[8,9] This approach produces more uniform populations of tumor than inoculating tumor chunks, because the cell suspension can be counted and the number of cells inoculated can be precisely controlled. It is critical that any cell line inoculated into mice be prescreened for pathogenic bacteria and viruses. Cell cultures and transplanted tumors can acquire and carry rodent and human pathogens. Implantation of contaminated tumor cells can result in systemic infection of the host mice; the resulting infection may be spread via urine, feces, fomites, and/or aerosols to animals throughout the colony and, in the case of zoonoses, even to researchers and animal handlers.[8]

ASSAYS OF TUMOR RESPONSE The effects of therapy can be assayed in several different ways: biochemical, histological, and metabolic assays, tumor growth assays, tumor cell survival assays, and tumor cure assays are most common.[8] The basic design of all such experiments begins similarly: a large number of animals are inoculated with tumors and the tumors are allowed to become established. At a predetermined time, the tumors are treated with the agent of interest. The "time of treatment" may be selected in two ways. If the tumors grow relatively uniformly, an optimal experimental design may be to randomize the tumors on the day they reach a predetermined average volume, then treat all tumors on the same day. If there is considerable variability in the growth of the tumors, it may be preferable to assign each tumor to an experimental or control group using a predetermined stratification or randomization scheme when it reaches a predetermined volume, then treat it. The volume of treatment is an important consideration. It is important that this volume not be so large that the ratio of the tumor size to host size does not reflect tumors seen clinically. All experiments should include untreated control groups followed in parallel with the experimental tumors. If the treatment involves significant manipulations (e.g., anesthesia for irradiation or imaging; injection of drugs in a vehicle with possible effects) additional sham-treated controls should be included to test for any stress responses or immunological changes associated with the experimental procedures.

Biochemical assays and histological and metabolic assays of tumor response generally are of limited value in assaying the outcome of experimental cancer therapy. There is usually a very tenuous relationship between the transient biochemical and metabolic changes (e.g. DNA synthesis, glucose utilization, ATP levels) seen soon after treatment and the long-term effects of the treatment on the viability and growth of the tumor cells.[8,9,19] Similarly, early measures of histology can be misleading. For example, radiation and many alkylating agents kill tumor cells through DNA damage and chromosomal aberrations that become manifest several cell cycles after irradiation. As a result, the histology of a heavily treated tumor hours to days after treatment may look almost normal, even though most of the cells will eventually die and the tumor will regress. Measurements of apoptosis, cell proliferation, or DNA synthesis soon after treatment can likewise provide misleading underestimates of the efficacy of therapy.[8]

A more rigorous assay of the response of tumors to treatment can be obtained using a cell survival assay, in which the tumors are removed after treatment, then minced, and dispersed to form a single cell suspension. The survival (clonogenicity) of the suspended tumor cells is then measured. This can be done by injecting known numbers of cells into new hosts and quantitatively measuring their ability to form tumors in the lungs (after intravenous injection of cells from many solid tumor), in the spleen (after intravenous injection of some leukemias and lymphomas), or in subcutaneous sites (using an endpoint dilution assay).[8,9] For tumor cell lines that grow well in cell culture, the survival of the tumor cells can be assayed by plating the suspended cells at low densities in cell culture and testing individual cells for their ability to grow into macroscopic colonies.[19] The advantage of these techniques is that they directly measure the survival of the tumor cells, a critical metric, and allow the determination of dose–response curves for cell survival after graded treatments. With many tumor systems, the survival determinations are very reproducible and precise and allow accurate comparisons of the effects of different agents and regimens. The major disadvantage of the approach is that suspension of the cells after treatment removes the cells from the natural environment within the tumor, which may alter their response. Moreover, these techniques cannot be used to study protracted or fractionated regimens in which cell death or cell proliferation results in changes in cell number during treatment. The details of the techniques for measuring tumor cell survival and the appropriate use and pitfalls of these techniques have been discussed in several reviews.[8,9]

Tumor growth studies comparing the growth of treated and control tumors have many advantages for use as assays in experimental cancer therapy.[8,9] They are technically simple (albeit labor intensive). They can be used with a wide variety of murine and xenograft systems. Little prior knowledge of the efficacy of the therapeutic agents to be tested is required to design the experiments. Information on toxicity is needed to plan the experiments, because loss of mice from toxicity would preclude analysis of efficacy. Rigorous growth studies require identification of individual tumors, so that the growth of each individual tumor can be monitored before and after treatment. For subcutaneous or intradermal tumors, the three external diameters of the tumor can be measured using vernier calipers and the volume calculated from these measurements. To ensure maximal consistency and objectivity, tumors should always be measured by the same person and that observer should be blinded to the treatment. Tumors should be monitored frequently (one to three times per week, depending on growth rate) and each tumor should be followed until its volume reaches a predetermined final volume that is several times the treatment volume. The most rigorous measure of the differences in tumor growth produced by different treatments is an analysis of the difference in the time needed for tumors to grow from the treatment volume to a slightly larger predetermined assay volume, most commonly four times the treatment volume.[8,20] Animal care committees often allow maximum tumor weights no greater than 10% of the host body weight, and require euthanasia of individual animals sooner if tumor growth or the development of metastases produces signs of injury, pain, or distress; experiments should be planned to meet these requirements. Certain approaches frequently seen in the literature are to be avoided. One is measuring only one or two dimensions of the tumor and estimating the volume from these unnecessarily limited measurements. Another is the growth of control tumors to unacceptably large sizes to produce a dramatic graph. Another is ending the experiment when the control tumors become large, for convenience, to reduce costs, or to remove and weigh tumors to get "final" treated and control tumor weights. (Tumor weights can be calculated readily from tumor volumes if this metric is desired.) Such a protocol results in the loss of potentially valuable data on the regrowth of tumors that responded well to treatment. An experiment that ends with one or more groups of tumors that have not yet regrown, especially if there are groups that are still indistinguishable from one another, is a flawed experiment that has wasted time and money by providing a result that cannot be analyzed rigorously. Rigorous mathematical techniques for the analysis of tumor growth delay data are described in detail in several reviews.[8,9,20]

Tumor control studies test the ability of an experimental treatment to cause complete tumor regression that endures long enough that the tumor is not expected to recur during the lifetime of the host.[8,20] Tumor control studies measure the desired outcome of clinical cancer therapy: tumor cure. Their use is limited by the fact that they can be used to test only highly effective treatments that permanently eradicate the malignancies without producing unacceptable host toxicity and by the very large numbers of mice needed to produce precise dose–response curves for each different regimen tested. The basic approach used in these studies is similar to that outlined for tumor growth studies, except that each tumor that continues growing after treatment is followed only long enough to ensure that it is not controlled, while mice with tumors that regress are monitored for months to watch for recurrence. The tumor control dose (TCD_{50}) is then calculated from the data relating the proportion of tumors controlled to the dose of the treatment agent, using probit or logit techniques.[8,20]

In summary, several different techniques are available for assaying the response of rodent tumors to experimental cancer therapies. The assays are conceptually different: they have different biological bases, use different experimental techniques and designs, require different levels of preknowledge, measure different regions of the dose–effect curve, and are analyzed using different statistical approaches.[10,22] Researchers need to consider carefully the goals of their experiments and the agents to be tested before selecting the assay system to be used in their studies.

HUMAN TUMOR XENOGRAFTS The use of human tumor cells xenografted into immune-deficient mice raises some unique issues. These systems were developed some years ago to test

cytotoxic therapies using human tumor cells in the microenvironments found within solid tumors.[8,9] Human tumor cells lines and human tumor xenografts have become increasingly important in experimental cancer therapy with the increasing development of agents aimed at molecular targets unique to human cells. Such targets include, for example, antibodies against specific human cell surface markers and SiRNA molecules that silence specific human genes. Mouse tumor lines cannot be used to test the efficacy of these agents because they lack the human target. Human tumor xenografts are therefore used to test the effects of these agents. This must be done with great care and with respect for the limitations of these model systems. First, it must be remembered that human tumor cell lines and the xenografts derived from them are established, highly selected, rapidly growing cell lines that no longer recapitulate fully the characteristics of the primary tumors from which they were derived. Furthermore, only the malignant cells of the xenografts are human: the vascular bed, the supportive stroma, and the immune cells (which together comprise about half the tumor mass) are mouse. Moreover, the host is a mouse, and the uptake, distribution, and elimination of the agent therefore reflect that of a human-targeted molecule administered to a murine host that contains only a very small proportion of human cells. In the mouse, the target will be unique to the tumor cells, but this may not be true in a human patient. The targeting of the agent to the tumor cells in a xenograft therefore may be very different from the tumor targeting that will occur in the human patient. Analogously, the toxicity to the mouse, which lacks the target, can be very different from that for human patients, who may well have critical cell populations that exhibit the same or similar targets, and therefore are susceptible to attack by the agent. Xenograft systems therefore cannot be used to assess the toxicity of these agents or to predict the potential ratio of risks and benefits.

CONCLUSIONS

Tumors and normal tissues in inbred mice and rats have long been the major model systems used in experimental cancer therapy. A wide variety of different model systems have been used in these studies. The advantages and the limitations of the different model systems should be considered carefully by researchers as they select models for use in their projects, as they design and perform their experiments, as they analyze their data, and as they translate their studies to regimens designed to improve the diagnosis or treatment of human cancers.

65 Rat Models of Skin Wound Healing

WANDA A. DORSETT-MARTIN AND ANNETTE B. WYSOCKI

ABSTRACT

Rats provide an excellent model for skin wound healing by allowing the standardization of the type, size, shape, and depth of the wound injury, which facilitates comparison of data between studies of healing in all mammalian species. The rat is often selected for skin wound-healing models because of its ready availability, low cost, and small size, which result in a more economical and efficient use of limited laboratory space and housing facilities. Despite species differences, the availability of animals with well-defined health and genetic backgrounds along with a bounty of literature documenting biological responses and parameters for rats allows the rat to serve as a valuable research tool in the search for faster, stronger, and more anatomically correct wound healing with the ultimate goal of exact skin replacement.

Key Words: Rats, Wounds, Skin, Wound healing, Models.

INTRODUCTION

Animal models are commonly used in wound research in an attempt to replicate human wound-healing problems such as burns, dehiscence, ischemia, venous or pressure ulceration, infection, and scarring,[1] or as a way to study the molecular mechanisms of acute wound healing, which could not be determined in human studies. Wound healing is a complex process involving cell and extracellular matrix interactions that can affect various hard and soft tissues and organ systems.[2] The normal mammalian response to cutaneous injury includes inflammation, formation of granulation tissue, epithelialization, and remodeling of new tissue to restore tissue integrity.[3] The use of an *in vivo* model is inevitable in trying to obtain information on the multifactorial nature of the wound-healing process, which may be influenced by externally introduced factors[4] or by the presence of underlying pathology.

Ethics prohibit the use of humans in some wound-healing studies, especially individuals with impaired wound-healing ability who are already at risk for delayed or arrested healing resulting in further harm. One of the advantages of using animal models, such as rats, is that the wound-healing process is accelerated; this makes it possible to study the process in days rather than weeks required for humans.[3,5] Another major advantage to using animal models is the ability to standardize the type, size, shape, and depth of the wound injury, which facilitates comparison of the data between studies. Excisional wounds and analyses of tissues in quantities that could not be obtained from human subjects ensure the continuing use of animals for wound-healing studies.[3]

It is the investigator's responsibility to determine which model will yield data that are clinically relevant to humans and still feasible to use when considering the unique conditions of a specific study.[6] Chronic wounds found in humans are often a combination of impaired circulation, poor nutrition, comorbid conditions, advanced chronological age, restricted physical activity, bacterial colonization, persistent physiological imbalance, or the exposure to radiation and use of chemotherapeutic drugs or prolonged stress. Venostasis ulcers, ischemic ulcers, diabetic ulcers, pressure sores, and genodermatoses (epidermolysis bullosa) are examples of commonly occurring chronic wounds. To maintain scientific reproducibility and cost effectiveness, most researchers must limit investigations to isolated segments of human chronic wound problems with their animal models.[1] Researchers use genetic, surgical, and pharmacological approaches or a combination of approaches in animals to replicate the pathological conditions associated with chronic wounds.[3]

HEALING IN RATS

Rats have been used widely in the study of skin wound healing and the efficacy of different treatment modalities. This particular animal species is often selected for its availability, low cost, and small size. Incisional and excisional models commonly use the rat's dorsum as the wound location and have been implemented in numerous wound-healing studies. Dorsal sites tend to be more effective in keeping the animal from reaching and manipulating the wound. Rats and humans share the following skin characteristics: the presence of an epidermis, basement membrane, hair follicles, and dermis**.** Obviously, there are numerous anatomical and physiological differences between human and rat, some of which are listed in Table 65–1. Among the differences is the fact that rats do not form keloids or hypertrophic scars[2] but people of certain ethnic backgrounds, such as African-Americans and Asians, are predisposed to excessive scarring.[7]

CONTRACTION AND EPITHELIALIZATION Contraction is one of the major features of healing in rat wounds.[3] Contraction is primarily mediated by myofibroblasts, which are characterized by their muscle-like interaction with the extracellular matrix, especially collagen. Rats are loose-skinned animals because of their skin's elasticity or redundancy and its lack of a strong adherence to the underlying structures.[1,3,5] The skin of loose-skinned

Table 65–1
Comparison of skin traits

Trait	*Human*	*Rat*
Skin adherence	Tight	Loose
Panniculus carnosus	None	Present
Hair growth	Mosaic	Patches
Apocrine glands	Present	None
Eccrine glands	Present	None
Vitamin C source	Exogenous	Endogenous
Keloid/hypertrophic scar	Possible	No

rats can slide and retract over the subcutaneous fascia at the time of incision to initially produce a large gap.[1] Consequently, wound contraction, which is usually more rapid than epithelialization since new tissue is not created, causes a decrease in the overall healing time of rat wounds.[3] The tight skin found in humans makes comparison with loose-skinned animal models difficult.[1,3] Contraction can be measured by noninvasive, morphometric techniques such as video images with computer programs or by simply tracing the wound every other day. Contraction can be represented as a percent change in the wound surface area compared to the original wound's size.[3] If contraction is not desirable, the wound can be splinted by physical barriers such as retaining rings, biopolymer plugs, or other mechanical means.[1]

Epithelialization is the primary response in burns, abrasions, and partial thickness wounds when only the epithelium and superficial dermis are missing.[3] Epithelial cells move quickly out from the hair follicles and sweat glands left in the remaining dermis as well as from the leading wound edges.[3] In full-thickness open wounds, epithelialization comes only from the wound edge and occurs at the rate of 1–2 mm/day.[3] In a normal surgical incision with edge-to-edge approximation, the epithelialization process occurs in 24–48 h.[3]

PANNICULUS CARNOSUS Rats possess a subcutaneous panniculus carnosus muscle that contributes to skin healing by both contraction and collagen formation.[4] Leaving the panniculus carnosus with its rich vascular supply intact provides an anatomically constant wound bed. Thus, if the panniculus carnosus is left intact, wound healing will be facilitated.

HAIR CYCLE The hair of the rat goes through a cyclic pattern in which anagen is the active growth phase; hair follicles start to shut down during catagen, and in telogen, the resting stage, the hair may or may not fall out. All hair follicles do not proceed through the same cycle at the same time. Rats typically have an active growth phase that passes like a wave from ventral to dorsal and from rostral to caudal.[8] Rat skin thickness is affected during this hair growth cycle so that skin during the anagen phase is markedly thicker, in mice 1.5–2 μm thicker, and more vascular than areas with resting, telogen-phase skin.[9,10] Littermates can exhibit differences in skin thickness. Contraction is decreased in anagen compared to telogen skin. In contrast, humans have a mosaic pattern of hair cyclic activity, thus ensuring a more uniform skin thickness relative to body location.

Partial thickness wounds made with devices such as a dermatome may have inherent problems for the study if performed in haired animals such as the commonly used Sprague–Dawley and Wistar strains of rats. The high density of hair in the rodent model causes an exaggeration in the rate of reepithelialization.[1] Consideration of the advantages and disadvantages of the use of depilatory agents and/or shaving in haired rats needs to be made on each study.

VITAMIN C Another potential consideration in using rats to recapitulate human skin wound healing is that unlike humans, rats are not subject to scurvy and therefore do not require diets with added vitamin C. Rats possess the enzyme L-gluconolactone that converts L-gluconogammalactone to vitamin C. Primates and guinea pigs need vitamin C supplementation for collagen synthesis.

STRAIN AND SEX PREFERENCES Rats fall into two basic groups: either inbred or outbred. Inbred strains are developed through at least 20 generations of brother–sister matings.[11] Sharp and Regina describe outbred rats as those with less than 1% inbreeding per generation and maintenance in a closed colony for at least four generations.[11] Of the two most commonly used outbred stocks, the Sprague–Dawley is generally larger than the Wistar, but both are considered docile and serve well as general purpose models.[12–14] The Fisher rats are smaller than the Sprague–Dawley and the Wistar rats.[13] The Fisher and Norway rats are identified as inbred strains and the Fisher rats are also described as being a general purpose model, whereas the Norway rats are listed as appropriate for studies such as aging and kidney research.[12]

Nude rats, which are athymic, have been used in immunology-based research.[12,15] Lewis rats, an inbred strain, have been used for transplantation studies, endocrinology, multiple sclerosis, and experimentally induced autoimmune diseases.[12,13] The inbred strain ACI, a cross between the August and Copenhagen–Irish strains, has been used in research dealing with congenital genitourinary anomalies and prostatic adenocarcinomas.[13] A rationale for the selections of strains or sexes of rats is usually not included in journal articles. Currently, there is scant literature indicating the superiority of one strain over another for wound-healing studies. When determining wound contraction coefficients, Cross *et al.* found that Hooded Lister rats were more docile as compared to Sprague–Dawley rats, allowing multiple precise wound area measurements to be made daily.[5] The ability to trace wound areas with great accuracy is crucial to mathematical analysis. Personal preferences, convenience, past experiences, and expense may weigh heavily in the choices. In general, preference for the models is more likely a result of long-term experience, known breeding characteristics, cost, genetic stability, and ready accessibility.[16]

Sharp and LaRegina warn that different stocks and strains of rats have shown variability in biological parameters such as clinical chemistry, hematology, and anesthesia response, so they advise investigators not to change rat strains or their rat suppliers for the duration of the study.[11] Such variability could potentially skew data from wound-healing research. One of the reasons to produce the various strains of rats is to have diverse animal populations within the species so that they do not have the exact same behavioral characteristics and physiological parameters. Since cost-conscious reasoning usually plays a role in animal selection, it is important to note that in general, male rats consistently cost less than females of the same size.[12] A point to consider in selecting the sex of study animals would be the possible hormonal influence on wound healing, because it has been reported that estrogen deficiency is associated with impaired cutaneous wound healing.[17,18] Also, as reported by Cross *et al.*, the thinner skin found in female rats allows a faster rate of wound healing with a higher wound contraction rate, while the wounds of male rats have a greater tendency to heal by epithelialization,[5] although the

effects of the hair growth cycle in this study were not addressed. Since the National Institutes of Health and the Food and Drug Administration now require the use of females in human clinical studies, it is predicted that the inclusion of female animals in studies will increase over time.

NUDE RATS Nude rats have no functioning thymus and since T-lymphocytes mature in the thymus, their rudimentary thymus renders these animals immunodeficient.[15] Immune function from killer and natural killer cells that do not depend on the thymus appears to be normal.[19] Nude rats grow at only 60–80% of the rate of normal rats.[20] Hair-deficient rats include strains such as Charles River hairless, Rowett nude, and New Zealand nude.

DIABETES Diabetes mellitus is one of the most common causes of impaired wound healing in humans.[1] Diabetic models of wound healing are either chemically induced or a result of genetics.[3] Streptozotocin sulfate at 55 mg/kg intramuscularly can be used to induce diabetes mellitus in rats.[1] Wound-healing parameters of diabetic rats include defects in biomechanical strength of incisional wounds, closure of excisional wounds, formation of granulation tissue in porous implants, and angiogenesis.[1]

Zucker rats have been developed with a diabetic phenotype. Genetically diabetic rats often have obesity levels to the point that excisional wound closure is impeded not only by physiological dysfunctions but also by excess fat, preventing skin contraction.[1] Like humans, diabetic animals show a greater tendency toward wound infection.[21] The reduced wound-healing capacity in diabetics is most likely associated with diabetic neuropathy and ischemia.[22]

KNOCKOUTS/STEROID USE AND GENETICALLY IMMUNODEFICIENT ANIMALS Glucocorticoids have an antiinflammatory activity leading to thinning of the skin and reduced healing capacity.[1] Steroids reduce the capacity of monocytes to differentiate into growth factor-expressing macrophages and then reduce the capacity of fibroblasts to synthesize collagen.[1] Steroids have been used to lengthen the normally rapid healing times seen with rats in order to study the effects of various wound-healing agents.[3] Dostal and Gamelli have reported that hydrocortisone and dexamethasone reduce wound strength.[23]

Antiproliferative agents such as doxorubicin (Adriamycin) cause immune compromise by disrupting the production of immune cells and can impair wound healing.[1] Extravasation of Adriamycin can cause severe ulceration, and the drug produces side effects such as weight loss, anemia, and cardiotoxicity that can affect the interpretation of wound-healing studies.[3,24,25] Experimental depletion of specific elements of the repair system such as antimacrophage or platelet-derived growth factor-neutralizing antibodies could provide impaired models of wound healing.[1]

The rat genome project will make it possible to create additional knockin/knockout models for wound-healing studies. Previously, most of these studies were conducted in mice. Completion of the rat genome project in 2004 with the sequencing for the Brown Norway (BN) rat led by the Bayer College of Medicine should open new areas of study for rat wound-healing research and permit analysis of genotype to ensure consistent results.

WOUND MODELS AND METHODS

Reviews[1–4] of various animal wound-healing models describe chronic wound models, ischemic conditions, and acute surgical wounds that can be categorized as incisional models and/or excisional models. Additional models include (1) dead space, (2) wound chambers, (3) burns, and/or (4) impaired. To date, most experts agree that there are no chronic wound models comparable to the chronic, nonhealing wounds found in humans.[4] Many purported chronic models are actually ischemic models and are not sufficient models for venous wounds.

INCISIONAL MODELS Incisional models can be used to investigate the wound-healing process and the influence of different systemic and local products along with various dressings, sutures, and wound-therapy protocols.[4] Incisional wounds can be analyzed for wound-breaking strength, histology, immunohistology, collagen and protein content, and *in situ* hybridization.[3] When the incisional edges are reapproximated and sutured or stapled, healing will occur primarily by reepithelialization (primary initiation healing) within 1–2 days with minimal contraction.[3]

Scalpels and scissors are the most common surgical instruments used to create a full-thickness linear wound that can be sutured closed. This is one of the most frequently used models in wound-healing research.[2] A sharp blade cutting the skin causes a rapid disruption of tissue integrity with minimal collateral damage.[1] Immediately upon incision, there is extravasation of plasma and blood cells into the new space, and dependent on the extent and timing of hemostasis, the formation of a fibrin clot that will act as a bridge between the margins of injury[1] and prime the wound for healing as soon as the wound is made.

Electrocautery or Bovie knives, while commonly used in the operating room, are not commonly reported in animal skin wound-healing studies. Incisions with laser and electrocautery may produce some collateral thermal damage but less hemorrhage than just straight edge blades.[1] The pulsed CO_2 laser may also be used as a burning device with, depending on energy input, substantial collateral damage, but computer-assisted beam control allows the creation of precise size areas of damage.[1] A newer generation of cold lasers has largely eliminated the thermal damage seen with the older class of lasers.

After performing an incision, porous materials such as the Hunt-Schilling chamber, polyvinyl alcohol, viscose sponges, and polytetrafluoroethylene are used to create a subcutaneous pocket.[3] Granulation tissue and wound fluid can be examined by implanting a chamber or sponge in a subcutaneous pocket.[4] Implant materials are chosen to be relatively inert so there is minimal inflammatory response, and biochemical assessments can be made with most implants because of the well-defined volume enclosed.[1] At early time points (3–5 days) the interstitial fluid that accumulates within the implant can be aspirated and analyzed for metabolites, cytokines, growth factors, and nonadherent cells.[1] The cavity created for an implant can be used as a reservoir for injectable or implantable material such as growth stimulants, chemoattractants, or antibodies.[1] Limitations of implants include the interference of the implant with normal scar maturation and the possibility of eventual foreign body immune responses.[1] Even polyvinyl alcohol sponges induce a giant cell reaction and lead to ectopic calcification; therefore wound data are collected for only the first 3–4 weeks with most implant models.[1]

The polyvinyl alcohol sponge was probably one of the first devices used in healing studies.[2] These sponges elicit a pronounced foreign tissue reaction with rapid infiltration of the sponge by connective tissue deposited at the wound site.[2] Connective tissue formation can be isolated from epithelialization and contraction by the use of porous subcutaneous implants.[1] These implants create an artificial tissue space into which plasma infuses, which leads to the formation of a fibrin clot and the

subsequent formation of granulation tissue.[1] The polyvinyl alcohol sponge model can be used to study granulation tissue by histological and biochemical analysis.[4] Further maturation into scar tissue may occur and the implant may become surrounded by a connective tissue capsule made of several layers of collagenous fascia.[1]

Like wound chambers, polytetrafluoroethylene tubing, which is porous and allows the diffusion of gas and fluids through the device, is most often inserted in the dorsal region of an anesthetized animal.[4] These tube models are used to study the amount of collagen deposited expressed as hydroxyproline and total protein or DNA deposited per length unit of the tube.[4] Uptake of radioactively labeled thymidine can be used to determine the number of replicating cells in the tubes.[4]

In 1976 Viljanto described a combination tube/sponge device that is placed as a drain; the wound fluid can then be analyzed in the early inflammatory phase of wound healing.[4,26] The material trapped in the sponges has been studied by histology, enzyme histochemistry, biochemistry, and cytology at the light and electron microscope level.[27]

The wire mesh Hunt-Schilling chamber is placed subcutaneously and rapidly fills with wound fluid; later, as healing proceeds, it is filled with connective tissue.[2,4,28,29] Fluids, cells, and connective tissue can be collected for histological, histochemical, and biochemical analysis and the presence of various substances can be followed over time in a single wound, providing data regarding differences found over time in the wound.[2,4] In some cases, samples can be acquired for several months.[29] Equally important, the effects of different agents can be studied upon their placement in the chamber.[2]

EXCISIONAL MODELS In excisional wound models, the effect of different types of dressings, dermal substitutes, and topical agents can be investigated with the outcome measurements being an evaluation of wound size by measuring changes in area and time to complete healing and by examining the histology of the wound tissue.[4] Early healing can be documented histologically through serial/sequential biopsies and later scarring, and any deformation of the surrounding area can be observed.[4] The excision site not only provides a wound for study but also provides a sample of tissue for the analysis or quantification of substances such as collagen, RNA, DNA, glycosaminoglycans, inflammatory cells, growth factors, and other biochemical mediators involved in the healing process.[1,2] Excisional wounds can be covered with occlusive dressings, which can allow wound fluids to be collected for analysis or to assess the status of various soluble factors in the wound environment such as proteinases and cytokines.[1,30]

Excisional wounds may be enclosed with occlusive materials to permit collection of wound fluids or to concentrate topical treatments.[1] Saline-filled external vinyl chambers, "Eriksson chambers," can also be employed and are placed over the wound, maintaining a sealed wet environment to study healing in both partial and full thickness wounds.[31,32]

The split thickness injury involves the use of a sharp blade, usually a dermatome, which cuts parallel to the skin surface at a depth that includes the epidermis and upper dermis.[1,3] A substantial amount of dermis, mostly the reticular or deep dermis, remains as well as the base of most epidermal appendages. Epithelialization will occur both from the margins and the epidermal appendages.[1,3] Many animals are unsuitable for this because of the extremely high hair density, which greatly exaggerates the rate of reepithelialization; therefore hairless strains provide an advantage when using a split thickness model.[1] There is no or minimal wound contraction with partial thickness excisional wounds and the surface area can be calculated exactly.[4] Evaluation of healing is made either by separating the healing epidermis from the dermis with chaotropic or enzymatic digestion, in which case planimetric methods are conducted, or serial sections are made for histomorphometric analysis.[1] The split thickness model is useful for testing many agents and devices that promote reepithelialization, including wound dressings, topical agents, and growth factors.[1,3,4] Extravasation of lymph and blood occurs when using split thickness models, and an eschar made of the fibrin clot and expended granulocytes will form over the wound.[1] Desiccation can also be used to impair wound healing; therefore, conversely, a semiocclusive dressing or other moisture-retaining or -promoting products could be used to cover the area and promote healing.[1]

Full thickness wounds can be created by removing the skin with scissors, scalpel, biopsy punches, or a dermatome using several passes.[1,33] In full thickness models, both the epidermis and dermis are removed to the fascial planes or the subcutaneous fat. In loose-skinned animals such as the rat, the panniculus carnosus, which is firmly adherent to the base of the dermis, may or may not be removed. Healing occurs from the margins and the base of the wound by the formation of a fibrin clot that is invaded by granulation tissue and by the migration of an epidermal tongue along the interface between the granulation tissue and the clot.[1,3] Bleeding and fluid loss are more extensive in this model compared with split thickness models.[1] There is also a greater susceptibility to infection. The open defect will heal by a combination of contraction, reepithelialization, and dermal reconstitution.[4] With a full thickness model there is involvement of all the dermal components; thus, epithelialization occurs only from the wound margins. Full thickness wounds allow/permit analysis of biochemical components, histology, and cell populations found in the wound.[1] Healing rates can be monitored by measuring the filling of the space with granulation tissue, extent of reepithelialization, histological organization of connective tissue, angiogenesis, and biological content of collagen or proteoglycans.[1] Contraction, dermal reconstitution, inflammation, chemotaxis, and aesthetic and functional outcome can also be evaluated in this type of model.[4]

Sequential epidermal layers can be removed using adhesive tape applied repeatedly. This removes the stratum corneum and stratum granulosum layers to expose the basal keratinocyte skin layer.[1] If the basement membrane is left intact, this type of injury will activate the processes of epidermal repair.[1] Tape stripping is less damaging to the epidermis than the use of blister models [4] in which the basement membrane can be damaged. Abrasions of various depths have also been produced with the use a mechanically driven emery wheel. Blistering involves the rupture of the epithelial basement membrane zone, forcing detachment of the epidermis from the underlying dermis.[1] Blister models can be used for the evaluation of epidermal regeneration and the influence of different treatment options.[4] The epidermal structures will lose their nutrient supply and become necrotic unless quickly placed back in contact with the basement membrane zone.[1] If separation persists, the epidermal healing must come from the margins not from beneath.[1] Suction devices, chemical (ammonium hydroxide) or biological vesicants, heat, or a combination of suction and heat may be used to raise blisters.[1] Healing of

suction blister wounds is made by reepithelialization alone.[4] Blister models can be used to study absorption of drugs,[34] dressing products, topical agents, and transepidermal water loss to study the effectiveness of the epidermis as a barrier.[35]

Partial and full thickness burns can be made by applying a heated metal object or by scalding the skin.[3] Burns have been produced by methods such as hot water (75–99ºC), hot metal plates (250ºC), steam, hot oil, gas torches, radiant energy, and ignited alcohol gauze.[36,37] Since burn injuries have a progressive course for up to 2 days after the inciting cause,[38,39] model standardization and consistent timing are important in reproducing burns.[3] Post-burning ice baths can also be used to control the extent of injury, but all wound depths should be determined by histology.[3]

Thermal burns create an extensive zone of necrosis that includes denatured or charred connective tissue.[1] Out of the destroyed zone there is a zone of coagulation necrosis in which denatured plasma and cellular proteins cause obstruction of blood vessels and lymphatics, which in turn prevent nutrient flow to the involved tissue.[1] General anesthesia and postoperative care including analgesics and antibiotics should be utilized with burn models.[1]

Walker and Mason, of the U.S. Army surgical Research Unit, use a scald burn produced on anesthetized rats held in a protective template that limits the area exposed to burning and the thickness of the burn is limited by timing the exposure to the water.[40] Hot water (95–100ºC) or ethanol bath partial immersions can produce extensive third-degree burns without charring, but as Davidson warns, this produces a much greater physiological stress than groups of small lesions.[1]

Thermal burns can be induced on shaved skin by placing a heated conductive object such as a brass rod of uniform size heated in either a water or oil bath. The degree of tissue damage is consistent and controlled by a combination of weight, time, and temperature with the extent of damage confirmed through histological sections.[1]

The transient freezing of tissue causes the formation of internal ice crystals that rupture the cell membrane resulting in local necrosis without extensive protein denaturation or coagulation necrosis.[1] The mass of the cooled metal object and the length of exposure will determine the depth of the injury, which can be determined by histology.[1]

A number of caustic agents, especially alkalis, can produce skin lesions.[1] Dermonecrotic wounds have been made by agents such as Adriamycin and the venom of the Brown recluse (*Loxosceles*) spider.[1] Brown recluse spider venom contains sphingomyelinase, with the lesion showing hemorrhage and gradual development into a ulcer, which can be used to develop treatments to control excess activity of serine proteinases released by neutrophils.[1]

Raised flaps with compromised circulation will show necrosis and impaired healing.[1] If flaps are allowed to reattach to the dermal base, revascularization can occur.[1] To prevent reattachment, the strip of tissue can be sutured or clipped to form a tube flap that will have a perfusion gradient from each end toward the center.[1] Wounds produced along the length of the pedicle will have graded healing patterns depending on circulation proximity, which can be determined with transcutaneous pO_2 measurements or laser Doppler.[1]

Ischemia is perhaps the most significant factor contributing to the chronicity of wounds associated with diabetes, some types of peripheral vascular disease, and pressure sores.[3] Quirinia and Viidik have developed an ischemic incisional model on the dorsum of the rat in which a bipedicled H-shaped flap is created so that the cross bar of the H is the test wound.[41] The cross bar of tissue is made ischemic (up to 93% at 1 day after wounding) by transecting the branches of the central vein, which serve as the primary drainage for the arterial supply of the rat's back.[3,41] Pressure applications can prove difficult to standardize and maintain to study decubitus.[1] Peirce *et al.* report on the use of magnets and implanted steel plates to pinch the skin and cause pressure ulcer formation.[42]

Flow models with skin windows have been developed to provide direct microscopic observation of blood flow for the entire thickness of skin. A hamster model with a chronic implantation dorsal skin flap window chamber has been used to observe and quantify alterations in the cutaneous vasomotion function caused by scald burns.[43] This flow model could also be used with rats.

FACTORS THAT MAY AFFECT RESULTS

Chronic wounds commonly involve the skin, but can be very diverse in etiology and therapy. The chronic wound, though common in the human population, is not common in laboratory rats, and no model has proved to be entirely satisfactory.[1,4] Wound healing can be altered by any factor that affects the whole animal such as stress, nutrition, minor illnesses, age, weight, infection, inflammation, bleeding, necrosis, genetics, noise, environmental factors, radiation exposure, pharmacological agents, and the presence of foreign bodies.[3]

Kennedy and Cliff stated that in their studies of wound contraction, the sex of the animal, the time of day of wounding, and the size and shape of the wounds had no influence on the wound contraction curves expressed as percent of original area against time.[44]

The wound(s) can be made anywhere on the body surface, but in most cases researchers usually choose the dorsum of the animal.[4] Auberach and Auerbach reported regional differences found in the growth of normal and neoplastic cells in mice, and they reported concerns of other scientists over the need for consistency in the application of experimental procedures to cancer research.[45] Kullander and Olsson showed the tensile strength of dorsal incisional wounds of rats diminished the more caudally they were placed.[14] Kullander and Olsson suggested that when studying wound healing, it is important to compare cutaneous wounds made in exactly corresponding positions.[14] They speculated that the differences in the vascularity of different skin regions may be the reason for the differences found in tensile strength.[14]

Since an important variable in governing the rate of wound contraction is how tightly the skin is adherent to the underlying tissue, wound location is very significant. Medical personnel and their patients alike have been frustrated in their attempts to heal chronic wounds such as venous and diabetic ulcers of the lower legs and feet. In these cases, contraction is thought to make up approximately a 30% or less contribution to wound healing.[3] To ensure the accuracy of results, a standardized position for measuring the wounds must be maintained for all the animals when using "loose-skinned" species such as rats.[5]

The shape of the wound depends on the purpose of the study.[4] Size is a key consideration in the study of wounds.[5,46] Within experimental studies, no matter what the original intended shape,

the resulting size and shape are influenced by the remaining skin's elastic forces with a pull along the tension lines of the particular area.[46] Montandon *et al.*[46] suggest that the decreased contraction observed in round ulcers is often a secondary phenomenon due to the lack of extensibility or to the adherence to the surrounding skin. For the study of wound healing, they recommend the use of square wounds no less than 4 cm^2 to allow the study of the effects of contraction as well as epithelialization on closure. On the other hand, Cross *et al.* explained that the metabolic and physical stress of a large wound relative to total body surface area will independently influence the results of the wound-healing research.[5] In an effort to minimize stress, Cross *et al.* chose to use a 15×15-mm wound on 200–350 g adult female Hooded Lister rats rather than 20×20 mm in size.[5] Limiting the size of wounds to avoid stress also suggests that stress could be caused by too many wounds on one animal.

Single caging is recommended once wounds are created. Animal interference in wound healing, especially by cage mates, has to be weighed against space and cost limitations.

Traditional rodent litter type bedding may become imbedded in the wound and may incite infection or a foreign body reaction. Nontraditional bedding that is softer and does not form a foreign body in the wound is recommended in light of added handling/care time, increased bedding costs, and possible increased disposal costs.

Food and water placement should be checked to ensure they are readily accessible to wounded animals that may have wound- or pain-limiting mobility. For example, rats may not wish to retrieve food from the top portions of cages if they have abdominal wounds and water conveyance tubing may have to be lowered to ease accessibility.

The nutritional status of animals that have impaired mobility or are dealing with pain should be monitored. Lack of adequate nutritional status could have detrimental effects on healing.

Wound pain, rough handling, noise levels, altered light and dark cycles, and other environmental stimuli may all influence the animal's overall state of being, which may lead to physiological changes that could effect the ability of the animals to heal. Many early studies on the effects of stress on the body were performed by Hans Selye and remain valid. Cross *et al.* used the frequent measuring of the rats' body weights as an indicator of stress in their studies.[5]

Radiation can be used to reduce local or systemic propagation of cell populations critical to tissue repair.[1,3] Localized radiation will show the importance of local cell proliferation from recruitment of peripheral**,** circulating populations.[1] Total body radiation can affect marrow precursors that are necessary for wound repair.[1,3] In conjunction with local therapy, local versus systemic effects of a wound treatment can be determined.[1] High-energy irradiation limited to skin cells can impair surface healing for up to 3 weeks without loss of monocytes or other hematopoietic cells.[3] Knowledge of the effects of radiation on wound healing is necessary in the use of cancer treatment radiotherapy.[3]

Most infected wounds will fail to heal if contamination is greater than 10^5 organisms per gram of tissue,[47] with the exception of β-hemolytic streptococcus in humans. The presence of infection can cause impairment due to a combination of the exaggeration and exhaustion of host defenses along with the damage caused by bacterial proteases and endotoxins.[1] Bacterial counts should ideally be confirmed by biopsy.[1] However, rats have good host immune systems and are not infection prone unless bacteria are purposefully introduced.

Rat ages and body weights can be correlated,[12] and aging has been reported to result in prolonged or poor wound healing.[5,48,49] The age and/or weight of the animal may present an additional variable in the wound-healing analysis and details about these animal characteristics should be reported.

The Harlan Laboratory Animal Company reports that weights of 200–224 g correspond to male Sprague–Dawley rats that are 49–52 days old.[12] Rats that are 3–6 months old would be comparable to young humans.[3] Mogford and Mustoe state that it is generally accepted that the elderly have less capacity to deal with environmental stress and are more apt to suffer from comorbidities, especially those that cause a decrease in skin blood flow.[3] Sensory nerve function declines during the aging process, and this is associated with decreased neurogenic inflammation and poor wound healing.[49] Experts question whether accurate comparisons can be made regarding wound healing between young rats and humans who are not all young, vigorous healers, especially in chronic wound cases that are more apt to be found among the geriatric populations.[1] Age-related healing impairment is seen in the rat between juvenile and adult animals (8 versus 16 weeks in Sprague–Dawley rats) where there is a marked decline in the rate of wound healing.[1] Age-related differences in wound healing are evident in studies using rats as well as other animal models, yet many continue to use young rapidly growing animals to study problems of impaired healing in which the overall robust nature of a young animal's healing can prove difficult to manipulate.[1]

Injectable anesthetics commonly used in the rat include sodium pentobarbital or mixtures of ketamine and xylazine. Common inhalation agents often used are ether, halothane, and isoflurane. Combinations of injectable and inhalation agents have been employed in research with rat models. Whether the use of various anesthetic agents plays a role in the rate of wound healing in regards to comparability has been questioned. Li *et al.*[50] reported that anesthetics such as ether and ketamine may influence the action of laser light treatment on wound healing. In choosing anesthetic agents, the cost, the availability, and the investigator's familiarity with the drugs must be considered. Personnel and the institution must be compliant with governmental narcotics regulations. This usually requires additional documentation and added security measures. Achieving a consistent anatomical position for measuring wounds may require the use of anesthesia, but it must be remembered that repeated exposures to anesthesia may be harmful and could potentially cause wound damage during some methods of anesthesia induction.[5] The influence of various analgesics on wound healing adds another variable in analyzing animal-derived data for relevance to humans.

OUTCOME MEASURES

Wound-healing models have been employed to determine the effectiveness of dressings, systemic and topical pharmacological agents, skin equivalents, sutures, and both viral and stem cell therapies. Investigators have used a combination of macroscopic and histological observations, biochemical and biomechanical measurements, and measurements of wound-healing markers, often in combination with analyses of cellular and immunological responses, to evaluate the progress of wound repair.[4,5] For example, histological assessments such as the progression of new epithelium, inflammation, and vascular response, thickness of the skin

layers, and the formation of collagen in the wound defect are often made. Histology is used for quantitating angiogenesis.[4] Staining for nonspecific esterase activity will detect the presence of macrophages.[2] Alcian blue can be used to detect proteoglycans and Masson's trichrome will show collagen.[2] Antibodies with fluorescent tags can be used to identify specific types of collagen and growth factors.[2]

Various testing methods have been used to determine the success or failure of treatment modalities. The purpose of wound healing is to restore tissue continuity and resistance to externally applied forces.[51] In animal models, the progress of this process can be assessed by measuring the development of the mechanical strength of the wound.[51] In the majority of the studies reviewed, evaluation of the skin models was accomplished by testing both the tensile and breaking strength of the wounded area with a tensiometer. Granulation tissue, especially collagen, is the main constituent for the development of biomechanical strength of the wound.[4] The breaking strength of the closed linear wound is the force required to dissociate the healing tissue and the tensile strength is the breaking strength per unit thickness of tissue.[2] Tensile strength studies must be considered in terms of the timing of collagen deposition.[2] The incisional wound model lends itself to the evaluation of the development of breaking strength, either physiologically or when influenced by local or systemic agents.

Areas of contraction and reepithelialization were documented with tracings and area grid techniques, usually in conjunction with computer analysis.[5] Electron microscopy, dye testing of vasculature patency, immunohistochemical testings, and genetic level investigation are a few examples of the other types of testing employed to evaluate outcomes. Varying methods used in reporting results only add to the difficulties encountered in the attempt to make direct comparisons between studies[5]; testing conditions, seasonal skin variations, and wounding technique varied so widely that comparisons may not be scientifically justifiable. A separate study would have to be initiated to concentrate on the wound-healing abilities of separate strains of rats while maintaining as little variation as possible in the size and the age of the animal, the sex used, environmental conditions, animal handling, wounding technique, and all parameters used for healing analysis.

CONCLUSIONS

Characteristics such as a short gestation, short life span, docile behavior, and ready availability of animals with well-defined health and genetic backgrounds are critical in the decision to use the rat as the choice of a research animal.[13]

Developing an animal model that has all the complexity of human chronic wounds may be an unattainable goal, since nonhealing and delayed healing wounds in humans are often the result of combinations of impaired circulation, inadequate nutrition, age, limited physical activity, and/or chronic physiological imbalance.[1] Animal models cannot replace the ultimate verification of actions in human wounds due to the differences in tissue architecture and immune response.[1] Models need to be developed that demonstrate and validate these impairments to be sure they are comparable. This would permit a higher level of confidence in animal data. Results of wound contraction coefficients show that choices of strain, sexes, and ages of rats are variables that somehow must be standardized in the search for reproducibility.[5] The need for consistency is of great importance in the study of wound healing to increase the ability to compare studies and further the knowledge base.

Human clinical trials have been disappointing in comparison to the promising results seen with growth factor therapies in animal studies; thus there is a great deal of concern regarding the ability to transfer animal research data to the human clinical situation.[52] In attempting to explain impaired wound healing, most investigators try to divide the problem into components that can be shown to be reproducible while keeping costs to an acceptable level.[1] Having a model that is merely reproducible is not enough to investigate modifications to the wound-healing process.[5] The model must also have the capacity to allow the detection of the effects of potential treatments or procedures.[5] Thus, it cannot be overemphasized that models with standardization of techniques and reproducibility need to be explored so that results from different treatment modalities can be compared in a scientific manner. Accurate comparisons between studies regarding the ultimate efficacy of treatments would add to the knowledge base of wound healing. The desire to compare studies for the advancement of wound-healing knowledge is being hampered by the differences found between the studies. Standardization in reporting, as suggested in Table 65–2, could facilitate comparisons and may initiate additional research that favors the inevitable comparisons between the studies.[16] This increased knowledge base would be vital in transferring animal-derived data to human clinical situations.

66 Animal Models of Prostate Cancer

ADEBUSOLA A. ALAGBALA AND BARBARA A. FOSTER

ABSTRACT

Prostate cancer is one of the most prevalent cancers in the United States. The current standard treatments for early stage confined disease include surgery and radiation therapy. However, advanced diseases or tumors that relapse are treated with hormone deprivation therapy. Unfortunately, most men relapse with advanced metastatic and aggressive hormone refractory disease for which there is no cure. Although prostate-specific antigen (PSA) screening and digital rectal examinations have improved detection of early stage disease, prognosis for advanced metastatic disease is still poor. Therefore, there is a need to understand the biology and genetics of the normal prostate gland and the molecular and biochemical pathways that are deregulated in prostate malignancy. Animal models of prostate cancer have been developed to delineate the key factors that contribute to the initiation, progression, and metastasis of prostate cancer. Such models are also used for preclinical screening of therapeutic regimens for the prevention and treatment of prostate cancer. Animal models of prostate cancer such as rat, canine and mouse models will be discussed. Emphasis will be placed on autochthonous genetically engineered mouse (GEM) models of prostate cancer.

Key Words: Prostate cancer, Genetically engineered mouse models, Rodent models, SV40 T antigens, Prostate gland, Canine models, Human prostate cancer xenograft models, Transgenic mice, Bigenic mice.

INTRODUCTION

Prostate cancer is one of the leading causes of cancer and cancer-related mortality in the United States.[1] It is estimated that one in six men will develop prostate cancer in their lifetime.[2] Age is one of the major risk factors for prostate cancer as most men diagnosed with prostate adenocarcinoma are over 65 years old.[3] Other risk factors for prostate cancer include race[3] and a positive family history of prostate cancer.[4,5] Early stage organ-confined prostate cancer is clinically manageable by surgery or radiation therapy. Advanced metastatic diseases or tumors that relapse are treated with hormonal therapies. However, most men progress with advanced hormone refractory prostate cancer for which there is currently no cure. The high incidence and mortality associated with prostate cancer in the United States have driven interest in the development of appropriate animal models to study the biological and genetic basis of prostate cancer progression. Such models are also useful for evaluating therapeutic interventions such as chemotherapy, immunotherapy, gene therapy, and chemoprevention.[6] Human prostate cancer is a latent, multistep process that preferentially metastasizes to the bone. It is also a heterogeneous disease as indicated by variabilities in genetics, oncogenic signaling, and tumor grade.[6] Spontaneous prostate cancer is relatively uncommon in nonhuman species with the few exceptions being some strains of rats[6,7] and dogs.[8–10] These factors create challenging obstacles in attempts to study human prostate cancer in animals. Animal models that recapitulate the key features of prostate cancer initiation, progression, and metastasis are critical for studies designed to understand prostate tumorigenesis and to screen preventive and chemotherapeutic interventions. Several animal models of prostate cancer have emerged including human prostate cancer xenograft models that are implanted in mice, canine models, and rodent models. These animal models are valuable tools for delineating the mechanisms of prostate cancer initiation, progression, and metastasis.

THE PROSTATE GLAND: DEVELOPMENT, MORPHOGENESIS, AND ANATOMY

The embryonic development of the prostate gland originates from epithelial prostatic buds that arise from the urogenital sinus (UGS) in the endoderm. Prostatic buds appear during gestation at 10 weeks in humans and 17.5 days in mice. In rodents, these buds undergo androgen-dependent growth and ductal branching into the surrounding mesenchyme in the early weeks of postnatal development.[11] In contrast, ductal growth and morphogenesis in the human prostate occur prenatally and during puberty when androgen levels are higher. The development and growth of the prostate gland are dependent on androgens and the function of the androgen receptor. Surgical or chemical castration with antiandrogens or estrogen inhibits the development and growth of the prostate.[12–15]

The prostate is a secretory male accessory sex gland that surrounds the urethra and is situated beneath the urinary bladder.[15] Prostatic ducts secrete several components of semen including proteins, fructose, and zinc ions that are released into the urethra during ejaculation. The benign and pathological conditions that are associated with the prostate have generated interest in the study of its development, biology, functions, and malignancy. Interestingly, while prostate cancer occurs frequently, tumor incidence in other male accessory organs such as the seminal vesicles and bulbourethral glands are negligible or nonexistent in men.[16]

This chapter will discuss genetically engineered mouse (GEM) models mainly because of their widespread utility and the innovative research in the area. However, other animal models of prostate cancer including canine, rat, and human prostate cancer xenograft models will be briefly discussed.

PROSTATE CANCER MODELS

HUMAN PROSTATE CANCER XENOGRAFT MODELS Human prostate cancer xenograft models are generated by grafting prostate tissue samples into immunodeficient host mice. The PC-82 model was the first prostate cancer xenograft model that was successfully established by subcutaneous heterotransplantation of tissue samples in athymic nude BALB/c mice.[17] Other xenograft models were developed including androgen-dependent PC-295 and PC-310 models and hormone refractory PC-133, PC-135, PC-324, and PC-339 xenograft models.[18,19]

More details on the prostate cancer xenograft models that are available, well-characterized, and widely utilized are reviewed by Navone *et al.*[20] and van Weerden and Romijn.[19] Briefly, other human prostate cancer xenograft models include the androgen responsive CWR22[21] and hormone-refractory CWR22R[22] models, the LuCaP 23 lines that were generated from metastatic tissue samples,[23] the androgen-responsive LAPC-4 and hormone-refractory LAPC-3 models,[24] and the MDA PCa xenograft series that were established from metastatic tissue samples.[20] In addition, subrenal capsule grafting and orthotopic transplantation of human prostate cancer tissues into mice have been used to generate transplantable and metastatic prostate cancer sublines.[25] Several factors can influence the establishment of prostate cancer xenograft models. These include the strain of athymic nude mice used, transplantation in nude mice versus severe combined immunodeficiency (SCID) mice, the site of tumor implantation (subcutaneous or orthotopic), and the quality of tissue samples used.

A major limitation of human prostate cancer xenograft models is that tissues are obtained from late stage primary tumors or metastatic deposits. Therefore, these models are largely unsuitable for studying the molecular mechanisms of early prostate carcinogenesis. The use of these models for chemoprevention trials is also limited because they represent end-stage disease.

CANINE MODELS Dogs spontaneously, naturally, and frequently develop prostate carcinoma.[9] Canine prostate cancer mimics several characteristics of its human counterpart in terms of heterogeneity, prevalence in elderly populations, histopathology of the disease, and association with skeletal metastasis.[6] The median age of prostate cancer diagnosis in dogs (10 years) is equivalent to the average age of diagnosis in older men (70 years) when converted to human-years.[26] Studies of elderly pet dogs and military working dogs indicate that the frequency of high-grade prostatic intraepithelial neoplasia (HGPIN) and adenocarcinoma is higher in canines as they age.[8,9] Bone metastasis is the most common lethal clinical complication that is associated with advanced prostate cancer in men. Dogs develop osteoblastic bone lesions that mimic the human disease,[6] thus making this model relevant for preclinical testing of bone-targeted therapies. In an autopsy study that consecutively examined 129 dogs with prostate cancer, 24% presented with skeletal metastasis.[9]

Advantages: Most men die of advanced metastatic prostate cancer after failing hormone therapy. Canine models can be utilized for imaging and evaluating therapeutic modalities for prevention and treatment of bone metastasis.

Disadvantages: Clinically evident disease and skeletal metastasis occur in older dogs with low penetrance. Thus, the long latency associated with the emergence of prostate cancer presents a major obstacle for using canine models for research. Therefore experiments with canine models require a long time commitment and are rather costly.

RODENT MODELS Rodent models of prostate cancer including the laboratory rat and mouse have emerged as powerful tools for studying the biological basis of prostate cancer initiation, progression, and metastasis because they can be managed in large numbers and are easy to use.[7] There are several key similarities and differences between the rodent and human prostate that should be taken into consideration when utilizing rodent models of prostate cancer. There is a distinct anatomical difference between the rodent and human prostate. The rodent prostate is organized into four distinct lobes around the urethra (Figure 66–1A): ventral, dorsal, and lateral (dorsolateral), and anterior (coagulating gland). The individual lobular structures of the rodent prostate have unique branching duct patterns.[11] A normal adult mouse prostatic duct consists of an open lumen that is surrounded by tall columnar secretory epithelial cells and basal epithelial cells that are closely associated with the basement membrane.

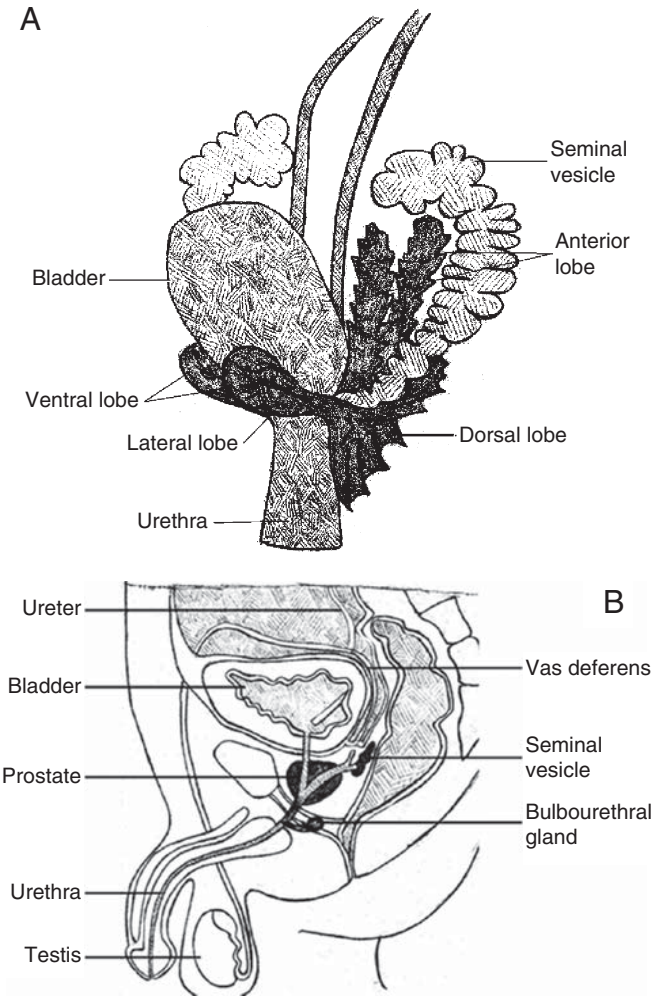

Figure 66–1. Diagrams of the male genitourinary systems of an adult (A) mouse and (B) human. (Adapted from Cunha *et al.*[15])

In contrast, the human prostate (Figure 66–1B) consists of a single gland that is located adjacent to the urethra at the base of the bladder.[15] It is classified into four anatomically distinct morphological regions, namely, the anterior fibromuscular stroma, transition zone (TZ), central zone (CZ) and peripheral zone (PZ).[27–29] These zones differ histologically and in their predisposition to benign and malignant prostatic diseases. Benign prostatic hyperplasia (BPH) is a nonneoplastic increase in proliferation of prostatic tissue and generally occurs in the TZ. In contrast, prostate carcinoma is frequently found in the PZ. There have been suggestions that the dorsolateral lobe of the rodent prostate is most similar to the human PZ where most prostate cancers occur[30]; however, this contention is still debatable.[31,32] The lobular structures of the human and rodent prostate glands are analogous during embryonic development.[32] Although similarities are found in the embryonic development of the rodent and human prostates, the anatomy of the adult prostate gland is strikingly different in each species (Figure 66–1). The rodent models that are used for prostate cancer research include rat and mouse models. Much emphasis will be placed on autochthonous GEM models, while rat models will be briefly highlighted.

Rat Models

Spontaneous Rat Models Certain strains of rats are predisposed to spontaneously developing prostate cancer. The rat models of prostatic carcinoma that are currently available were either derived from spontaneous[33,34] or induced tumors.[35] There are a number of rat models that are currently in use; however, not all models are applicable for research studies. For example, the ACI/Seg spontaneous rat model has limited usefulness because of long latency, low tumor incidence, and low incidence of invasive prostate carcinoma.[6,7]

The Dunning rat model is one of the first rat models that was established.[36] The Dunning R-3327 tumor was a spontaneous adenocarcinoma that developed in an inbred Copenhagen rat and was transplanted into syngeneic Copenhagen × Fischer F_1 hybrid rats.[33] The Dunning system currently consists of several *in vitro* and *in vivo* transplantable sublines that were derived from the original well-differentiated, slow-growing, and nonmetastatic Dunning R-3327 tumor.[37–41] These sublines represent different stages in prostate cancer progression and metastasis. R-3327-H is a well-differentiated, slow-growing, and androgen-sensitive tumor, R-3327-HI is a well-differentiated, slow-growing, and androgen-insensitive tumor, and R-3327-AT is a fast-growing, androgen-insensitive, and anaplastic tumor.[38] A Dunning R-3327 MAT LyLu line that metastasizes to the lymph nodes and lungs was derived from the R-3327-AT line.[39,40] Copenhagen rats inoculated with R-3327 MAT LyLu cells by tail vein injections develop skeletal metastasis.[42] The different sublines of the Dunning model represent a wide spectrum of stages in prostate cancer progression and metastasis. This model has been extensively characterized and is widely utilized, thus making it very attractive for research purposes. The expression of nonprostatic proteins in the Dunning H tumor has raised questions about the origin of the Dunning tumors.[43] Analysis of Dunning H tumor extracts indicated that prostate-specific secretory proteins such as SVS II and transglutaminase were not expressed; however, proteins associated with the mammary gland were detected in the tumor.[43] These findings suggest that the mammary gland or other male accessory sex glands might be the origin of the Dunning H tumor. However, these observations are tempered by the fact that the Dunning model was useful for identifying several clinically relevant markers of human prostate cancer including KAI-1, CD44, and β-thymosin.[6,7]

The Lobund–Wistar (L-W) prostate adenocarcinoma rat model originated from a colony of random bred, germ-free Lobund–Wistar rats.[34] The L-W model consists of spontaneous, induced, and transplantable tumors that metastasize.[6,34] The low tumor incidence and long latency period associated with the spontaneous L-W model have limited its use for research.[7] However, tumor incidence and metastasis are increased in the L-W model using chemical carcinogens (methylnitrosourea, MNU)[44] and hormones (testosterone propionate, TP).[45] The combination of MNU and TP further enhances tumor formation and metastasis in the L-W model.[35,44] This model is unique because it is the only rat model that spontaneously develops hormone-induced adenocarcinoma of the prostate with metastases. Most men fail androgen deprivation therapy and relapse with advanced hormone refractory prostate cancer for which there is currently no cure. The spontaneous, metastatic, and hormone-refractory L-W model[46] can be utilized to study the molecular mechanisms of progression of hormone-refractory prostate cancer and to test chemopreventive and treatment regimens for late stage and metastatic disease.

Advantages of spontaneous rat models: A broad spectrum of human disease progression ranging from PIN to metastasis is represented in the models, making them useful for studies on prevention and metastasis of prostate cancer. The long latency of spontaneous models makes them ideal for studies aimed at elucidating the mechanisms of early carcinogenesis.[7] The Dunning and L-W models are among the best-characterized and well-studied rat models of prostate cancer. Rodents have been widely used for prostate cancer research because maintenance of rodent colonies is economical, they are easily handled, and tumors can be induced or implanted.[6]

Disadvantages of spontaneous rat models: Some limitations associated with rat models include long tumor latency, lack of reproducibility, and low percentage of rats that spontaneously develop adenocarcinoma and metastasis in some models.

Transgenic Rat Models Transgenic animals carry an exogenous vector construct (transgene) inserted into the genome of all their cells, including germ cells, allowing germ line transmission to offspring.[47] Most transgenic animal models that have been developed to study the molecular basis of prostate cancer initiation, progression, and metastasis are mouse models, but transgenic rat models exist. Transgenic mouse models of prostate cancer will be discussed in detail in the next section. Rats are larger in comparison to mice, thus more sample materials (tissues, blood, etc.) can be obtained from rats. Spontaneous and carcinogen- or hormone-induced rat models sometimes have long latency periods and low tumor incidence. Asamoto *et al.* developed a transgenic rat model of prostate cancer using the androgen-regulated prostate specific minimal rat probasin (PB) gene (–426 to +33) to drive expression of oncogenic simian virus 40 (SV40) early genes (T and t antigens, Tag) in Sprague–Dawley rats.[48] The phenotype is 100% penetrant, as all PB/SV40 Tag rats develop androgen-dependent prostate adenocarcinoma in ventral, dorsolateral, and anterior lobes before 15 weeks of age.[48] Castration of 5-week-old PB/SV40 Tag rats completely inhibits prostate tumorigenesis and castration of 20-week-old tumor-bearing rats induces apoptosis, inflammation, and complete tumor involution.[48] This model may be suitable for studies designed to elucidate the

mechanisms of androgen-dependent prostate cancer progression and to test therapeutic interventions targeted for early stage androgen-dependent prostate cancer. In contrast to the low tumor incidence and long latency period associated with spontaneous rat models, transgenic rats develop prostate cancer over time. This presents a window of opportunity that can be targeted for molecular, genetic, and therapeutic intervention studies.

Mouse Models Transgenic or GEM models of prostate cancer have been widely used to delineate the genetic and molecular events that contribute to prostate cancer progression and metastasis. Although there are significant anatomical differences between the mouse and human prostate, these models have been used to validate several genetic events that are clinically relevant for human prostate cancer. Several approaches can be employed to create transgenic mouse models of prostate cancer including overexpression of heterologous genes using tissue-specific promoters and genetic manipulation of oncogenes and tumor suppressor genes that are implicated in prostate carcinogenesis.

There are several GEM models of prostate cancer that develop only benign prostatic lesions such as prostatic intraepithelial neoplasia (PIN), while others develop tumors in tissues other than the prostate. Several groups have developed GEM models to mimic several aspects of human prostate carcinogenesis; however, not all these models develop invasive carcinoma in the prostate or distant metastasis. Special emphasis will be placed on models that develop autochthonous prostate cancer that mimics the relevant and lethal aspects of prostate carcinogenesis in man including progressive development of low-grade PIN, invasive carcinoma, and metastasis to distant organs. Some factors to consider when using GEM models of prostate cancer include the site of integration of the transgene, the choice of promoter used in the targeting construct, and the strain background of the mice.

The site of integration of a targeting construct into the chromosome influences the level of expression of transgenes in transgenic mice. The random insertion of a transgene into the genome produces a position effect,[47] which may result in transgenic offsprings with varying levels of transgene expression or aberrant expression of the transgene in nonspecific tissues or cell types.[49] Greenberg *et al.*[50] observed that the level of expression of a rat probasin (rPB)/chloramphenicol acetyltransferase (CAT) transgene in the mouse prostate was independent of copy number. Variabilities in the expression of the transgene in the prostate of transgenic mice were attributed to position effects that occur due to random integration of the transgene into the genome.

The use of prostate-specific promoters is critical for the expression of a target vector in the prostate. Promoter elements that have been used to generate GEM models of prostate cancer include the rat probasin (rPB),[51,52] rat C3(1) steroid-binding protein,[53,54] fetal globin γ,[55] cryptdin-2,[56] gp91-pho,[57] and prostate secretory protein of 94 amino acids (PSP94).[58] However, not all these promoter elements direct prostate-specific gene expression. In addition, the size of the promoter of choice influences the regulation of transgene expression, thereby affecting prostate cancer progression. The long 12-kb fragment of the 5′ flanking region of the rPB promoter (LPB) drives higher levels of transgene expression in prostatic epithelial cells compared to the minimal –426/+28 region of the same promoter.[59] The biological differences in prostate cancer progression in the transgenic adenocarcinoma of the mouse prostate (TRAMP) model that was generated using the minimal rPB to drive expression of SV40 large and small T antigens,[51] and the LADY transgenic model that was made with a LPB-SV40 large T antigen construct,[52] are due to the size of the promoter elements and differences in transgenes used in each model. The promoter of choice can also dictate the severity of the prostatic lesions developed in a transgenic model. For example, the ARR_2PB promoter that was constructed by linking two androgen-responsive regions (ARR) to the PB promoter strongly directs prostate-specific transgene expression in transgenic mice.[60] Compared to (–426)PB-Myc-PAI mice in which prostate-specific gene expression is driven by the weaker –426/+28 PB promoter, ARR_2PB-Myc-PAI mice develop PIN lesions and prostate carcinoma more rapidly.[61]

The strain background of mice used to create GEM models may also influence the phenotype and rate of prostatic disease progression in transgenic mice. This is exemplified in the TRAMP model, where the genetic background of the mice influences the phenotype of prostatic disease.[62] TRAMP mice in the C57BL/6 background develop tumors that invade the seminal vesicles and urethra, while mice in the C57BL/6 × FVB background develop highly vascularized solid tumors within the prostate that are less likely to invade the seminal vesicles. C57BL/6 TRAMP mice can live for up to 52 weeks, while C57BL/6 × FVB TRAMP mice are euthanized by 33 weeks due to large tumors that can obstruct the urinary tract.[62] In addition, bone metastasis has been observed only in C57BL/6 × FVB TRAMP mice.[63] These data indicate that the genotype of a mouse can influence the phenotype obtained in GEM models.

Autochthonous Transgenic Mice/Genetically Engineered Mice Several GEM models have been created to recapitulate key features of human prostate cancer. However, there is no single model that mimics the full spectrum of the human disease. Some GEM models develop tumors in nonprostatic tissues while others develop mild epithelial hyperplasia that does not progress to invasive carcinoma or metastasis. More emphasis will be placed on the discussion of mouse models that are well characterized and widely used and that recapitulate key features of human prostate cancer such as development of progressive, autochthonous prostate carcinoma and metastasis to distant organs.

The neoplastic changes in the prostate of GEM are considered to be the consequences of the genetic alterations induced in the animals by the transgene. This is based on observations that the incidence of spontaneous neoplastic prostatic diseases is very low in the mouse prostate.[32,64] Individual investigators have generally established the histopathological grading systems used to classify benign and malignant prostatic lesions of GEM models.[53,62,64–66] The Bar Harbor Classification system is a hierarchical histopathological classification system that was developed to facilitate uniformity in the descriptions of the pathological changes in the prostate of GEM.[32] Briefly, nonneoplastic changes in the prostate of mice are described as epithelial and stromal hyperplasia. Mouse prostatic intraepithelial neoplasia (mPIN) is classified as a noninvasive neoplastic proliferation of the prostate epithelium that can possess premalignant potential. Malignant proliferation of the prostate gland is described as invasive carcinoma, adenocarcinoma, and neuroendocrine carcinoma.

SV40 T Antigen (Tag)-Based Models Transgenic mouse models generated using vector constructs in which a promoter drives expression of SV40 large and small T antigens (T and t antigens, Tag) have been used extensively to study prostate carcinogenesis because of the transforming properties of SV40

Tag. There are currently no definitive links between SV40 infections and risk of prostate cancer; however, SV40 contaminations in polio vaccines administered from 1955 to 1963 may be associated with human mesotheliomas, ependymomas, and osteosarcomas.[67,68] The major functions of large T antigen include promotion of cellular transformation and viral replication in target cells by interacting with and blocking the functions of tumor suppressor genes including p53[69] and the retinoblastoma (Rb) family.[70] Large T also binds to transcriptional coactivators such as CBP and p300.[71] One mechanism by which small t antigen promotes uncontrolled cell proliferation is by interacting with the serine–threonine protein phosphatase 2A (PP2A) that leads to constitutive activation of the Wnt signaling pathway.[72]

TRAMP model: The TRAMP model is an autochthonous model of prostate carcinoma that was generated using the minimal rat probasin (rPB) –426/+28 regulatory element to drive expression of the SV40 early genes (T and t antigens, Tag) to the epithelium of the prostate.[51] The androgen-regulated rPB fragment directs prostate epithelium-specific expression of the transgene to the dorsolateral and ventral lobes. Transgene expression is controlled developmentally and hormonally, thus it is expressed postnatally at sexual maturity when androgen levels are high.[50,51] Besides abrogation of the tumor suppressor functions of p53 and Rb by large Tag, other genetic "hits" occur to drive tumor progression.[73] Expression of the transgene is 100% penetrant, therefore all mice eventually develop prostate cancer.[51] TRAMP mice develop progressive prostate cancer that metastasizes to distant organs.[63,64] By 12 weeks of age, TRAMP mice typically develop PIN lesions and invasive cancer.[64] By 24 weeks of age, 100% of mice develop poorly differentiated prostate cancer that is associated with metastasis to the periaortic lymph nodes and lungs and less frequently to the bone, liver, salivary glands, and kidney.[64] Based on the histological grading system established for the TRAMP model, mice develop progressive prostatic neoplasia from low grade prostatic intraepithelial neoplasia (LGPIN) to poorly differentiated cancer.[64] Another grading system for the TRAMP model is based on a unique numerical grading system that avoids terminologies associated with human prostate cancer pathology due to differences in the mouse and human prostate.[66] Transgene expression in the TRAMP model is initially androgen dependent; however, following castration of mice at 12 weeks of age, 70–80% of mice develop hormone refractory prostate cancer while ~20–30% do not present with palpable tumors by 24 weeks following androgen deprivation.[74] Neuroendocrine differentiation is associated with tumor progression, metastasis, and androgen insensitivity in human prostate cancer.[75] There is a stochastic development of the neuroendocrine phenotype that mostly occurs in poorly differentiated tumors that emerge in intact and castrated TRAMP mice.[64] The TRAMP model has been used to elucidate the role of tumor angiogenesis in prostate cancer progression. A distinct "angiogenic switch" that correlates with increased vascularity is associated with prostate cancer progression in the TRAMP model.[76] VEGFR1 is highly expressed in PIN lesions, while increased VEGFR2 expression is detected in invasive carcinoma. Changes in the temporal and spatial expression patterns of the FGF signaling axis also correlate with tumor progression in the TRAMP model.[77] The identification of distinct molecular markers of angiogenesis in the TRAMP model has been exploited to evaluate the effects of antiangiogenic therapies on tumor progression.[78] Cell lines have been established from TRAMP tumors that can either be used for *in vitro* studies or grafted into syngeneic C57BL/6 mice.[79] The TRAMP model is an autochthonous, progressive, and heterogeneous model of prostate cancer that recapitulates several key features in the natural history of human prostate cancer. It is one of the most extensively characterized and widely used transgenic models of prostate cancer and is useful for evaluating therapeutic interventions such as chemoprevention and immunotherapy.

LADY models: These models were generated using a large 12-kb fragment of the 5′-flanking sequence of the probasin gene (LPB) to drive expression of an SV40 large T antigen deletion mutant (that eliminates expression of small t antigen) in the prostate epithelium (LPB-Tag).[52,65] The decreased aggressiveness of the prostate cancer phenotype observed in LPB-Tag models is attributed to the expression of only SV40 large T antigen, thus eliminating the contributing effects of small t antigen. Expression of the transgene is 100% penetrant and mice progressively develop prostate cancer that recapitulates key aspects of human cancer. The 12T-7f line of mice develop multifocal lesions, nuclear atypia, and progressive prostatic lesions including PIN and invasive carcinoma.[52] Metastasis rarely occurs in this model; however, the prostatic lesions that develop are androgen dependent as they regress following castration. The 12T-10 line of the LADY model displays progressive high-grade PIN, poorly differentiated cancer, neuroendocrine differentiation, and metastasis to the lymph nodes, lung, spleen, and kidney.[65] These tumors also demonstrate hormone refractoriness following castration. An allograft model (NE-10) that is hormone refractory, neuroendocrine, and metastatic was derived from the prostate tumor of a 12T-10 mouse.[80] The 12T-10 model may be used to study hormone refractory, neuroendocrine prostate carcinoma progression and to test novel therapeutic modalities that inhibit development of the neuroendocrine phenotype.

C3(1)-SV40 large T/small t model: In this model, expression of SV40 early genes is controlled by the androgen-responsive rat steroid-binding protein C3(1) regulatory elements.[53] By 8 weeks of age, male mice develop PIN lesions in the ventral and dorsolateral lobes that progress to invasive carcinoma by 28 weeks of age. The model recapitulates several aspects of human prostate cancer in terms of development of PIN lesions that harbor mutations in Ha-Ras. Metastasis to distant organs occurs in <5% of mice. However, the C3(1) promoter is not prostate specific as the transgene is expressed in nonprostatic tissues such as the mammary and urethral glands. Similar observations were made in C3(1)-Polyoma middle-T (Py-MT) transgenic mice where the C3(1) regulatory sequences were used to drive expression of the Py-MT gene in the prostatic epithelium.[54] Mice develop dorsolateral and ventral prostate tumors; however, invasive tumors also develop in the vas deferens and salivary glands.

PSP94-SV40 large T/small t antigen model: The prostate secretory protein of 94 amino (PSP94) is one of the most abundant prostate secretory proteins.[81] The promoter/enhancer region of the androgen-regulated and prostate-specific mouse PSP94 gene was used to control expression of SV40 early genes in PSP94-SV40 Tag mice.[58] Histopathological changes in the dorsolateral and ventral prostate lobes correlate with the onset of puberty. Mice progressively develop low- and high-grade PIN by 12 weeks of age, poorly differentiated cancer by 16 weeks, and lymph node metastasis. Castration of PSP94-SV40 Tag mice results in involution and atrophy in the prostate, indicating that tumor progression

is androgen dependent. Importantly, PSP94 is conserved across several species including humans and mice.[82] However, there is no human equivalent of the prostate-specific rat probasin (PB) gene that has been widely utilized for generating GEM models. As a result, PSP94 is being developed for generating vector constructs for gene therapy because it is a strong prostate-specific gene.[58]

Cryptdin-2-SV40 large T/small t antigen model: Cryptdins are nonprostatic, antimicrobial peptides that are secreted by the Paneth cells of the intestinal epithelium.[83] Cryptdin-SV40 Tag mice were generated using nucleotides −6500 to +34 of the mouse cryptdin-2 gene to direct expression of SV40 early genes to neuroendocrine cells in the lobes of the mouse prostate.[56] Mice rapidly develop PIN lesions and neuroendocrine carcinoma. In addition, metastasis to lymph nodes, liver, lungs, and bone occurs frequently in the model. This model may be appropriate for studies on the mechanisms of neuroendocrine prostate cancer progression.

Fetal globin γ (Gγ)-SV40 large T/small t antigen model: Targeted expression of the fetal Gγ-SV40 Tag construct in mice unexpectedly results in the development of prostate tumors consisting of mixed neuroendocrine and epithelial cells.[55] Further characterization of the model indicated that dorsolateral and ventral prostate tumors develop following castration.[84] Metastasis to the lymph nodes and other distant sites is also observed. The fetal Gγ-SV40 Tag model is a hormone-refractory and metastatic transgenic mouse model that is suitable for studies of the mechanisms of progression of aggressive and advanced prostate cancer. However, these mice also develop nonprostatic tumors including adrenocortical and brown adipose tumors.[55]

Extensive descriptions of other SV40-Tag-based models are reviewed by Kasper[85] and Abate-Shen and Shen.[31] The TRAMP and LADY models are among the first described and therefore best characterized and widely used SV40 Tag-based transgenic models. These models progressively develop prostate cancer and metastasis that recapitulates key features of the human disease. However, one limitation of these models is the rapid onset of aggressive prostate cancers with neuroendocrine features.

ONCOGENES AND TUMOR SUPPRESSOR GENES Overexpression of oncogenes or inactivation of tumor suppressor genes is associated with progression of human prostate cancer. A number of GEM models have been created to mimic the genetic perturbations that promote progression of human prostate cancer (reviewed by Huss *et al.*,[86] Abate-Shen and Shen,[31,87] and Kasper[85,88]). In contrast to most SV40 Tag models that develop PIN, invasive carcinoma, neuroendocrine carcinoma, and metastasis, significant proportions of these mice develop mild hyperplasia or noninvasive PIN lesions. Therefore, more emphasis will be placed on models that develop severe prostatic lesions. Aberrant expression of oncogenes is implicated in human prostate cancer pathogenesis. C-Myc is an oncogene that is overexpressed in invasive and metastatic human prostate cancer samples.[89] C3(1)-c-Myc transgenic mice primarily develop hyperplasia in the ventral prostate.[90] Compared to (–426) PB-Myc-PAI mice that were generated with the minimal rat probasin promoter, ARR_2PB-myc-PAI transgenic mice rapidly develop high-grade PIN with invasive carcinoma in less than 6 months.[61] Homozygous deletion of MXI1 ($MXI1^{-/-}$), a c-Myc antagonist,[91] results in prostatic dysplasia and hyperplasia.[92] Mutations in members of the Ras family of oncogenes are found in human prostate cancer specimens.[93] Overexpression of RasT24 in PB-T*ras* transgenic mice produces mild prostatic changes including epithelial and stromal hyperplasia. In PB-*RAS* mice that overexpress activated Harvey-*RAS*, PIN lesions and intestinal metaplasia develop.[94] Transgenic mice were generated to model genomic instability using the minimal probasin promoter to force expression of the c-*fos* oncogene and *ECORI* restriction enzyme.[95] While only low-grade PIN lesions develop in PB-*fos* mice, PB-*Eco*RI mice develop high-grade PIN and invasive carcinoma. Increased expression of the antiapoptotic Bcl-2 gene in C3(1)-bcl-2 mice produces epithelial and stromal hyperplasia in the prostatic epithelium.[96] However, no hyperplastic or neoplastic phenotypes were observed in the prostates of PB-bcl-2 mice.[97]

Deregulation of components of the PI3K/Akt pathway has been implicated in prostate carcinogenesis. PTEN/MMAC1 is a ubiquitously expressed protein/lipid phosphatase that functions as a tumor suppressor by inhibiting the PI3K/Akt pathway and promoting apoptosis.[98] PTEN maps to chromosome 10q23 and undergoes loss of heterozygosity in many cancers including human prostate cancer.[98] PTEN heterozygous ($PTEN^{+/-}$) mice develop epithelial hyperplasia, dysplasia, and PIN lesions in the prostate.[99,100] Homozygous PTEN ($PTEN^{-/-}$) mice are embryonic lethal[99,101]; therefore, conditional knockout mice were generated to specifically delete PTEN in the prostatic epithelium (PB-Cre4 × $PTEN^{loxp/loxp}$).[102] Probasin (PB) directs prostate epithelium-specific expression of the Cre enzyme. This leads to Cre-mediated recombination and deletion of the PTEN gene between two *loxP* sites. PB-Cre4 × $PTEN^{loxp/loxp}$ mice progressively develop PIN, prostate adenocarcinoma, and metastasis to the lymph nodes and lungs.[102] The conditional PTEN model is unique because it is the first transgenic mouse model of prostate cancer that displays multistep carcinogenesis that closely mimics the initiation, progression, and metastasis of human prostate adenocarcinoma.[102] Loss of PTEN activity promotes constitutive activation of the PI3K/Akt pathway.[103] To model the elevated Akt activity that is frequently detected in human prostate cancer,[104] a PB-myr-HA-Akt1 (MPAKT) transgenic mouse model with constitutive Akt activity was generated.[105] MPAKT mice develop PIN lesions in the ventral prostate lobe that are strikingly similar to PIN lesions in $PTEN^{+/-}$ mice.

Nkx3.1 is a prostate-specific homeobox gene that is important for normal prostate development and differentiation.[106] Although Nkx3.1 mutations have yet to be identified in prostate cancer, it is considered a candidate tumor suppressor gene because it maps to the chromosome 8p12–21 region that is frequently lost in cancer,[107,108] including prostate tumors.[109,110] Defective branching morphogenesis, epithelial hyperplasia and PIN-like prostatic lesions were observed in $Nkx3.1^{-/-}$ null mice.[106] Prostate-specific deletion of Nkx3.1 in PSA-Cre × $Nkx3.1^{f/f}$ conditional knockout mice results in the formation of PIN lesions.[111]

CELL CYCLE PATHWAYS AND GROWTH FACTOR/PEPTIDE SIGNALING Aberrant cell cycle progression and evasion of apoptosis are hallmarks of prostate cancer progression from early stage disease to late stage advanced metastatic disease.[112] $p27^{Kip1}$ is a cyclin-dependent kinase (CDK) inhibitor that is frequently lost in human prostate cancer.[113] Loss of $p27^{Kip1}$ expression in mice ($p27^{-/-}$) promotes only mild hyperplasia in the prostate.[113] Expression of the SKP2 complex that targets p27 for ubiquitination and proteolysis is elevated in prostate cancer.[114] Overexpression of SKP2 in ARR_2PB-SKP2 transgenic mice promotes high-grade

PIN and decreases p27 expression in the prostate.[114] Loss-of-function mouse models of negative cell cycle regulators and tumor suppressor genes such as $p53^{-/-}$ [115] and $Rb^{-/-}$ [116] null mice display normal prostate development or embryonic lethality, respectively.

Deregulation of growth factor signaling networks facilitates survival of cancer cells. Mild hyperplasia and dysplasia were observed in the fibroblast growth factor 7 (FGF7) overexpressing PB-FGF7 (PKS) mouse model.[117] Minimal probasin promoter-directed expression of dominant negative FGFR2iiib to the prostate in KDNR mice results in development of a neuroendocrine-like phenotype.[117] In ARR_2PB-FGF8b transgenic mice, increased expression of FGF8b promotes development of high-grade PIN lesions.[118] Elevated serum levels of insulin-like growth factor-1 (IGF-1) increase the risk of prostate cancer.[119] Bovine keratin 5 (BK5)-IGF-1[120] and PB-IGF-1[121] mice were generated to study the role of IGF-1 in prostate cancer progression. In contrast to PB-IGF-1 mice that did not develop hyperplastic or neoplastic changes in the prostate epithelium,[121] BK5-IGF-1 mice develop multistep prostate carcinogenesis including hyperplasia, PIN, and invasive carcinoma with neuroendocrine features.[120] Transforming growth factor-β (TGF-β) acts as a tumor suppressor via TGF-β receptors (TβR) in normal prostate cells;[122] however, it also promotes prostate cancer progression.[123] Transgenic mice were created to block endogenous TGF-β receptor type II (TβRII) using a metallothionein promoter to control dominant-negative TβRII (MT-DNIIR).[124] Crossbreeding of MT-DNIIR mice with the LADY (LPB-SV40 large Tag) model enhances metastasis in bigenic mice.[125] Activated ERBB2 (HER-2/Neu), a member of the epidermal growth factor receptor (EGFR) family, is implicated in hormone refractory prostate cancer progression.[126] Probasin promoter-driven expression of oncogenic Neu in the prostate epithelium of PB-Neu mice results in progressive PIN lesions and invasive carcinoma.[127]

STEROID RECEPTORS Overexpression of the androgen receptor (AR) promotes prostate cancer survival following androgen deprivation.[128] Minimal probasin promoter-driven expression of murine AR in the prostate epithelium of mice (PB-mAR) results in mild prostatic dysplasia, hyperplasia, and PIN after 1 year.[129] The antiproliferative effects of retinoic acid[130] and vitamin D[131] in prostate cancer are mediated by retinoic acid receptors (RARs or RXRs)[132] and the vitamin D receptor (VDR).[131] RXRα conditional knockout mice were generated by crossing PB-Cre4 mice with $RXR\alpha^{f/f}$ mice (PB-Cre4 × $RXR\alpha^{f/f}$) for Cre-mediated targeted deletion of RXRα in the prostate epithelium.[133] These mice develop hyperplasia and low-grade and high-grade PIN lesions.

BIGENIC MODELS The prevalence of mild dysplasia, hyperplasia, and noninvasive neoplastic lesions in the prostates of most GEM models with targeted loss-of-function or gain-of-function mutations of one gene suggests that prostate cancer progression and metastasis involve a complex, multistep process. Therefore, several GEM models with two or more genetic hits have been generated to better recapitulate the complex natural history of human prostate cancer.

Although no histological changes were observed in the prostates of PB-bcl-2 mice that overexpress the antiapoptotic Bcl-2 gene,[97] PB-bcl-2 × TRAMP bigenic mice rapidly develop prostate tumors.[134] This suggests that Bcl-2 decreases tumor latency in TRAMP mice. In $PTEN^{+/-}$, $p27^{-/-}$ ($Cdkn1b^{-/-}$), and $Nkx3.1^{-/-}$ knockout mice, the prostatic lesions observed include dysplasia, hyperplasia, and sometimes PIN, but not invasive carcinoma.[99,100,106,113] Bigenic $PTEN^{+/-}$ × $Cdkn1b^{-/-}$ mice develop PIN lesions that progress to invasive carcinoma in 25% of mice.[135] Crossbreeding of $PTEN^{+/-}$ and $Nkx3.1^{-/-}$ null mice is also synergistic as mice develop invasive carcinoma[136] that frequently metastasizes to the lymph nodes.[137] These studies indicate cooperativity between PTEN haploinsufficiency and loss of p27 or Nkx3.1 tumor suppressor functions. Furthermore, crossbreeding of $PTEN^{+/-}$ mice with TRAMP mice results in rapid development of invasive prostate carcinoma.[138] FGF2 levels are elevated in advanced stage metastatic human prostate cancer.[139] In TRAMP mice that were crossbred with $FGF2^{-/-}$ null mice, the incidence of metastasis and the tumor grade were decreased.[139] Hepsin is a type II transmembrane serine protease that is overexpressed in human prostate cancer.[140–142] Probasin promoter-driven overexpression of hepsin in the prostate epithelium of PB-hepsin mice causes weakened epithelial–stromal adhesion.[143] Crossbreeding of the 12T-7f line of the LADY model that develops invasive cancer without metastasis to PB-hepsin mice triggers liver, lung, and bone metastasis.[143]

In contrast to GEM models with targeted manipulation of only one gene, most bigenic mouse models develop more severe prostatic lesions that are sometimes associated with distant site metastasis. This suggests that multiple genetic events are necessary for development of prostate cancer.

ALTERNATIVE GENETICALLY ENGINEERED MOUSE MODELS The prostate gland is composed of different cellular compartments including epithelial cells, stromal cells, and endothelial cells. The epithelial cell compartment consists of secretory luminal cells, basal cells, and neuroendocrine cells. Most innovations in the field of transgenic mouse modeling involve targeted disruption or overexpression of genes in the luminal epithelial cell compartment using prostate epithelium-specific regulatory elements such as probasin and PSP94. The genetic and molecular changes that arise in other cellular compartments of the prostate must be critically evaluated to adequately recapitulate the complex, multistep changes that contribute to prostate carcinogenesis.

To examine the role of TGF-β signaling in stromal–epithelial interactions, the TGF-β type II receptor (Tgfbr2) was conditionally inactivated in mouse fibroblasts by crossing fibroblast-specific protein 1 (Fsp1)-Cre mice with $Tgfbr2^{f/f}$ mice ($Tgfbr2^{fspKO}$).[144] Fsp1 controls prostatic fibroblast-specific expression of Cre recombinase, and Cre mediates recombination at the *loxP* sites surrounding the Tgfbr2 gene in $Tgfbr2^{f/f}$ mice. Stromal hypercellularity and PIN develop in the dorsolateral, ventral, and anterior prostate lobes of $Tgfbr2^{fspKO}$ mice. The prostate stem cell antigen (PSCA) promoter directs prostate-specific gene expression to a subpopulation of epithelial cells that expresses basal and luminal epithelial cell markers.[145] The PSCA promoter may be utilized as a promoter that targets a unique subset of epithelial cells in the prostate gland. Prostate-specific promoters that can direct gene expression to prostatic endothelial cells have yet to be reported.

Some of the limitations associated with traditional GEM models such as the TRAMP and LADY models include the rapid onset of aggressive prostate cancer and a high incidence of neuroendocrine tumors. In addition, there is currently no evidence that the SV40 early genes are involved in development of human prostate cancer. Random insertion of the transgene into the

genome can cause a "position effect" that leads to differences in genotype and phenotype in traditional GEM models. To circumvent some of these problems, knockin technology is being utilized to generate mouse models of prostate cancer. Knockin mice are created by targeted insertion of a heterologous gene into a specific gene locus.[146] This facilitates single copy insertion of the targeting vector into the genome, thereby resulting in uniform transgene expression and a stable phenotype. PSP94 mouse adenocarcinoma prostate model knockin mice (PSP-KIMAP) were generated by targeted insertion of SV40 early genes to the prostate-specific PSP94 promoter/enhancer gene locus.[147] Compared to PSP94-SV40 Tag transgenic mice that were generated using traditional transgenic technique to create mice with PSP94 promoter-driven prostate-specific expression of SV40 Tag,[58] prostate cancer progression was more prolonged and synchronous in PSP-KIMAP mice.[147]

CONCLUSIONS

Each spontaneous, inducible, and transgenic animal model of prostate cancer that is currently available has strengths that have been exploited to understand the genetic and molecular basis of prostate carcinogenesis. However, there is currently no single model that fully recapitulates the full spectrum of human prostate cancer initiation, progression, and metastasis. One obvious limitation of the GEM models that have been widely utilized for prostate cancer research is the lack of reproducible development of bone metastasis. Most gain- or loss-of-function models have targeted disruption of candidate genes directed to the prostate luminal epithelium. To fully model the entire continuum and natural history of prostate cancer development, it will be critical to utilize regulatory sequences that target gene expression to other prostatic cellular compartments such as basal, stromal, and endothelial cells.

67 Animal Models of Diabetes

Willy J. Malaisse and Abdullah Sener

ABSTRACT

This review deals with animal models of diabetes mellitus. Experimentally induced diabetes, such as that caused by antiinsulin serum, pancreatectomy, glucose infusion, β-cytotoxic agents, and viruses, is first considered. Attention is also paid to diabetogenic nutritional and hormonal factors, inhibitors of insulin release, and animal models of glycosuria. Second, both non-insulin-dependent spontaneous diabetes, such as that encountered in several rodent species, and insulin-dependent spontaneous diabetes, especially in NOD mice and BB rats, are briefly discussed. Last, the more recent use of gene targeting and transgenic techniques to explore the physiopathology of diabetes and the introduction of several insulin-secreting and other pancreatic endocrine cell lines in experimental diabetology are reviewed.

Key Words: Diabetes mellitus, Animal models, Antiinsulin serum, Pancreatectomy, β-Cytotoxic agents, Spontaneous diabetes, Gene targeting and transgenic techniques, Insulin-secreting cell lines.

INTRODUCTION

Diabetes mellitus has occurred in humans at least as long as written medical reports exist, i.e., approximately 4000 years. It has been found in all human societies where any consistent search has been made. In the introduction of a Workshop on Spontaneous Diabetes in Laboratory Animals, held in Augusta (MI) in 1966, A.E. Renold and W.E. Dulin proposed that the same may be true in animals, particularly those living in association with humans, whether as domestic animals or as animals bred in the laboratory.[1] They indicated that diabetes was reported in species such as the tree shrew[2] and the dolphin.[3] They also provided a table listing, under the title "Type of inherited diabetes in mus musculus and in other small laboratory rodents," six single gene mutations and three inbred strains and F_1 hybrids in mice, and four other species, including spiny-mouse, sand rat, Chinese hamster, and the single "fatty" mutant gene in the rat. This introduction was followed by 222 pages of articles devoted to the same issue. Needless to add, in this chapter, the issue of animal models of diabetes could be reviewed in only a quite restricted and, at best, illustrative manner.

EXPERIMENTALLY INDUCED DIABETES

Several experimental procedures can be used to induce hyperglycemia in otherwise normal animals. Seven of these procedures are considered below.

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

DIABETES INDUCED BY ANTIINSULIN SERUM A transient state of insulinopenia for several hours up to a few days can be induced by the injection, e.g., in rats or dogs, of guinea pig antiinsulin serum.[4] The restoration of normoglycemia occurs when all circulating antibodies are neutralized by endogenously secreted insulin.[5] This approach makes it possible to characterize the metabolic consequences of insulinopenia without any primary alteration of endocrine pancreatic function. It was also used to explore the consequences of a sustained increase in insulin output upon the functional behavior of pancreatic islets, e.g., after their isolation from animals previously injected with guinea pig antiinsulin serum.[6]

PANCREATECTOMY In the 1880s, von Mering and Minkowski observed that after removal of the pancreas of a dog, the animal developed polyuria and polydipsia and was eventually found to have diabetes mellitus.[7] History has also given a special place to Marjorie, one of the dogs used by Banting and Best in their seminal experiments on the isolation and purification of insulin in the 1920s.[8]

In a more recent work, partial pancreatectomy, e.g., removal of 70–90% of the β cell mass, was used to induce a mild type 2 diabetes-like state associated with a stable increase in glycemia. This approach is still widely used to explore its functional consequences upon the remaining insulin-producing cells.[9]

GLUCOSE INFUSION The hyperglycemia provoked in healthy animals by the infusion of glucose differs in several respects, e.g., by the changes in unesterified fatty acids and production of ketone bodies, from that prevailing in diabetic animals. Nevertheless, the sustained infusion of a hypertonic solution of glucose represents a suitable model to reproduce some of the hydroionic consequences of diabetic hyperglycemia. For instance, prolonged glucose infusions to dogs served as an animal model for the study of hyperosmolar nonketotic coma.[10] In exceptional cases, glucose administration for several weeks was also reported to induce permanent diabetes.[11] Moreover, chronic intravenous infusion of glucose for periods of up to 7 days has been used, inter alia, to explore the biochemical determinants of the insulin secretory defect caused by sustained hyperglycemia and often referred to as a phenomenon of B cell glucotoxicity or in-competence. For instance, it was proposed that under these experimental conditions, glycogen accumulation in pancreatic islet β cells may account for two typical features of B cell glucotoxicity, mainly a paradoxical short-lived inhibition of insulin release in response to the bolus intravenous injection of glucose and a

perturbation of the anomeric specificity of glucose-induced insulin release.[12]

β-CYTOTOXIC AGENTS Alloxan and streptozotocin are the two most commonly used β-cytotoxic agents in the perspective of nonsurgical induction of experimental diabetes in animals.

The diabetogenic action of alloxan was first reported by Dunn *et al.*[13] The intravenous administration of freshly dissolved alloxan (0.3–0.7 μmol/g body weight) after 24 h starvation is recommended as the usual procedure. The selective cytotoxic action of alloxan on insulin-producing cells was attributed to the coincidence of two distinct and independent features: a rapid accumulation of the drug into islet β cells and their exquisite sensitivity to peroxides.[14]

Streptozotocin, an antibiotic isolated from *Streptomyces achromogenes*, also exerts a selective β-cytoxic action.[15] It is usually administered intravenously, at a dose close to 0.25 μmol/g body weight, to overnight starved animals. Three further modalities of streptozotocin administration merit mention. First, the combined administration of streptozotocin and nicotinamide, which protects against the diabetogenic action of the antibiotic, is currently used to develop, within about 1 year, pancreatic insulinomas.[16] Second, a multiple low-dose streptozotocin model has been extensively used to study the immunological pathways that lead to insulitis and β cell death.[17] Last, injection of neonatal rats with streptozotocin within 2 days of birth results, later in life, in a model of non-insulin-dependent diabetes, with reduced β cell mass and mild hyperglycemia.[18]

Vacor, dithizone dehydroascorbic acid, pentamidine, and 8-hydroxyquinoline were also examined for their diabetogenic effects in experimental animals.[19–21]

VIRUS-INDUCED DIABETES Viruses, such as encephalomyocarditis virus (EMC), may induce diabetes in experimental animals.[22] This occurs not by autoimmunity but by direct infection and cytolysis of pancreatic β cells.

DIABETOGENIC NUTRITIONAL AND HORMONAL FACTORS It has long been known that the long-term administration of different hormones may lead to either glucose intolerance or frank diabetes. Such is the case for growth hormone, glucocorticoids, glucagon, and thyroid hormones.[23] Likewise, obesity, such as that induced by gold thioglucose or a fat diet, may affect glucose homeostasis.[24] Attention was also drawn to the perturbation of both fuel homeostasis and islet function found in starvation,[25] protein malnutrition,[26] and pregnancy and lactation.[27] In these several instances, suitable animal experimental designs were developed to assess both the pancreatic endocrine and extrapancreatic determinants participating in the response to such diabetogenic factors. In this respect, two examples could be mentioned. First, attention has been paid to the role of diabetes in pregnancy and the intrauterine environment in the subsequent development of diabetes among offspring.[28] Second, second-generation rats deficient in long-chain polyunsaturated ω3 fatty acids were recently examined to further explore the impact of these fatty acids on metabolic variables such as liver triglyceride content, visceral obesity, insulin resistance, and pancreatic islet metabolic, ionic, and secretory parameters.[29]

INHIBITION OF INSULIN RELEASE Several chemical agents inhibit insulin secretion. For *in vivo* studies, D-mannoheptulose, adrenalin, and diazoxide merit consideration.[20]

D-Mannoheptulose is a natural ketoheptose present in several plants, e.g., avocados. By inhibiting glucose phosphorylation in islet cells, it suppresses insulin secretion. The *in vivo* use of D-mannoheptulose (1–4 μmol/g body weight given intravenously) is limited by its biological half-life, itself linked to its renal clearance.[5]

Adrenalin inhibits insulin release at the intervention of β cell α-adrenergic receptors. *In vivo* it needs to be continuously infused (about 5 pmol/g body weight/min), the insulinemia rapidly reaching high values when the infusion of the adrenergic agent is halted. Obviously, another limitation concerns the extrapancreatic effect of the hormone, e.g., in terms of glycogenolysis and lipolysis.

Diazoxide also inhibits insulin release by causing the gating of ATP-sensitive K+ channels. It has been used *in vivo* (e.g., 0.5–2.0 μmol/g body weight given orally each day), for instance, to distinguish between the respective role of hyperglycemia and sustained high insulin secretion in the functional behavior of islet cells, including granulolysis, slackening of proinsulin conversion, or anomeric specificity of glucose-stimulated insulin release.[30,31]

ANIMAL MODELS OF GLYCOSURIA Phlorizin, a naturally occurring flavinoid, inhibits the resorption of glucose in the proximal renal tubule. It can be used to restore near-normoglycemia in diabetic animals by provoking massive glycosuria and polyuria.[32] This procedure may help to distinguish between the effects of hyperglycemia and other consequences of experimental diabetes in pathological processes, such as diabetic complications.

SPONTANEOUS ANIMAL DIABETES

As already alluded to in the introduction of this chapter, an exhaustive analysis of all spontaneous animal models of diabetes would largely be beyond the limits of this review.

NON-INSULIN-DEPENDENT MODELS For instance, more than a dozen spontaneous animal models of type 2 diabetes are currently under investigation.

Chinese Hamster The incidence of diabetes is high in Chinese hamsters (*Cricetulus griseus*). In this animal, the syndrome is inherited and polygenic. Typical experiments involve comparison between aglycosuric control animals, mildly diabetic animals with slight and/or occasional glycosuria, and more severely diabetic animals with histories of severe glycolysia detected at weekly intervals for more than 2 months.[33] For instance, in such a design, insulin secretion was found to be highest in the animals with intermittent glycosuria and lowest in the more severely diabetic animals.

Goto-Kakizaki Rat The Goto-Kakizaki (GK) rat was developed by the selective breeding of Wistar rats with the highest blood glucose concentration over may generations.[34] This inherited model of type 2 diabetes presents several features that can be compared with human type 2 diabetes. Such features include inter alia, polygenic inheritance, high maternal transmission, and the occurrence of diabetic complications, such as renal lesions, structural changes in peripheral nerves, and abnormalities of the retina.

Sand Rat In its natural habitat, the sand rat (*Psammonys obesus*) has an essentially vegetarian diet. However, when fed laboratory chow, the animals become obese, insulin resistant, and hyperglycemic. Hence, the sand rat model is particularly useful when studying the effects of diet and exercise in the development

of type 2 diabetes.[35] As a matter of fact, the identification of diabetes in the sand rat, which was first investigated by physiologists interested in the kidney regulation of urine volume in this desertic animal, was initially based on the observation of oral infectious lesions in the animals given free access to laboratory chow.

Spiny Mouse Environmental factors such as exercise and nutrition also play a crucial role in the development of diabetes in spiny mice (*Acomys cahirinus*), whether transferred from their normal foraging habitat or bred in the laboratory.[36] Moreover, in this model, a primary abnormality of the β cell microtubular system may participate in the impaired dynamics of insulin release.[37]

KK Mouse KK mouse were first described in 1967 as a strain bred for large body size. Typically, the mouse gradually becomes obese in adult life, this being associated with insulin resistance, compensatory islet cell hyperplasia, and hyperinsulinemia, and eventually resulting in mild hyperglycemia.[38] Some differences may now exist among the KK mouse strains maintained as colonies in different laboratories.

Nagoya-Shibata-Yasuda Mouse As with the KK mouse, the Nagoya-Shibata-Yasuda (NSY) mouse was developed by selected inbreeding. The NSY mice spontaneously develop diabetes in both an age-dependent manner and with a marked gender difference. This model is quite useful, therefore, when considering age-related phenotypic changes, such as the progressive alteration of β cell function.[39]

Otsuka Long-Evans Tokushima Fatty Rat A spontaneously diabetic rat with polyuria, polydipsia, and slight obesity was discovered in 1984 in an outbred colony of Long–Evans rats, which had been purchased from Charles River Canada in 1982 and since kept at the Tokushima Research Institute in Japan. By selective breeding, the Otsuka Long–Evans Tokushima fatty (OLETF) rat was then developed and characterized by a chronic course of disease with late onset of hyperglycemia, mild obesity, inheritance by males, hyperplastic foci of pancreatic islets, and renal complications.[40]

New Zealand Obese Mouse Diabetes in the New Zealand obese (NZO) mouse, developed in 1972 by Larkins and Martin, displays polygenic inheritance and is characterized by defective insulin secretion as a prominent feature of the syndrome.[41] Dietary restriction and normalization of body weight can partly ameliorate the β cell defect.

Fatty Zucker Rat The Zucker diabetic fatty (ZDF) rat (fa/fa) is a well-characterized model of non-insulin-dependent diabetes mellitus in which homozygous males demonstrate obesity and insulin resistance, but have normal plasma glucose levels until about 10 weeks of age when overt hyperglycemia develops. Heterozygous littermates are lean and do not develop diabetes. Since diabetes-prone ZDF rats go through a clearly defined prediabetic period, they offer the opportunity to compare selected metabolic and hormonal variables in the prediabetic and diabetic state.[42]

Diabetes Mouse The diabetic syndrome in C57BL/KsJ db/db mice is inherited as an autosomal recessive trait. Diabetic mice are hyperphagic, obese, functionally sterile with atrophic gonads and accessory structures, and hyperinsulinemic. In 1970, Coleman and Hummel proposed that the primary defect in diabetic mice may involve the hypothalamus, particularly in the regions of the satiety centers.[43] The db/db mouse, like the fa/fa rat, was eventually found to indeed harbor a mutation in a hypothalamic receptor for leptin.

Obese Mouse A single autosomal recessive gene is responsible for the obesity–diabetes syndrome in ob/ob mice. Animals homozygous for the ob gene exhibit hyperphagia and obesity as well as hyperinsulinemia and insulin resistance. The ob gene has been transferred to several strains of mice, which have been employed extensively to study various aspects of insulin secretion, obesity, and diabetes. In 1994, Friedman and colleagues reported the cloning of the mutation responsible for the massive obesity seen in the ob/ob mouse.[44] The defective ob gene coded for a protein secreted by adipocytes and termed leptin.

New Genetic Animal Models of Type 2 Diabetes New animal models of diabetes are still sought. For instance, a new genetic model of type 2 spontaneous diabetes, the Tsumura Suzuki obese diabetic (TSOD) mouse, which develops moderate degrees of obesity and diabetes that are especially apparent in animals more than 11 weeks old, displays both impairment of insulin-stimulated GLUT4 translocation in skeletal muscle and adipose tissue, and diabetic renal and neural complications.[45,46] Likewise, an outbred animal model of early onset polygenic obesity and diabetes was recently reported as the M16 mouse.[47]

INSULIN-DEPENDENT MODELS The insulin-dependent animal models of diabetes experimentally induced by alloxan, streptozotocin, or total pancreatectomy were already mentioned in this chapter. The two models of spontaneous insulin-dependent diabetes are the Bio Breeding (BB) and the nonobese diabetic (NOD) mouse. They are eventually characterized by hyperglycemia, extensive or complete degeneration of B cells, insulinopenia, weight loss, hyperphagia, polydipsia, and, if untreated, ketosis and death.

The NOD Mouse The NOD mouse was developed by selectively breeding offspring from a laboratory strain that in fact was first used in the study of cataract development.[48] Insulitis, present in mice 4–5 weeks old, is followed by subclinical β destruction, frank diabetes being present between 12 and 30 weeks of age. Genetic studies have revealed multiple susceptibility genes, the MHC region apparently playing a key role.[49] The immunological cascade that includes T-helper type 2 (Th2) cells, effector cells (CD4+, CD8+), and cytokines was also examined in the NOD mice. Immunosuppression with cyclosporine in combination with other immunomodulatory compounds such as vitamin D helps to prevent diabetes in NOD mice and also in BB rats.

The BB Rat The BB rat was first recognized in 1974 in the Bio Breeding Laboratories, a commercial breeding company based in Ottawa.[50] Current studies in this animal model of type 1 diabetes involve the comparison between diabetes-prone and control BB rats. In the diabetes-prone BB (BBdp) rats, insulinopenia develops at about 12 weeks of age, the pancreatic islets being subjected to an autoimmune attack with T cells, B cells, macrophages, and natural killer cells recruited to the insulitis.

In light of the effect of diets on the incidence of diabetes in BBdp rats, a type-1 diabetes-related protein from wheat was recently identified as the first candidate wheat protein that is not only antigenic in both diabetic rats and human patients, but is also closely linked with the autoimmune attack of the pancreas. As a matter of fact, Scott and colleagues proposed that intestinal dysfunction and dysregulation of the gut immune system play a role in the development of diabetes in BBdp rats fed a diabetes-promoting diet.[51]

Other Models Other animal models of type 1 diabetes cited by Rees and Alcolado[21] include the Long–Evans Tokushima lean

(LETL) rat, New Zealand white rabbit, Keeshond dog, Chinese hamster, and Celebes black ape (*Macacca nigra*).

GENE TARGETING AND TRANSGENIC TECHNIQUES

An explosion in the number of animal models used for the study of diabetes has come from the use of molecular biological techniques. For instance, knockout animals were produced by using a genetic construct that will disrupt a normal gene. This approach is not without limitations. To mention only one example, overexpressing or underexpressing a single gene may lead to changes in the expression of other genes as a compensatory mechanism.

Transgenic animals in diabetes research include, to cite only a few ones, knocking-out the insulin receptor gene, its substrate 1 (IRS1) or 2 (IRS2) gene, the glucokinase gene, and the GLUT4 gene.[21]

Tissue-specific knockouts can be produced so that the animals have a gene knocked out in specific tissues, such as pancreatic β cells, liver, adipose tissue, or brain. This quite powerful technique has produced much interesting data in recent years. For instance, an animal model of mitochondrial diabetes was developed by knocking out the mitochondrial transcription factor mtFA only in pancreatic β cells.[52] Likewise, the establishment of liver-specific glucokinase gene knockout mice was recently proposed as a new animal model for screening antidiabetic drugs.[53]

It is beyond the limits of this chapter to enumerate all animal models relevant to the pathophysiology of diabetes mellitus and established by gene targeting or transgenic techniques. Truly speaking, this approach conceivably covers an almost unlimited field of investigations on each factor possibly involved in the development of this disease. Only two further examples will be cited to illustrate such a diversity.

First, establishment of an NOD-Pdcd1$^{-/-}$ mice was recently proposed as an efficient model of type 1 diabetes.[54] In this study, advantage was taken of the use of NOD mice knocked out for programmed cell death (Pdcd1), an immunoreceptor belonging to the CD28/cytotoxic T-lymphocyte-associated antigen-4 family. Second, another recent study deals with the generation of mice lacking the SHIP2 gene, SHIP2 being a member of the inositol polyphosphate 5-phosphate family.[55] Loss of SHIP2 leads to increased sensitivity to insulin with severe neonatal hypoglycemia, deregulated expression of the genes involved in gluconeogenesis, and perinatal death. Adult mice that are heterozygous for the SHIP2 mutation have increased glucose tolerance and insulin sensitivity associated with an increased recruitment of the GLUT4 glucose transporter and increased glycogen synthesis in skeletal muscle.[55]

INSULIN-SECRETING AND OTHER PANCREATIC ENDOCRINE CELL LINES

INSULIN-SECRETING CELL LINES The use of primary B cells in biochemical and molecular research is limited not only by the availability of endocrine tissue, but also by the sophistication of the methods required to isolate pancreatic islets, prepare dispersed islet cells from them, and eventually separate and purify β cells from other islet cell types. Numerous investigators have attempted, therefore, to establish an insulin-secreting cell line that retains normal regulation of insulin secretion. As previously reviewed,[56,57] different approaches have been used, including induction of pancreatic tumors by irradiation or viral infection, immortalization of β cells *in vitro*, and development of transgenic mice with targeted expression of a recombinant oncogene in the β cell. The success of these attempts was limited because cell differentiation and proliferation capacities are, as a rule, mutually exclusive.

The following information refers to the most commonly used tumoral insulin-producing cell lines

RINm5F Cell Line RIN lines were derived from a transplantable islet-cell tumor, itself induced by high-dose irradiation in an inbred NEDH (New England Deaconess Hospital) rat strain.[58] Two lines (RIN-r and RIN-m) were derived from the initial tumor. An RIN-m5F subclone, derived from the RIN-m line, was selected for further studies based mainly on its relatively high insulin secretion rate. The RIN-m5F line exhibits only a modest secretory response to D-glucose and this mainly in a low range of hexose concentrations.[59]

INS-1 Cell Line Another widely used cell line for insulin secretion studies is the INS-1 cell line. It was established from the original radiation-induced tumor described above by growing the tumor material in the presence of 2-mercaptoethanol.[60] This INS-1 cell line yields a steady increase of insulin release in the 0–11.2 mM D-glucose concentration range.

HIT-T15 Cell Line The HIT-T15 cell line was obtained by subcloning one of the original cell lines derived from isolated Syrian hamster pancreatic cells that had been transformed by infection with simian virus 40.[61] This HIT-T15 cell line was selected for its high insulin content.

βTC6 Cell Line The βTC class of insulinoma cell lines was established from transgenic mice by targeted expression of the SV40 large T-antigen in β cells, under the control of the rat insulin II promoter. The first cell lines established from the insulinomas developed in these mice (βTC1, βTC2) displayed a maximal secretory response to D-glucose at a 1.25 mM control concentration of the hexose. Further cell lines (βCT3, βCT6) exhibited a half normal response to the sugar at 0.5 mM D-glucose.[62]

MIN6 Cell Line The MIN6 cell line was obtained by a procedure similar to that used for the engineering of βTC lines. It initially exhibited a secretory response to D-glucose over a range of concentrations of the hexose and with a magnitude similar to that of normal islet cells.[63] However, MIN6 cells were found to lose these attributes with time of culture.

BRIN-BD11 Cell Line The BRIN-BD11 cell line was established by electrofusion of normal pancreatic cells from NEDH rats with immortalized RINm5F cells. They are currently used in several investigations dealing, for instance, with the process of so-called β cell glucotoxicity.[64]

The present list is not exhaustive. For instance, further cell lines (e.g., NIT-1 and βHC line) and subclones of the βTC6 and INS-1 cell lines were also investigated. Attempts at preparation and stable propagation of human β cells lines have met so far with only limited success.

Although an uncommon procedure, it could be proposed that the selection of a given insulin-producing cell line may require comparison between distinct cell lines according to the very experimental device selected for the purpose of the projected investigations. To cite only one example, in a recent study dealing with the stimulus-secretion coupling of hypotonicity induced insulin release, pilot experiments were conducted in MIN6, INS-

1, and BRIN-BD11 cells. The relative magnitude of the increment in insulin output caused by extracellular hypoosmolarity was much greater in the latter cells, the only ones in which the secretory response to hypotonicity was also modulated by the extracellular concentration of D-glucose. Hence, the BRIN-BD11 cells were eventually selected for further investigations on this issue (R. Beauwens *et al.*, unpublished observations).

OTHER PANCREATIC ENDOCRINE CELL LINES Glucagon-producing α-cell-derived lines are also available, inter alia, from the Endocrine Pancreas Transcription Regulatory Regions Database (EP-TRRD). They include α-TC1 (mouse), α-Tc6 (mouse), AN 697 (rat), and MSL-GAN (rat) cell lines or glucagonoma cells (Takaki). Incidentally, glucagon storage, release, and degradation could also be investigated in tumoral insulin-producing cells of the RINm5F line.[65] Both the qualitative and quantitative aspects of these processes differed vastly, however, from those previously characterized in normal islet cells, so that the tumoral cells were eventually considered as a model of dysfunction rather than normal function of glucagon-producing cells.

Last, somatostatin-secreting cell lines were also established, e.g., from a human pancreatic islet cell carcinoma.[66] Secretion of somatostatin from these cells could be stimulated at a high extracellular K+ concentration (50 mM) and by theophylline (10 mM). They were considered, therefore, as useful for studying the regulatory mechanism of somatostatin secretion.

CONCLUSIONS

This chapter illustrated the considerable variety of animal models and animal cells presently available in the field of experimental diabetology. Such a snapshot should not obscure the tremendous contributions of scientists in this field, whether in the past, the present, and, for sure, the future.

68 Animal Models of Kidney Diseases

CHUNSUN DAI, LAWRENCE P. KISS, AND YOUHUA LIU

ABSTRACT

Kidney diseases can be devastating illnesses with a high morbidity and mortality. The incidence of end-stage renal failure is increasing at a rate of 6–8% annually worldwide. Animal models are essential for understanding the pathogenetic mechanisms governing the onset and progression of various kidney diseases and for preclinically testing novel, more effective, treatments for the patients afflicted with renal impairment. Despite the presence of several nonrodent models, rats and mice remain principal and indispensable species used by investigators in the field of nephrology. In this chapter, we provide a concise review of the most commonly used kidney disease models. Emphasis is placed on several well-established models, such as the ischemic/reperfusion acute renal failure model, remnant kidney model, and unilateral ureteral obstruction model. Undoubtedly, establishment of authentic animal models is of vital importance in delineating the mechanisms of a range of human kidney diseases and in evaluating the feasibility and efficacy of novel therapeutic interventions.

Key Words: Acute renal failure, Chronic kidney disease, Renal fibrosis, Ischemia/reperfusion, Diabetic nephropathy, Unilateral ureter obstruction, Remnant kidney.

INTRODUCTION

Despite significant improvements in patient management, kidney diseases are still devastating illnesses with a high rate of morbidity and mortality worldwide.[1–4] Understanding the pathogenetic mechanisms of kidney dysfunction is of fundamental importance in finding new and effective treatments for patients afflicted with renal disease.[5–7] For this goal, animal models have proven extremely valuable when investigating the pathogenesis of kidney diseases and in evaluating the efficacy of novel therapeutic strategies. In the past decades, many rodent and nonrodent models have been created and used by investigators in the field of nephrology. Due to easy genetic manipulations, nonrodent models, such as the worm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster,* and the zebrafish *Danio rerio*, are very useful for studying fundamental renal biology such as embryonic and organ development.[8] However, rodent models remain essential tools that are widely employed by nephrological investigators.[9,10]

Both mice and rats have their advantages and disadvantages when creating kidney disease models. It is easier to perform surgical procedures and to collect samples from rats; additionally, rat models are usually able to faithfully recapitulate the major pathological manifestations of human kidney diseases, whereas mice are notorious for resistance to development of clinical lesions after injury.[11] However, as genetically modified mice are increasingly available, the unique transgenic or knockout mouse models provide us with an unprecedented opportunity to study the role of a particular gene in normal renal physiology as well as in the development of kidney diseases.[12] In this regard, it seems inevitable that more and more nephrological studies will be carried out in mouse models in the future. It should be noted that different strains and genetic makeup of the same species often display tremendous heterogeneity in developing renal lesions after injury.[13,14] Likewise, different genders have shown a drastic variation in susceptibility to an identical manipulation, often with males more prone to renal injury.[15,16] Therefore, several critical factors, such as animal species, strain, gender, age, and body weight, may play a decisive role in determining the outcome of a particular experiment. In this chapter, we provide a concise review of the most commonly used kidney disease models.

ACUTE RENAL FAILURE MODELS

Acute renal failure (ARF) is characterized by a rapid loss of renal function due to acute, and often severe, damage to the kidney. It is often caused by acute tubular necrosis (ATN), a term widely used in clinical practice. ARF affects as many as 20% of patients in the intensive care unit (ICU) and imposes a high mortality rate of ~50%.[17] The pathogenesis of ARF is very complicated. Ischemia, toxins, or sepsis alone or in combination could be involved in the onset and progression of ARF in clinical patients.[18] For this reason it is extremely difficult to create an ARF model that exactly stimulate the clinical findings. Based on the major causes of clinical ARF, three types of rodent models have been developed: ischemic/reperfusion, toxins, and sepsis-induced ARF.

ISCHEMIC ACUTE RENAL FAILURE MODELS Four types of ischemic models have been reported: warm ischemia–reperfusion (I/R), cold ischemia–warm reperfusion, isolated kidney with perfusion, and contrast nephropathy.[19] Here we discuss only the warm I/R model, which is the most widely utilized in both mice and rats. In rats, 1 day after I/R, serum creatinine increases significantly. Hypoxic tubular injury usually occurs in the S3 segments of the proximal tubule and in the medullary thick ascending limbs (MTAL) of the outer medulla and medullary rays. The kidneys exhibit obvious tubular atrophy and dilation, accom-

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

panied by interstitial inflammation.[20,21] The procedure of I/R is as follows. After placing the rat on a heating pad to maintain its body temperature during surgery, a laparotomy is performed and the renal pedicle is isolated by blunt dissection. Both of the renal vascular pedicles are clamped with surgical clips. The occlusion of blood flow should be confirmed by visually observing blanching of the kidneys. After 30–60 min, the clamps are released and the kidney should be reperfused in 1 min. The duration of ischemia should be optimized according to the age, gender, and genetic background. During the ischemic period, body temperature control is also very important; animals should be kept at about 37°C on a heating pad to avoid renal protective effects induced by low body temperature.

In mice the I/R procedure is similar to that in rats. Males are more susceptible to I/R injury compared to females.[15] Mouse serum creatinine and blood urea nitrogen (BUN) levels reach peak at 24–48 h after I/R.[22] The outer stripe of the medulla is the major site of injury to the kidneys during I/R. Pathological findings include loss of the proximal tubular brush border, the presence of cellular debris and casts, medullary congestion, inflammatory response, and proximal tubular cell apoptosis. Activation of caspases and endonucleases and tubular cell apoptosis have been documented in the development of ischemic ARF.[23,24] Apoptotic cells can be identified in various segments of the renal tubule.[25] Kidney function starts to recover within 2–3 days. In contrast to I/R insult, human ARF is most commonly caused by hypoperfusion. Given the obvious differences between the complete occlusion of the renal artery in animals and the complicated clinical conditions in human ARF, the I/R model appears not to replicate the human situation exactly. In this regard, care should be taken when interpreting the results obtained from this animal model.

TOXIC ACUTE RENAL FAILURE MODELS Many commonly used medications, such as gentamycin and cisplatin, can act as toxins and induce ATN-related ARF. Many toxins have been used in animal models to cause ARF.

Cisplatin-Induced Acute Renal Failure Cisplatin is a chemotherapeutic agent widely used to treat a large number of carcinomas in humans. Administration of a high dose of cisplatin often leads to renal toxicity, a severe side effect that limits its clinical use in cancer patients. In rodents, a single dose of cisplatin at 20~40 mg/kg body weight (for mice) or 7 mg/kg (for rats) by intraperitoneal injection can induce ARF.[26] In mice, cisplatin-induced injury is usually associated with tubular necrosis, predominantly in the S3 segments of the proximal tubules, manifested by cast formation, loss of tubular brush border membranes, and dilation of tubules. Kidney failure starts at day 2 and reaches a maximum at day 3 to 4, depending on the doses. Contrary to the ischemia model, females are much more susceptible to injury induced by cisplatin than their male counterparts.[15] This model is quite simple and reproducible. The tubular dysfunction and disease recovery phase is comparable to that found in humans. The mechanisms of cisplatin-induced nephrotoxicity remains largely unknown. Several mechanisms including oxidant stress, inflammation, genotoxic damage, and cell cycle arrest may account for its nephrotoxicity.

Folic Acid-Induced Acute Renal Failure An intravenous injection of high dose folic acid (FA) can induce ARF in mice or rats, which is associated with a rapid decline of renal function, tubular epithelial cell death, morphological abnormalities, and the appearance of FA crystals in renal tubules.[27,28] Mice display a rapid and marked increase in serum creatinine as early as day 1, which remains significantly elevated at least to day 3 after injection of FA (Figure 68–1). The serum creatinine level declines

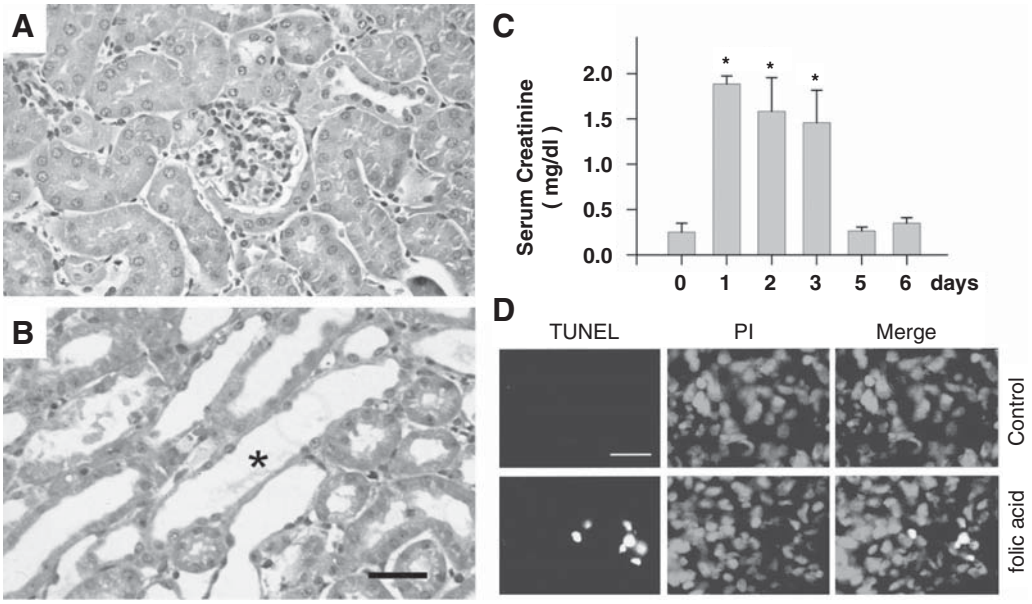

Figure 68–1. Folic acid induces acute renal failure (ARF) in mice. (A, B) Representative micrographs show kidney morphology at day 1 after folic acid injection. (A) Normal control; (B) folic acid. (C) Serum creatinine levels at different time points after folic acid injection. Data are presented as mean ± SEM from six animals per group at each time point. *$p < 0.05$. (D) Representative micrographs show apoptosis detected by *in situ* terminal deoxynucleotidyltransferase-mediated dUTP nick-end labeling (TUNEL) staining. Left panel, apoptosis-positive cells detected by use of TUNEL. Central panel, propidium iodide (PI) staining shows cell nuclei. Right panel, merge of the TUNEL and PI staining. Scale bar, 20 μm. (Adapted and modified from Dai *et al.*[29])

toward baseline thereafter. Kidney morphology typically reveals tubular cast formation, dilation, loss of brush borders, tubular epithelial cell necrosis and apoptosis, and interstitial infiltration (Figure 68–1). These pathological findings are comparable with human ARF. An increase in proliferating cell nuclear antigen (PCNA) expression, which peaks at day 2 after FA injection, can be detected. This suggests active cell cycle progression and, presumably, cell proliferation in the kidneys during the tubular repair and regeneration phase.[29] FA is administrated by a single intravenous or intraperitoneal injection at a dose of 250 mg/kg body weight in male mice or rats.[29,30] The mechanism of FA-induced ARF is believed to be associated with the upregulation of tumor necrosis factor (TNF)-α and is also related to the microcrystal formation within tubules. We have shown that FA causes a marked reduction in the expression of the prosurvival protein Bcl-xL in the kidneys, which could be an important mechanism underlying tubular epithelial cell death in this model.[29]

Gentamycin-Induced Acute Renal Failure Gentamycin, an aminoglycoside antibiotic, has been successfully used in the treatment of gram-negative bacterial infections. Due to its severe nephrotoxicity, it has become a widely used reagent to induce ARF in rodents. Gentamycin can be injected at 80–100 mg/kg by an intramuscular, subcutaneous, or intraperitoneal route daily for 6 days. After several injections, severe damage can be found in the cortex, including tubular necrosis, tubular dilation, accumulation of protein casts, and loss of the brush border.[31] In proximal tubular cells, myeloid bodies, a characteristic morphological feature of getamycin nephrotoxicity in human, can be found. Rats are more suitable for the studies of gentamycin nephrotoxicity than mice. The exact mechanisms of the gentamycin nephrotoxicity remain elusive, but they could be related to enhanced generation of reactive oxygen species in the kidney.

Pigment Nephropathy Administration of glycerol is another reliable method to induce ARF in rats or mice.[32] This disease model is very severe, accompanied by intravascular hemolysis and myoglobinemia. These pathological lesions are similar to ARF in humans induced by rhabdomyolysis and/or intravascular hemolysis.[33] Kidney dysfunction, as measured by an increased BUN, serum creatinine, and *N*-acetyl-β-glucosaminidase, can be found as early as 6 h after glycerol injection. The procedure of this model is very simple, with intramuscular injection of 50% glycerol at 8–10 ml/kg body weight. Glycerol should be administered through a deep intramuscular injection equally distributed to both hind legs. The tubular damage is caused by a combination of dehydration, toxic proximal tubular cell damage, vasoconstriction, renal inflammation, and tubular obstruction by casts.[34]

SEPSIS ACUTE RENAL FAILURE MODELS Gram-negative sepsis and septic shock-induced kidney failure is the most common cause of clinical ARF. The pathophysiological features of sepsis are high cardiac output and low systemic vascular resistance.[35] It is believed that a combination of immune, toxic, and hemodynamic conditions leads to ARF in septic patients.[36] Lipopolysaccharide (LPS), a major component of gram-negative bacteria, induces systemic upregulation of TNF-α and interleukin (IL)-1, and generates nitric oxide (NO) produced by inducible NO synthase. These in turn can directly or indirectly lead to systemic hypotension and tubular necrosis.[36] Four types of sepsis models have been reported: endotoxin infusion, intravenous bacterial infusion, cecal ligation and perforation, and intraperitoneal infusion of bacteria. Endotoxin-induced ARF is relatively simple. LPS can be given at 100 μg/kg body weight (for rats) by tail vein injection[37] or at a higher dose of 2 mg/kg (for mice) by intraperitoneal injection.[38] Kidney dysfunction and tubular epithelial cell death can be found at 24 h after LPS injection.

CHRONIC KIDNEY DISEASE MODELS

Chronic kidney disease (CKD) is a group of renal disorders with a wide variety of etiologies. The pathogenesis of CKD is a progressive process that eventually leads to end-stage renal failure (ESRF), a devastating condition that necessitates patient dependence on life-long treatments with dialysis or renal transplantation.[5] The number of patients with ESRF is growing at a rate of 6–8% annually worldwide, with the financial burden of health care costs becoming increasingly unaffordable.[2–4] In this context, it is important to characterize the mechanisms and the factors responsible for CKD progression and to identify and evaluate novel and effective renoprotective strategies. Clearly, animal models of CKD are essential in these efforts.

DIABETIC NEPHROPATHY Diabetic nephropathy (DN) is the single most important cause of CKD and accounts for 40% of the patient population with ESRF. The pathogenesis of DN is characterized by persistent albuminuria and an accumulation of extracellular matrix (ECM) that leads to glomerulosclerosis, tubulointerstitial fibrosis, and progressive loss of renal function.[39,40] Thus far, a DN animal model with typical pathological findings has not been documented.[41] All currently used DN models have some of the early DN features, including albuminuria, glomerular hypertrophy, and mild to moderate mesangial ECM deposition. However, little or no glomerular sclerosis and/or renal failure exactly mimicking human DN has been reported.

Streptozotocin (STZ) is used to induce hyperglycemia by destroying pancreatic β cells in both mice and rats, which imitates type I diabetes in humans.[42] There are two different administration methods: a high dose with a single injection or small doses with multiple intraperitoneal injections. It is believed that a single high dose of STZ can directly damage the islet β cells, leading to necrosis or apoptosis, whereas multiple small doses of STZ could induce the animal's autoimmunity to β cells. Both methods can induce islet β cell dysfunction and hyperglycemia. For the high-dose STZ protocol, rats are intravenously injected with STZ at 60 mg/kg body weight, and diabetes is typically induced at 3–5 days after injection. Insulin is sometimes used to maintain an appropriate blood glucose level. For the small-dose protocol, rats are intraperitoneally injected with STZ at 20–30 mg/kg body weight daily; elevated blood glucose is usually detectable after four or five injections. The blood glucose level may keep increasing and reach a peak 1 month after the last injection. Diabetic rats with long-term moderate hyperglycemia, however, do not develop characteristic glomerular lesions of human DN and, in fact, develop minimal glomerular injury only after 1 year of diabetes. This suggests that diabetic rats with moderate hyperglycemia can be used as an appropriate model only for early DN.[43–45] STZ can also induce diabetes in mice; however, the dose of STZ used is higher than that in rats. Usually, a single intravenous injection of STZ at 150–200 mg/kg can induce diabetes. Daily intraperitoneal injection at 40–50 mg/kg for 5 days is an alternate approach. Hyperglycemia often occurs within 2 weeks following low-dose STZ injections, and albuminuria develops in 5 weeks after diabetes is induced. Glomerular hypertrophy and mesangial expansion typically develop as the disease progresses.

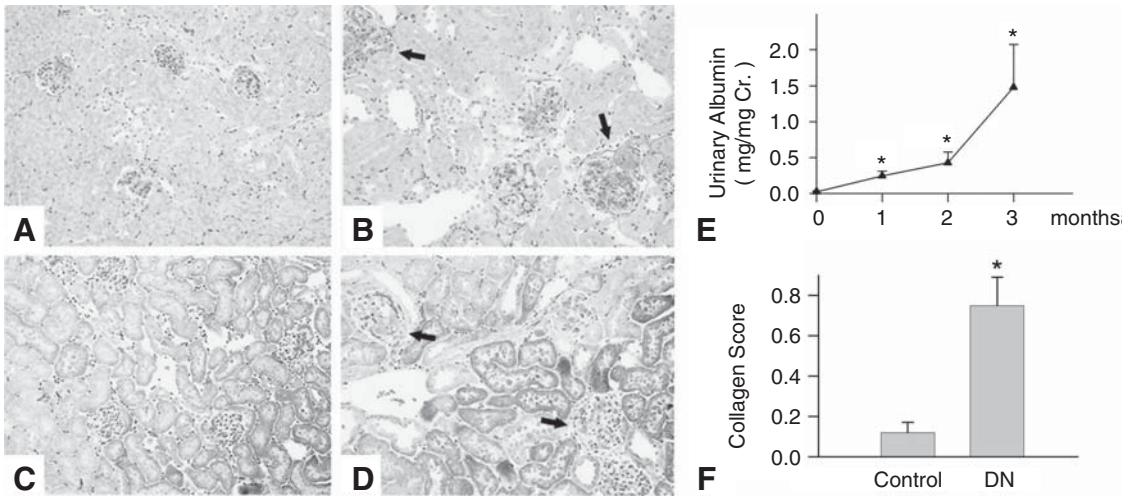

Figure 68–2. Diabetic nephropathy induced by streptozotocin (STZ) in uninephrectomized mice. One week after uninephrectomy, male CD1 mice received an intravenous injection of STZ. (A–D) Representative micrographs demonstrate glomerular enlargement, mesangial expansion, and segmental glomerulosclerosis (periodic acid–Schiff staining; A, B) and glomerular collagen deposition (Masson–Trichrome staining; C, D). (A and C) Normal control; (B and D) diabetic mice. Arrows indicate injured glomeruli. (E) Albuminuria develops in diabetic mice in a time-dependent manner. Data are presented as means ±SEM. *$p < 0.05$. (F) Glomerular collagen deposition score in diabetic and normal mice. *$p < 0.05$. (Adapted and modified from Dai *et al.*[46]) (See color insert.)

To accelerate the progression of DN, we recently reduced renal mass by unilateral nephrectomy (UNx), followed by a single intravenous injection of STZ at 150 mg/kg in male CD-1 mice.[46] Diabetic kidneys at 4 and 12 weeks after injection of STZ display a marked enlargement in size, but serum creatinine levels increase only slightly in diabetic mice at 12 weeks after STZ, when the urine albumin level reaches 1.5 mg/mg creatinine (Figure 68–2). Diabetic glomeruli exhibit an expanded mesangial area and narrowed capillary lumen, as well as an increased collagen deposition at 12 weeks (Figure 68–2). However, only three of six mice show focal and segmental glomerulosclerosis (FSGS) in 1–4% of the glomeruli (Figure 68–2).

The susceptibility of the mice to diabetes and DN is drastically different among various strains.[14,47] Males often display more robust hyperglycemia with STZ than females. It is well known that C57BL/6J is more resistant to DN than other strains. However, C57BLKS/J is more susceptible to renal lesions than C57BL/6. 129/SvJ is more susceptible to glomerulosclerosis, but this strain of mice is resistant to hyperglycemia.

Of the genetic mouse models of diabetes, *db*/*db* mice are the best characterized and widely used to study the progression of DN. The *db/db* mice in a C57BLKS/J background are considered a genetic DN model, with many features similar to human type II diabetes.[48] Compared to nondiabetic *db/m* mice, *db/db* mice develop hyperinsulinemia by 10 days of age and marked obesity and severe hyperglycemia by 10 weeks. The blood glucose level is ~300 and 500 mg/dl at the age of 8 and 25 weeks, respectively, in *db/db* mice, indicating an advanced diabetic state. Increased urinary albumin excretion is found in *db/db* mice and it reaches ~550 µg/24 h at 25 weeks. These mice also develop glomerular mesangial expansion and histological lesions that resemble those found in human DN. In *db/db* mice the animals display kidney hypertrophy and enlarged glomerular size, and increased fibronectin and type IV collagen accumulation in glomerular mesangium.[49,50] There is no evidence of tubular atrophy or tubulointerstitial fibrosis.

REMNANT KIDNEY MODEL Renal mass ablation is a classic approach to induce glomerular injury and tubulointerstitial lesions. The remnant kidney model after 5/6 nephrectomy, also known as subtotal nephrectomy (SNX), is the most widely used and arguably the best model of CKD that mimics many features of human diseases.[51] The kidney advances through three histological stages after SNX: phase 1, kidney hypertrophy appears at 2–4 weeks after surgery; phase 2, detectable changes of the residual renal tissue occur up to 10 weeks; and phase 3, glomerular sclerosis and interstitial fibrosis become apparent 10 weeks after SNX. The procedures of renal mass ablation are as follows.[52] After the abdominal cavity is opened with a dorsal incision, the right kidney is freed, decapsulated, ligated at the renal hilus, and finally removed. Seven days later, the cortex of the left kidney is ablated by ligation of the poles or the branches of the renal artery or by resection of the poles of the kidney while protecting the adrenal glands during the surgery. The strain (Wistar and Sprague–Dawley rats) and gender may influence the functional and morphological consequences of the remnant kidney model. After SNX, rats develop proteinuria at 4 weeks, which increases up to 10 weeks in females and males of both strains. The glomerular filtration rate (GFR) is significantly reduced after SNX, which is nearly independent of animal strain, gender, and operation protocol. At 10 weeks after surgery, rats develop moderate interstitial fibrosis with reactive lymphocytic infiltrates and progressive tubular atrophy.

In mice, a two-step procedure is also used to create uremia.[53] Briefly, cortical electrocautery is applied to the right kidney through a 2-cm flank incision and a left total nephrectomy is performed through a similar incision 2 weeks later. At 6 weeks after surgery, BUN levels increase by 225% above baseline and tend

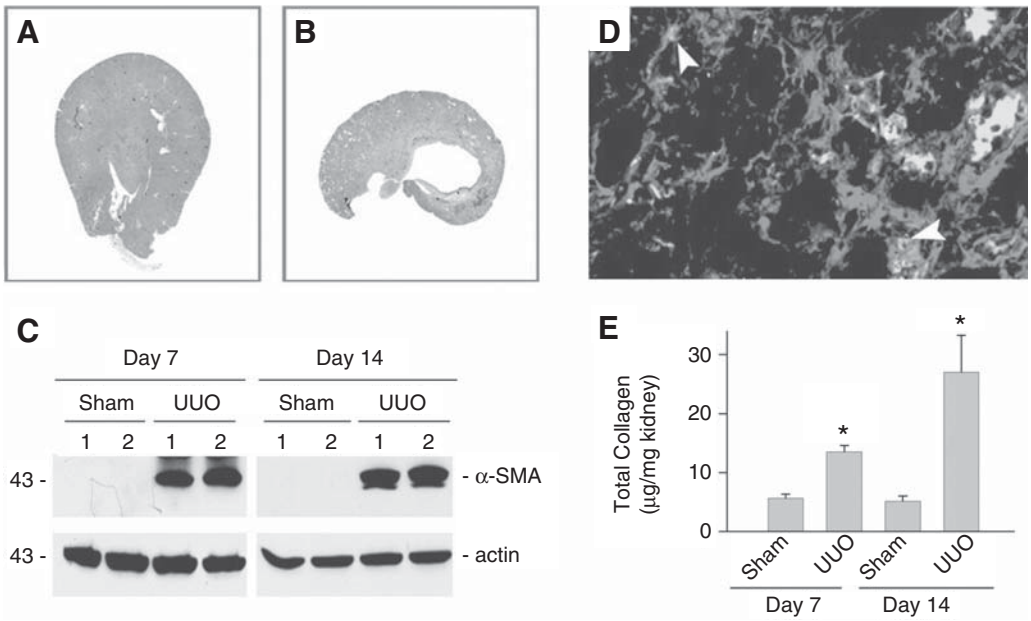

Figure 68–3. Interstitial fibrosis in the mouse model of obstructive nephropathy. (A, B) Representative micrographs show the cross sections and gross morphology of the obstructed kidneys at day 14 after ureteral ligation. (A) Sham control; (B) UUO. (C) Western blot analyses demonstrate a marked induction of α-smooth muscle actin (α-SMA), a molecular marker for myofibroblasts, in the obstructed kidney at day 14 after UUO. (D) Double immunofluorescence staining shows the α-SMA (red) and proximal tubular epithelial cell marker, fluorescein isothiocyanate (FITC)-conjugated lectin from *Tetragonolobus purpureas* (green). (E) Quantitative determination of total kidney collagen contents in sham and obstructed kidneys. Data are presented as means ±SEM. $*p < 0.01$. (Adapted and modified from Yang *et al.*[59]) (See color insert.)

to be stable, with minimal variations during the 6-week period. Uremic animals have high serum levels of calcium, phosphate, and parathyroid hormone. A model with 75% renal mass reduction in mice as a single-step procedure has also been reported.[54] Before removing the right kidney, the contralateral kidney is partially infarcted by ligating the anterior renal branch of its main artery. Histological examination of the remaining kidneys reveals progressive changes. From 1 to 12 months postsurgery, the major alterations are mesangial expansion, the presence of hyalinosis, particularly on the afferent arterioles, and the presence of some protein casts in the tubules. Segmental sclerosis is observed in some mice at 2 months after surgery. At 12 months, severe mesangial expansion, focal segmental sclerosis, hyalinosis, and protein casts in the tubules are evident.

UNILATERAL URETER OBSTRUCTION In infants and children, obstructive nephropathy is the leading cause of chronic renal failure. In older patients between 60 and 65 years old the incidence of obstructive nephrology increases again overall, particularly in men, due to the prevalence of prostate disease. Kidney histology reveals tubular atrophy and interstitial fibrosis after ureter obstruction.[55,56]

Many animal models of urinary tract obstruction have been developed, including studies of fetal sheep and neonatal rats and mice.[57] A model with complete unilateral ureteral obstruction (UUO) performed either in rats or mice has been well established and is widely used currently.[12] This model of fibrosis is characterized by renal myofibroblast activation, tubular atrophy, and interstitial fibrosis with minimal glomerular lesions. In male CD-1 mice, the obstructed kidneys display marked activation of myofibroblasts at 7 days after surgery, characterized by a dramatic increase in the abundance of α-smooth muscle actin (α-SMA) (Figure 68–3). Colocalization of α-SMA and a proximal tubular cell marker suggests a tubular epithelial-to-mesenchymal transition (EMT) in this model.[58,59] After UUO, the obstructed kidneys displayed a marked increase in transform growth factor (TGF)-β1 and its type I receptor expression at 7 days. Importantly, both TGF-β1 and its type I receptor expression are mainly upregulated in renal tubular epithelium in the diseased kidneys. One week after UUO, cellular infiltration, tubular proliferation and apoptosis, tubular EMT, myofibroblast accumulation, ECM deposition, and tubular atrophy are observable. These changes are highly predictable and reproducible, and also generally mimic the tubulointerstitial fibrosis in humans, particularly that seen in obstructive nephropathy. The disadvantage of the UUO model is that it is impossible to assess kidney dysfunction, since another kidney remains intact and appears sufficient to support normal renal function.

ADRIAMYCIN AND PUROMYCIN MODEL Puromycin, an aminonucleoside, and adriamycin (ADR), an antineoplastic antibiotic, can induce nephrotic syndrome in rats when delivered by intravenous injection.[10,60] A single dose of puromycin at 50 mg/kg body weight in rats can induce severe proteinuria within 10 days, followed by apparent resolution, and then with lower level proteinuria associated with early glomerular segmental sclerotic lesions. Rats usually develop glomerular segmental sclerosis by week 18. Multiple intraperitoneal injections of puromycin (at 10 mg/kg body weight for the first dose and additional 40 mg/kg doses every 4 weeks) will accelerate the progression of disease. Intravenous ADR injection at 2 mg/kg twice with a 3-week interval leads to early phase proteinuria after the second injection.

Kidneys often develop widespread glomerulosclerosis with tubulointerstitial fibrosis by 24 weeks. A single injection of adriamycin at 5 mg/kg body weight produces proteinuria in 1 week.

ADR is also used in mice to induce podocyte dysfunction and proteinuria.[61,62] All male BALB/c mice treated with ADR at a dosage of 10.5 mg/kg body weight develop nephrotic syndrome, and progressive renal injury. Overt proteinuria appears at day 5 and is maximal at day 7. High levels of proteinuria are maintained after 1 week. Some mice develop hematuria (35.7%) or leukocyturia (53.6%). Histological examination reveals a focal increase in resorption droplets in tubular cells and intraluminal casts at weeks 1 and 2. At week 4, tubules display severe changes, including a decrease in height of tubular epithelial cells, a loss of brush borders, and vacuolization. There is a moderate interstitial monocyte infiltration. Glomeruli are reduced in size with several vacuoles, collapse of tufts, as well as expansion of the mesangium. At week 6, in the cortex, widespread tubular atrophy and intratubular cast formation with tubulointerstitial expansion are observed. Extensive focal glomerulosclerosis and severe interstitial fibrosis and inflammation are present. Male C57BL/6J mice do not develop any significant proteinuria or histological change, even at 8 weeks after ADR injection of 15 mg/kg body weight and die within 2 weeks of ADR injection at 20 mg/kg body weight. However, in our laboratory we treat mice with mixed genetic backgrounds including C57BL/6J with ADR at 25 mg/kg body weight by intravenous infusion. All mice develop prominent albuminuria by day 3 after injection, although some mice begin to die at day 5. Immunofluorescence staining reveals that nephrin and CD2AP protein abundance are reduced after ADR administration.

CYCLOSPORINE NEPHROPATHY Cyclosporine (CsA) is an immunosuppressive agent that is used clinically in organ transplantation. However, its ability to induce acute and chronic nephrotoxicity in humans limits its usage in clinical settings. CsA was first found to induce kidney dysfunction in rodents on a low salt diet. When rats are on a salt-depleted diet, CsA administration through daily subcutaneous injection at 15 mg/kg body weight induces a striped pattern of tubulointerstitial fibrosis, tubular atrophy, and afferent arteriolar hyalinosis with renal failure at 4 weeks after injection.[63] Khan *et al*. also report that CsA given orally (50 mg/kg body weight, daily) for 14 days induces kidney dysfunction characterized by elevated serum creatinine, severe isometric vacuolization, and widening of the interstitium in male Wistar rats.[64]

PROTEIN OVERLOAD PROTEINURIA Proteinuria is the most common sign of CKD and is increased along disease progression. Filtered protein may upregulate the genes encoding vasoactive and inflammatory mediators in tubular cells, thereby exerting their detrimental effects. The protocol of protein overload is quite simple, with intraperitoneal injections of bovine serum albumin (BSA) (low endotoxin) at 2 g/day, 6 times a week, for 3 consecutive weeks in rats.[65] Kidney disease gets worse when accompanied by uninephrectomy.[66] Rats develop massive proteinuria, with mild focal glomerulosclerosis and focal areas of tubular dilation and fibrosis.

A protein overload model has also been developed in mice. Male and female C57BL/6J and 129S2/Sv mice receive increasing BSA (from 2 g/kg to 10 g/kg body weight) for 11 days. Male (but not female) C57BL/6J mice develop proteinuria. In 129S2/Sv mice, proteinuria is evident in both males and females.[67] In another protocol, mice with a mixed gene background of C57BL/6 and 129/J undergo uninephrectomy, followed by BSA injection at 10 g/kg body weight, 5 days per week, for 11 weeks. Mice develop marked glomerulosclerosis, interstitial inflammation, and tubulointerstitial injury.[67]

CONCLUSIONS

Experimental animal models are indispensable for delineating the pathogenetic mechanisms of kidney diseases and for evaluating the efficacy of various potential renoprotective strategies. Although many animal models are well established and widely used, thus far no animal model can exactly replicate the pathogenesis of various kidney diseases in humans. Therefore, faithfully modeling human renal pathogenic processes in animals continues to be a challenge in renal medicine. Novel experimental approaches, as exemplified by combining renal mass ablation and STZ-induced hyperglycemia, may generate a unique model that mimics the major pathological findings of human CKD. In addition, nonrodent models could be enormously valuable, as demonstrated by the recent observation that cisplatin also induces typical histological changes and a decline in renal function in larval zebrafish; this could be a possible unique model, amenable to both genetic manipulation and high-throughput drug screening.[68] Furthermore, as transgenic and knockout mice are increasingly available, there is an unparalleled opportunity for exploring the mechanisms of a particular gene in a range of kidney diseases. It is hoped that establishment of authentic animal models of human kidney diseases will facilitate the preclinical testing of novel therapeutic interventions, thereby ultimately benefiting patients with various kidney disorders.

69 Animal Models of Multiple Sclerosis

COLIN R. YOUNG AND C. JANE WELSH

ABSTRACT

To determine whether an immunological or pharmaceutical product has potential for therapy in treating multiple sclerosis (MS), detailed animal models are required. To date many animal models for human MS have been described in mice, rats, rabbits, guinea pigs, marmosets, and rhesus monkeys. The most comprehensive studies have involved murine experimental allergic (or autoimmune) encephalomyelitis (EAE), Semliki Forest virus (SFV), mouse hepatitis virus (MHV), and Theiler's murine encephalomyelitis virus (TMEV). Here, we describe in detail multispecies animal models of human MS, namely EAE, SFV, MHV, and TMEV, in addition to chemically induced demyelination. The validity and applicability of each of these models are critically evaluated.

Key Words: Multiple sclerosis, Experimental autoimmune encephalomyelitis, Semliki Forest virus, Mouse hepatitis virus, Theiler's murine encephalomyelitis virus.

INTRODUCTION

Multiple sclerosis (MS) affects about 350,000 people in the United States and is a major cause of nervous system disability in adults between the ages of 15 and 45 years. The symptoms are diverse, ranging from tremor, nystagmus, paralysis, and disturbances in speech and vision. Extensive demyelination is seen in the neuronal lesions. The clinical heterogeneity of MS, as well as the finding of different pathological patterns, suggests that MS may be a spectrum of diseases that may represent different pathological processes.[1] This has led to the development of many different animal models, including rodents and nonhuman primates, that reflect the pathological processes and could allow for the development of therapeutic approaches. At the present time, the exact etiological mechanism in humans is not clear; however, several animal models are available providing insight into disease processes. The relative inaccessibility and sensitivity of the central nervous system (CNS) in humans preclude studies on disease pathogenesis, and so much of our understanding of infections and immune responses has been derived from experimental animal models. The experimental systems include Theiler's virus, mouse hepatitis virus, and Semliki Forest virus infections of laboratory rodents. Additional information has been obtained from studies of experimental infections of other animals that result in demyelination, notably maedi-visna virus in sheep and canine distemper virus in dogs. In humans and animals, most natural cases of demyelinating disease are rare complications of viral infections. One possible reason for the low incidence of demyelination following viral infections could be the low efficiency of neuroinvasion. However, a correlation between CNS infection and clinical disease is difficult to determine.

The role of genetics and environmental factors in MS is complex. Factors such as geographical location, ethnic background, and clustering in temperate climates all contribute to susceptibility. Individuals with a North European heritage are statistically more susceptible to MS than those from a more tropical environment and it is more common in women.[2] Epidemiological data indicate that MS is not a single-gene disorder and that additionally environmental factors contribute to the disease.[3] Data from genetic studies indicate that although MHC genes clearly contribute to disease susceptibility and/or resistance, it is probable that a combination of environmental factors may additionally contribute to disease development in genetically predisposed individuals.

To understand the initiating factors and progression of MS, researchers have turned to experimental model systems. Since this disease cannot be recreated in a tissue culture system, much effort has been directed to the use of laboratory animals. Those animal models should mirror the clinical and pathological findings observed in human MS. Ideally, the animal model should be in a species that is easy to handle, inexpensive, can be kept in large numbers, and is easily bred in laboratory conditions. The most frequently used animals are laboratory rodents, including mice, rats, guinea pigs, and hamsters. One of the most useful aspects of laboratory rodents as animal models of disease is the vast array of inbred strains of the species available, most notably in experimental mice. Additionally, very valuable information has been obtained from studies using larger animals including sheep, dogs, cats, and nonhuman primates.

Models of MS fall into two main groups: viral and nonviral. Viral models are immensely relevant since epidemiological studies suggest an environmental factor, and almost all naturally occurring CNS demyelinating diseases of humans and animals of known etiology are caused by a virus. These include in humans, subacute sclerosing panencephalitis (SSPE)—caused by measles or rubella viruses, progressive multifocal leukoencephalopathy (PML)—caused by JC virus, and human T lymphotrophic virus-1

(HTLV-1)-associated myelopathy (HAM)—caused by HTLV-1; in animals, these include visna virus in sheep and canine distemper in dogs. However, no one virus has consistently been associated with human MS, although it is likely that more than one virus could trigger the disease.

Of the nonviral models of MS, experimental allergic encephalomyelitis (EAE) is the most widely studied. EAE is characterized by inflammatory infiltrates in the CNS that can be associated with demyelinating lesions. In EAE, the disease is initiated by the extraneural injection of CNS material, or purified myelin components, emulsified in an adjuvant, the most commonly employed one being complete Freund's adjuvant containing *Mycobacterium tuberculosis* H37Ra. However, no naturally occurring autoimmune correlate of this experimental disease is known, although it is extensively researched as a model of MS, with the reasoning that MS may be such a disease.

The most widely studied models of MS are the experimental infections of rodents resulting in an inflammatory demyelinating disease in the CNS, such as Theiler's virus, mouse hepatitis virus, and Semliki Forest virus.[4] Each of these infections gives rise to lesions of mononuclear cell inflammatory demyelination throughout the brain and spinal cord but not in the peripheral nervous system. As such, this histopathology correlates with human MS, although it does not preclude the fact that the viruses could gain access to the CNS via the peripheral nervous system. These viral models demonstrate how a virus can easily reproduce CNS disease, which is comparatively rare in humans, and how this can be influenced by many factors including both genetic and immunological.

Experimental studies in induced animal models have the advantage over studies in spontaneous models in that the onset and progression of the disease can be controlled. Although it has been proposed that some autoimmune diseases may have a viral etiology, virus-induced autoimmunity is a controversial subject. Epidemiological studies of MS provide strong evidence for the involvement of a viral etiology in the onset of disease. Theiler's virus-induced demyelination, a model for human MS, bears several similarities to the human disease: an immune-mediated demyelination, involvement of $CD4^+$ helper T cells and $CD8^+$ cytotoxic T cells, delayed type hypersensitivity responses to viral antigens and autoantigens, and pathology. Indeed this mouse model may provide a scenario that closely resembles chronic progressive MS.

THEILER'S VIRUS-INDUCED DEMYELINATION

Theiler's murine encephalomyelitis virus (TMEV) is a picornavirus that causes an asymptomatic gastrointestinal infection, followed by occasional paralysis. There are two main strains of TMEV, the virulent strains and persistent Theiler's original (TO) strains. The virulent GDVII strains of Theiler's virus are highly neurovirulent and when injected intracranially, cause death by encephalitis within 48 h. GDVII strains also cause differing forms of paralysis depending on the route of inoculation (see Table 69–1). From these studies it appears that the GDVII virus may gain access to the CNS by retrograde axonal transport rather than by a hematogeneous route.[5]

Infection of susceptible strains of mice with the persistent TO strains BeAn, DA, WW, or Yale results in a primary demyelinating disease that closely resembles human MS.[6] Infection of resistant strains of mice with BeAn does not result in demyelinating disease, since these mice are able to clear virus from the CNS. Susceptible mice fail to clear virus from the CNS, possibly resulting from poor natural killer (NK) cell and cytotoxic T lymphocyte (CTL) responses. Persistent viral infection of the CNS is required for demyelination. Following the intracranial injection of susceptible mice with BeAn, virus replicates both in the brain and spinal cord.[7] One month postinfection, viral titers decrease, and high levels of neutralizing antibodies are detected (Figure 69–1). At this point in the disease, neurons may become infected with virus and mice may develop a nonprogressive flaccid paralysis of the forelimbs and/or hindlimbs.[8] This is sometimes referred to as a polio-like disease, but this is confusing since flaccid paralysis in mice infected with poliovirus is progressive and normally results in death. In the late phase of the disease, astrocytes, oligodendrocytes, and macrophage/microglial cells become infected with virus. Also in the demyelinating disease there is both B and T cell autoimmunity, directed against myelin and its antigenic components.

GENETICS OF PERSISTENT INFECTION AND DEMYELINATING DISEASE All inbred mouse strains inoculated intracerebrally with TMEV show early encephalomyelitis, but not all strains remain persistently infected. Resistant strains normally

Table 69–1
Specificity of paralysis due to routes of injection of Theiler's murine encephalomyelitis virus (TMEV)

Route of injection[a]	*Volume of virus*[b]	*pfu injected*[c]	*Paralysis, encephalitis, or mortality*[d]	*Days of paralysis*[e]
Intramuscular	100 µl	10^6 pfu	URLP/BRLP paralysis	2–4
Intragastric	100 µl	10^6 pfu	0%	0
Intravenous	100 µl	10^6 pfu	Fore/hindlimb paralysis 80%	6
Intraperitoneal	100 µl	10^6 pfu	Fore/hindlimb paralysis 100%	6
Intratongue	100 µl	10^6 pfu	Tongue paralysis 100%	4
Intracranial	10–20 µl	10^5 pfu	No paralysis, 100% mortality, 100% clinical encephalitis	0
Footpad	100 µl	10^6 pfu	Fore/hindlimb paralysis 100%	2–4

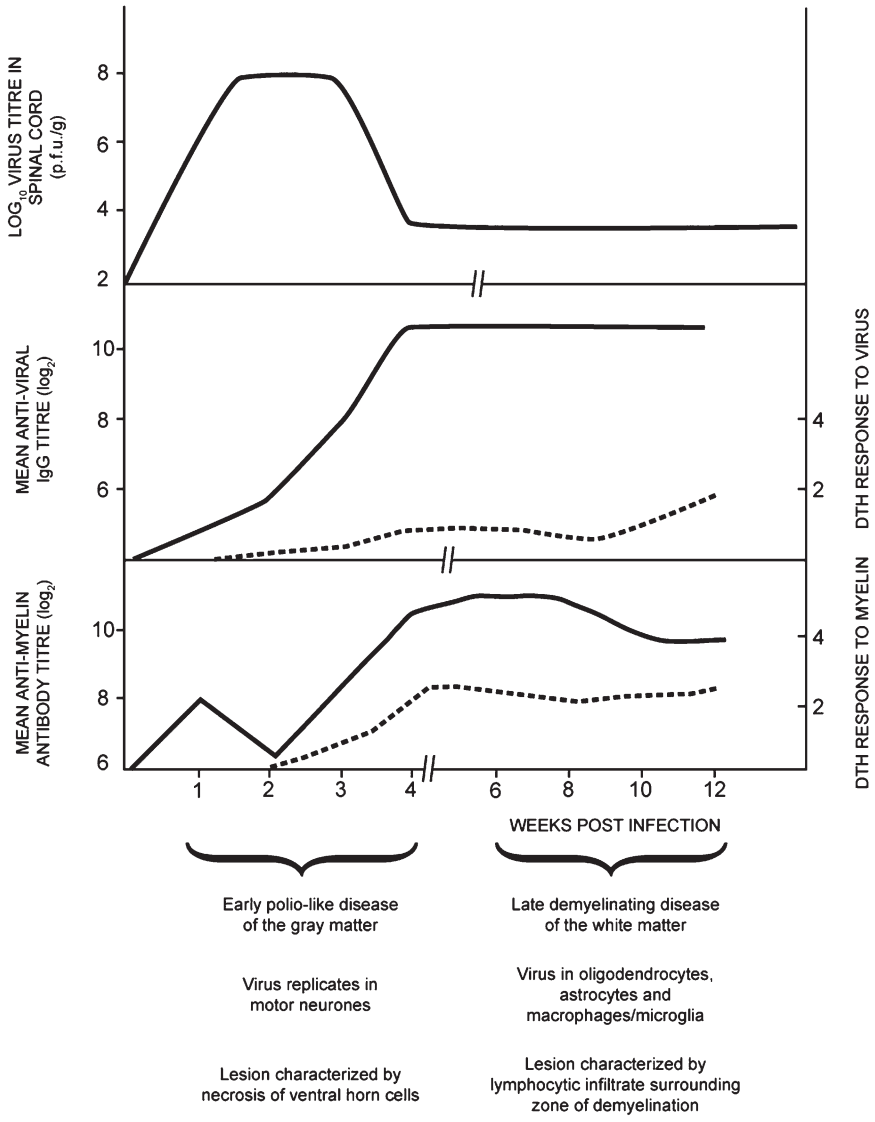

Figure 69-1. Disease course of Theiler's virus-induced demyelination in CBA mice. Intracerebral infection of CBA mice with 5×10^4 pfu of the BeAn strain of Theiler's virus results in high levels of virus in the spinal cord during the first month of infection (top panel). The CNS viral titers decrease at 4 weeks pi when neutralizing antiviral antibodies and viral T cell responses are detected (middle panel). During late disease, the virus is detected in astrocytes, oligodendrocytes, and macrophage/microglial cells and autoreactive T and B cell responses to myelin are detected in TMEV-infected mice (lower panel). clear the virus after 14 days, whereas susceptible strains remain persistently infected for life. Thus, susceptibility/resistance refers to the demyelinating late disease and not to the encephalomyelitis. CNS viral load during persistence varies among susceptible strains, making susceptibility a quantitative trait.[9] This trait is under multigenic control, with H-2 MHC class I genes being the most prominent. Additionally, several non-H-2 quantitative trait loci (QTL) have been identified within the same H-2 haplotypes that control persistence. There is generally a good correlation in inbred strains between susceptibility to three phenotypes (viral load, pathology, and symptoms), suggesting that variations in both demyelination and clinical disease may result from how each mouse strain can control the viral load during the persistent infection.[10] Using B10 congeneic and recombinant strains of mice, susceptibility to disease has been mapped to the H-2D region.[11] Furthermore, resistant haplotypes are dominant and the same locus controls viral load during persistence and demyelination. Currently, 11 non-H-2 susceptibility loci have been identified as having an effect on susceptibility to Theiler's virus-induced disease (TVID) (see Table 69–2).

The mechanism(s) of TVID may be different for different mouse strains, but most of the information has come from studies of SJL/J mice infected with the DA or BeAn strain of virus. The virus infects oligodendrocytes, and the resulting demyelinating disease could be due, in part, to the virus killing oligodendrocytes directly or by the virus-specific $CD8^+$ CTLs present in the lesions.[7]

Table 69–2
Non-H2 loci of susceptibility to Theiler's virus-induced disease

Locus	Chr	Location (cM)	Phenotype	Viral strain
Tmevd1	6	22	Clinical signs	BeAn
Tmevd2	3	46	Clinical signs	BeAn
Tmevd3	14	12.5	Demyelination	DA
Tmevd4	14	39.5	Demyelination	DA
Tmevd5	11	60	Clinical signs	DA
Tmevd6	1	19.5	Clinical signs	BeAn
Tmevd7	5	72	Clinical signs	BeAn
Tmevd8	15	4.7	Clinical signs	BeAn

A series of experiments has demonstrated that demyelination correlates with the presence of a $CD4^+$ T cell-mediated response against viral epitopes. These cells secrete cytokines such as interferon (IFN)-γ that activate both microglial cells and invading monocytes, which subsequently secrete factors such as tumor necrosis factor (TNF)-α and thus can cause "bystander" demyelination. Activated macrophages ingest and degrade damaged myelin. Autoantibodies[12,13] and myelin-specific $CD4^+$ T cells have been shown in SJL/J mice several months after intracranial inoculation.[14,15] Epitope spreading in these mice commences with recognition of a proteolipid protein (PLP) epitope, and then progresses to additional PLP epitopes and then to myeloid basic protein (MBP) epitopes.[14] A direct demonstration that disease can be maintained on a purely autoimmune footing, after infection has been eradicated, has not been shown.

IMMUNITY AND THEILER'S VIRUS The first response to viral infection is the production of type I interferons, which are critical for viral clearance. IFN-α/β receptor knockout mice injected with TMEV die of encephalomyelitis within 10 days of infection. NK cells are activated early in infection with certain viruses. In TMEV infection susceptible SJL mice have a 50% lower NK cell activity in comparison to the highly resistant C57BL/6 mice. This low NK activity in SJL mice is in part due to a defect in the thymus impairing the responsiveness of NK cells to stimulation by IFN-β. The pivotal role of NK cells in early TMEV clearance is demonstrated by the finding that resistant mice depleted of NK cells by monoclonal antibodies to NK 1.1 develop severe signs of gray matter disease.[16]

In the early disease, both $CD4^+$ and $CD8^+$ T cells have been shown to be important in viral clearance. In early disease $CD4^+$ T cells are required for B cells to produce antibodies for viral clearance.[12] These $CD4^+$ T cells secrete IFN-γ, which *in vitro* inhibits TMEV replication and has a protective role *in vivo*. $CD8^+$ T cells are also important in viral clearance, as demonstrated by the finding that $CD8^+$ T cell-depleted mice fail to clear virus and develop a more severe demyelinating disease.[17] $CD8^+$ T cells also provide protection against TVID when adoptively transferred to a TVID-susceptible strain, BALB/c.AnNCr. Thus, $CD8^+$ T cells are implicated in viral clearance and resistance to demyelination. Higher CTL activity has been demonstrated in TVID-resistant C57BL/6 mice as compared to resistant SJL/J mice.[18] These CTLs may play an important role in viral disease since they may recognize viral determinants and/or they may inhibit delayed type hypersensitivity responses.

The relative roles of Th1/Th2 cells in TVID are very complex, and a simple picture of a Th1 or Th2 polarization during infection may not be apparent. A pathogenic role for Th1 cells during late demyelinating disease is demonstrated by the finding that both TVID correlates with delayed type hypersensitivity responses to TMEV and that the depletion of $CD4^+$ T cells during late disease results in the amelioration of clinical signs. High levels of the proinflammatory Th1 cytokines IFN-γ and TNF-α in late disease correlate well with maximal disease activity. Evidence demonstrating the protective role of Th2 in TVID has been shown in experiments in which skewing the immune response toward Th2 immunity in TMEV infection diminishes the later demyelinating disease.[19] However, other studies have shown that the Th1/Th2 balance did not explain the difference in susceptibility to TVID. Th1 cytokines are generally pathogenic during late demyelinating disease, whereas Th2 cytokines are protective.

USE OF THEILER'S MURINE ENCEPHALOMYELITIS VIRUS MODEL TO STUDY REMYELINATION Remyelination in MS lesions was first documented in 1906[20] and is characterized by abnormally thin myelin sheaths in relation to axon diameter. To date, however, there are few reliable data on the frequency of remyelination in MS patients. Stimulation of remyelination is a potential treatment for MS. The TMEV model of MS can be used to study remyelination using remyelination-promoting antibodies. In this remyelination model, SJL/J mice, aged 4–8 weeks, are injected with a 10 µl volume containing 200,000 pfu of Daniel strain intracerebrally. All animals develop mild encephalitis, which resolves within 14 days after the injection. The infected mice then develop the chronic demyelinating disease that gradually progresses over several months. To study remyelination, mice that had been infected with TMEV for 6 months receive a single intraperitoneal injection of 0.5 mg (~0.025 g/kg body weight) of a recombinant remyelinating antibody (rHIgM22) in phosphate buffered saline (PBS).[21] In one study, 82.8% of lesions in animals treated with rHIgM22 showed retraction of varying degrees, presumably the effect of remyelination in these lesions. The direct binding of rHIgM22 to demyelinated lesions is consistent with the hypothesis that these antibodies work directly in the lesions, probably by binding to the CNS glia to induce remyelination. Thus, this murine TMEV model can also be used as a model with which to examine different modes of remyelination.

MOUSE HEPATITIS VIRUS

Mouse hepatitis virus (MHV) is a member of the Coronaviridae, a group of large positive sense enveloped RNA viruses. Depending on the strain of virus used, MHV causes a variety of diseases including enteritis, hepatitis, and demyelinating encephalomyelitis.[22] Infection of mice with the neutrotropic JHM strain of MHV causes encephalitis, followed by chronic demyelination. Virus is not cleared from the CNS, resulting in a persistent infection.

After intracerebral or intranasal infection with MHV, virus enters the brain and causes encephalitis.[23] Intranasal infection with MHV-JHM or -A59 leads to viral spread through the olfactory bulb and along the olfactory tracts, as well as along the trigeminal nerve to the mesencephalic nucleus.[23] Up to 4 days postinfection (pi) early viral spread is via specific neural pathways and neural connections. Viral titers peak at about day 5 pi in the brain and later in the spinal cord and virus is cleared by days 8–20 pi.[24] However, viral antigen is still detectable up to day 30 pi. Additionally, viral RNA is detectable in the brain as late at 10–12 months postinfection, although the amount of RNA decreases with time. Liver infection can occur after any route of infection (in, ic, ig, or ip), with viral titers peaking at day 5 pi and hepatitis developing during the first 1–2 weeks.[25]

CNS demyelination develops as active MHV infection resolves. The lesions observed are histologically very similar to those observed in MS patients. These MHV lesions are characterized by primary demyelination accompanied by naked axons,[23] and are found scattered throughout the spinal cord.[26] The peripheral nervous system is not affected. Chronic lesions are associated with lipid-laden macrophages, scattered lymphocytes, and perivascular cuffing. These chronic lesions can persist as late as day 90 pi, and demyelinating axons can be seen as late as 16 months postinfection.

Chronic diseases in MHV-infected mice are associated with ataxia, hindlimb paresis, and paralysis, followed by a recovery. This animal recovery is mediated by CNS remyelination, beginning anywhere from 14 to 70 days pi.

C57BL/6 mice (H-2^b) are susceptible to MHV infection. In this murine model adult mice (of weight 20–22 g) are anesthetized by inhalant anesthesia and receive an intracerebral injection of approximately 500 pfu of a neurotropic MHV strain in a volume of approximately 20 µl of PBS. This intracerebral injection of MHV results in a biphasic disease: an acute encephalomyelitis with myelin loss, followed 10–12 days later by an immune-mediated demyelinating encephalomyelitis with progressive destruction of the CNS.[27] There is an 80–90% survival rate of mice injected with this MHV, with animals usually succumbing during the first 2 weeks of acute infection. Animals surviving this acute stage show a 95% chance of survival.[28] Control animals injected intracerebrally with sterile PBS show no clinical signs or histological defects.

Electron micrographs of demyelinating lesions show that macrophage processes slip between layers in the myelin sheath, implying that macrophages could indeed be mediating demyelination.[29] The appearance of macrophages within the CNS also correlates with the development of lesions. Additionally, they do not appear in large numbers in the absence of lymphocytes, so it is possible that myelin damage is caused by a nonmacrophage-dependent mechanism and that macrophages may only clear up the damaged myelin. In contrast to other mouse models of demyelination, there does not appear to be a clear role for any single lymphocytic or monocytic subset mediating the demyelination. Rather, it appears that a balance of immune components may be necessary for viral clearance and that various pathways, both immune and nonimmune, may cause the ensuing demyelinating events.

Recently, progress has been made in further identifying the immune cells required for demyelination. Experimental infection of severe combined immunodeficiency (SCID) mice, lacking T cells, results in fulminate encephalitis without demyelination.[30] Adoptive transfer of splenocytes from syngeneic immunocompetent mice into infected SCID mice results in demyelination within 7–9 days posttransfer. Additional experiments indicated that either $CD4^+$ or $CD8^+$ T cell subsets are capable of initiating this process. However, mice that receive splenocytes depleted of $CD4^+$ T cells survive longer and develop more demyelination than mice receiving splenocytes depleted of $CD8^+$ T cells. Thus, experimental SCID mice demonstrate that the roles of each T cell subset in demyelinating diseases are not equal.[31]

IFN-γ is a critical mediator of homeostasis and inflammation in MS and many of its rodent models. Bone marrow chimera mice have been used to address the role of IFN-γ in bystander demyelination mediated by $CD8^+$ T cells. These chimeras as rodent models for JHM have addressed a hypothesis that IFN-γ produced by $CD8^+$ T cells, and not from other sources, was the critical component in mediating bystander demyelination. This chimeric approach did not compromise IFN-γ production by cells such as NK cells and dendritic cells, thus preserving the innate immune response to the virus.[32] The results demonstrated that IFN-γ produced by these innate cells was unable to initiate the demyelinating disease, even in the context of activated $CD8^+$ T cells lacking only the ability of produce IFN-γ. These findings highlight the role that $CD8^+$ T cells have in demyelination in JMH-infected mice.[33] It has been demonstrated that IFN-γ is critical in other animal models of demyelination and in MS.

SEMLIKI FOREST VIRUS

Semliki Forest virus (SFV) is an alphavirus of the Togaviridae. The virus has been isolated from mosquitoes, but the natural host is unknown. SFV is a single-stranded positive strand RNA virus that has been cloned and sequenced. The most commonly studied strains used in adult mice are the virulent L10 strain and the avirulent A7(74) strain. Both of these strains are avirulent in neonatal and suckling mice by all routes of infection. Experimental infection of mice with SFV is widely used as a model to study the mechanism of virus-induced CNS disease. SFV has the advantage of being neuroinvasive as well as neurotropic, thus allowing studies of viral entry into the CNS and the integrity of the blood–brain barrier (BBB). Following intraperitoneal injection with 5000 pfu SFV in 0.1 ml PBS containing 0.75% bovine serum albumin,[34] all strains replicate in muscles and other tissues, resulting in a plasma viremia. Virus then crosses the cerebral vascular endothelial cells, resulting in infection of neurons and oligodendrocytes.[35] In neonatal or adult mice, infection with virulent strains results in widespread infection that is lethal within a few days. In contrast, infection of mice with the A7(74) strain results in a CNS infection, and infectious virus is cleared from the brain by day 10. Infiltrating mononuclear cells are observed 3 days pi and peak at about day 7. Focal lesions of demyelination throughout the CNS are observed 10 days pi and peak between 14 and 21 days pi.[36]

SFV-induced demyelinating diseases have been widely studied following intraperitoneal injection of adult mice with the A7(74) strain of the virus. Following intraperitoneal injection, virus is detected in the brain by 24 h. Viral titers then rise, but rapidly decline following initiation of the immune response. Interestingly, although infectious virus can be detected only up to day 8 pi, real-time polymerase chain reaction (rt-PCR) studies detect viral RNA up to day 90 pi.[37] Thus, it is possible that there is persistence of viral antigen(s). Disturbance of the BBB occurs between 4 and 10 days pi, which corresponds to the increase in inflammatory cell infiltration and reduction in viral titer and which may be related to the influx of cells or cytokine-mediated effects. The presence of macrophages, activated microglia, and the proinflammatory cytokines TNF-α, IFN-γ, interleukin (IL)-1α, IL-2, IL-6, and granulocyte-macrophage colony-stimulating factor (GM-CSF) during SFV-induced demyelination, in addition to enhancing the inflammatory response, may also play a role in controlling viral infection since IL-6, IFN-γ, and TNF have direct antiviral activity.[38] Additionally, IFN-γ and TNF production peripherally coincides with SFV-induced encephalitis in SJL and B6 mice. Interestingly, these same cytokines predominate in MS lesions.[39] An intense inflammatory response characterized by perivascular cuffing is apparent histologically from 3 days. Demyelination, as demonstrated using luxol fast blue staining of sections, is apparent by 14 days. However, small focal lesions of demyelination can be observed using electron microscopy by day 10. A striking feature of SFV infection appears in the optic nerve, where there are demyelinating lesions and changes in visually evoked responses and axonal transport.[40] This optic neuritis also occurs in human MS.

It appears that SFV-induced demyelination in this mouse model is accompanied by neurophysiologically demonstrable

visual deficits very similar to those found in MS patients. Thus, this may provide a very useful animal model for research into MS. The advantages of this model are that genetic and environmental factors can be readily controlled, while the low cost and fast reproductive rate make experimental design considerably easier.

No demyelination is observed following SFV infection of SCID mice or athymic mice. In the absence of specific immune responses, SCID mice infected with SFV A7(74) have a persistent viremia, a persistent and restricted CNS infection, and no lesions of demyelination. Comparison of the infection to that in nu/nu and BALB/c mice and studies on the transfer of immune sera show that immunoglobulin M (IgM) antibodies clear the viremia but not the brain virus and that infections of brain virus can be reduced by IgG antibodies. These IgG antibodies can abolish infectivity titers in the brain but cannot remove all viral RNA.[41] Adoptive cell transfer studies and administration of anti-CD8 antibodies demonstrate that demyelination following SFV infection is dependent on $CD8^+$ T cells.[4] This is consistent with the finding that the CNS inflammatory infiltrate is dominated by $CD8^+$ T cells. This finding is analogous to that in MS and is in contrast to that in EAE, where $CD4^+$ cells predominate.[42]

In the EAE autoimmune model of MS, studies suggest that a Th1 cytokine profile predominates. Another point of difference between the EAE model and the SFV model is shown in the Th1/Th2 profiles. Following infection with SFV, Th1 and Th2 cytokines were detected in the CNS and both were present throughout the time course studied, indicating that there was no bias of Th response in the CNS, nor were changes apparent with time.[43]

EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS

The experimental disease EAE has been investigated in many strains of animals including mice, rats, guinea pigs, rabbits, marmosets, and rhesus monkeys. EAE is an autoimmune inflammatory disease of the CNS and is characterized by perivascular and subpial inflammatory infiltrates and demyelinating lesions. The disease is usually initiated by injection of autoantigens emulsified in an adjuvant. The progression and pathology of lesions observed depend on the type of antigen used in the injection, the method of injection, and the strain of animal used. Because of its very nature, EAE as a model of MS does not address certain pertinent questions relating to MS, such as age-related onset of disease or epidemiology. A major difference between EAE and viral models of MS is that in EAE the inflammatory response is directed to autoantigens. A feature of the EAE model is that the course of the disease can be relapsing and remitting.

Studies of EAE have been used to identify antigenic determinants on components of myelin. Using bioinformatic technology these determinants have been used to search available databases of viral and bacterial proteins. Results indicate numerous viral and bacterial protein segments with probable sequence similarity to myelin basic protein determinants.[44]

EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS IN RABBITS EAE has been induced in rabbits by footpad inoculation with rabbit spinal cord homogenate, resulting in hindlimb paresis or paralysis.[45] Rabbits with 5-day paraplegia showed increased spinal cord incorporation of radioactive drugs administered in the epidural space. Thus, this demyelinating disease process may expose the spinal cord to larger amounts of substances administered neuraxially. It is therefore possible that this rabbit model could be used to investigate the incorporation of radioactive therapeutic drugs in the epidural space.

EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS IN GUINEA PIGS Guinea pigs have also been investigated to determine whether they may serve as useful EAE models of MS. The interest in guinea pigs stems from the fact that group 1 CD1 glycoprotein homologues, which in humans present foreign and self lipid and glycolipid antigens to T cells, are not found in mice and rats but are present in guinea pigs. In this guinea pig model, animals have been sensitized for EAE, and CD1 and MHC class II expression has been measured in the CNS. In normal guinea pigs low level MHC class II occurred on meningeal macrophages and microglial cells, whereas immunoreactivity for CD1 was absent. In the EAE CNS, however, the majority of infiltrating cells were MHC II^+ and microglia showed increased expression, whereas CD1 immunoreactivity was detected on astrocytes, B cells, and macrophages. Minimal CD1 and MHC II coexpression was detected on inflammatory cells or glia. Thus, in this guinea pig EAE model group 1 CD1 molecules are upregulated in the CNS on subsets of cells distinct from the majority of MHC II-bearing cells.[46] This expression of CD1 proteins in such EAE lesions broadens the potential repertoire of antigens recognized at these sites and highlights the value of this guinea pig model of human MS.

EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS IN RATS Rats were injected with spinal cord homogenate or the encephalitogen; myelin basic protein induced EAE in genetically susceptible Dark Agouti (DA) rats but not in Albino Oxford (AO) rats. Here 8- to 12-week-old rats were immunized in either or both hind footpads with 0.1 ml antigenic emulsion containing 100 μg rat spinal cord tissue in complete Freund's adjuvant (CFA).[47] Rats are monitored from day 5 after inoculation and the severity of disease was assessed by grading tail, hindlimb, and forelimb weakness, each on a sale of 0 (no disease), 1 (loss of tail tonicity), 2 (hindlimb weakness), 3 (hindlimb paralysis), to 4 (moribund or dead). Clinical disease in susceptible strains of rats is apparent in all animals, and the onset of disease occurs at day 11 postinjection. At the peak of the clinical manifestation of EAE there is a marked increase in the level of infiltration of cells accompanied by a lack of activation in susceptible DA rats, whereas it remains elevated in resistant AO rats. At the peak of clinical disease DA rat spinal cords contain high levels of $CD4^+$ T cells. DA rats also contained 10 times as many live $CD4^+$ T cells as AO rats. Astrocytosis, as an indication of CNS reaction to the presence of inflammatory cells, was clearly observed in both rat species. Microglial activation persists in resistant AO rats, whereas activation is downregulated in DA rats. In this model it is speculated that at the peak of disease, infiltrating monocytes and macrophages are the main antigen-presenting and effector cells.

Rat EAE may also be induced by the injection of xenogeneic myelin. For example, 8- to 12-week-old Lewis rats injected in both hind footpads with an emulsion containing 100 μg of guinea pig myelin basic protein and CFA develop acute EAE. Also chronic relapsing EAE (CR-EAE) may also be induced in this rat model using a regimen of intraperitoneal injections of 4 mg/kg of cyclosporin A.[48] Pathology studies indicate that in acute and CR-EAE, MCP-1 and its receptor CCR2 are significantly upregulated throughout the course of CR-EAE and that a large number of macrophages infiltrated the CR-EAE lesion. This suggests that

macrophages recruited by MCP-1 and CCR2-expressing CNS cells are responsible for the development and relapse of EAE. Thus, in this rat model, in addition to T cells, macrophages are another target for immunotherapy studies for neurological autoimmune diseases.

A more recent development of a rat EAE model involves using human MBP as antigen. Here EAE was induced by the immunization of female Wistar rats with human MBP. It was found that most of the rats developed tail tone loss and hindlimb paralysis together with demyelination, infiltrative lymphocyte foci, and "neurophagia" in the cortex of cerebra and in the white matter of the spinal cord.[49] This study further demonstrated that this rat model of EAE induced by human MBP resembles many features of human MS and may promise to be a better animal model for the study of MS.[49]

The use of CFA is not a prerequisite for the development of rat EAE. For example, EAE can be induced in 10- to 16-week-old DA rats by a single hind footpad injection of an encephalitogenic emulsion consisting of rat or guinea pig spinal cord homogenate (SCH) in PBS.[50] The reason for not wanting to use CFA is that in itself it induces a strong inflammatory response and exerts numerous immunomodulatory properties. Additionally, CFA induces a strong anti-purified protein derivative (PPD) response and may induce adjuvant arthritis, another autoimmune disease. The susceptibility of DA rats to EAE induction with SCH depends upon the origin of the CNS tissue, the homologous tissue being the more efficient encephalitogen. DA rats that recovered from EAE that had been induced with homologous SCH without adjuvant and then immunized with the encephalitogenic emulsion containing CFA developed clinical signs of the disease. Neurological signs in rechallenged rats were milder, but first signs appeared earlier. The earlier onset of EAE observed in DA rats after rechallenge has been attributed to the reactivation of memory cells. Taken together, these experiments demonstrate that EAE can be efficiently and reproducibly induced in DA rats without the use of CFA. This experimental model for understanding the basic mechanisms involved in autoimmunity within the CNS, without the limitations and inherent problems imposed by the application of adjuvants, may represent one of the most reliable rodent models of MS.

The rat as an experimental model could be used to evaluate new immunotherapies of EAE. These include antigen-induced mucosal tolerance, treatment with cytokines, and dendritic cell-based immunotherapy.

The ideal treatment of diseases with an autoimmune background such as MS should specifically eliminate autoreactive T cells without affecting the integrity of the immune system. One way to achieve this would be to induce immunological tolerance to autoantigens by the oral or nasal administration of autoantigen. Several studies have shown that nasal administration of soluble antigens results in peripheral tolerance by immune deviation or the induction of other regulatory mechanisms. In the rat model this tolerance has been investigated using synthetic peptides of MBP, MBP68–86, 87–99, and 110–128. Nasal administration of the encephalitogenic MBP68–86 or 87–99 suppresses EAE. MBP68–86 and 87–99 given together had synergistic effects in suppressing EAE and reversed ongoing EAE. A problem, however, of antigen-specific therapy by the nasal route is that one antigen, or peptide, may be effective in inducing tolerance in one strain of animal but not in another. One way of treating ongoing EAE may be the use of an altered peptide ligand with high tolerogenic efficacy when administered nasally.[51]

Cytokines have been widely used in disease prevention and treatment. Cytokine immunotherapy in MS could employ one or two basic strategies: first, to administer immune response downregulatory cytokines, or second, to administer inhibitors of proinflammatory cytokines. The nasal route of administering these cytokines has been studied in the rat EAE model. Nasal administration of low doses of antiinflammatory or regulatory cytokines such as IL-4, IL-10, or tumor growth factor (TGF)-β1 inhibits development of rat EAE when given before or on the day of immunization, but by differing mechanisms. Nasally administered IL-10 reduced both peripheral immune responses and microglia activation in the CNS, whereas nasal administration of IL-4 or TGF-β1 triggered the activation of dendritic cells (DCs).

However, nasal administration of cytokines alone fails to treat ongoing Lewis rat EAE. Interestingly, nasal administration of MBP68–86 + IL-4 or MBP68–86 + IL-10 suppresses ongoing EAE in Lewis rats. The suppression of EAE by MBP68–86 + IL-10 is associated with the induction of a broad lymphocyte hyporesponsiveness. Although this combined administration of autoantigen plus cytokine may be effective in treating rat EAE, the applicability of this to human MS is severely limited by the lack of knowledge of the pathologically relevant autoantigen(s) in MS.

DCs not only activate lymphocytes, but also induce T cell tolerance to antigens.[52] Use of tolerogenic DCs is thus a possible immunotherapeutic strategy for treatment of EAE, and indeed this has been studied in some detail. However, MBP68–86-pulsed DCs only prevented the development of EAE and failed to treat ongoing EAE in Lewis rats.[53] In an attempt to treat ongoing EAE, splenic DCs have been isolated from healthy Lewis rats and modified *in vitro* with cytokines IFN-β, IL-2, IL-10, or TGF-β1. Upon subcutaneous injection into Lewis rats on day 5 pi with MBP68–86 + FCA, IFN-β or TGF-β1-modified DCs promoted immune protection from EAE.

EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS IN NONHUMAN PRIMATES

The common marmoset *Callithrix jacchus* is an outbred species characterized by a naturally occurring bone marrow chimerism. The marmoset is a primate phylogenetically close to humans, and has been studied as an animal model for MS.[54] EAE can be induced in the common marmoset by the injection of human brain white matter, dispersed in demineralized water to a concentration of 30 mg/ml and emulsified with CFA containing 0.5 mg/ml of *Mycobacterium butyricum* H37A. Monkeys are injected intracutaneously with 600 µl of emulsion into the dorsal skin at several locations. Clinical disease in this model is scored daily on a scale from 0 to 5: 0 = no clinical signs; 0.5 = apathy, loss of appetite, and an altered walking pattern without ataxia; 1 = lethargy and/or anorexia; 2 = ataxia; 2.5 = paraparesis or monoparesis and/or sensory loss and/or brainstem syndrome; 3 = paraplegia or hemiplegia; 4 = quadriplegia; and 5 = spontaneous death attributable to EAE.[55] Here the onset of disease, as measured by clinical scores, is variable among animals between 7 and 13 weeks postinoculation. Additionally, the maximal clinical scores are variable among animals and range between 2 and 4. On histopathological examination, large plaques of demyelination are observed in the white matter of cerebral hemispheres, mainly localized around the

wall of lateral ventricles, in the hemispheric white matter, corpus callosum, optic nerves, and optic tracts. The demyelinated areas show a moderate or severe degree of inflammation characterized by perivascular cuffs of mononuclear cells. In the spinal cord, widespread demyelination is also observed. Areas of demyelination involve the ventral, lateral, and dorsal columns of the spinal cord, especially in the outer part of the spinal tracts. Thus, pathology in the marmoset model is characterized by inflammation, demyelination, and astrogliosis. Interestingly, this model demonstrates the presence of axonal damage in demyelinating plaques. Indeed, axonal damage and loss are well-known events in MS. In MS, axonal damage appears to be an early event, related to an acute inflammation. In the marmoset EAE, axonal damage also occurs in areas of acute and early inflammation and demyelination. This EAE in *C. jacchus* is of special interest because of the resemblance of this model to the human disease, and the similarity between the immune systems of marmosets and humans.

The type of clinical signs of EAE in marmosets depends largely on the antigens used for disease induction. Sensitization of marmosets to human myelin induces a relapsing-remitting, secondary-progressive disease course.[56] Lesions in this model represent all stages present in chronic MS. Marmosets inoculated with MBP develop only mild inflammatory disease unless *Bordetella pertussis* is used with the encephalitogen. CNS demyelination critically depends on the presence of antibodies to myelin oligodendrocyte glycoprotein (MOG), a minor CNS component. Marmosets sensitized to a chimeric protein of MBP and proteolipid protein (of myelin) develop clinical EAE only after the autoimmune reaction has spread to MOG. Marmosets immunized with recombinant human MOG 1–125 do not develop relapsing-remitting disease but only chronic-progressive disease.[57] During the asymptomatic phase of this primary progressive-like disease, which can last from 2 to 20 weeks, brain lesions are detectable using magnetic resonance imaging (MRI), but are not expressed clinically.

The induction of EAE with MBP or white matter tissue homogenate (WMH) has been well established in rhesus monkeys (*Macaca mulatta*). The rhesus monkey was the first animal species in which EAE was deliberately induced.[58] That autoimmunity to brain antigens could induce paralytic disease was confirmed by studies in rhesus monkeys given repeated inoculations of brain homogenates.[58] MOG-induced EAE has also been produced in this nonhuman primate species[59] that is a highly relevant model for the human disease. The close similarity of the human and rhesus monkey immune system is illustrated by the high degree of similarity between the polymorphic MHC and T cell receptor genes between these two primates. To produce this MOG-induced EAE, monkeys are injected, under anesthesia, with a total of 1 ml of 1:1 emulsion composed of 320 μg MOG in PBS and CFA at 10 sites into the dorsal skin. Overt clinical signs are scored daily according to the following criteria: (0) no clinical signs; (0.5) loss of appetite, apathy, and altered walking; (1) lethargy, anorexia, substantial reduction of the general condition, and loss of tail tonus; (2) ataxia, tail biting, sensory loss, and/or blindness; (2.5) incomplete paralysis of one (hemiparesis) or two sides (paraparesis); (3) complete paralysis of one (hemiplegia) or two sides (paraplegia); (4) complete paralysis (quadriplegia); and (5) death. The onset of clinical disease varies between animals, and occurs at days 15–23 after encephalitogenic challenge. All monkeys, however, develop clinical disease and all achieved a score of 4 on clinical severity.

The current available panel of nonhuman primate EAE models may reflect the spectrum of inflammatory demyelinating diseases in the human population. These EAE models can therefore be used to investigate pathogenic mechanisms and to develop more effective therapies.

EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS IN MICE

The most widely studied animal model of EAE is that of the mouse. In common with other animal models of EAE, disease induction varies depending on both the sex of the animals, the mouse strain used, as well as the origin of the spinal cord encephalitogen. In this model mice, aged 6–8 weeks, are immunized subcutaneously in four sites over the back with 200–400 μg of guinea pig MBP emulsified in equal volumes of CFA containing 200–400 μg heat-killed *Mycobacterium tuberculosis*.[60] Mice also receive 200 μg of pertussis toxin in 0.2 ml PBS intraperitoneally at the time of immunization and 48 h later. Mice are then scored daily for clinical signs of EAE for at least 35 days as follows: 0, no clinical signs; +1, limp tail or waddling gait with tail tonicity; +2, ataxia or waddling gait with tail limpness; +3, partial hindlimb paralysis; +4, total hindlimb paralysis; and 5, moribund/death. For each strain of mice there is variation in day of onset of disease, varying from day 7 to day 22 postinfection; incidence of disease, varying from 30% to 100% of animals; incidence of mortality, varying from 0% to 40% of animals; and mean clinical scores, varying from 0 to 1.6. Many mouse strains have been employed in the study of EAE, and while the SJL strain has been most frequently used to model gender differences in both disease onset and severity, the SJL model has some limitations due to its diminished $CD4^+$ T cell repertoire. Certain susceptible strains of mice, such as FVB mice, show a relapsing-remitting course of disease that bears some resemblance to MS. FVB mice therefore may serve as a mouse strain into which various transgenes may be introduced for the purpose of studying their influence on EAE and for exploring new therapeutic approaches.[61]

Since EAE is a well-studied disease in mice, mimicking many clinical and pathological features of MS, including CNS inflammation and demyelination, it is of significance that it can also be used as an appropriate model to study MS-related pain. It has been clearly demonstrated in SJL that in both "active" and "passive" EAE, there is an initial increase in tail withdrawal latency (hypoalgesia) that peaked several days prior to the peak in motor deficits during the acute disease phase. During the chronic disease phase, tail withdrawal latencies decreased and were significantly faster than control latencies for up to 38 days postimmunization. Thus, it is possible to use both murine active and passive EAE as models for MS-related pain.[62]

While specific immunotherapeutic strategies are effective in experimental model systems, translation to the human disease has genetically been poorly tolerated or has proved to be ineffective. This conflict may in part be due to the model systems used as well as the poor correlation of *in vitro* findings compared to those observed *in vivo*. In Biozzi ABH mice, which express the novel MHC class II A, EAE occurs following immunization with myelin proteins and peptide epitopes of these proteins; however, only PLP peptide 56–70, MOG peptide 8–21, or spinal cord homogenate reproducibly induces chronic relapsing EAE (CREAE) with inflammation and demyelination.[63] CREAE provides a well-characterized reproducible system to develop therapeutic strate-

gies during established relapsing autoimmune neurological disease and is pertinent to MS. In CREAE in ABH mice, relapse and progression of disease are associated with emergence and broadening of the immune repertoire due to release of myelin antigens following myelin damage.[64] Thus, this CREAE model in Biozzi ABH mice is very well suited as a model with which to examine the effect of therapeutic strategies in a dynamic system.

Disease susceptibility in human MS is associated with three MHC class II alleles in the HLA-DR2 haplotype, DRB1*1501, DRB5*0101, and DQB1*0602.[65] An autoimmune pathogenesis has been hypothesized in which one or more of these MHC class II molecules presents CNS-derived self-antigens to autoaggressive $CD4^+$ T cells, which infiltrate the CNS initiating an inflammatory response. However, the target autoantigens in MS are unknown. Immunization of mice with myelin or other brain-associated proteins induces EAE, a disease resembling MS both clinically and pathologically. The proteins, MBP, PLP, and MOG, components of the myelin sheath, are candidate antigens.[66] Indeed, T cells that are reactive to these antigens have been demonstrated in MS patients.[67] Mice expressing the human HLA-DR2 (DRB1*1501) molecule are capable of presenting peptides from all these three MS candidate autoantigens. It is possible in MS that while T cells responding to one of these antigens may initiate the disease, epitope spreading and the recruitment of T cells with additional specificities, as the disease progresses, could lead to inflammatory responses to several proteins resulting in an escalation of the autoimmune response.[68]

Transgenic mouse models of multiple sclerosis are now well established. The following are two examples of such transgenic models. First, MS is associated with HLA class II molecules HLA-DR2, -DR3, and -DR4. In humans it is difficult to analyze the individual roles of HLA molecules in disease pathogenesis due to the heterogeneity of MHC genes, linkage disequilibrium, the influence of non-MHC genes, and the contribution of environmental factors. However, the specific roles of each of these class II molecules can be addressed using transgenic models expressing these HLA genes. This model could prove useful in deciphering the role of HLA molecules and autoantigens in MS.[69] Second, while EAE has been a valuable model for the immunopathogenesis of MS, it has sometimes been difficult to reconcile the findings and therapies in the rodent models and the cellular and molecular interactions that can be studied in human disease. Humanized transgenic mice offer a means of achieving this, through the expression of disease-implicated HLA class II molecules, coexpressed with a cognate HLA-class II-restricted, myelin-specific T cell receptor derived from a human T cell clone implicated in disease. Such transgenic mice could provide an excellent model for studying epitope spreading in a humanized immunogenetic environment and for testing of immunotherapies.[70]

APPLICABILITY OF EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS MODELS OF MULTIPLE SCLEROSIS

The majority of the current therapies being planned for phase II and III trials in MS were first examined in EAE. Thus a particularly pertinent question is whether EAE is a suitable relevant research tool for MS? Some researchers believe that while EAE is a useful model of acute human CNS demyelination, its contribution to the understanding of MS is limited.[71] EAE is an acute monophasic illness, as compared to MS, which is a chronic relapsing disease, and may be more suited as a model of acute disseminated encephalomyelitis (ADEM). Drawbacks of the EAE model include the following: (1) the nature of the inflammatory response in EAE as compared to MS; (2) Th-1-mediated disease in EAE as compared to MS; (3) differences in the pathology between EAE and MS; and (4) pitfalls in extending immunotherapies from EAE to MS (see Table 69–3).

Consequently it may be concluded that the clinical picture of EAE presented depends not only on the animal species used, but also on the route of administration of the encephalitogen and the nature of the encephalitogen, MBP, PLP, or MOG. It is thus possible that these EAE models are somewhat imprecise methods to study the pathogenesis of MS or to develop therapeutic strategies.

The nonhuman primate EAE models are of primary importance for the safety and efficacy of testing new therapeutics for

Table 69–3
A comparison of some of the characteristics of EAE and MS[a]

Characteristics	*EAE*	*MS*
Inflammatory response	$CD4^+$ MBP-reactive T cells in perivascular lesions	Predominantly $CD8^+$ T cells in lesions, whereas $CD4^+$ T cells are infrequent
Th-1 or Th-2-mediated disease	Adoptive transfer of EAE by Th-1 cells	IFN-γ (Th-1 cytokine) seen in MS lesions
	Not true in all EAE models since MBP-reactive Th-2 cell clones can also cause EAE	No clear cytokine preponderance
Fundamental differences in pathology		
Location of pathology	Perivenous sleeves of myelin loss in spinal cord and brain	Demyelination not restricted to perivenous regions of white matter. Extensive demyelination of cerebral cortex
Location of lesions	Dependent on encephalitogen used; MBP-and PLP-induced EAE shows inflammation in lumbar spinal cord, MOG-induced EAE shows inflammation in the brainstem	Periventricular, brainstem, optic nerves, upper cervical cord
CSF immunology	Antibodies to myelin antigens in CSF	Antibodies to myelin antigens in CSF infrequent

continued

Table 69–3 (continued)

Characteristics	*EAE*	*MS*
Effect of immunotherapies		
IFN-γ	Variable and depends on route of administration	Worsens the inflammatory lesions?
IFN-β	Variable and depends on the route of administration	Decreases relapse rate
Anti-TNF Ab	Reverses EAE	Worsens MS
Anti-CD4	Cures EAE	No evidence of clinical efficacy on relapse or progression

[a]EAE, experimental allergic encephalomyelitis; MS, multiple sclerosis; MBP, myeloid basic protein; IFN, interferon; TNF, tumor necrosis factor; PLP, proteolipid protein; MOG, myeloid oligodendrocyte glycoprotein; CSF, colony-stimulating factor.

MS that may not work sufficiently well in species distant from humans, such as rodents. Questions concerning the immunogenicity of biological therapeutics have also been addressed in nonhuman primates. Many biological therapeutics, such as anti-CD4 antibodies[72] and altered peptide ligands,[73] have been investigated in rodents. Although some of these therapeutics have been effective in treating EAE in rodents, they have proven to be partially effective, or in some cases detrimental, in MS patients.[74] This ultimately raises the question of whether rodent models are the appropriate animal models for testing new therapeutic strategies for use in human MS.

CHEMICALLY INDUCED DEMYELINATION

There are several examples, in humans and animals, of demyelinating diseases not associated with viral infections, such as demyelination associated with vitamin deficiency or toxins. Many different animal models of EAE have been studied using various MRI techniques.[75] The clinical features of such models depend greatly upon the route of inoculation of the encephalitogen as well as the species and strain of animal used. Inoculation routes such as subcutaneous, footpad, or intraperitoneal are not helpful in determining the onset or location of the lesion in the brain or spinal cord. Thus, to create demyelinating lesions of precisely known locations and time courses, stereotaxic techniques are used to inoculate animals with chemicals that induce demyelinating lesions in the brain. Several chemicals, such as ethidium bromide, cuprizone, and lysophosphatidylcholine (LPC), when injected directly into nerves or into the CNS, produce lesions of demyelination. For demyelination studies with LPC, male Wistar rats are anesthetized with sodium pentathal and fixed in a rat head restraining stereotaxic surgical table, head shaved, a burr hole created, and 0.2 µl of a 1% LPC solution in isotonic saline injected using an injector cannula. Then LPC is infused at the rate of 0.05 µl/min for the next 4–5 min. The cannula is then removed and the burr hole closed using bone wax. Rats are then observed daily and histological studies are carried out from day 3 to day 15 after LPC injection to cover the entire process of disease evolution.[76]

Using this LPC-induced demyelination it is possible to observe the complete pathological process of demyelination and remyelination in this animal model of MS. Demyelination can be observed with the maximum value occurring on day 10. After day 10, remyelination starts with a reduction in edema. This model could be particularly useful for studying remyelination. One prominent feature of all chemically induced lesions is that the demyelinating lesions, and subsequent remyelination, can be studied without the interference of immune mechanisms. This has a tremendous advantage over virally induced models of MS: since no virus was inoculated none can remain to affect the remyelination.

ACKNOWLEDGMENT

The authors would like to thank Dana Parks for expert secretarial assistance with this manuscript.

70 Canine and Feline Models for Cancer

GIONATA DE VICO AND PAOLA MAIOLINO

ABSTRACT

Animal models still play a crucial role in biomedical research. Among them, spontaneous canine and feline tumors could be useful to accelerate the entry of new effective drugs into clinical practice. This is because dog and cats develop neoplastic diseases in a manner more similar to human beings than to both the *in vivo* and *in vitro* models usually employed. We will discuss the scientific foundation as well as the ethical and legal concerns related to the use of this "pet model" in comparative oncology, suggesting some "key words" as the necessary starting point for a correct approach to this. Finally, the possible use of such models for the development of effective cancer theory is also discussed.

Key Words: Spontaneous canine and feline tumors, Animal models, Ethics, Law, Cancer theory.

INTRODUCTION

In modern oncology, there is a quite evident discrepancy between the great quantity of pathogenetic knowledge accumulated and its limited translation into clinical practice and therapy of human cancers.[1–3] Usually, the time required for a new antineoplastic drug to enter into clinical oncology is estimated to be 10–15 years.[2,4] It has been suggested that this could be due in part to the complex logical sequence involved in most of the preclinical studies of new antineoplastic drugs, in which the choice of the experimental models for testing the safety and efficacy of such new therapeutics represents a critical point.[3,4]

In fact, both the *in vivo* and *in vitro* models usually employed, such as rodents and/or cell lines, display intrinsic limits related to the specific characteristics of the biological systems used, whose management is frequently very complex,[5] and whose pathology, usually induced under artificial laboratory conditions, is frequently dissimilar to the studied spontaneous human disease.[2–4]

It has therefore been suggested that clinical trials based on preclinical data obtained after a screening of animal models that develop neoplastic disease in a manner more similar to human beings could accelerate the entry of new effective drugs into clinical practice.[1,4,6]

In this regard, it is widely accepted that spontaneous canine and feline tumors could represent a unique opportunity. (1) Canine and feline genetics are closer to human genetics than that of the other animal models usually employed. (2) Dogs and cats develop tumors spontaneously after years of exposure to the same environmental oncogenic factors as the owners. (3) Canine and feline spontaneous tumors share morphological, biological, and molecular characteristics similar to human tumors (interestingly, many of the antibodies employed for human molecule identification actually cross-react with similar canine molecules). (4) The incidence of cat and dog tumors is frequently higher than human tumors, and the natural evolution of the neoplastic disease is usually more rapid. (5) The life span and the size of these animals are both sufficient to detail the safety and efficacy of single or multiple drug treatments and to perform procedures such as blood sampling, bone marrow harvests, organ biopsies, and radiation therapy in a manner similar to that in humans in subjects with no artificially altered immunity. (6) The availability of clinical and pathological material is sufficient to guarantee reliable etiopathogenetic and preclinical studies in a relatively short time.[2,3,7,8]

It has also been suggested that the involvement of pet animals in biomedical research should be accompanied by specifically developed professional, ethical, and legal arguments.[1] In this context, ethical and considerations able to unravel the conflict between the interest of the various participants involved should be implemented.[9]

In particular, in biomedical research, the concern for the concept of ethical cost in experiments involving animals has led to the general acceptance of Russell and Burch's three "Rs" (replacement, reduction, and refinement)[10]: whenever it is impossible to perform scientific tests on different nonanimal models, the number of subjects employed as well as their pain, suffering, and distress should be minimized.[8,11] However, the three Rs of Russell and Burch could be inadequate for pet trials, given the specific conditions that these involve. In fact, enrolled diseased dogs and cats should be considered primarily as animal "patients,"[1] a position rather different from that of a "mere" animal model. The management of this oncological veterinary patient could require a close and complex partnership between the owners, the veterinarians in research institutions and in public institutions, as well as selected veterinary practitioners with specific training in clinical oncology, so as to involve the greatest number of patients in the experimental trials and guarantee the adequate reliability of the results and animal well-being.[1] Therefore, different key words will have to replace the "three Rs" to address correctly the necessary social, professional, and institutional behavior. We have suggested that some of these key words could be adapted from the

criteria for informed consent in veterinary practice.[1,12] Information for both the owners and veterinary physicians could play a crucial role in guaranteeing the enrollment of the greatest possible number of pets in experimental trials. Information on both the benefits and risks of the trial should be adequate, with an attempt to reach an appropriate balance between them.[13] Information should deal in particular with strict eligibility criteria to enable the physicians to identify eligible patients for a specific clinical trial and to enable the owners to identify the best trials for their pet.[1] This should lead to an awareness of the commitment and responsibility of both the owners and the veterinarians involved with regard to the animal patient's well-being during the trials. Furthermore, animal patient entry in experimental trials could frequently follow conventional treatment failure.[14] Thus, a care-based approach[15] could be a further important step in working out our responsibilities to the animal patient's welfare. Caring for these terminal veterinary patients should involve palliative or analgesic treatment to minimize the suffering and pain derived from their disease. This kind of approach based on information, responsibility, and care could, in our opinion, increase the enrollment of dogs and cats in experimental trials, by providing the owners with an ethical choice different from euthanasia.[1]

CANINE AND FELINE MODELS FOR CANCER

Several spontaneous canine and feline tumors are currently considered to be relevant models for human cancers.[1–3,7,8] Canine and feline tumors may serve either as "specific tumor type" models, that is models of the corresponding human disease, or as "molecular" models, that is models of some molecular profiles that could be targeted by therapeutics, independently of the histological tumor type.[1,2]

CANINE MODELS FOR CANCER

Canine Non-Hodgkin's Lymphoma Non-Hodgkin's lymphoma (NHL) comprises about 7–24% of all neoplasms in the dog and 83% of all hematopoietic malignancies in this species.[16] Its etiology is unknown, and middle-aged to older dogs are more frequently affected, with no sex predilection. German shepherds, boxers, basset hounds, and Saint Bernards, among other breeds, develop the disease more frequently.[17] Canine NHL equates to intermediate and high-grade NHL in humans. In the dog, NHL is generally multicentric (characterized by superficial lymphadenopathy) and has a predominantly B cell origin (70–80% of cases). Other anatomic forms of NHL, in order of decreasing prevalence, are the cranial, mediastinal, gastrointestinal, and cutaneous ones. The cutaneous form is usually epitheliotrophic and of T cell origin. Primary extranodal and epitheliotrophic forms have also been reported in intestine and bladder.[18,19] NHL of T cell origin (20–30 % of cases) generally has a poor prognosis.[20] Immune system alterations in the dog, as well as in humans, seem to be associated with a higher incidence of NHL. Like human NHL, canine NHL is very sensitive to chemotherapy and is currently used as a model for testing new chemotherapeutics and new forms of immunotherapy, as well as for the study of multiple drug resistance.[21] Furthermore, NHL has been a relevant model for (1) developing hypoxic cell markers, (2) studying the effect of whole-body hyperthermia on the pharmacokinetics of systemic chemotherapy, and (3) studying autologous bone transplantation.[3]

Soft Tissue Sarcomas Soft tissue sarcomas (STSs) are a heterogeneous group of tumors derived from a variety of mesenchymal tissues.[20] They represent about 15% of all skin and subcutaneous canine tumors, and are locally invasive (with the exception of the hemangiosarcomas) with a low-to-moderate metastatic potential (less than 20%).[21] Their etiology is unknown, but in the dog these tumors have been associated with a number of exogenous factors: parasites, radiation, trauma, and artificial orthopedic implants. Older dogs are more frequently affected, and no sex predilection is observed, except for both rhabdomyosarcomas, which occur in young dogs, and synovial sarcomas, which occur more frequently in males. STSs in dogs have a pathological appearance, clinical presentation, and behavior similar to human STSs. In humans, however, STSs seem to be more common in young subjects and metastasis would appear to be more frequent then in dogs. This is in part explained by the higher numbers of nerve sheath tumors (low metastatic rate) seen in the canine species. The relevance of this model is that canine STSs respond to radiation therapy and chemotherapy in a manner similar to human STSs.[3] Thus, canine STSs have been used to test local and whole-body hyperthermia techniques, as well as the effect of hyperthermia on the pharmacokinetics of chemotherapy, and the development of both hypoxic cell markers and imaging techniques.[2,3] Among STSs, hemangiosarcomas have a higher prevalence in dogs than in humans, but are extremely similar to the human tumor with respect to histological pattern and metastatic behavior.[2]

It is, thus, actually considered an interesting model for the treatment of metastatic disease and for developing new antiangiogenic strategies and immunotherapy.[2,3,20]

Osteosarcomas Osteosarcomas (OSAs) are the most common primary bone tumor in dogs, accounting for up to 85% of malignancies originating in the skeleton.[22] Canine OSAs develop three to four times more often in the appendicular skeleton than in the axial skeleton, being classically a cancer of large and giant breeds, and occurring in middle-aged to older animals, with a median age of 7 years.[23] OSAs are locally very aggressive and cause lysis and/or production of bone. They usually metastasize (90% of cases), mainly to the lungs, via the hematogeneous route; other bones or other soft tissues are reported sites for metastasis. Canine osteosarcoma is similar to human osteosarcoma with respect to the histology, metastatic behavior, and clinical evolution of the disease, and is considered a relevant model for immunotherapy and chemotherapy.[18] In this regard it has been demonstrated that administration of liposome-muramyl tripeptide-phosphatidylethanolamine (L-MTP-PE), a potent monocyte/macrophage activator, results in increased survival time in dogs with OSA.[3,21] These studies led to a multicenter, phase III, intergroup study involving the use of L-MTP-PE in children with OSA.[2] Furthermore, new drug delivery systems, particularly for cisplatin therapy, have been studied in dogs with OSA.[3]

Oral Malignant Melanoma Canine malignant melanoma (CMM) is a highly metastatic spontaneous tumor most commonly arising in the oral cavity, and represents about 4% of all canine tumors.[24] CMM and advanced human melanomas (HM) are diseases that are initially treated with aggressive local therapies, including surgery and/or fractionated radiation therapy, and are usually followed by a systemic metastatic disease.[25] Also, CMM and HM are chemoresistant neoplasms and share many immunological targets.[3,24] For these reasons canine oral malignant melanoma (OMM) is considered a relevant model for developing new immunotherapeutic approaches for both dogs and humans suffering from the disease.[3] In a recent study, Bergman *et al.*[25] demon-

strated that human tyrosinase DNA vaccination of dogs with advanced malignant melanoma is safe and potentially active, warranting additional xenogeneic DNA vaccine investigations as Phase II studies in CMM and Phase I studies in HM.

Transitional Cell Carcinomas Transitional cell carcinomas (TCCs) are the most common urinary bladder tumor in dogs and have high metastatic potential.[26] The majority are papillary infiltrative tumors of intermediate to high grade and about 80% are aneuploid. The etiology is multifactoral. Females are more frequently affected than males and Scottish terriers develop the disease more frequently than other breeds. TCCs are localized most often in the trigone and induce partial or complete urinary tract obstruction. Canine TCCs share a histological appearance, biological behavior, and response to therapy similar to invasive human TCCs.[27] It is considered a useful model for testing new photodynamic therapy technologies and chemotherapeutic combinations, particularly for the cyclooxygenase inhibitor piroxicam.[3,28,29]

Canine Mast Cell Tumors Canine mast cell tumors (CMCTs) are one of the most common malignancies in dogs, occurring with an incidence of 16–21% in the canine population.[30] Because of their variable (frequently unforeseeable) biological behavior, most investigators regard all CMCTs as potentially malignant.[31,32] Survival time and metastasis in dogs with CMCTs have been associated with the histopathological grade of the tumor.[32] Recently, however, Maiolino *et al.*[33] and Preziosi *et al.*[34] also demonstrated that the nucleomorphometric evaluation and intratumoral vessel of CMCT tissue sections could be a useful adjunct to histopathological grading in identifying tumors at increased risk of progression, to arrive at a more objective diagnosis, and to recommend more appropriate treatment. These tumors display a molecular alteration in the c-*kit* protooncogene, whose protein product, the receptor tyrosine kinase (RTKs) KIT, plays a critical role in mast cell differentiation, proliferation, survival, and activation.[35] Mutation of exon 11 of c-*kit* occurs in 30–50% of advanced mast cell tumors (MCTs), and is related to their recurrence and metastatic potential.[35] A similar mutation in the c-*kit* protooncogene has been demonstrated in 50–90% of human gastrointestinal stromal tumors (GISTs).[35,36,37] Based on this molecular correlation, translational studies with new oncology drugs (inhibitor of RTKs) for human GISTs in canine MCTs have been proposed.[36,38]

Canine Mammary Carcinomas Canine mammary carcinomas account for 30–50% of all canine tumors. These tumors have, so far, been considered a promising specific tumor-type model, being very similar to human breast cancers because of their hormonal dependence, spontaneous development in middle-aged to older animals (higher incidence in dogs between 8 and 15 years old), metastatic behavior toward regional lymph nodes and lungs, as well as adhesion molecules and neoangiogenesis patterns.[39,40,41] Furthermore, as in human mammary carcinomas, expression of *erb-B* protooncogenes has been documented,[42] and a familiarity has been demonstrated,[43] along with the expression of BRCA genes and Rad51 proteins.[44]

Abnormalities in the nuclear DNA content have been documented both in malignant and benign canine mammary tumors, but are more frequent in humans. As in humans, nutritional factors may increase the risk of mammary tumor development. Given some molecular patterns of canine mammary tumors, it has recently been suggested that they could be used as a molecular model.[38] In this context, the dysregulation of the molecular pattern of cyclin D1 and cyclin-dependent kinases (cdks) in these tumors has recently been clarified, and the results suggest that mammary neoplasia in dogs could be a good molecular model for developing new antineoplastic strategies involving cyclin D1 and cdks.[4,45]

Canine Seminomas Spontaneous testicular tumors are common in aged dogs. The principal canine testicular tumors consist of seminomas, Sertoli cell tumors, and Leydig cell tumors, and they occur with about equal frequency.[46] Seminomas are usually solitary and unilateral, and are more frequent in the right testicle. They can coexist with Sertoli and Leydig cell tumors.[47] Despite their malignant histological appearance, in dogs, metastases occur only in a small percentage of cases. In contrast, human seminomas are the most common testicular neoplasms affecting young men and have a marked tendency to metastasize.[48] This discrepancy has been the object of two recent studies[46,49] that suggested that most canine seminomas could correspond to human spermatocytic seminomas (an uncommon histological variant in men with a low metastatic potential), thus justifying their low metastatic behavior. It will be interesting to study whether canine typical seminomas, as identified by morphological and morphometric methods in the study of Maiolino *et al.*,[46] also share a histogenetic behavior similar to that of human typical seminomas, that is, the origin from so-called *in situ* carcinoma or intratubular malignant germ cell neoplasia. If so, the canine seminomas will become a very interesting spontaneous animal model.

Canine Transmissible Venereal Tumor Canine transmissible venereal tumor (TVT) is a naturally occurring transplantable round cell tumor of histiocytic origin in dogs.[50] TVT occurs most often in young, roaming, sexually intact and active dogs, with no breed or sex predilection. It commonly affects the external genitalia and it is usually transmitted at coitus. The TVT may also involve other sites, as well as the nasal and oral cavity, and rarely subcutaneous areas, and this may also be due to autotransplantation (licking and sniffing). It has a high recurrence rate and a low metastatic rate. A viral etiology has been investigated but not verified. The TVT is antigenic in dogs and an appropriate antitumor immunological response plays an important role in inhibiting growth (can induce tumor regression) and spread of the tumor. TVT is considered a promising model for human Kaposi's sarcoma (KS). It has been suggested that analogous to TVT, KS can be transplanted by viable malignant cells during sexual intercourse.[51] Furthermore percutaneous inoculation and intraarterial transplantation of canine TVT fragments in the canine lung result in predictable patterns of tumor growth resembling the solitary pulmonary nodules and metastatic disease found in humans. Thus, this tumor is considered useful to develop a lung tumor model in a large animal to simulate human lung cancer for preclinical assessment of novel therapeutic options. A tumor model in a large animal would have a wide range of biomedical research applications, including the study of various interventional imaging techniques.[52]

FELINE MODELS

Feline Non-Hodgkin's Lymphoma Feline non-Hodgkin's lymphoma (NHL) accounts for 50–90% of all hematopoietic malignancies in the cat and for approximately one-third of all malignant neoplasms in this species.[53] The feline leukemia virus (FeLV) was the most common cause prior to the widespread use of FeLV vaccination and testing programs. Cats with a median age of approximately 10 years are predominantly affected. It is

primarily a B cell lymphoma (75% of cases): the mediastinal, spinal, and leukemic forms are of T cell derivation and FeLV positive; the alimentary forms are usually of B cell derivation and FeLV negative.[53] Anatomic forms traditionally associated with FeLV (mediastinal or multicentric) occur in younger cats. Male cats and Siamese/oriental breeds may be predisposed to NHL.[54] Feline immunodeficiency virus (FIV) infection can increase the incidence of lymphoma in cats (particularly the alimentary lymphoma of B cell origin) by dysregulation of the immune system or activation of oncogenic pathways. Feline NHL equates to intermediate and high-grade NHL in humans. Like human and canine NHL, feline NHL is very sensitive to chemotherapy, which is very well tolerated by cats, and it is currently used as a model for testing new alternative treatments for cancers.[53]

Feline Mammary Carcinoma Mammary neoplasia is the third most common tumor type affecting female cats.[55] The mean age of development is 10–11 years with an age-relative risk that increases up to 14 years. Domestic short-haired and Siamese cats are more frequently affected than other cats. Malignancy occurs frequently (80–96%) with high mortality and a ratio between malignant and benign neoplasms varying from 9:1 to 4:1.[56,57] Feline mammary carcinoma (FMC) shows age incidence, histopathology, and pattern of metastasis[2,3] similar to human breast cancer.[55] In particular, the lack of estrogen dependency in most tumors[4] suggests that FMC could be a suitable animal model for human hormonal unresponsive breast cancer. Furthermore, some FMC subtypes have recently been described that share common features with human inflammatory mammary carcinoma and human mammary carcinoma with osteoclast-like giant cells.[58,59] Prognostic factors are nuclear polymorphism and polymetrism, as assessed by nuclear morphometry, PCNA label index, Ag-NOR count, and mitotic index.[60–63]

From a molecular point of view, HER2 and RON overexpression qualifies FMC as homologous to the subset of HER2 overexpressing, poor prognosis human breast carcinomas and as a suitable model to test innovative approaches to therapy of aggressive tumors.[64]

Feline Vaccine-Associated Sarcoma Feline vaccine-associated sarcoma (VAS) is a biologically aggressive sarcoma that can develop in the skin of cats at sites where inactivated feline vaccines (feline leukemia virus and rabies) have been administered. The increase in the incidence of this tumor has shown a strong link between vaccination and subsequent tumor development.[65] A multistep carcinogenesis model, including genetic, iatrogenic, and local factors, seems to be the most plausible explanation for the occurrence of the tumor. Inflammation is the most accepted pathogenetic hypothesis and adjuvant, the component most commonly associated with vaccines, is considered a cause of tumor development. Among VAS, fibrosarcoma is the most common (incidence of 1–10 per 10,000 cats). The tumor displays an extremely malignant biological behavior, being both locally aggressive and metastasizing in 25–70% of the cases.

Immunohistochemical detection of p53 protein, fibroblast growth factor-β (FGF-β), tumor growth factor-α (TGF-α) and platelet-derived growth factor (PDGF) and its receptor[66] has been documented, suggesting that these growth-regulating proteins may play different roles in the development of VAS cells. Mutation in p53 has been studied in a variable number of sarcomas, but has been demonstrated in only 2 out of 10 fibrosarcomas.[67] The standard treatment is aggressive surgical removal of the tumor, but combinations of surgery, radiation, and chemotherapy [doxorubicin and decarbazine (DTIC)] are usually recommended. A significant decrease in STAT3 expression in VASs treated with doxorubicin after surgical resection has also been reported, supporting evidence for the potential role of STAT3 in oncogenesis and tumor progression.[68] The possibility of the development of fibrosarcomas at presumed sites of injection not only in cats but also in dogs has been reported.[69] It is considered a useful model of hyperthermia in cancer immunogene therapy, particularly for the cytokine genes.[70]

PET MODELS AND CANCER THEORY: COULD THEY BE USEFUL?

According to current practice, we have dealt with spontaneous canine and feline tumors as models for testing new antineoplastic strategies for human cancer. In our opinion, however, besides this "utilitarian" approach, animal tumors may also be a very useful model for searching and testing new theoretical ideas in carcinogenesis.

According to the prevailing current paradigm, the so-called somatic mutation theory (SMT), cancer derives from a single somatic cell that has accumulated multiple DNA mutations; furthermore, the default state of cell proliferation in metazoa is quiescence and cancer is considered mainly a disease caused by mutations in genes that control the cell cycle.[71,72]

However, it has been suggested that mutation alone is not sufficient to induce cancer. Accordingly, a "Darwinian" approach could represent a better theoretical framework for understanding the complex cellular, molecular, and epidemiological events leading to cancer.[73,74] According to this theory, accumulation of mutations during tumor emergence could be triggered by an adequate selective cell microenvironment, the latter being able to select mutations useful for neoplastic cells to survive and grow.

A further (and very intriguing) theoretical approach to carcinogenesis is the so-called tissue organization field theory (TOFT), which regards tumors as a disease of developmental processes.[71,72] This theory is based on premises that place cancer in a different hierarchical level of complexity from that proposed by the SMT and "Darwinian" points of view, that is (1) carcinogenesis represents a problem of tissue organization comparable to organogenesis, and (2) proliferation is the default state of all cells.[71,72]

Accordingly, neoplastic development could result from disruption of the normal dynamic interaction of neighboring cells and tissues both during early development and throughout adulthood.

From a philosophical point of view, the SMT and the "Darwinian" theories result from a reductionist approach to biology and regard tumors as a molecular or at least a cellular problem; however, according to TOFT, "development and cancer will not be reduced to complex series of protein interactions, but rather a multilevel explanation will be required. In some instances molecules will do the explanatory job, in others physical forces, but at the core they will remain a problem of tridimensional tissue organization."[71]

In this context spontaneous pet tumors could provide a novel way of thinking about these questions, which takes all levels of biological organization into consideration.

For example, canine trichoblastomas, a "benign tumor derived from or reduplicating the primitive hair germ of embryonic follicular development,"[75] seem to display all the necessary

peculiarities for testing some aspects of the above cancer theories. According to their growth pattern canine trichoblastomas are subdivided into four types—ribbon type, trabecular type, granular cell type, and spindle cell type—and represent about 25% of all canine epithelial skin neoplasms.[76] These tumors are similar to human trichoblastomas, which are "not exclusively epithelial tumors, but . . . heterogeneous biological systems of epithelial–mesenchymal interaction."[77] In these neoplasms the epithelial component appears to be equivalent to the hair germ and the mesenchymal component equivalent to the dermal papilla, both essential for hair follicle development.[77] Perturbed interactions within the above tissue compartments may cause or even reflect morphofunctional alterations that eventually give rise to follicular tumors.[77,78] Interestingly, we demonstrated that the complex growth pattern of these tumors may be adequately described and quantified in mathematical terms using a morphometric approach based on fractal geometry.[79,80] Furthermore, a close correlation seems to exists between the alteration of Wnt molecular signals, cellular events occurring in early follicle development, and the emergence and growth in the above tumors (personal observations). Thus, these tumors could provide, in quantitative terms, useful information about the link between molecular, cellular, and tissue changes during tumor development. Certainly, many other spontaneous pet tumors could be useful in this context. Future efforts in this direction could provide interesting models for effective cancer theory development.

71 Obese Mouse Models

DEBORAH J. GOOD

ABSTRACT

In 1902, the *lethal yellow* or *Agouti yellow* (A^y) mouse was described by French geneticist Lucien Cuenot in a paper detailing coat-color inheritance in mice. Although the Agouti mouse reportedly had been bred by European mouse fanciers since the 1800s, the phenotype of obesity was not published until 1927. In the late 1960s, the obese (*ob/ob*) and diabetic (*db/db*) mouse models were described. All three of these models have been widely used in obesity research since that time. With the advent of technologies to create transgenic and knockout strains of mice there has been a rapid increase in the number of mice displaying different defects in body weight regulation. This chapter will categorize the more than 200 mouse models of body weight disorders that now exist, more than 100 years after the *agouti yellow* mouse was first characterized. The Obesity Gene map database (http://obesitygene.pbrc.edu/) is updated yearly and is a thorough reference for all genes and loci, both rodent and human, known to modulate body weight or energy utilization. This chapter categorizes mouse models listed in that database, and includes recently published models in five groupings: juvenile-onset obese models, adult-onset obese models, obesity-resistant models, polygenic obese models, and models with altered responses to induced obesity.

Key Words: Obesity, Overweight, Mouse models, Energy homeostasis, Anorexia.

INTRODUCTION

The incidence of obese and overweight humans worldwide has skyrocketed in the past two decades. Likewise, the number of published papers describing mouse models used for the study of body weight regulation also has also increased during that time period[1–5] (Figure 71–1). With strong protein sequence homologies between mouse and human gene products, many mouse models replicate human disorders of body weight regulation, and some are identical to known human genetic disorders.[6] The large numbers of available mouse models recapitulate the different phenotypes of both obesity and anorexia, including juvenile-onset obesity, adult-onset obesity, and obesity-resistant models. Mouse models of both monogenic and polygenic obesity are being used to uncover new genetic pathways that converge to maintain energy balance homeostasis.

MODELS OF JUVENILE-ONSET OBESITY

Juvenile-onset obesity in mammals is characterized by increased body weight that occurs prior to the onset of sexual maturity. In mice, sexual maturity occurs between 7 and 8 weeks of age.[7] Therefore, models listed as having juvenile-onset obesity will be limited to those that show distinct body weight differences prior to 8 weeks of age. A total of 34 mouse models can be categorized as examples of juvenile-onset obesity (Table 71–1).

Polymorphisms in three of the four most common genes associated with human obesity, namely leptin, leptin receptor, and proopiomelanocortin (POMC),[8] have mouse model counterparts that display a juvenile-onset obesity phenotype.[9–11] These genes, along with the fourth common gene involved in monogenetic forms of obesity in humans, the melanocortin-4 receptor (MC4R) gene, constitute part of the well-characterized melanocortin pathway. The MC4R mutant mouse model displays adult-onset obesity,[12,13] while animals with mutations in both MC4R and leptin are obese at weaning—earlier than either of the single mutants.[14] These mutants of the melanocortin pathway will be useful in dissecting the role of POMC neuropeptides and their receptor on the timing of body weight gain in animals.

In addition to relatively well-characterized pathways, the list of mouse models of juvenile-onset obesity reveals some interesting gene products and signaling pathways whose specific influence on the regulation of human body weight remains unclear. For example, overexpression of a dominant negative form of N-cadherin specifically in osteoclasts leads to increased adipogenesis and body weight only in young animals.[15] The effect of the transgene on body fat is absent in adulthood with no body weight changes in age-matched adult mice. It was suggested that cell fate decisions affect the proportion of adipocytes to osteoclasts in these animals through β-catenin signaling, which leads to the differences in body composition in juveniles. This interesting role for β-catenin and N-cadherins was unknown prior to the development of the mouse model. Another interesting model is the Gnas-deficient mouse.[16] This mouse model can be used to elucidate sex-specific modes of inheritance that cause body weight gain or loss. The protein product of Gnas is a stimulatory G-protein α-subunit that binds guanine nucleotides and is involved in multiple pathways including those signaling through phospho-

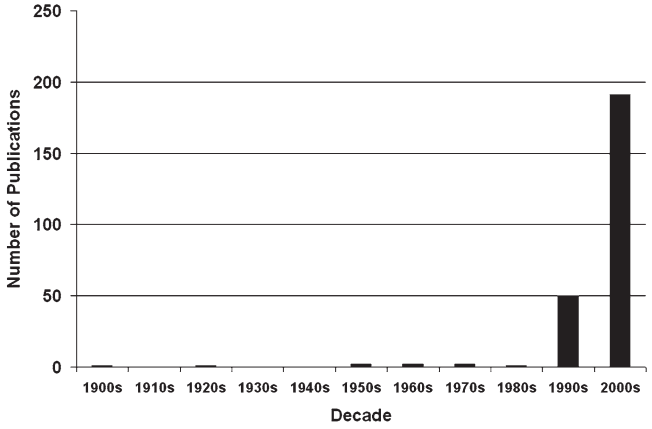

Figure 71–1. Number of publications identifying new mouse models of body weight regulation compiled by decade. References used in this chapter that describe new mouse models of obesity, anorexia, obesity resistance, or animals with altered response to diet, and genetically or chemically induced obesity were grouped by decade.

lipase C and adenylate cyclase. In this mouse model, maternal inheritance of the mutant allele leads to body weight gain by 30–40 days, while paternal inheritance has the opposite effect of reduced body weight. There is no difference in food intake between those that inherit the allele maternally or those that inherit it paternally, suggesting that the difference lies in energy utilization pathways. Humans with Albright hereditary osteodystrophy (AHO) syndrome, which is linked to mutations in GNAS,[17] display the phenotypes of obesity, skeletal defects, and short stature, similar to Gnas-deficient mice. Individuals with maternal inheritance of the mutation also display multihormone resistance.[16] The mouse model therefore resembles the human syndrome to some extent, and offers some unique insight into the role of G-proteins in sex-specific modes of inheritance that specify differences in body weight regulation and adipocyte differentiation. These are just some examples of the numerous types of models available to study aspects of juvenile-onset obesity and the possibility of extending these findings to studies of human obesity.

Table 71–1
Models of juvenile-onset obesity

Model	*Genetics*	*Phenotype*
Agouti yellow[41]	Dominant spontaneous mutation in the agouti protein	Obesity, diabetics, and some tumor formation
AGRP transgenic[42]	Transgenic overexpression of human agouti-related protein	Obesity without changes in pigmentation (as found in lethal yellow mouse) by 4–6 weeks of age
ASIP transgenic (3 types)[43–45]	Transgenic overexpression of agouti protein using three different promoters	Increased body fat and body mass
Alpha 2 transgenic-beta 3 AR deficient[46]	Transgenic containing overexpression of α_2- and deletion of β_3-adrenergic receptors in adipose tissue	Obesity due to adipocyte hyperplasia
ApoE$^{-/-}$; db/db double knockout mice[47]	Deletion of both leptin receptor and apolipoprotein E genes	Obesity similar to db/db mice with atherosclerosis
BAT ablated[48]	Transgenic expression of diphtheria toxin from the uncoupling protein 1 promoter, leading to ablation of all brown fat	Obesity by 6 weeks of age with hyperphagia
CDKI p21 deficient[49]	Deletion of the p21 subunit of cyclin-dependent kinase inhibitor (Cdkn1a) gene	Mild obesity due to adipocyte hyperplasia
CDKI p27 deficient[49]	Deletion of the p27 subunit of cyclin-dependent kinase inhibitor (Cdkn1b) gene	Mild obesity due to adipocyte hyperplasia
CDKI p21/p27 double knockout[49]	Deletion of both subunits of CDKI	Increased body fat and adipocyte numbers by 6 weeks of age
CRF transgenic[50]	Overexpression of the corticotrophin-releasing factor gene	Cushing's syndrome phenotype, including large adipose tissue deposits
Db (diabetic obese)[9,51]	Spontaneous mutation of the leptin receptor	Obesity with diabetes evident around 4 weeks of age
DRD3 deficient[52]	Deletion of the dopamine-3 receptor gene	Males show obesity on a high fat diet with normal weight on normal chow; females demonstrate no change in body weight, but increased body fat on either diet
Gal/NPY deficient[53]	Deletion of both galanin and NPY genes	Significantly increased body weight by 1 week of age and 30% increase by 24 weeks of age; hyperphagia is present
GASKO mice[54]	Deletion of the gastrin gene	Increased body fat by 2 months of age with hyperinsulinemia by 1 month of age; body weight is not visibly increased until 7 months of age; food intake is reduced

Table 71–1 (continued)

Model	*Genetics*	*Phenotype*
Gnas deficient (maternal inheritance)[16]	Deletion of the maternally inherited copy of the G-protein α-subunit; note that deletion of the paternally inherited allele has the opposite phenotype (see Table 71–3)	Mice with the maternally inherited mutant allele show increased body weight by 30–40 days of age, reduced metabolic rate, but no change in food intake relative to control animals
GSK-3βtransgenic[55]	Transgenic overexpression of human glycogen synthase kinase 3β gene by a muscle-specific promoter	Significant increase in body weight by 6 weeks of age with modest gain by 28 weeks of age; modest increase in body fat
IAP deficient[56]	Deletion of the intestinal alkaline phosphatase gene	Obesity on high fat diet with normal weight on normal chow
IDPc transgenic[57]	Transgenic overexpression of the cytosolic NADP(+)-dependent isocitrate dehydrogenase gene with liver and adipose expression	Obesity by 4–5 weeks of age in male and female transgenics with no hyperphagia
Lep/MC4R deficient[14]	Double deletion of leptin and melanocortin-4 receptor genes	Mouse models show an additive effect on obesity compared to the single mutants
LepR deficient, neuronal specific[58]	Cre-lox-mediated deletion of leptin receptor gene in neuronal cells	Increased body weight beginning by 5 weeks of age accompanied by increased food intake
bLHbeta-CTP transgenic[59]	Expression of a chimeric bovine luteinizing hormone (LH) β-subunit/human chorionic gonadotropin β-subunit COOH-terminal extension	Increased body weight by 5 weeks of age in females only with increased food intake and decreased metabolic rate; no body weight differences were found in male mice
MT deficient[60]	Deletion of both the metallothionine-I and -II genes	Increased body weight noticeable by 5–7 weeks, with significantly increased white fat by 7 weeks and hyperphagia
NMU deficient[61]	Deletion of the neuromedin U gene	Increased body weight and fat by 4 weeks of age with hyperphagia and reduced energy expenditure
Ob (obese)[11]	Spontaneous mutation of leptin	Obesity with diabetes evident around 4 weeks of age
OG2-NcadDeltaC transgenic[15]	Transgenic overexpression of a dominant negative N-cadherin	Increased juvenile adipogenesis and body weight that are absent in adulthood
POMC deficient[10]	Deletion of the proopiomelanocortin gene	Increased body weight and fat prior to 2 months of age accompanied by hyperphagia and yellow pigmentation
PSLCR1 deficient[62]	Deletion of the phospholipid scramblase 1 gene	Mildly increased adiposity prior to 2 months of age
PSLCR3 deficient[62]	Gene-trap-mediated deletion of the phospholipid scramblase 3 gene	Increased adiposity prior to 2 months of age
Resistin transgenic[63]	Adipose-specific overexpression of a dominant negative form of the resistin gene	Mild obesity by 40 days of age on normal chow or high fat diet with protection from the development of insulin resistance
SH2-B deficient[64]	Deletion of the src homology 2 domain B protein gene	Increased body weight in both males and females by 6 weeks of age with significantly increased food intake
Sim1 heterozygous[65,66]	Deletion of the mammalian single-minded 1 homologue gene using either standard knockout or floxed gene	Increased body weight before 8 weeks of age that is exacerbated by a high fat diet; increased linear growth with increased food intake and decreased energy expenditure
SLC6A1 transgenic[67]	Overexpression of the γ-aminobutyric acid transporter subtype I gene	Increased body weight and fat with reduced spontaneous activity
SREBF1 transgenic[68]	Transgenic overexpression of the sterol regulatory element-binding protein-1a in adipose tissues	Enlargement of brown fat, accompanied by fatty livers
STAT3 deficient[69]	Neuronal-specific deletion of the signal transducer and activator of transcription 3 gene	Obesity by 6–8 weeks of age with a 5-fold increase in total fat content; animals are hyperphagic, diabetic, and infertile

MODELS OF ADULT-ONSET OBESITY

In humans, adult-onset obesity is currently about twice as common as juvenile-onset obesity.[18] Mouse models of adult-onset obesity are characterized as those models displaying obesity on normal rodent chow after 9 weeks of age (Table 71–2). In all, 60 models that can be classified as having adult-onset obesity have been characterized, which is nearly twice the number of models of juvenile obesity.

An intriguing observation is that mouse models of adult-onset obesity appear to have only one side of the energy balance equation altered. Of 34 models of juvenile-onset obesity, only three models (~9%) were reported to have normal or reduced food intake, suggesting that up to 90% of mouse models of juvenile-onset obesity could be hyperphagic. For models of adult-onset obesity, 12 of 60 (~20%) display reduced or normal food intake, while only 11 of 60 (~18%) are reported to be hyperphagic. Models with juvenile-onset obesity were more likely to be both

Table 71–2
Models of adult-onset obesity

Model	*Genetics*	*Phenotype*
AqP7 deficient[70]	Deletion of the aquaporin 7 gene	Obesity after 12 weeks of age with no difference in oxygen consumption but decreased rectal temperatures after 20 weeks of age
ARKO mouse[71,72]	Deletion of the androgen receptor	Late-onset gonadal fat accumulation and increased body weight after 10 weeks of age and testicular feminization
AP2 deficient[73]	Deletion of the adipocyte fatty acid-binding protein gene	Diet-induced obesity without insulin resistance; not obese on regular chow
Ataxin-2 deficient[27]	Deletion of the ataxin-2 (Sca2) gene	Obesity on high fat diet; on normal chow increased body weight is evident after 1 year of age
Beta-less[74]	Deletion of all three β-adrenergic receptors	Slight obesity on chow by 14 weeks of age; massive obesity on high fat diet due to failure of diet-induced thermogenesis
BBS1 deficient[75]	Deletion of Bardet–Biedl syndrome 1 homolog	Obesity by 10 weeks in a subset of the animals
BBS4 deficient[75,76]	Deletion of Bardet–Biedl syndrome 4 homolog	Obesity by 12 weeks of age in males and 8 weeks of age in females
BDNF heterozygous[26,77]	Heterozygous deletion of the brain-derived neurotrophic factor gene	Approximately 50% of mice become obese by 3 months of age on normal chow; obesity can be induced earlier on a high fat diet; animals display hyperphagia with increased locomotion
BRS3 deficient[78]	Deletion of the bombesin receptor subtype-3 gene	Mild obesity by 14 weeks of age
CRF-BP transgenic[79]	Overexpression of the CRF-binding protein gene	Weight gain in female mice only between 8 and 12 months of age
Fat (cpe)[80,81]	Spontaneous mutation in the carboxypeptidase gene; there is also a Cpe knockout mouse that has the same phenotype	Obesity by 10–12 weeks of age; defects in proinsulin processing
FORKO mice[20]	Deletion of the follicle-stimulation hormone receptor gene	Mild obesity by 3–3.5 months of age in the homozygous females and obesity by 10–12 months of age in the heterozygotes; males do not become obese at any age
Gck transgenic[82]	Transgenic overexpression of glucokinase in liver	Impaired glucose tolerance by 6 months of age; obesity and insulin resistance on high fat diet
GDF-3 transgenic[83]	Adenovirus-induced growth differentiation factor-3	Adenovirus transduction occurred via tail vein at 3 weeks of age; no difference in body weight or fat on normal chow; increased body weight and fat on high fat diet
Gpr7 deficient[84]	Deletion of the receptor for neuropeptides B and W	Increased body weight by 10 weeks of age with hyperphagia, hypoactivity, and decreased metabolic rate
Gpr10 deficient[85]	Deletion of the prolactin-releasing peptide receptor gene	Obesity and hyperphagia by 16 weeks of age on a normal chow diet
Gpx1 transgenic[86]	Transgenic overexpression of the glutathione peroxidase gene	Significant body weight gain by 24 weeks of age with increased body fat and insulin resistance
GR (NR3C1) deficient[87]	Deletion of the glucocorticoid receptor (nuclear receptor 3C1) gene in neuronal cells	Reduced overall body weight with increased body fat in adulthood; reduced food intake and energy expenditure

Table 71–2 (continued)

Model	*Genetics*	*Phenotype*
H1 deficient[88]	Deletion of the histadine H1 receptor gene	Obesity by 30 weeks of age with greater food intake in obese animals and differences in nocturnal feeding in the mutants
H3 deficient[89]	Deletion of the histadine H3 receptor gene	Obesity by 28–30 weeks of age with greater food intake in obese animals and reduced locomotor activity
hGHRH transgenic[90]	Transgenic overexpression of the human growth hormone-releasing hormone gene	Modest increase in body weight by 4–6 months of age
HCRT trangenic[91]	Transgenic construct targeting ataxin-3 to orexin-containing neurons, effectively ablating them	Late-onset obesity despite eating less than normal controls; narcolepsy
HDC deficient[25]	Deletion of the histidine decarboxylase gene	Obesity by ~20 weeks of age with increased white and brown fat; there is no hyperphagia, but animals display increased metabolic efficiency and impaired glucose tolerance
11β-HSD-1 transgenic[92]	Overexpression of the 11β-hydroxysteroid dehydrogenase type 1 gene in adipose tissue	Increased body weight and body fat by 10 weeks of age on normal chow and exacerbated response to high fat diet; hyperglycemia, hyperinsulinemia, and hyperleptinemia on normal chow
5-HT(2C) deficient[93]	Deletion of the serotonin 5-HT(2C) receptor gene	Obesity after 6 months of age, with early hyperphagia accompanied by elevated physical activity
ICAM deficient[24]	Deletion of the intercellular adhesion molecule-1 gene	Increased body weight and fat by 18 weeks of age on normal diet with increased susceptibility to a high fat diet with some sex-dependent differences; no hyperphagia
IL-1R deficient[94]	Deletion of the interleukin-1 receptor gene	Increased body weight and fat by 5–6 months of age with lack of leptin responsiveness
IL-1/IL-6 double knockout[95]	Deletion of both the interleukin-1 and interleukin-6 genes	Earlier onset of obesity (by 10 weeks of age) compared to the single knockouts
IL-6 deficient[96,97]	Deletion of the interleukin-6 gene	Obesity after 6 months of age with a 20% weight gain by 9 months of age, accompanied by a 50–60% increase in total body fat; another report shows no obesity in IL-6-deficient mice
IL-18 deficient[98]	Deletion of the interleukin-18 gene	An 18.5% increase in body weight and significantly increased body fat by 6 months of age with hyperphagia and normal energy expenditure
IL-18R deficient[98]	Deletion of the interleukin-18 receptor gene	Similar phenotype to IL-18 knockout mice, with obesity developing by 6 months of age
*f*Irs2:cr^2 mice[99,100]	Conditional deletion of insulin receptor substrate 2 in β cells and hypothalamus	Adult-onset obesity by 10 weeks of age with diabetes that resolves due to β cell repopulation later in life
mIRKO mice[101,102]	Muscle-specific deletion of the insulin receptor gene	Increased adipose tissue deposits by 4 months of age without hyperinsulinemia or diabetes
Kir6.2KO[103]	Deletion of the potassium inwardly rectifying channel, Kir6.2	Adult-onset obesity following a mild impairment of glucose tolerance and failure to secrete glucose in response to insulin at younger ages
MC3R deficient[104,105]	Deletion of the melanocortin-3 receptor gene	Increased body weight and fat by 3–4 months of age with normal food intake and metabolic rate, but reduced spontaneous activity
MC4R deficient[12,13]	Deletion of the melanocotrin-4 receptor gene	Increased body weight and fat by 7–12 weeks of age with hyperphagia, reduced metabolic rate, and reduced spontaneous activity
MMP19 deficient[23]	Deletion of the matrix metalloproteinase 19 gene	On normal chow the animals show increased weight when very aged, and show diet-induced obesity due to adipocyte hypertrophy within 20 weeks of high fat diet feeding in males; animals are resistant to skin cancer

continued

Table 71–2 (continued)

Model	*Genetics*	*Phenotype*
NEIL1 deficient[22]	Deletion of the neil1 gene	Males develop significant obesity after 6 months of age with mild obesity in the females during the same time frame
Nhlh2 deficient[19,106]	Deletion of the nescient (neural) helix-loop-helix gene	Adult-onset obesity by 10–12 weeks of age in males and 7–9 weeks of age in females; animals have normal food intake but reduced spontaneous activity
NPY Y1 receptor deficient[107]	Deletion of the neuropeptide Y1 receptor gene	Increased body weight by 9 weeks of age with females showing more substantial increases than males; no hyperphagia but animals show increased feed efficiency
NPY Y5 receptor deficient[108]	Deletion of the neuropeptide Y5 receptor gene	Mild adult-onset obesity with hyperphagia
NTSR1 deficient[109]	Deletion of the neurotensin type 1 receptor gene	Obesity by 11 weeks of age accompanied by hyperphagia and a slight reduction in locomotion
P62 deficient[110]	Deletion of the signaling adapter protein p62 gene	Obesity after 4 months of age with increased food and water intake
PARP1 deficient[111]	Deletion of the poly(ADP-ribosyl)transferase gene	Increased body weight in aged animals on a mixed C57BL/6 × 129/Sv background
PC1 heterozgyous[112,113]	Deletion of the prohormone convertase I gene	Heterozygotes show increased body weight by 10–12 weeks of age; homozygous animals are growth delayed; increased proinsulin levels and reduced mature insulin levels due to lack of processing by PC1
PC1 point mutants[114]	Induced mutagenesis with identification of a point mutation in the prohormone convertase I gene	Mild obesity after 8 weeks of age that is more prominent on breeder diet than normal chow; there is no development of diabetes despite defective insulin processing
PKCtheta deficient[115]	Deletion of protein kinase C θ subunit gene	Normal body weight with increased body fat and decreased physical activity without hyperphagia on normal chow
PKCtheta transgenic[116]	Transgenic expression of a dominant negative protein kinase C θ subunit in skeletal muscle	Obesity by 4 months of age with hyperinsulinemia and reduced insulin sensitivity by 6 months of age
ProSAAS transgenic[117]	Transgenic overexpression of the PC1 inhibitor protein pro-SAAS from the β-actin promoter	Mild obesity by 9–10 weeks of age with no hyperglycemia
Prox1 deficient[118]	Deletion of the Prox1 homeobox gene	Significant increase in body weight after 9 weeks of age with large adipocytes and increased lipid deposits; mice also have defective lymphatic vasculature
PPARγ deficient[119]	Muscle-specific deletion of the peroxisome proliferators-activated receptor γ gene	No overt body weight difference by 12 months of age, but increased body fat at 4 months of age and increased susceptibility to a high fat diet; no hyperphagia
PPKO mice[120]	Deletion of the PIP3 phosphatase Pten gene in POMC neurons	Mild obesity after 16 weeks of age on normal chow in increased food intake but normal energy expenditure
PPP1R3A deficient[121]	Deletion of the glycogen targeting subunit of the protein phosphatase 1 gene	Mildly increased body weight by 4 months of age with only a 20% increase over normal animals by 1 year of age; large increases in body fat are accompanied by insulin resistance
R6/2 transgenic[122]	Transgenic for exon 1 of the human HD gene containing over 100 copies of the repeat region in Huntington disease protein	Increased body fat by 8–9 weeks of age, then wasting and death by 15 weeks of age; overall growth retardation
Rn8–12 transgenic[21]	Transgenic expression of the human renin gene	Male-specific adult-onset obesity and increased body fat by 15 weeks of age
Syndecan-1 transgenic[123]	Transgenic misexpression of syndecan-1 in the hypothalamus	Noticeably increased body weight after 8 weeks of age with a transgene dosage effect and up to a 70% increase in food intake

Table 71–2 (continued)

Model	*Genetics*	*Phenotype*
SPARC deficient[124]	Deletion of the secreted protein acidic and rich in cysteine/osteonectin/BM-40	Increased body fat (including skin) without significant increases in body weight after 10 weeks of age; increased adipocyte number and size
Tfam deficient (POMC neurons)[125]	Cre-lox-mediated deletion of the mitochondrial transcription factor Tfam in POMC neurons, resulting in progressive neurodegeneration of POMC neurons	Significant increase in body weight by 4 months of age with hyperphagia and reduced oxygen consumption
TRα mutant[126]	Insertional mutagenesis of the thyroid hormone receptor α gene with a dominant-negative form	Increased body weight (3-fold) and fat (4-fold) after 3 months of age without hyperphagia
Tub[127–129]	Spontaneous and induced (knockout) mutations in the Tubby-1 gene	Adult-onset obesity occurring after 8 weeks of age with nearly double body weight by 19 weeks of age, reduced fertility, reduced food intake, and locomotor defects; Tubby-1 mutants also display degenerative eye disease and progressive blindness

hyperphagic and have altered energy expenditure, either through metabolism or physical activity, than models with adult-onset obesity, which were more likely to be either hyperphagic or have reduced energy expenditure. While not all mice have these parameters reported, it is interesting that hyperphagia in combination with reduced metabolism or exercise appears to lead to earlier onset obesity than reduced energy expenditure alone without increased food intake. As an example of this type of model, the neuronally expressed nascient helix-loop-helix-2 (Nhlh2) gene[19] knockout mouse shows no hyperphagia or reduced body temperature, but a significant reduction in spontaneous physical activity, leading to late-onset obesity. Models of adult-onset obesity may reflect the result of having one side, but not both sides of the energy balance equation altered.

Several models in this grouping display sex differences in body weight gain. While the prevalence of obesity in humans is similar for males and females, there is a trend toward higher rates of obesity in U.S. women.[18] There are some models of adult-onset obesity that display sex-dependent differences in body weight gain. For example, in the mouse model that contains a deletion of the follicle-stimulating hormone receptor gene, only females display weight gain by 3–5 months of age, even though both males and females show the expected disruption of the reproductive axis.[20] Male-specific weight gain occurs with transgenic overexpression of the human renin gene,[21] and is more severe in males containing a deletion of the NEIL DNA endonuclease.[22] An interesting future use of these models will be in discerning the role of these proteins in sex-specific patterns of weight gain.

Several models in this category display late-onset obesity, but display an earlier onset of weight gain triggered by a high fat diet. These models are to be distinguished from some of those in Table 71–5 (p. 695) that show obesity only on high fat or modified diets. While intriguing, it is not clear whether most or even all of the adult-onset models would respond to high fat diets in this way. Those that have been identified to date range from genes involved in extracellular matrix function (MMP19,[23] ICAM,[24] and 11βHSD-1[25]), to nervous system growth and development (BDNF[26]), to proteins that may be involved in the assembly of polyribosomes (ataxin-2[27]). In each of these examples, onset of obesity can be shortened by several weeks or even several months when models are given access to a high fat diet. While there does not seem to be any obvious connection between these few genes that have been characterized thus far, more work in this area may reveal new genes and new links between genes involved in the regulation of diet-induced changes in body weight.

MODELS WITH REDUCED BODY WEIGHT

This group of models includes those with anorexia, reduced weight, or reduced body fat under normal feeding conditions (Table 71–3). There are almost as many models showing reduced body weight (74) as those with obesity (95, including both juvenile and adult-onset obesity). This suggests, as might be expected, that similar numbers of positively and negatively acting regulatory pathways exist in the control of body weight.

Many of the genes linked to reduced body weight appear to regulate adiposity and body weight through the control of food intake, as noted by the anorexic phenotype of many of the models. As an example, the M3 muscarinic receptor knockout mouse shows anorexia under normal food availability conditions and consequently displays reduced peripheral body fat and body weight.[29] While these animals also show an abnormal reduction in melanin-concentrating hormone in response to fasting,[29] it is not clear whether the effect of the receptor deletion on body weight regulation is centrally or peripherally mediated, as these receptors are found in both the nervous system and gastrointestinal smooth muscle and endocrine cells.[30]

Other models in this group exhibit no change in food intake, but a compensatory upregulation of energy utilization via either increased metabolism or increased physical activity. Examples of this include both the VGF (nonacronymic) knockout mice and the dopamine D1 receptor knockout mice. These mutant mice display increased physical activity with no change in normal food intake.[31,32] Evidence suggests that both of these factors signal through central melanocortin receptors to mediate locomotor activity.[33,34] As MC4R mutant mice show reduced locomotor activity with increased body weight,[12,13] it will be interesting in the future to determine if control of physical activity is mediated exclusively through the melanocortin system, and if agents that

Table 71–3
Models with reduced body weight

Model	*Genetics*	*Phenotype*
anx/anx[130]	Recessive mutation on chromosome 2 (spontaneous)	Anorexia, death by postnatal day 35, reduced body fat, ataxia
ACC deficient[131]	Deletion of acetyl-CoA carboxylase 2 leading to reduced malonyl-coenzyme A levels	Reduced body fat due to higher rate of fatty acid oxidation
ADAMTS1 deficient[132]	Deletion of the ADAMTS-1 gene	Reduced body weight due to adipose tissue malformation and growth retardation
ADCYAP-1 deficient[133]	Deletion of pituitary adenylate cyclase-activating polypeptide 1 (also called PACAP)	Wasting, death by postnatal day 14
AKT1 transgenic[134]	Overexpression of AKT1 in skeletal muscle	Reduced adipose tissue
AKT2 deficient[135]	Deletion of AKT2 gene	Age-dependent loss of adipose tissue
C3 deficient[136]	Deletion of complement C3, leading to loss of acylation-stimulation protein (ASP)	Reduced body weight, reduced body fat, and ability to suppress ob/ob phenotype
CAV1 deficient[137]	Deletion of caveolin 1 gene	Late-onset reduced body weight due to abnormal lipid homeostasis
CB1 deficient[138]	Deletion of the CB1 cannabinoid receptor gene	Lean with a resistance to diet-induced obesity
ChREBP deficient[139]	Deletion of the carbohydrate response element-binding protein gene	Reduced epididymal white fat and brown fat with mild insulin resistance
Cidea deficient[140]	Deletion of the cidea gene	Lean with resistance to diet-induced obesity, most likely due to higher metabolism through brown fat
Clock deficient[141,142]	Deletion of the clock gene	Impaired absorption of dietary fat with resistance to diet-induced obesity; increased body weight on normal chow with changes in diurnal feeding pattern
Contactin deficient[143]	Deletion of contactin-1 gene	Anorexia and ataxia
CPT1c deficient[144]	Deletion of the carnitine palmitoyltransferase-1c	Reduced body weight and food intake, but a unique increased susceptibility diet-induced obesity
D1R deficient[32]	Deletion of the D1 dopamine receptor	Reduced body weight, hyperactivity
DD[145,146]	Deletion of the tyrosine hydroxylase gene in all cells with restoration only in nonadrenergic cells	Anorexia, reduced spontaneous activity, death by postnatal day 28
DeltaFosB transgenic[147]	Overexpression of DeltaFosB	Reduced adipogenesis
DGAT deficient[148]	Deletion of acyl CoA:diacylglycerol acyltransferase gene	No increased weight on high fat diet, although food intake is similar, increased metabolic rate
DHCR24 deficient[149]	Deletion of the desmosterol reductase gene	Reduced cholesterol biosynthesis, reduced subcutaneous fat, infertility
DLK1 deficient[150]	Transgenic expression of the Pref-1 ectodomain fused to the human immunoglobulin constant domain driven by either the adipocyte fatty acid-binding protein promoter or the albumin promoter	Loss of adipose tissue
EIF4EBP1 deficient[151]	Deletion of the translation initiation factor 4E-binding protein gene	Reduced adipogenesis and in males, increased metabolic rate
ERRalpha deficient[152]	Deletion of the estrogen-related receptor α gene	Reduced body weight and fat, normal food intake and energy expenditure; resistance to high fat diet-induced obesity
Fatty liver dystrophy[153]	Spontaneous mutation in the lipin-1 gene	Loss of body fat and resistance to diet-induced obesity
FoxC2 transgenic[154]	Expression of human FoxC2 from adipocyte-binding protein 2 promoter	Reduced intraabdominal fat on normal diet and resistance to diet-induced obesity; increased brown fat
GAMT deficient[155]	Deletion of the guanidinoacetate *N*-methyltransferase gene	Reduced body weight and fat with no change in food intake, activity, or serum leptin levels
GDF8 deficient[156,157]	Deletion of myostatin	Reduced fat accumulation with increasing age; partial suppression of ob/ob phenotype; increased myogenesis
GFA2 deficient[158]	Deletion of glial cell-line-derived neurotrophic factor receptor α2 gene	Reduced fat mass and elevated metabolic rate
GHSR transgenics[159]	Overexpression of the human growth hormone secretagogue receptor 1A in GHRH neurons	Decreased adipose mass, most significant in females, without body weight change
GIPR deficient[160]	Deletion of the gastric inhibitory peptide receptor gene	Reduced metabolic rate and preferential use of fat as a substrate for energy expenditure; resistance to diet-induced and genetic obesity

Table 71–3 (continued)

Model	*Genetics*	*Phenotype*
GLUT4 deficient[161]	Deletion of the insulin-sensitive glucose transporter gene	Growth retardation and reduced fat with normal glucose regulation
GNAS deficient (paternally inherited)[16]	Deletion of the paternally inherited copy of the G-protein α subunit; note that deletion of the maternally inherited allele has the opposite phenotype (see Table 71–1)	Mice with the paternally inherited mutant allele show decreased body weight by 30–40 days of age, increased metabolic rate, but no change in food intake relative to control animals
Gng3 deficient[162]	Deletion of the G-protein γ3 subtype gene	Both males and females display reduced body weight, but in females this is more pronounced with a 25% reduction in body weight and reduced fat pads
Gpam deficient[163]	Deletion of the mitochondrial glycerol-3-phosphate acyltransferase gene	Reduced body weight and gonadal fat pads
Gpr24 deficient[36]	Deletion of the melanin-concentrating hormone-1 receptor gene	Lean, with increased metabolic rate and activity, and with increased food intake; resistant to diet-induced obesity
11β-HSD-1 deficient[164]	Deletion of the 11β-hydroxysteroid dehydrogenase type 1 gene	Reduced gonadal fat on regular chow diet and increased resistance to effects of a high fat diet in obesity-resistant MF-1 mice and C57BL/6 diabetes-susceptible mice
HSL deficient[165,166]	Deletion of the hormone-sensitive lipase gene	Reduced body fat with similar body weight on normal chow and resistance to diet-induced obesity with higher core body temperature on high fat chow
IL-1ra deficient[167,168]	Deletion of the IL-1 receptor antagonist gene	Reduced body weight by 6 weeks of age; resistant to monosodium glutamate-induced obesity
Kv1.3 deficient[169]	Deletion of the potassium voltage-gated channel subtype 3	Decreased body weight with increased basal metabolic rate and protection from diet-induced obesity
LgsKO mice[170]	Liver-specific deletion of the stimulatory G-α subunit gene	Reduced fat mass with normal body weight
Little[171]	Recessive mutation in the growth hormone-releasing hormone receptor (spontaneous)	Decreased body weight with dwarfism
LXRbeta deficient[172]	Deletion of the liver X receptor β gene	Reduced adipose mass and resistance to diet-induced obesity
M3 deficient[29]	Deletion of the M3 muscarinic receptor	Anorexia, reduced peripheral body fat
MAPK8IP1 deficient[173]	Deletion of the mitogen-activated protein kinase 8 interacting protein 1 (JNK1) gene	Reduced weight gain on normal chow and high fat diet with decreased adiposity and ability to suppress obesity in ob/ob mice
MCH deficient[174]	Deletion of the promelanin-concentrating hormone gene	Anorexia, lean, reduced metabolic rate
MCH neuron ablated[175]	Targeted ablation of melanin-concentrating hormone neurons using transgenic ataxin-3 gene expression	Reduced fat mass and body weight by 7 weeks of age with reduced food intake correlated with the reduced body weight, and increased energy expenditure, especially in male transgenics
Md[176]	Recessive mutation in the mahoganoid gene (spontaneous)	Ability to suppress obesity in A^y mice; hyperphagia with elevated metabolic rate
Mg[176]	Recessive mutation in the mahogany gene (spontaneous)	Identical to the Md mouse
Mrf-2 deficient[177]	Deletion of the Mrf-2 gene	Low weight gain in surviving homozygotes; reduced levels of white and brown adipose tissue
NPY deficient[178]	Deletion of the neuropeptide Y gene	Ability to suppress obesity in ob/ob mice
Perilipin deficient[179]	Deletion of the perilipin gene	Reduced adipose mass with increased leptin production and resistance to diet-induced obesity
PGs1 deficient[180,181]	Deletion of Gtrgeo22 using the gene trap method; later identified as polyglutamylase subunit 1	Reduced body fat and infertility in males
PI3KR1 deficient[182]	Deletion of the phosphoinositol-3-kinase regulatory subunits p50α and p55α splice variants	Increased insulin sensitivity with reduced adipose accumulation
PIP5K2B deficient[183]	Gene-trap-mediated deletion of the phosphatidylinositol-4-phosphate 5-kinase, type II, β gene	Enhanced glucose sensitivity and reduced adiposity

continued

Table 71–3
(continued)

Model	*Genetics*	*Phenotype*
PP transgenic[184]	Overexpression of the pancreatic polypeptide cDNA	Results in approximately 50% postnatal lethality due to reduced food (milk) intake; the surviving animals have reduced body weight and fat; a reduced rate of gastric emptying may be causative
PPARδ transgenic[185]	Overexpression of peroxisome proliferators activated receptor δ-VP16 fusion gene in adipose tissue	Transgenics range from reduced adipose mass to no detectable white fat; protection from both diet-induced and genetic obesity
PPARγ heterozgyous[99,185,186]	Deletion of one allele of peroxisome proliferator-activated receptor[187] or Cre-lox-mediated deletion of the gene in adipocytes[186]	Reduced fat mass and absence of insulin resistance following high fat diet
PTP-1B deficient[188,189]	Deletion of the protein tyrosine phosphatase 1B gene, or neuronal-specific deletion with similar phenotype	Reduced body weight and leanness in male mice by 7 weeks of age; resistance to high fat diet for both male and female mice
PTTG deficient[190]	Deletion of the pituitary tumor-transforming gene	Reduced body weight with no increases after 6 months of age in males and loss of epididymal fat pads; hyperglycemia and reduced insulin in response to glucose in aged males; gonadectomy of females results in hyperglycemia
RIIβ deficient[191]	Deletion of the protein kinase A RIIβ subunit	Lean with elevated metabolic rate and resistance to high fat diet-induced obesity despite normal food intake
Ras-GRF1 deficient[192]	Deletion of the Ras guanine nucleotide-releasing factor 1 gene	Reduced body weight and leanness due to lipid turnover
RSK1 deficient[193]	Deletion of the ribosomal S6 kinase 1 gene	Reduced body weight and fat with reduced adipocyte size and beta cell mass
RSK2 deficient[194]	Deletion of the ribosomal S6 kinase 2 gene	Loss of white adipose tissue and reduced body weight with age, accompanied by reduced serum leptin levels
SCD1 deficient[195]	Deletion of the steroyl-coenzyme A desaturase 1 gene	Reduced body weight and fat despite a 25% increase in food intake
SOCS3 deficient[196]	Neuron-specific deletion of the suppressor of cytokine signaling 3 using either nestin or syndecan-promoter-driven Cre recombinase	Reduced body weight due to enhanced weight loss and food intake suppression in response to leptin; resistant to diet-induced obesity
STAT5b deficient[197]	Deletion of the signal transducer and activator of transcription 5b gene	Loss of sexually dimorphic growth rates with reduced growth in males and slightly increased growth in females; overall reduced body fat in young animals with obesity occurring by 9 weeks of age in older males and females
TGFβ1 transgenic[198]	Overexpression of the transforming growth factor β1 protein in liver, kidney, and white and brown adipose tissue	Reduced body weight and 30% reduction in body fat with ability to suppress obesity in ob/ob mice; the animal is a model of lipodystrophy
TKT deficient[199]	Heterozygous deletion of the transketolase gene	While homozygous deletion is lethal, heterozygotes are growth retarded and have reduced fat
UCP1 deficient[200]	Deletion of the uncoupling protein-1 gene	Increased brown fat deposits in areas of inguinal white fat, accompanied by increased energy expenditure, reduced body temperature, and resistance to diet-induced obesity
UCP1 transgenic[201]	Overexpression of uncoupling protein-1 gene in heart and skeletal muscle	Thirty percent reduction in body weight by 5 weeks of age accompanied by similar to increased food intake and increased energy expenditure
UCP2 and UCP3 transgenic[202]	Expression of both the human uncoupling protein 2 and 3 from a bacterial artificial chromosome	Significantly reduced fat mass for one of the lines, and nearly significant reduction for a second transgenic line; both hyperphagia and reduced physical activity are present in the transgenics
Unc5c insertional transgenic[203]	Insertion of a telomerase reverse transcriptase gene in intron 1 of the Unc5c receptor gene	Up to a 30% reduction in body weight with reduced epididymal fat, ataxia, and increased spontaneous activity
Wnt10B transgenic[204]	Expression of Wnt10B from the FABP4 promoter that targets to white and brown adipose tissue	Increased body weight with a 30% reduction in body fat and resistance to diet-induced obesity
Vgf deficient[31,34]	Deletion of Vgf (no acronym) peptide	Reduced adiposity, increased metabolic rate, increased physical activity; Vgf deletion blocks development of obesity in several models
Zfp-36 deficiency[205]	Deletion of the Zfp-36 gene, encoding the putative tristetraprolin transcription factor	Reduced body weight and cachexia that may be due to aberrant tumor necrosis factor α expression

can modulate melanotonergic tone can be used for treating human body weight disorders.

MODELS TO STUDY POLYGENIC CONTRIBUTIONS TO OBESITY

Only up to 5% of all cases of human obesity can be attributed to monogenetic causes. These include single gene mutations that affect melanocortin signaling, including mutations in the leptin gene, the leptin receptor gene, the POMC gene, and the MC4R gene.[8] Most common human obesity can be attributed to multiple genes (polygenic causes), with environmental influences on the genetic penetrance or susceptibility of the resultant phenotype.[18] At present, 17 polygenic mouse models with disorders in body weight regulation exist for the study of polygenic obesity (Table 71–4) and more are being created in order to study this complex genetic disorder. There are also a number of studies not included in this listing that have demonstrated the presence of linked loci on specific mouse chromosomes that influence body weight.[5] These chromosomal regions and the genes within them may contribute to polygenic forms of obesity in humans, but this research is still ongoing. It is expected that future mouse models of polygenic obesity will be created using transgenic mutagenesis, knockout, and conditional knockout technologies to study the interaction of multiple alleles of body weight regulatory genes on this complex phenotype.

Table 71–4
Polygenic models of body weight control

Model	*Genetics*	*Phenotype*
AKR/J[35,206,207]	A substrain of AKR, which was derived by a mouse dealer named Detwiler in Norristown, PA; the AKR/J substrain has been maintained by the Jackson Laboratories	Increased body weight and fat on both normal chow and high fat diet with a strong preference for high fat foods and hyperphagia; QTLs have been identified on chromosomes 9 and 15 using these animals
Berlin fat lines[208]	Selective breeding of an outbred population of mice for increased body fat without overall increased body weight; three lines exist with different sensitivity to diet-induced obesity	Increased body weight is evident by 3 weeks of age with significant increases in body fat contents
BSB[209,210]	Strain derived from a backcross of C57BL/6J × *Mus spretus*	Body fat ranges from 1% to 50% in a backcrossed strain with no detectable sex difference in weight gain; QTLs for body fat on 6, 7, 12, and 15 have been identified using this model
C57BL/6J[35,206]	The most widely used inbred line of mice; created by mating female 57 with male 52 from Miss Abbie Lathrop's stock	Increased body fat compared to other common inbred mouse strains, with a tendency to select high fat foods
CAST/Ei	Derived from a strain of *M. musculus castaneus* from Thailand	Relatively lean with no increased body weight when given a high fat diet for up to 32 weeks; this strain is commonly used in crosses with obese lines
DBA/2J[35,206]	Very commonly used inbred line of mice; it is reportedly the oldest of all inbred strains of mice and was derived by C.C. Little by selective breeding for a dilute coat color	Moderate body fat gain with no change in body weight and a preference for high fat foods
Du6i[211]	This line is the largest selected inbred strain of mice; the line is an inbred derivative of Du6 selected for high body weight over 78 generations	Increased body weight in both males and females by 21 days of age with increases in male body weight surpassing females by 42 days of age
Fat "F" mice[212,213]	Derived in a selection strategy over 50 generations using an original three-way cross of parental lines CBA, JU, and CFLP	There is a 5- to 8-fold increase in body fat over the similarly selected lean mouse line; fat mice have a slight reduction in fertility; QTLs on chromosomes 2, 12, 15, and X have been mapped
KK mouse[214,215]	Spontaneously arising inbred line of mice selectively bred for obesity and diabetes	Maturity-onset obesity with earlier onset by high fat diet; QTLs for body weight and diabesity have been mapped to chromosomes 4, 6, and 16
M16[216,217]	Long-term selection for weight gain from an ICR parental population	Increased body weight by 6 weeks of age accompanied by increased feed efficiency, but no difference in food intake when adjusted for body weight; a QTL for fatness on chromosome 2 has been mapped using this line
NONcNZO10/LtJ[218]	Derived by crossing NZO/H1LtJ × NON/LtJ	Early-onset obesity in males with diabetes appearing in the animals with the highest level of weight gain
New Zealand obese (NZO/HlLt)[219]	Originated in a colony of inbred agouti mice and selected for coat color and obesity to F_{17}	Males show early-onset obesity and develop late-onset diabetes, while females show only obesity and appear resistant to diabetes

continued

Table 71–4 (continued)

Model	*Genetics*	*Phenotype*
SMXA-5[220,221]	Derived from SM/J and A/J parental strains	Increased body weight and fat by 10 weeks with hyperinsulinemia and impaired glucose tolerase; a QTL mapped to chromosome 2 has been characterized
SMXA-9[220]	Similar to SMXA-5	Similar to SMXA-5 with slightly higher weight gain; no QTLs have been characterized for this strain
SWR/J[206]	Inbred mouse line derived from Swiss mice in 1926	Resistant to obesity caused by a high fat diet
TallyHo[222,223]	Theiler original males identified in a colony as hyperglycemic and hyperinsulinemic were used to create an inbred line [TH(F7)] or TallyHo; this line was crossed to C57BL/6 females for QTL analysis	Obesity and diabetes with possible QTLs on chromosomes 6 and 19
TSOD[224,225]	Created from the outbred ddY strain as an inbred strain exhibiting obesity and diabetes	Both males and females exhibit juvenile onset obesity, but only male mice show a diabetic phenotype; a QTL on chromosome 5 has been linked to adiposity in this model

One interesting note on the polygenic models listed here is that the C57BL/6J inbred strain of mouse is included in this group. This inbred line of mice displays an obesity-prone phenotype when given a high fat diet.[35] Many of the knockout mouse models listed in the other tables have used the C57BL/6J line in the creation of their models. This is because blastocysts from black coat-colored mice are commonly used to distinguish chimeras containing cells from the brown coat-colored 129SvJ line. It is possible that modifying loci that have been selected for during strain creation of the C57BL/6J line have the potential to influence the phenotypes of the knockouts using this strain as a background or a mixed background of both the C57BL/6J and 129SvJ lines. One example of the effect of background strain selection on the robustness of phenotype was recently shown for mice with a mutation of the melanin-concentrating hormone (MCH). The original MCH line was created on a mixed background and displayed leanness and a trend toward hypophagia.[36] Backcrossing this line to either pure 129SvJ or C57BL/6J mice resulted in slight differences in the penetrance of the lean phenotype. MCH knockout mice on a pure 129SvJ background resisted obesity caused by the high fat diet, but not to the level of significance of those backcrossed onto a C57BL/6J line, which normally shows susceptibility to body weight gain on a high fat diet. With the MCH deletion, C57BL/6J line mice resist high fat diet-induced obesity.[37] With this example in mind, proper use of specific mouse strains and future characterization of the polygenic influences on body weight control will help in elucidating the multiple regulatory pathways in this complex phenotype.

MODELS TO STUDY ALTERED RESPONSES TO DIETARY, GENETIC, OR CHEMICALLY INDUCED OBESITY

This grouping of mouse models is separated from the others, as none of them is reported to display increased or decreased body weight, relative to their control group, on normal rodent chow and with standard housing conditions. This group of 29 mouse models reveals altered responses, relative to normal mice, to dietary, genetic, or chemically induced obesity.

In general, mouse models that show a response only to induced obesity are very interesting as they can be used to dissect pathways controlling responses to a sole stressor on the system, instead of the many facets of body weight regulation. Only seven of these mouse models show an exaggerated response to a high fat diet. An example of this phenotype is seen in mice with a deletion of the AMP-activated protein kinase (also called PRKRR2). These animals are obese only when fed a high fat diet, although they are not hyperphagic,[38] and their overall increase in body weight is greater than normal mice given the same diet. These animals can be classified as having an abnormal response to high fat diets, which is an interesting avenue to study given the changes in human diets to more processed and high fat foods in the past few decades.

The majority of the animals listed in Table 71–5 (75%) show resistance to diet-induced, genetic-induced, or chemically induced obesity. For example, the CRF2-deficient animal contains a deletion in the corticotrophin-releasing factor receptor 2 gene and displays hyperphagia when given a high fat diet but resists diet-induced obesity that ensues in normal mice given this type of diet.[28] Another interesting model in this category is the tumor necrosis factor (TNF)-α-deficient mouse model treated with gold thioglucose (GTG) injection. GTG induces obesity in mice by lesioning the ventromedial hypothalamus. The TNF-α mutation partially protects against GTG-induced obesity, particularly with respect to development of overt diabetes.[39] These animal models with resistance to obesity are vital to research that seeks to gain an understanding of the genes and protein products than can protect against body weight gain.

An understanding of the genes that control the altered responses to induced obesity is crucial to those researchers seeking pathways to target for future drug development. It is possible that these gene products may be responsible for minute adjustments in the balance of food intake and energy expenditure by the body or in the responses of this system to moderate stresses (high fat, cold, genetic modulators). These are in contrast to those listed in the other groups, which appear to have more global affects on body weight parameters, affecting energy intake and utilization under normal or standard conditions.

Table 71–5
Models with an abnormal response to diet-induced, chemically induced, or genetic obesity

Model	*Genetics*	*Phenotype*
Alpha 1bAR	Deletion of the adrenergic receptor, α_{1b}	Obesity on a high fat diet; impaired glucose metabolism
ApoC1 transgenic[226]	Transgenic overexpression of human apoC1 gene	Resistance to genetic obesity in ob/ob mouse
Beta-1 AR transgenic[227]	Transgenic overexpression of the β_1-adrenergic receptor in adipocytes	Resistance to diet-induced obesity (DIO)
CCR2 deficient[228]	Deletion of the chemokine receptor-2 gene	Resistance to DIO with reduced inflammation in adipose tissue
c-myc transgenic (liver expression)[229]	Hepatic overexpression of the myelocytomatosis oncogene, c-myc	Resistance to a high fat diet with no change in liver-specific genes normally altered with changes in diet
CRF2 deficient[28]	Deletion of the corticotrophin-releasing factor receptor 2 gene	Consume more food on a high fat diet, but are resistant to DIO
FABP4 deficient[73]	Deletion of the fatty acid-binding protein 4, or adipocyte protein 2 (aP2)	Resistance to DIO
Foxa-2 heterozygous[230]	Heterozygous deletion of the adipocyte protein Foxa-2; homozygotes are embryonic lethal	Marked obesity and induction of Foxa-2 after 7 weeks of high fat diet feeding
Ghrelin deficient[231,232]	Deletion of the ghrelin gene and replacement with a lacZ reporter	Changes in the type of metabolic substrate (fat versus carbohydrate) preferred for energy; protection from obesity
GCK[233]	Transgenic overexpression of glucokinase in skeletal muscle	Resistance to DIO accompanied by increased metabolic rate
mGPD deficient[234,235]	Deletion of the mitochondrial glycerol-3-phosphate dehydrogenase gene	Increased body weight in females by 3 weeks of age or females on a high fat diet; no effect in males, and overall thrifty phenotype
HMGIC[236,237]	Deletion of the high mobility group DNA-binding protein 1-C gene; also known as the pygmy mouse; the gene is also known as HMGA2	Resistant to both DIO and genetic obesity
Inppl1 deficient[238]	Deletion of Inppl1, which encodes SHIP2, the SH2-domain containing inositol 5-phosphatase 2	Resistant to DIO
Mac-1 mice[24]	Receptor to ICAM-1 (leukocyte integrin $\alpha M\beta 2$)	Diet-induced obesity, but it is not clear if these animals have spontaneous obesity on chow as their body weights are too variable
MPOG human transgenic × LDLR-deficient mouse[239]	Contains the human myeloperoxidase gene with a mutation in the promoter region that results in higher expression, crossed to mice containing a deletion of the LDL receptor	Increased weight gain on high fat diet only
Myostatin propeptide transgenic[240]	Muscle-specific depression of myostatin through expression of the myostatin propeptide region	Increased muscle mass with no increase in adipose tissue on a high fat diet
loxTB Mc4r restoration[241]	Floxed MC4R locus that is inactive until crossed with Sim1-Cre, which specifically activates and restores melanocortin-4 receptor to the paraventricular nucleus (PVN)	Reversal of obesity
PAI transgenic[242]	Overexpression of plasminogen activator inhibitor (PAI) 1 from the adipocyte aP2 promoter	Transgenic overexpression has a similar effect to PAI deficiency with protection from DIO in one report
Pla2g1b deficient[243]	Deletion of the pancreatic phospholipase A2, group IB gene	Resistant to DIO with reduced fat absorption (fatty stools)
PPARGC1B transgenic[244]	Transgenic overexpression of PPARγ coactivator 1 using chicken β-actin promoter	Resistant to DIO with reduced fat and body weight
PRKRR2 deficiency[38]	Deletion of the AMP-activated protein kinase gene	High fat diet-induced obesity; no difference in weight or fat when fed a normal diet
RXR gamma deficient[245]	Deletion of the retinoid X receptor gene	Resistance to DIO with lower fat mass and leptin levels
SERPINE-1[246,247]	PAI deficiency	Resistance to DIO but no difference in weight or fat on chow in two reports; rederivation of knockout line and use of wild-type littermates from the knockout line reveals an increased accumulation of gonadal fat compared to wild-type animals
Sim1 overexpression[248]	Transgenic expression of human Sim1 on a BAC clone	Resistance to DIO and genetic obesity but no change on normal chow

continued

Table 71–5 (continued)

Model	*Genetics*	*Phenotype*
Syndecan-3 deficient[249]	Deletion of the syndecan-3 gene	Resistance to DIO, but no difference in body weight or fat on chow diet for males; there is a very slight reduction in body fat for females on a low fat diet
TNF alpha deficient[39]	Deletion of the tumor necrosis factor-α gene	Reduced body fat content following gold-thioglucose injection compared to wild-type mice
TNF alpha transgenic[250]	Expression of a noncleavable transmembrane form of tumor necrosis factor-α gene	An increased adipose content on a high fat diet with no change on normal chow
UCP3 transgenic[251]	Skeletal muscle specific expression of uncoupling protein 3	A significant resistance to a high fat diet after just 4 weeks on the diet; there is a nonsignificant trend of reduced body weight on chow
Y2Y4 deficiency[252]	Double deletion of both the NPY Y2 and Y4 receptors	Resistance to a high fat diet and genetic obesity caused by Y1 receptor deletion

CONCLUSIONS

With over 200 available mouse models to study body weight regulation from a variety of aspects, including food intake, energy expenditure, genetic obesity, diet-induced obesity, and obesity resistance, the mouse has become a very powerful model system in the field of obesity research. Basic researchers are using mice to identify and connect the signaling pathways that are activated or repressed following changes in energy availability in the body. Applied researchers are using mouse models of obesity to identify potential obesity or anorexia blocking proteins and to test newly developed drugs prior to testing in humans. It is expected that more examples of these aspects of body weight regulation using the models listed in this chapter will be published in coming years.

It is also expected that additional models will be developed. As shown in Figure 71–1, the current decade of the 2000s has nearly 4-fold more published models than the decade of the 1990s, and a nearly 200-fold increase over the 1980s. The completion of the mouse genome and the push to elucidate the function of some of the newly identified gene products using resources from The Knockout Mouse Project[40] and independent research programs should yield even more unique genetic models of obesity and disturbance in weight regulation.[41–252] What should be even more prevalent in the next few years are mouse models that are refined relative to some of the global knockouts or transgenics listed here. These include models that use conditional knockout technology or targeted transgenic mice to restrict expression or confine deletion of a gene to a particular cell type or time frame during development. Finally it is expected that mouse models of polygenic obesity or obesity resistance will increase, as investigators combine models to characterize hypothesized interactions between genes, and identify new inbred or outbred strains with unique phenotypes with respect to body weight control. The coming decade promises to bring many more developments in this field using the most common laboratory rodent, *Mus musculus.*

72 Study of Polycystic Kidney Disease in the Nematode *Caenorhabditis elegans*

MATTHEW J. BUECHNER

ABSTRACT

Polycystic kidney disease (PKD) is characterized by the uncontrolled slow swelling of tubules in the kidneys and other tissues. PKDs are some of the most common genetic diseases, and are caused by defects in the function of either of two polycystin ion channels, or of their transport to the primary cilium, one of the locations where these proteins function to detect mechanical stress on the cell. Homologues of the polycystins are found in the nematode *Caenorhabditis elegans*, where these proteins function in male-specific neurons to detect the location of the hermaphrodite vulva. Mutations in nematode polycystin genes cause defects in male mating behavior, which can be measured via various behavioral and electrophysiological assays. Mutations that affect formation of sensory cilia, or transport of materials into the cilium, also cause defects in male mating behavior, as well as defects in various tactic behaviors mediated through other neurons. The affected genes identify many homologues of other human disease genes, including nephronophthisis and Bardet–Biedl syndrome. The nematode mutations can be detected through multiple behavioral and cell biological techniques, including measurement of fluorescently-labeled polycystin into the cilium.

Key Words: *Caenorhabditis elegans*, Polycystin, Polycystic kidney disease, Nephronophthisis, Bardet–Biedl, TRP channels, Behavioral assay, Chemotaxis assay, Electrophysiology.

INTRODUCTION

Caenorhabditis elegans does not have the advanced metanephric kidney of mammals; nonetheless, this little roundworm has been instrumental in greatly increasing our understanding of polycystic kidney disease (PKD). A brief review of the discoveries found in these studies provides a good example of the strengths and limitations of invertebrate animal models in the study of human disease, and the importance of genomic information for determining the function of a protein family in cell structure. The ability of evolution to adapt conserved biochemical mechanisms to new tissues and biological roles in different organisms has dictated that study of PKD in *C. elegans* requires the ability to develop and perform behavioral and electrophysiological assays, rather than assays used to examine mammalian renal function and development.

POLYCYSTIC KIDNEY DISEASES

PKDs are a series of genetic diseases that affects the diameter of tubules in many tissues.[1] In the kidney, a subset of the numerous small nephrons and collecting tubules swells over the course of years into large fluid-filled cysts that block flow through the kidney and lead to end-stage renal disease. In addition to the kidney, PKD affects other tubular tissues, especially the liver and pancreas, and death is often caused by aneurysms of the cerebral vasculature.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE Autosomal dominant PKD (ADPKD) is the most prevalent lethal genetic disease, with estimates as high as 1 out of 200 people affected.[1,2] The high incidence of the disease is the result of the disease being caused by dominant mutation, and by the late age of onset of disease symptoms, often in the 30s, so that patients have passed the affected gene on to the next generation before symptoms occur. PKD is caused predominantly by mutations in one of two genes: PKD1 on chromosome 16, accounting for 85% of cases; and PKD2 on chromosome 4. Polycystic kidneys can also occur as a symptom of other genetic diseases, including the recessive nephronophthises,[3] von Hippel–Lindau disease,[4] Bardet–Biedl syndrome,[5] oral-facial-digital syndrome,[6] and Meckel–Gruber syndrome.[7]

Major advances in our understanding of polycystic kidneys have come from the cloning of the affected genes for PKD in the 1990s,[8,9] and of the nephronophthises and Bardet–Biedl syndrome genes[10–12] in the past decade. Studies in model organisms[13] have provided crucial information toward understanding the function of the encoded proteins in normal nephrons, and how the loss of that function in PKD patients causes unregulated growth of tubule cysts.

PKD1 and PKD2 both encode large transmembrane proteins, called "polycystins," of the TRP family of divalent ion channels.[14–16] TRP channels are a widespread and ancient family, with members found in all animals, and are used as receptors for a wide range of stimuli, including chemical odors, taste, heat, and osmolarity. Human PKD2 contains six transmembrane domains, and a cytoplasmic EF-hand to bind to calcium,[9] an endoplasmic reticulum-targeting signal, and a coiled coil to interact with other proteins, including PKD1 and CD2-associated protein.[17–19] At the cytoplasmic N-terminus was found a site to target the protein to the cilium, and a GSK3 phosphorylation site. Between the last two transmembrane domains is a loop found to interact with HAX-1[20] (Figure 72–1). *C. elegans* PKD-2 has a similar structure,

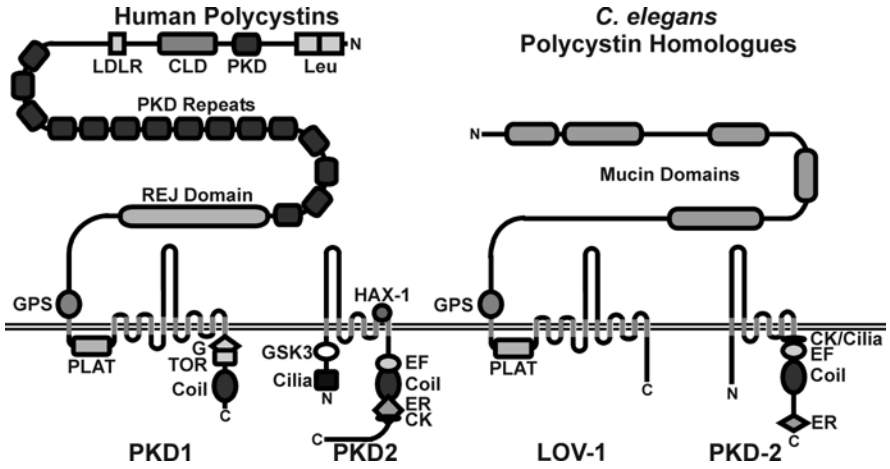

Figure 72–1. Diagram of the relative size and domains of human and *C. elegans* polycystins. Human polycystin-like proteins (e.g., PKDREJ, PKD2L) are not shown. Diagrams are not to scale, but overall protein lengths are approximately accurate. Termini of proteins are designated by N and C. Transmembrane domains are shown as gray lines crossing the membrane. For cilia and plasma membranes, the extracellular domain is on the top half and the cytoplasmic below. Other domains indicated: PKD, PKD repeats (Ig-like folds); Leu, leucine-rich domains; CLD, C-lectin domain; LDLR, low-density lipoprotein-like region; REJ, sea urchin receptor for egg jelly domain; GPS, G-protein-coupled receptor site of proteolysis; PLAT, polycystin/lipoxygenase/α-toxin domain; G, G-protein-binding and -activating site; TOR, region of interaction with the target of rapamycin pathway; Coil, coiled-coil domain; Cilia, domain necessary to target protein to cilium; GSK3, glycogen synthase kinase 3 phosphorylation site; HAX-1, binding site for HAX-1; EF, EF-hand calcium-binding motif; ER, endoplasmic reticulum retention site; CK, casein kinase 2 phosphorylation site; Mucin, numerous serine/threonine O-glycosylation sites.

with regions homologous to most of these domains, although binding at all of these has not been proven. While *C. elegans* PKD-2 does not have a canonical EF-hand, it does have a region that is theoretically similar enough to function as an EF-hand.[21] A phosphorylation site for casein kinase II is present in both mammalian and *C. elegans* PKD2 that modulates activity, and in *C. elegans*, this site is required to target the protein to the cilium.[22,23]

PKD1 is a much larger protein. It includes the same six transmembrane domains as does PKD2, plus an additional five transmembrane domains upstream of these, and a huge extracellular domain.[8] It is believed that PKD1 acts as a mechanosensor,[24] but it is not known if the extracellular domain binds to a specific target in order to become active, or if the protein has intrinsic ability to detect membrane stretch as do other pressure and stretch receptors.[25] Both the mammalian protein and its *C. elegans* homologue have a receptor for egg jelly and a GPS domain just upstream from the first transmembrane domain, which allow the N-terminal domain to be cleaved from the rest of the protein after binding to its extracellular ligand.[26] The cytoplasmic domain has several signaling domains in addition to a coiled coil used to bind to PKD2. Mammalian PKD1 has been linked to signaling through the mTOR, phosphatidylinositol 3-kinase/Akt, JAK/STAT, protein kinase C, AP-1, Wnt, mitogen-activated protein (MAP) kinase, and heterotrimeric G-protein pathways.[27–32] The *C. elegans* location of vulva (LOV)-1 protein C-terminus shares a conserved tyrosine phosphorylation site with human PKD1, but the homology to other domains is not as clear.

C. elegans was of course the first animal whose genome was completely sequenced.[33] This effort revealed the presence of homologues of both polycystin genes. Initial efforts focused on a reverse genetics approach to create mutants deleted for one or both of the polycystin homologues. Surprisingly, these mutants showed no structural or functional defects in the primitive nematode excretory system, nor did these mutants exhibit formation of cysts in any other tubular structures in the nematode. At the same time, incisive forward genetic studies on a seemingly completely unrelated aspect of nematode biology, the neurobiology of male mating behavior, found that the function of the PKD1 homologue, location of vulva (LOV)-1, is necessary to allow male nematodes to detect the location of the hermaphrodite vulva.[34]

Expression studies showed that both LOV-1 and the PKD2 homologue PKD-2 are expressed only in male-specific head and tail nematode sensory neurons that use a cilium as the sensory receptor.[34] LOV-1 is expressed in the cilium, while PKD-2 is strongly expressed in the neuronal cell body as well as in the cilium. Similar cellular positions were then confirmed for the mammalian PKD proteins, and emphasized the importance of the primary cilium in multicellular tubules as a sensory receptor for detecting mechanical stress on the cell. Exciting findings from many laboratories suggest that the primary cilium acts as a rigid antenna sticking up into the lumen of nephrons and other tubules to act as a flow sensor.[35] Physically bending the cilium causes calcium to enter the cell, but only if PKD1 and PKD2 are present in the cilium.[36]

The mammalian polycystins appear additionally to be present at cell–cell junctions[37] and at the focal adhesions[38,39] that anchor epithelial tubules to the underlying basement membrane. Both of these sites are also excellent locations for detecting mechanical pressure attempting to bend, move, or deform cells, and underscore a physiological role of polycystins as mechanosensors.

A question as to the usefulness of *C. elegans* as a model for PKD arises in considering why mutations in polycystins cause recessive mutations in nematodes, but a dominant disease in humans. The late onset of autosomal dominant PKD is consistent with the "two-hit hypothesis,"[40] which proposes that the onset of ADPKD requires inactivation of both copies of the polycystin gene. Individuals heterozygous for a mutated polycystin gene

will suffer a random mutation in the other copy of that gene in some renal cells during their lifetime, which allows a cyst to begin forming. Individuals homozygous for a mutation in one of the nonpolycystin genes (see below), however, will already have both copies of that gene inactivated, and so cyst formation will begin early, even in the embryo for some genes. The two-hit hypothesis also explains why many dominant mutations in polycystin genes are large deletions or nonsense mutations early in the gene. There are no known dominant mutations of the *lov-1* or *pkd-2* genes in *C. elegans*, but since dominance in mammalian PKD seems to reflect complete loss of function of polycystin genes in a few cells rather than a partial loss of function in the whole organism, the study of the nematode genes is not invalidated as a model for understanding the function of the mammalian proteins.

OTHER POLYCYSTIC DISEASES Rare mutations in several other genes can cause recessive forms of PKD. These recessive diseases tend to have an earlier onset than does ADPKD. One series of recessive genetic diseases that causes juvenile onset of polycystic kidneys are the nephronophthises.[41] Some of the extrarenal manifestations of these diseases include defects in the retina, a neural tissue. Six mammalian nephronophthisis genes have been cloned.[11,12] The encoded "nephrocystins" do not show homology with each other, but most of them are located in the primary cilium, the same location as PKD1 and PKD2. Some types of nephrocystins have also been found at the cell–cell junctions and focal adhesions, again places where polycystins are located; and several nephrocystins are additionally located at the centrosome. Overall, the positions of the nephrocystins and polycystins suggest that both of these sets of proteins are essential for measuring and transducing physical stretch, caused either by bending of the cilium or tension at other sites in the cell that causes it to pull on neighboring cells or on the underlying basement membrane.

Clear homologues to nephrocystin-1 and nephrocystin-4 are found in *C. elegans*.[42] These proteins associate with PKD-2 in male-specific neurons and are required for proper mating behavior. Other *C. elegans* proteins show weaker homology to segments of nephrocystin-2 (also called "inversin"), nephrocystin-3, and nephrocystin-6, but it is not clear if there is functional homology here between worms and mammals.

Mutations in another series of genes cause the rare Bardet–Biedl syndrome,[43] which is characterized by any of a large host of symptoms, some of which clearly involve the primary cilium, including polycystic kidneys, *situs inversus*, and retinal degradation. At least 11 such genes have been cloned so far, and 9 of these have clear homologues in *C. elegans*. One of the first indications of the function of these proteins came from the observation that the *C. elegans* homologues are expressed solely in ciliated sensory neurons[44] (in both sexes, not just males). Further study in vertebrates and the alga *Chlamydomonas*, as well as in *C. elegans*, found that the encoded proteins are present predominantly in the primary cilium, and in the ciliary basal body, a modified centrosome. The *C. elegans* BBS genes include *osm-12*, homologous to human BBS7. The *osm* mutants were originally isolated as being unable to undergo osmotaxis, the avoidance of areas of high osmolarity in behavioral assays.[45] This behavior is mediated primarily through ciliated sensory neurons in the head of the animal.

BBS protein function is necessary for the synthesis of the primary cilium, while it has no effect on the synthesis of motile cilia. In *C. elegans*, mutations in the BBS genes alter the transport of material both into and out of the cilium, a process called intraflagellar transport (IFT), first described for *Chlamydomonas*.[46] Lack of this process prevents the transport of receptors located in the cilium that mediate many types of behaviors. Knockdown of IFT gene function in *C. elegans* via RNAi of several of the BBS genes causes defects in osmotaxis and chemotaxis.

Mutations in several other genes have been found that alter the behavior of *C. elegans* as well as intraflagellar transport. One example is the mouse *polaris* gene, which was discovered as a mutant that caused polycystic kidneys and generated left-right asymmetry of internal organs.[47] This asymmetry was found to be caused by primary cilium defects in the node in early mammalian development. Close homologues are found in humans and *Chlamydomonas* IFT particles as well as the *osm-5* gene of *C. elegans*,[48] another gene required for normal ciliogenesis, and detected via defects in osmotactic behavior.

Other proteins related to polycystic kidney diseases are still being discovered, and *C. elegans* will undoubtedly be a useful model for some of these conditions. For example, recently the human gene defective in Meckel–Gruber syndrome was cloned.[7] Clone F35D2.4 is a close homologue in *C. elegans* and was independently identified as a likely ciliary gene.[49]

USE OF *CAENORHABDITIS ELEGANS* TO STUDY POLYCYSTIN FUNCTION

It is necessary to take advantage of the strength of the organism as an object of study and to investigate the proteins of interest in the tissues where they are expressed. To examine PKD function in nematodes, it is essential to take advantage of genetics, and to assay neural function through behavioral assays, electrophysiological assays, and cell biological observations.

Major genetic methods for working with *C. elegans* are described in more detail elsewhere (Brenner,[50] www.WormBook.org, and Chapter 12 in this volume), but time spent becoming familiar with the organism is invaluable. Subtle differences in movement or cell structure may be obvious to one observer, but undetectable to another. A compound microscope with DIC (Nomarski) optics is essential for observing the placement and development of individual cells within the organism. Since the creature is clear, tagging the gene of interest by linking it to a fluorescent gene, such as *gfp* from jellyfish or *dsRed* from coral, will allow visualization of the synthesized chimeric protein inside the organism, to allow determination of the time and place of expression including subcellular location.

Do take advantage of the tremendous online resources for working with this creature. The online resource WormBase.org includes the complete genome sequence, information on every gene in the creature, and references to every *C. elegans* paper published, as well as unpublished abstracts and experiments reported only in meetings and in the early *Worm Breeder's Gazette* newsletter (some of the initial data of Barr and Sternberg on the identity of LOV-1 as a PKD1 homologue were reported here long before publication of their initial report in *Nature*). WormAtlas.org has detailed ultrastructural information on all the cells and tissues of the animal, including clear diagrams of the ciliated neurons of the male reproductive system, where the polycystins are expressed. And the *C. elegans* Stock Center (cgsc.org) has available many of the mutant stocks needed to study these diseases, including deletion mutants in both *lov-1* and *pkd-2*. Two *C. elegans* knockout projects, one in Japan and one in Oklahoma

City and Vancouver, Canada are also attempting to isolate strains carrying deletion mutations of each of the 19,000 genes of *C. elegans*. The Oklahoma/Vancouver project routinely send their creations to the *C. elegans* stock center.

BEHAVIORAL ASSAYS The initial technique used to isolate nematode polycystin mutants was a forward genetic screen to identify mutagenized male worms that were no longer capable of performing one of the many steps required to complete mating.[34] Normally, male worms appear to sense the presence of a hermaphrodite through chemical receptors. The cilia of many of the neural endings that contain polycystins are contained in a series of epithelial open-ended tubes arranged around the male copulatory bursa. The rays are used by the male to detect chemical and mechanical cues to place the bursa over the hermaphrodite vulva for copulation. To do this, the male approaches the hermaphrodite and engages in a series of stereotypical behaviors.[51] These include placing his copulatory bursa alongside the hermaphrodite, and backing up along the hermaphrodite. If the male does not find the hermaphrodite vulva by the time its tail reaches the end of the hermaphrodite, the male flexes his tail sharply and continues moving backward along the opposite side of the hermaphrodite. Once the male passes his tail alongside the hermaphrodite vulva, the animal stops (it is not known if the signal is mechanical, chemical, or both), and inserts rigid cuticular structures called spicules into the vulva. The male then ejaculates motile sperm into the vulva, which then travel to the hermaphrodite spermatheca. In some strains of nematode, the male finally secretes a copulatory plug to prevent other males from mating with the hermaphrodite.

To study male mating behavior, it is very helpful to use the *him-5* mutant instead of wild-type worms. Since *C. elegans* is a self-fertilizing hermaphrodite, it does not need males to give rise to a new generation; in a typical well-fed colony, males make up only about 0.5% of the population. Mutations in the *him-5* gene allow a higher incidence of spontaneous disjunction of the X chromosome to occur,[52] which gives rise to a higher frequency of male (haploid for the X chromosome) animals instead of hermaphrodite (XX) animals. As much as one-third of a *him-5* colony will be male, which allows much easier observation of male mating behavior.

A series of studies primarily from the Sternberg laboratory isolated mutants in each of the steps described above. Arduous work by Barr and Sternberg[34] detected rare mutants in which the males were capable of detecting the hermaphrodite, moving backward along the hermaphrodite, and flexing the tail in order to search the other side of the animal, but had great difficulty finding the vulva (*lov*, for defective in *l*ocation *o*f *v*ulva). Mutant males continue to circle the hermaphrodite repeatedly, until they stumble upon the hermaphrodite vulva. This behavior can be observed in individual animals either by counting the number of times that a male circles the hermaphrodite before attempting to insert its spicules in the vulva, or by measuring the amount of time needed for a male to attempt to insert its spicules after brushing up against a hermaphrodite.

Genetic mapping of the *lov-1* mutation was accomplished through standard techniques for *C. elegans*, including measuring linkage to known mutants, and rescue of the mutant through microinjection of wild-type DNA. The complete genome sequence of *C. elegans* is freely available from the *C. elegans* Sequencing Project[33] as cosmid fragments, each containing approximately 40,000 base pairs of genomic DNA. The progeny of *lov-1* mutants could be cured through injection into the parent of DNA containing the nematode homologue of human PKD1.[34]

Later studies showed that mutants carrying a deletion of the nematode homologue of *pkd-2* are also incapable of locating the hermaphrodite vulva, and that a mutant deficient in both *lov-1* and *pkd-2* was no more defective in vulva location than a mutant for only one of these genes, consistent with the idea that these two proteins function together in a signal transduction pathway.[53]

Further searches for other mutations that prevent male nematodes from locating the hermaphrodite vulva revealed the *klp-6* gene,[54] which encodes a kinesin motor protein. Mutation in *klp-6* prevents LOV-1 from reaching the cilium (as visualized through the use of a *lov-1::gfp* transgene), a result that reinforces both the importance of ciliary function and the importance of proper trafficking of proteins to the cilium.

Another method of observing differences in wild-type nematodes and nematodes defective in polycystin function is to look at behavior in groups.[21] In addition to the male-specific neurons located in the male tail, four ciliated neurons (CEM neurons) are located in the head of males.[55] The function of the CEM neurons is not known, but it is reasonable to assume that they are involved in male detection of hermaphrodite nematodes. Male nematodes deleted for either *lov-1* or *pkd-2* exhibit less social behavior. By placing a large number of male nematodes together with hermaphrodites on a plate of food bacteria, it is possible to observe easily and immediately a large difference in behavior. While the hermaphrodites scatter about the plate foraging for food, most of the wild-type males will attempt to mate with hermaphrodites, and many will group in "clumps" of several males attempting to mate with a single hermaphrodite. In contrast, *lov-1* or *pkd-2* mutant males will mostly ignore the hermaphrodites, and predominantly spend their time foraging for food as well. It is important to use plates in which the lawn of food bacteria is spread evenly across the entire plate up to the edge, since thicker growth of bacteria at lawn edges attracts worms and can affect the rate of "clumping" by restricting the worms to specific areas of the plate. This assay has been useful in identifying suppressor strains that are "interested" in mating even though they are deleted for polycystin-2 function.

The strengths and disadvantages to the social behavior and LOV assays are complementary. The LOV assay is time and energy intensive, requiring placing an individual male with a hermaphrodite, and watching that individual's attempts to locate the hermaphrodite vulva. On the other hand, this assay clearly lets the observer know the individual male animal's phenotype. The social behavior assay, on the other hand, is relatively quick and easy to perform, and the result can be determined by an observer without extensive training or time at the microscope. The assay, however, cannot be performed on a single worm, but must be performed on a group. The test animals can all be the progeny of a single *him-5* hermaphrodite, but you must wait a generation until the animal to be tested has enough progeny to allow the performance of this assay.

Since polycystins must be expressed in the cilium in order to perform at least some of their functions in both worms and humans, mutants that affect the formation of cilia, or transport of proteins into the cilium (IFT), will show defects in polycystin function. In humans, this is the cause of polycystic kidneys in Bardet–Biedl syndrome and nephronophthisis. In *C. elegans*, the

male-specific neurons that express the polycystins are a subset of the sensory neurons. Many ciliated sensory neurons, especially in the head of the animal, detect other chemical, thermal, and osmotic stimuli. Defects in ciliary formation or IFT can be detected via effects on osmotactic and chemotactic behaviors. Assays for these behaviors are described in great detail elsewhere.[56] The standard method for assaying osmotaxis is to place worms on agar surrounded by a ring of either 8 M glycerol, 4 M NaCl, or 4 M fructose (plus dye to make the ring visible) gently pressed onto the surface of the agar and allowed to soak in for a few minutes.[45] The worms are observed as soon as they are placed in the center of the ring. Wild-type animals will avoid the glycerol and will generally stay within the ring for at least 10 min. Severely osmotaxis-defective animals will not detect the ring and most will attempt to cross it fairly quickly. *C. elegans* cannot survive osmolarities greater than about 600 mOsM, much lower than the concentration of glycerol imprinted on the agar surface, and so many of the animals will die in attempting to cross the barrier. If attempting to enrich mutagenized animals for those defective in osmotaxis, it is important to select potential mutants before they are dehydrated.

Chemotaxis has been examined from the very beginning of modern studies on *C. elegans*,[57,58] and multiple methods for assaying chemotactic responses to various compounds have been developed. Mutations in *che-3*, which encodes a dynein heavy chain component of the IFT machinery, were isolated through use of an assay with Petri plates divided into four sections via plastic separators.[59] Agar containing attractant is placed in two opposite quadrants, and agar with no attractant (or a lower concentration, or a mild repellent) is placed in the remaining two quadrants. After solidifying, agar (with no attractant) "bridges" are placed over the plastic dividers to connect the quadrants. A population of animals is then placed in the center of the plate, and allowed to swarm. Wild-type nematodes swim to quadrants containing high levels of attractant, while animals that move to sections of the plate containing no attractant are enriched for chemotaxis mutants.

An alternative method to gauge chemotaxis has been used to isolate mutants defective in detecting volatile odorants.[60] A population of worms is placed in the center of a single large plate that has been spotted at one point near the edge with the attractant and with an anesthetic (sodium azide), and with anesthetic alone on the opposite side of the plate. Most worms will smell the attractant and move toward it. Chemotaxis-defective mutants will crawl in many directions, and eventually be incapacitated above a spot of anesthetic. Worms trapped over the spot that contains no attractant will be greatly enriched for chemotaxis-defective mutations.

CELL BIOLOGICAL STUDIES Polycystin 1 (LOV-1) appears to be located predominantly in the primary cilium of the nematode neurons where it is active.[34] PKD-2 is also expressed in the cilium, although it is expressed at high levels in other compartments of the cell as well. If the polycystins are not brought to the cilium, then the animal is unable to mate properly. While polycystins are found only in male-specific cilia, other ciliated neurons in the head and tail are used as sensory receptors for a wide range of stimuli in both sexes.[61] The ciliated endings are open to the environment to allow detection of attractant and repellent chemicals as well as osmosensation. A classic study of ciliary structure was reported by Perkins *et al.*,[62] who stained the animals with the mucin-soluble dye 5-fluorescein isothiocyanate (FITC). Mucin is a highly glycosylated protein that forms a mucous layer to trap small chemicals to be sensed by the cilia, analogous to the function of mucus around mammalian olfactory receptors. Not all ciliated neurons stain with FITC, and in fact none of the male-specific ciliated neurons normally is stained by FITC. But isolation of mutants in which FITC staining is abnormal (*dyf* for *dy*e-*f*illing defective) has been used to identify mutants defective in ciliary construction and transport of proteins into the cilium. Many of these mutants turned out to be defective in osmotaxis, chemotaxis, and detection of a specific pheromone that enables nematodes to suspend growth under harsh conditions (the "dauer" form[63]). The researchers also isolated rare mutants defective in osmotaxis in which the male-specific ray neurons of the tail are stained by FITC. Mutants in this gene, *osm-1*, were later found to be defective in male mating as well as in osmotaxis.[64]

The availability of polycystin constructs linked to the *gfp* gene is very useful for examining transport of polycystins to the cilium, as well as IFT. The Barr and Scholey laboratories have demonstrated the transport of these proteins into sensory neuronal cilia.[54] As noted above, defective kinesin KLP-6 prevents GFP-tagged LOV-1 from reaching its proper ciliary position. Several other kinesin proteins, including OSM-3 and KAP-1, function together and sequentially to transport material into sensory cilia.[65] By examining mutagenized nematodes and isolating rare animals in which these fluorescent proteins do not travel into the cilium, these laboratories have also discovered mutants in genes required for polycystin activity in both *C. elegans* and humans. Such mutants have identified proteins required in many cell types for polycystin to be brought up to and into the cilium, as well as cell-type-specific factors that are required only in nematode male sensory neurons.

To observe transport, the nematodes must be transformed via microinjections of plasmids expressing the gene of interest fused to the *gfp* or *dsRed* marker gene. The methods for producing and observing transgenic nematodes are fairly standard in every *C. elegans* laboratory (see Chapter 12, this volume). A series of expression vectors was originally developed by the Fire laboratory (ftp://ftp.wormbase.org/pub/wormbase/datasets/fire_vectors/), and is now commercially available (www.addgene.org), that contains a multicloning site upstream of the marker gene, which contains introns to increase expression in *C. elegans*. Once constructed, the plasmid must be microinjected into the syncytial gonad of adult hermaphrodite worms, where the DNA is unstably incorporated in the oocytes as a linear array of multiple copies of the plasmid maintained separately from the chromosome.[66] It is generally straightforward to use a dissecting fluorescence microscope to search for progeny that express the array. Since the DNA array is not linked to a chromosome, it is unstably maintained at cell division, and is therefore not transmitted in subsequent generations. To prevent loss of the transgene, animals carrying the array are treated with DNA-breaking agents such as trimethylpsoralen plus ultraviolet light, in order to incorporate the array into a chromosome. A stable line that passes the transgene reliably to subsequent generations can thereby be generated.

Examining subcellular location of green fluorescent proteins (GFP)-labeled proteins is difficult in the small neurons of *C. elegans*. The animals must be anesthetized with sodium azide, levamisole, or phenoxypropanol, or contain a muscle mutation such as *unc-54* in order to prevent them from moving under the microscope. A good fluorescence DIC or confocal microscope is required, with a 63× or 100× objective, to see smaller processes,

and experience with identifying neurons is essential. Fortunately, the position of most neuronal cell bodies and axons in *C. elegans* is invariant, and has been well characterized.[55] Detailed descriptions of neuron structure is available online (http://www.wormatlas.org). With the well-characterized ciliated sensory neurons of the head, it has even been possible via time-lapse confocal microscopy to measure the rate of movement of labeled proteins in axons and on IFT particles into the cilium, and to distinguish differences in movement of polycystins into the cilium in various mutants.[65–69]

ELECTROPHYSIOLOGICAL STUDIES The polycystins are medium-conductance relatively nonselective divalent cation channels.[16] Direct study of polycystin function within the narrow cilia is not possible with current electrophysiological techniques. There are several ways to study the activity of ion channels in other areas of *C. elegans* neurons, but direct electrophysiological studies are difficult, both because *C. elegans* neurons are small (the cell bodies are only 2–3 μm in diameter), and because the nematode body plan features a flexible collagenous cuticle surrounding the animal, which acts as both skeleton and skin. Since muscles pull on the cuticle to move the animal, the cuticle must be maintained in a relatively rigid state. This is accomplished by osmotically maintaining a strong turgor pressure in the body fluid relative to liquid outside the animal's body.[70] Any cutting of the cuticle therefore causes the internal material to explode out of the animal. Indeed, mutants have been isolated in which the hermaphrodite uterus and gonads spontaneously pop out of the vulva, and mishandling of male worms often causes the spicules to protrude explosively, rendering the male incapable of mating. Attempts to isolate neurons for electrophysiological studies yield the same result, with the identity of neurons being unrecognizable after they have exploded from out of an incision.

Fortunately, there are a large number of molecular biology constructs linked to the *gfp* gene that can be used to identify specific neurons. By microinjecting these constructs into nematodes and selecting strains that pass the construct reliably to the next generation, researchers have generated a large series of strains that expresses GFP only in specific cells of the animal. Many of these strains are available from the *Caenorhabditis* Genetics Center, and many such constructs for a given gene are identified on WormBase.org. By opening the animal near the nerve ring, the major ganglion of the worm, and letting neurons or muscle cells pop out of the worm, on-cell electrophysiological recordings have been made from single identified neurons.[71–74] Animals can be opened either directly via cutting, or by use of collagenase to weaken the cuticle. The released cells can also be placed in primary tissue culture,[75] and electrical properties measured directly. To date, direct electrophysiological methods of recording from cells *in vivo* have not been reported for recording activity of male-specific neurons in the tail, however.

Another method that has been used to study other *C. elegans* ion channels is to express the gene in a cell to which electrodes can be attached easily, such as a *Xenopus laevis* oocyte. An excellent primer on the use of this technique for studying *C. elegans* channels is available from the Driscoll laboratory.[76] Using the gene predictions of WormBase.org, a cDNA clone can be synthesized from mRNA. It is important to make sure that the gene predictions are correct, especially for the 5′ and 3′ ends of the gene, since the GeneFinder computer algorithm used to predict exons is less accurate at the ends of genes. For example, the original computer prediction of the *lov-1* polycystin gene sequence showed two genes (clones ZK945.9 and ZK945.10), with only one of these predicted genes showing homology to human PKD1. Later work proved that these two predicted genes are in actuality two halves of a single transcript, and that the piece with low homology to human PKD1 is actually the N-terminal ligand-binding domain of LOV-1. Our work (unpublished) similarly found that a predicted SK3 potassium channel gene is actually twice as large as predicted, with a large unpredicted N-terminal domain.

Once a cDNA clone has been synthesized, it is linearized and a kit can be used to create cRNA, an artificially produced mRNA to be injected into oocytes. The oocytes can be prepared from commercially available sources of *Xenopus* ovaries, a great advantage since many *C. elegans* laboratories do not maintain the paperwork necessary for working with vertebrate animals. The oocytes are prepared, injected, and observed via a dissection microscope. Measurement of channel activity is either through standard two-electrode voltage clamp or via single-electrode patch clamp on oocytes whose vitelline membrane has been removed to allow formation of a clean gigaOhm seal to the pipette. These techniques have been used successfully with a large number of *C. elegans* channels, including the degenerin channels that mediate touch sensitivity.[73] They have not been reported for use on *C. elegans* polycystins as yet. In part this may reflect the fact that the *lov-1* gene is quite large for a *C. elegans* gene (though small by human gene standards), and reports of difficulties in functional expression of PKD1 have made this a less attractive target (although expression of the C-terminal half of the protein yields currents[77]). Human PKD2 has been studied more thoroughly in *Xenopus* oocytes, and such experiments confirmed that PKD2 is a calcium channel and interacts with the IP_3 receptor at the endoplasmic reticulum (ER) membrane.[78,79]

Both human and *C. elegans* polycystin electrical activity have been measured using planar bilayer membranes (BLM).[21,80,81] Several plates of animals are collected, and their cuticles weakened and lysed via treatment with collagenase, to release cells from inside of the animal. The ER vesicles are then purified via standard centrifugal techniques. It is essential to have antibodies to the ion channel of interest to identify the protein in ER vesicles. A great advantage in using *C. elegans* is the ability to compare vesicles from wild-type animals with those from mutants deleted for the *pkd-2* gene. The vesicles are placed in a BLM bath, and electrical activity is measured as the vesicles fuse with the membrane in the center. *C. elegans* PKD-2 was found to have electrical properties similar to those of mammalian PKD2. PKD-2 is strongly expressed in the ER, while LOV-1 is not, so it was not possible to determine if LOV-1 forms channel activities by itself or in combination with PKD-2. Purification of ciliary membranes has not been attempted in *C. elegans*, due to the small number of ciliated neurons in the animal. If ciliary membrane vesicles could be purified successfully from wild-type and mutant animals, the BLM technique would be very useful for determining the influence of many IFT and ciliary proteins on polycystin activity.

A new method of examining *C. elegans* polycystin electrical activity has been reported.[21] Nematodes (*him-5* mutants, to increase the number of males and therefore the percentage of cells that are ciliated neurons) were treated with collagenase as before, and triturated in order to separate cells from each other, and loaded with Ca^{2+} and the calcium-sensitive dye Fluo3-AM. The cells were depolarized by means of extracellular application of KCl. The excitable cells fluoresce as calcium is released from

extracellular stores, which can be measured via fluorescence microscopy. Again, if ciliated neuron cells were to be marked with a dsRed marker, it might be possible to use this technique to explore the ability of neuronal stimulation to release calcium from intracellular stores in various mutants that potentially affect polycystin function.

LIMITATIONS ON *CAENORHABDITIS ELEGANS* AS A MODEL As noted above, *C. elegans* provides a strong model for studying polycystin function in ciliated cells. But there are limitations to the usefulness of the nematode as a model for understanding polycystic kidney disease. First, not all of the proteins that are necessary for maintenance of proper nephron shape and prevention of cyst formation are present in *C. elegans*. It is not possible to study the function of, e.g., nephrocystin-5 in nematodes if the gene does not exist there. On the other hand, this indicates that nephrocystin-5 is not an essential protein for calcium signaling via ciliary polycystin function, and that the likely function of nephrocystin-5 in human nephrons involves some other aspect of polycystin's function in epithelial cells.

In addition, some of the proteins present in both worms and humans have significant differences. For example, the polycystin-1 homologue LOV-1 has a completely different extracellular N-terminus from that of mammalian PKD1 (Figure 72–1). This almost certainly indicates that these two proteins bind to different chemical substances in order to signal inside the cell. In fact, the N-terminal domain of PKD1/LOV-1 is very different in insects from that of nematodes and mammals as well,[82] which suggests that the PKD1 signaling domain regulates a common process (presumably chemo/mechanotransduction) that has been adapted to multiple purposes over evolution.

In nematodes, the polycystins are found only in male-specific neurons, and have a single task: When the cilium is stretched and/or/while LOV-1 binds to the mechanical/chemical stimulus presented at the vulva, the neuron must rapidly admit enough calcium to depolarize sufficiently to cause an action potential. In the mammalian tubular epithelial cells, polycystin has a more difficult function: The nephritic cell's primary cilium acts as a flow sensor that is presumably bent repeatedly as liquid passes through the nephron.[35] Each tubule cell encounters other conditions that stretch the junctions to other cells and to the basement membrane as well. Indeed, liquid passing through the tubule should exert pressure on the apical membrane that should be transmitted to the cytoskeleton and exert tension on these points. Hydrostatic pressure without fluid flow can cause tubule expansion.[83] And without polycystin function, tubules slowly enlarge to form a cyst; therefore, polycystin must act as an inhibitor for this process. Signaling from polycystins at these points must be integrated to provide information to the epithelial cell as to whether it should reform the basement membrane, change shape, or divide in order to make the tubule larger. Accordingly, mammalian PKD1 has a larger C-terminal cytoplasmic domain than does the nematode LOV-1 protein (Figure 72–1), with several functional homologies to signaling modules that are not obviously present in *C. elegans* LOV-1, such as to the mTOR, Wnt, and JAK/STAT signal transduction pathways. *C. elegans* has these signaling pathways, and regulation of epithelial shape and tubule size is seen in all metazoan organisms,[84] so these aspects of epithelial cell structure and regulation can be studied in *C. elegans*, but polycystin signaling to these processes would have to be proved before they could be well studied in this organism.

CONCLUSIONS

C. elegans provides an ideal model for understanding many, but not all, aspects of polycystic kidney disease. The use (and NIH support) of forward genetic studies, many times on seemingly unrelated biological phenomena such as nematode male mating or osmotaxis, can nevertheless prove to be critically important in understanding human disease. In particular, LOV-1 and PKD-2 provide an excellent model for mammalian primary cilium synthesis, polycystin synthesis and transport, and polycystin function in calcium signaling in the cilium and endoplasmic reticulum (Figure 72–2), but vertebrate models (e.g., zebrafish and mouse)

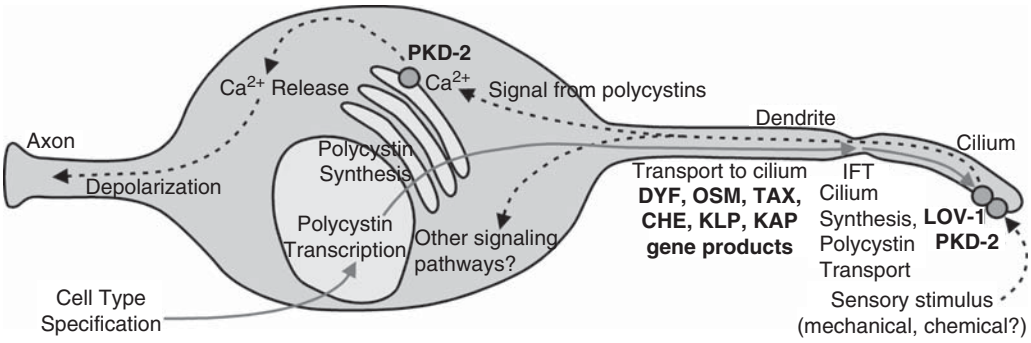

Figure 72–2. Diagram of synthesis, transport, and possible mechanism of signaling of polycystins in a *C. elegans* male-specific neuron. Gray solid lines indicate synthesis and transport of polycystins and of cell components necessary for polycystin function. Black dotted lines indicate signaling from polycystins in neurons. The sensory dendrite is on the right and the axon on the left. Constriction in the dendrite indicates the transition zone at the base of the sensory cilium. Cell type is specified by transcription factors. Components necessary to construct a sensory cilium are transported to the end of the dendrite. IFT (intraflagellar transport) is necessary to construct flagellum. Polycystins are transcribed and transported through the endoplasmic reticulum, where much of the PKD-2 protein is retained. Transport of LOV-1 and PKD-2 polycystins requires various kinesins (KLP proteins and KAP, kinesin-associated proteins) as well as other components discovered as defective in DYF (DYe-Filling), OSMotaxis, TAXis, and CHEmotaxis. IFT is required to transport LOV-1 and PKD-2 to sites of activity in the cilium. Mechanical and/or chemical stimulation of the LOV-1 protein at the vulval opening signals polycystin activity. LOV-1 and PKD-2 are presumed to act together as an ion channel to admit divalent cations into the cell. This signal partially depolarizes the cell, to stimulate PKD-2 at the endoplasmic reticulum to open to release calcium from intracellular stores. The neuron is thereby depolarized to elicit a behavioral response. Other signaling pathways after stimulation of ciliary polycystins are possible but unproven in *C. elegans* neurons.

may be more useful for studying aspects of polycystin function that may not be present in *C. elegans*. Most aspects of ciliary formation, and transport of receptor polycystins and nephrocystins into the cilium, can also be studied in *C. elegans* via a wide variety of behavioral, cell biological, and electrophysiological methods, and provide a promising source of future results to deepen our understanding of the normal physiology of the kidney tubules and the prevention of polycystic kidney disease.

ACKNOWLEDGMENTS

I am greatly indebted to the support of the entire *C. elegans* research community, and from NIH R01 DK55526 and the Kansas Interdisciplinary Center for PKD Disease Research.

73 Animal Models of Myelofibrosis

Alessandro M. Vannucchi, Jean-Luc Villeval, Orianne Wagner-Ballon, Paola Guglielmelli, and Anna Rita Migliaccio

ABSTRACT

The pathogenesis of idiopathic myelofibrosis has not yet been completely elucidated, but the availability of animal models of the disease has made it possible, in the past few years, to focus on the cells (megakaryocytes) and cytokines (transforming growth factor-β, among others) potentially involved. This review will deal with the two best characterized animal models (the TPO-overexpressing and the GATA-1^{low} mouse) as well as with the newest ones that have been developed following the identification of the *JAK2*^{V617F} and *MPL*$^{W515K/L}$ mutations in the human form of the disease. Each of these unique animal models conceivably represents an invaluable tool for further characterizing the disease mechanisms as well as for testing novel therapeutic agents.

Key Words: Myelofibrosis, Mpl, GATA-1, Animal models, Transforming growth factor-β, Megakaryocyte, Osteosclerosis.

INTRODUCTION

Idiopathic myelofibrosis (IM), also called myelofibrosis with myeloid metaplasia (MMM),[1] is a malignant hematological disorders that together with polycythemia vera (PV), essential thrombocythemia (ET), and other less frequent entities belongs to the Philadelphia-negative chronic myeloproliferative disorders (MPD), according to the World Health Organization (WHO) classification of myeloid neoplasms.[2] All these are clonal disorders that originate at the level of a pluripotent hematopoietic stem/progenitor cell that, while retaining a relatively normal differentiation program unlike that in acute leukemia, has lost some of the regulatory mechanisms that control proliferation; indeed, one of the best characterized abnormalities of hematopoietic cells in these disorders is their substantial independence from regulatory cytokines, in particular erythropoietin (EPO)[3] or thrombopoietin (TPO),[4] the two main cytokines for the erythroid and megakaryocytic (Mk) lineage, respectively. MMM is characterized by anemia, extramedullary hematopoiesis, bone marrow (BM) structural changes that include fibrosis, neoangiogenesis, and osteosclerosis, and by constitutive circulation of stem/progenitor cells with dacryocytes, nucleated erythroid cells, and immature myeloid cells in the peripheral blood (PB); in some cases, MMM represents the disease evolution of a preexisting PV or ET (so called, post-polycythemic/thrombocythemic MMM), and has an intrinsic tendency to evolve into acute leukemia.[1] Accumulated evidence indicates that the changes in the structure of the BM that are characteristic of MMM represent a typical reactive process (the cells of the stroma do not belong to the neoplastic clone), likely mediated by cytokines abnormally released by clonal hematopoietic cells. On the other hand, the primary lesion occurring in the hematopoietic stem/progenitor cell of MMM is still not well understood, although recently an acquired point mutation in the *JAK2* gene, consisting of a valine-to-phenylalanine substitution *(JAK2*^{V617F}) in the autoinhibitory JH2 (JAK homology) domain of the molecule, has been found to occur in most PV patients and in about half of those with ET or MMM.[5–8] An even more infrequent point mutation of the TPO receptor, *MPL*^{W515L}, has been detected in less than 10% of MMM patients.[9,10] Although both these mutations when expressed in murine models recapitulate several aspects of MMM (see below), their exact positioning in the sequence of a multistep series of events forming the basis of the pathogenesis of the disease remains to be defined.

A frequent observation in MMM patients has been the occurrence of the discrete involvement of the Mk lineage in BM biopsies[11]; actually, the morphological appearance of the BM Mk population, beyond its quantitative expansion, is one of the key points in the WHO classification, allowing differential diagnosis of MMM from other MPDs, as well as the identification of a "prefibrotic" form of IM.[12] This critical role of Mks has been corroborated by the study of animal models of the disease that, either incidentally discovered or not (Table 73–1), have been consistently characterized by the accumulation of Mks eventually associated with thrombocytosis. This chapter will review the production and characterization of two extensively studied models of MMM, represented by TPO^{high} and GATA-1^{low} mice, together with the newest findings concerning the development of IM in mice carrying hematopoietic cells mutated at the *JAK2* or *MPL* locus.

Table 73–1
Additional murine models presenting myelofibrosis[a]

Model	*Main features*
MPSV-induced mice	MPSV; splenic and medullary fibrosis; splenic myeloid hyperplasia; myelemia; anemia; thrombocytopenia; possibly due to high levels of IL-1a, IL-6, GM-CSF, G-CSF, CSF-1, and TNF-α[62–64]
TEL/PDGFRβR transgenic mice	Overproduction of mature neutrophils and dysplastic megakaryocytes in the bone marrow; splenomegaly with extramedullary hematopoiesis; high levels of IL-3 and GM-CSF[65–67]
TEL/JAK2 and *TEL/TRKC* transgenic mice	Extramedullary hematopoiesis, intensive myeloproliferation in the bone marrow and the spleen with splenomegaly, granulocytic leukocytosis; high levels of IL-3 and GM-CSF[66,68]
Bach1 transgenic mice	Transgenic mice bearing human BACH1 cDNA under the control of the GATA1 locus; significant thrombocytopenia associated with impaired maturation of megakaryocytes and development of myelofibrosis[69]
VEGFR-1 transgenic mice (op/op*Flt1*$^{TK-/-}$)	Extensive osteoclast deficiency, resulting in bone marrow fibrosis and extramedullary hematopoiesis[70,71]
LIF overexpressing mice	Developed in DBA/2 mice engrafted with FDC-P1 cells overexpressing LIF; myelosclerosis, splenomegaly, extramedullary hematopoiesis in the liver, neutrophil leukocytosis[72]
OPG/OCIF transgenic mice	Early and progressive osteopetrosis, splenomegaly, and extramedullary hematopoiesis[73]
BUBR1 mutant mice (*BUBR*$^{+/-}$)	Splenomegaly, extramedullary megakaryocytopoiesis; increased megakaryocytic, and decreased erythroid, progenitor content in the bone marrow[74]
FLT3-ITD mutant mice	Myelofibrosis, splenomegaly, extramedullary hematopoiesis, leukocytosis with a few immature myeloid cells; myeloproliferative disease has a latency of 40–60 days and does not evolve into AML[75]
Lnk mutant mice (*Lnk*$^{-/-}$)	Splenomegaly with fibrosis and extramedullary hematopoiesis, hyperplasia of the megakaryocytic lineage, increased number of erythroid cells in the spleen but decreased in bone marrow; defects of B lymphopoiesis; leukocytosis and thrombocytosis; increased proliferative responses of hematopoietic progenitors to cytokines such as SCF, IL-3, and IL-7[76]

[a]MPSV, myeloproliferative sarcoma virus; IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor; TNF, tumor necrosis factor; LIF, leukemia inhibitory factor; AML, acute myeloid leukemia; SCF, stem cell factor.

THE TPO^{high} MODELS

TPO, also known as MPL ligand or megakaryocyte growth and development factor (MGDF), is the major physiological humoral regulator of megakaryopoiesis and platelet production.[13,14] The TPO^{high} model of myelofibrosis was discovered during investigations aimed to determine pathologies and side effects associated with long-term exposure to high doses of the recently discovered TPO, an obvious drug to increase platelet levels in patients. Several models are described, including the simplest approach by systemic repeated administration of a truncated version of recombinant TPO associated with a polyethylene glycol tail (PEG-rh-MDGF)[15] and more sophisticated approaches by which TPO overexpression was achieved by adenovirus vectors,[16–19] retrovirus vectors,[20,21] or by transgenesis.[22,23] Except for one model of transgenic mice,[22] all the other models described the occurrence of BM fibrosis in mice. We will mainly focus on the retroviral models and adenoviral models that have been studied extensively.

TPO^{high} MODEL BY SYSTEMIC REPEATED ADMINISTRATION OF PEG-RH-MDGF Immunocompetent BALB/c mice were injected daily for 14 days with increasing doses of PEG-rh-MDGF from 10 to 500 μg/kg.[15] All animals developed dose-dependent thrombocytosis, moderate leukocytosis, anemia, splenomegaly, and extramedullary hematopoiesis. A BM fibrosis was observed at the highest dose injected, which reversed rapidly when the injections were stopped. Transient myelofibrosis was also observed in rats receiving PEG-rh-MDGF.[24] The effects of systemic administration of TPO in the GATA-1^{low} model of myelofibrosis will be described below.[25]

TPO^{high} MODELS BY ADENOVIRAL VECTORS An alternative approach was developed using replication-deficient adenovirus vectors. All the studies were performed using injections of adenovirus carrying a human TPO cDNA. However, the promoter driving the expression of TPO was either a cytomegalovirus (CMV) or a Rous sarcoma virus (RSV) promoter. Furthermore, several routes of injection were used (subcutaneous,[16] intratracheal,[17] intraperitoneal,[19] and intravenous[18]). Finally, different stains of mice were treated: immunocompetent BALB/c mice and immunodeficient nonobese diabetic/severe combined immunodeficient (NOD/SCID) and SCID mice. Immunocompetent mice did not develop fibrosis because an immune thrombocytopenia occurred after a brief thrombocytosis that peaked at day 7, accompanied by Mk hyperplasia in the spleen. This immune reaction was due to the generation of neutralizing antibodies directed against the transgene human TPO that cross-reacted with murine TPO.[26] To avoid this reaction, models were developed in immunodeficient mice.[16,17,19,26] SCID (severe combined immunodeficient; T and B cell deficient) mice developed thrombocytosis, leukocytosis, and marked Mk hyperplasia in the spleen and BM with a progressive myelofibrosis and osteosclerosis as early as 6 weeks after injection. Surprisingly, no fibrotic or sclerotic changes were seen in NOD/SCID [T and B cell deficient as well as presenting multiple other defects in innate immunity including natural

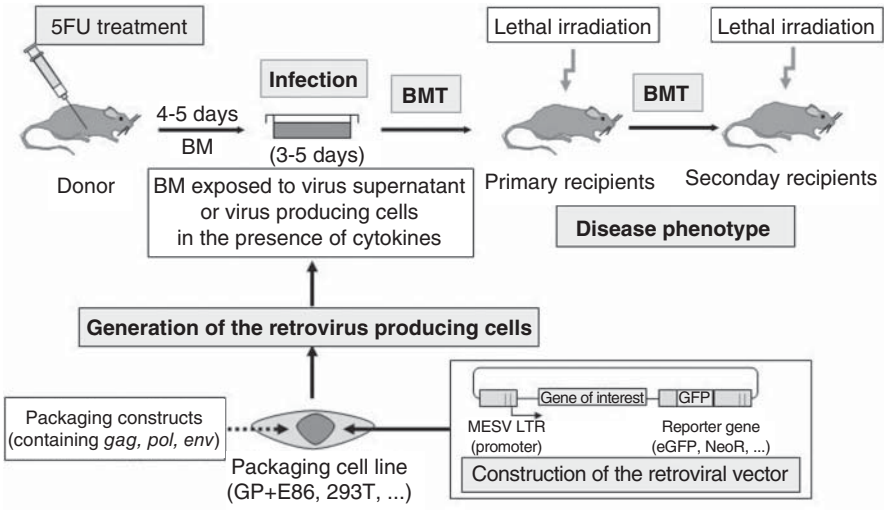

Figure 73–1. A representation of the procedure used for the adoptive transfer of bone marrow cells infected by a retrovirus expressing the gene of interest (TPO, *JAK2*^{V617F}). BMT, bone marrow transplantation; 5FU, 5-fluorouracil.

killer (NK) and monocyte–macrophage function] mice.[26] Because NOD/SCID mice differ from SCID mice by impaired mononuclear phagocyte functions, it was postulated that monocytes and macrophages are required for promotion of myelofibrosis in TPO^{high} mice. However, this theory is not supported by another recent study demonstrating that NOD/SCID mice exposed to high and sustained TPO levels develop BM fibrosis.[27]

TPO^{high} MODELS BY RETROVIRAL VECTORS Two models were described, one by Yan *et al.*[20] and one by our group.[21] In both investigations, the murine TPO cDNA was cloned into a retroviral vector and infectious nonreplicative recombinant retroviral particles were produced from the transfected GP + E86 packaging cell line. A high virus titer-producing clone was selected. In our study, this clone, called GP122, also produced very high TPO level (6000 U/ml).[21] The principle consists of transducing hematopoietic stem cells (HSC) of a mouse with the virus in order to sustain high levels of TPO production by the hematopoietic system throughout the life of a mouse. The procedure is based on BM transplantation (BMT). BM cells, collected from donor mice, are infected with the retrovirus and injected into recipient mice depleted of their own hematopoietic system as a result of lethal irradiation (9.5 Gy for the C57BL/6 strain). To transduce HSC efficiently, which will ensure the lifetime maintenance of a transduced progeny, donor mice are treated with 5-fluorouracil (5FU, a single intraperitoneal or intravenous injection at 150 mg/kg for 4 days). The duration of treatment allows the maximal number of HSC to be infected by the retrovirus, corresponding to the maximal number of cycling HSC. The infection is carried out by a coculture of the 5FU-treated cells (two femurs) with the virus-producing cells (10^5 cells in a 10-cm tissue culture Petri dish) for 4–5 days. The number of adherent virus-producing cells is calculated in order to obtain a confluent culture at the day of BM cell collection. The infection is carried out in the presence of cytokines able to induce HSC proliferation and survival. We used a spleen cell-conditioned medium, but this can be replaced with a mixture of early-acting cytokines such as interleukin 3 (IL-3), stem cell factor (SCF), and IL-6 (TPO being secreted by the virus-producing cells).[20] The infected BM cells are collected as the nonadherent cells, and care should be taken not to detach too many virus-producing cells, which will be detrimental to the mice during the injection (these cells, derived from Swiss mice, will be rejected by the immunocompetent C57BL/6J recipient mice). In the study by Yan *et al.*, the infection was not carried by coculture but by serial exposures of the 5FU-treated cells to a virus-producing cell supernatant.[20] Lethally irradiated syngeneic mice (2 months old) are finally injected with 10^6 BM cells (Figure 73–1). The mice are not studied before full blood reconstitution (5 weeks for myeloid and B cells and 7 weeks for T cells). The result of this procedure is the genomic integration of the virus in HSC and their progeny that could be analyzed by Southern blot to evaluate the numbers of both provirus copies, compared to the endogenous gene, and of individual transduced HSC marked by the sites of provirus integration. Provirus, as efficient vectors of expression, produced high level of TPO under the control of the viral long terminal repeat (LTR) promoter.

Using this strategy, we obtained a two-step disease that mimicked the evolution of human MMM and resulted in the death of 100% of the animals within 10 months after transplantation.[21] The first phase of the disease (2 months after BMT) is characterized by thrombocytosis (a 4-fold increase), leukocytosis (up to a 10-fold increase), and decrease of the hematocrit. Giant platelets were observed in PB smears. A striking elevation in the PB, BM and spleen progenitor cell numbers, except the colony-forming unit (CFU)-E, was noticed. Massive hyperplasia of Mks, often organized in clusters, and of granulocytes was observed in BM and spleen with a hypoplasia of erythroblasts in the BM. From the third month post-BMT, platelets, leukocytes, and red cell numbers dropped dramatically and mice developed a severe pancytopenia. Progenitor cell numbers dropped in BM and spleen but increased in the PB and peritoneal cavity. Extramedullary hematopoiesis was observed in liver, kidney, lymph nodes, and lung. Histological examination revealed severe fibrosis in the BM and spleen and osteosclerosis in BM. Notably, 2 mice out of 32 primary recipients and 1 mouse out of 30 secondary recipients died prematurely from undifferentiated acute leukemia. Thus, this fatal myeloproliferative disorder mimicked most of the features observed in the human disease.

Yan *et al.* reported a less dramatic phenotype.[20] The platelet counts increased 5-fold and remained at a steady level for up to 73 weeks. A moderate anemia was observed and a slight increase of the number of PB nucleated cells was described. Mice developed extramedullary hematopoiesis and splenomegaly with

hyperplasia of Mks and granulocytes. BM was also obturated with a dense network of reticulin fibers and new bone trabeculae. However, mice did not display the second phase of our disease model characterized by severe thrombocytopenia, anemia, and leukopenia. They remained alive and active over a year and no leukemic transformation was described. The difference may be related to the plasma level of TPO; in the study by Yan *et al.*,[20] plasma TPO reached 30 ng/ml compared to up to 1000 ng/ml in our study.[21]

TPO^{high} MODELS BY TRANSGENESIS Two models of transgenic mice with contradictory results were developed. In the first one,[22] transgenic mice overexpressing human TPO under the control of a liver-specific apolipoprotein E enhancer/promoter did not display fibrosis despite elevated plasma TPO levels (3 ng/ml), and a 4-fold increase in platelet counts and in tissue Mk content for more than 16 months. In contrast, in another recent transgenic model,[23] expressing full-length murine TPO under the control of the mouse H chain enhancer/promoter, similar mild leukocytosis (2-fold), anemia (a 10% decrease in hematocrit), thrombocytosis (3-fold), and increase of plasma TPO level (3 ng/ml) were associated with BM fibrosis starting at 9 months with further progression at 12 months of age. Local production of TPO in hematopoietic tissues in the second model, in contrast to the first one, might have been the reason for the occurrence of fibrosis.[23]

All these TPO^{high} models showed that TPO overexpression in mice leads to a myeloproliferative disorder featuring most aspects of MMM: leukocytosis, anemia, thrombocytosis, and in some cases pancytopenia, splenomegaly, extramedullary hematopoiesis, fibrosis, and osteosclerosis. Depending on the approach used, the severity of the disease (pancytopenia, leukemia, massive splenomegaly, fibrosis, and osteosclerosis) seems to be linked to the levels of TPO, the duration of exposure, as well as to the site of TPO production.[28]

THE GATA-1^{low} MODEL

GATA-1 is a transcription factor, encoded by a gene located on the X chromosome, that plays essential roles in the development of the erythroid,[29] megakaryocytic,[30] eosinophilic,[31] and mast cell[32] lineages, and that has been clarified by the phenotype of mice harboring experimentally induced alterations of its expression. Animal knockouts for the gene die *in utero* at day E10.5 because of severe anemia,[33] while those expressing ectopic levels of *Gata1* showed an increased rate of erythroid differentiation.[34] GATA-1 is member of the family of GATA transcription factors that controls the expression of target genes by binding to the consensus WGATAR sequence; since they share a highly conserved structure, the cellular functions of GATA-1 are strictly dependent on the appropriate lineage and on the differentiation stage of activation.[35] As a result of studies performed in the laboratory of Dr. Stuart Horkin in Boston, concerning the role of the region upstream to *Gata1* in regulating gene expression in erythroid and Mk differentiation, McDevitt *et al*. generated a strain of mice (*Gata1*$^{neo\delta HS}$) characterized by the targeted deletion of an ≅8-kb upstream region that included a DNase hypersensitive (HS) site (HSI) replaced by a neomycin-resistance cassette by homologous recombination.[36] A targeting vector, containing a *loxP* site-flanked neomycin resistance gene driven by the mouse phosphoglycerate kinase promoter and a herpes simplex virus thymidine kinase gene, was used to disrupt the region of interest. The construct was electroporated into 129S4/SvJae-derived J1 embryonic stem cells and correctly targeted embryonic stem cells were injected into C57BL/6 blastocysts[36] (Figure 73–2). The resulting *Gata1*$^{neo\delta HS}$ mice were anemic and demonstrated marked impairment in erythroid cell maturation[36] because of an increased apoptotic rate due to a 4- to5-fold decrease in GATA-1 expression. However, the most striking finding was that these mutants were severely thrombocytopenic because of the almost complete lack of *Gata1* expression in Mks that remain immature and release a few abnormally large platelets.[37,38] The proliferative rate of GATA-1^{low} Mks is increased, while the expression of lineage-specific genes, including the *mpl*, glycoproteins Ibα and Ibβ, and platelet factor 4, is reduced.[37,38] At the ultrastructural level, the Mks are blocked between stage I and II of maturation, and show poor organization of the α-granules due to a reduced expression of some α-granule-specific proteins, such as von Willebrand factor, or an atypical localization of other proteins, such as P-selectin, that, although being expressed at normal levels, are found on the demarcation membrane systems (DMS) rather than in the granules themselves[39] (see also below).

In the original C57BL/6 mutant strain, the mortality was >90% of the mutants around birth; however, when the mutation was introduced in the CD1 background in our laboratory by backcross-

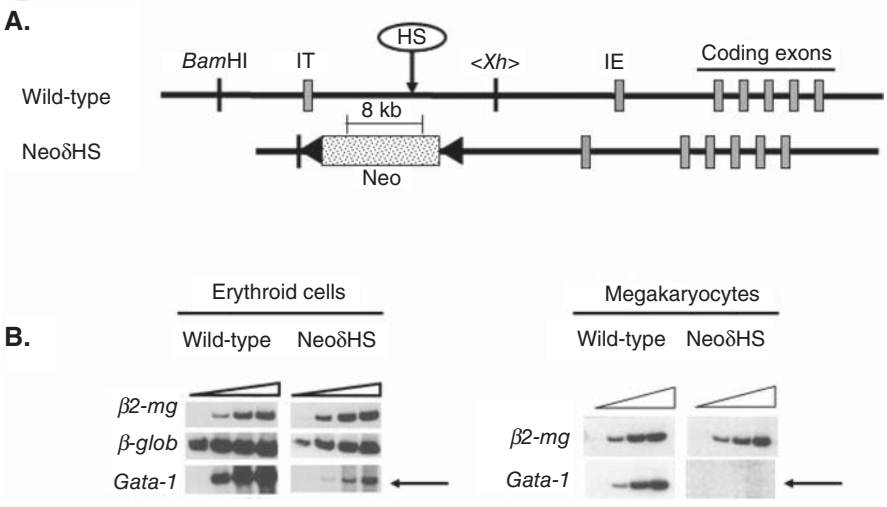

Figure 73–2. Generation and characterization of the GATA-1^{low} mice. (A) The procedure employed to generate GATA-1^{low} mice in the original C57BL/6 strain is described.[34] HS, DNase hypersensitive site I. IT and IE, "testis" and "erythroid" alternative first *GATA1* exons, respectively. (B) The expression levels (by semi-quantitative RT-PCR) of *GATA-1* in erythroid and megakaryocytic cells, to demonstrate the selective abrogation of *GATA-1* in the latter, are presented.

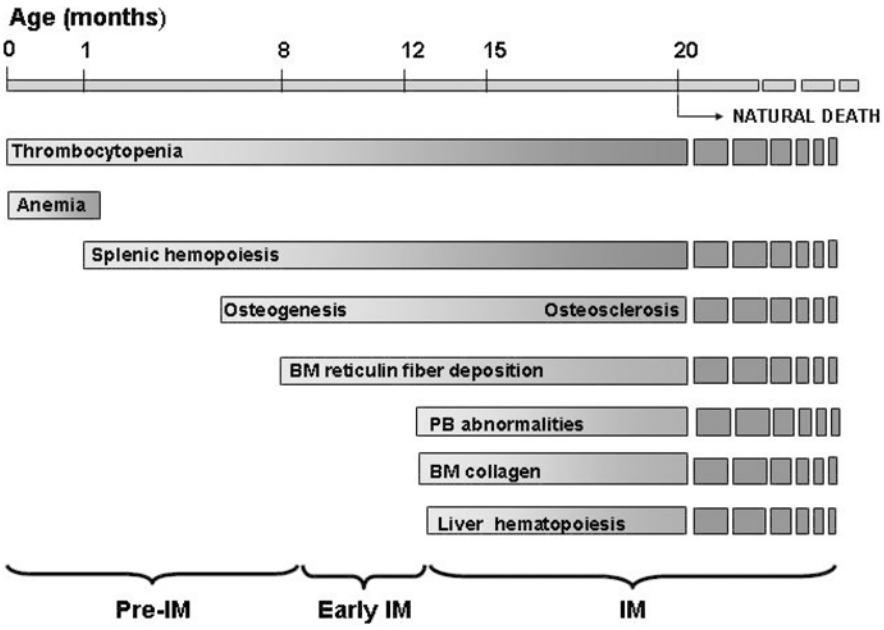

Figure 73–3. The age-dependent development of myelofibrosis in GATA-1^{low} mice.

ing to CD1 mice, starting from one breeder pair of B6 mice provided by Dr. S. Orkin, most of the mutants survived to reach adulthood, and, although severely anemic at birth, recovered from their anemia within the first month. On the other hand, marked thrombocytopenia (with counts less than 10% of the normal value) is maintained throughout their life. Thrombocytopenia is due to impaired Mk maturation, since the number of Mks in the BM and spleen is markedly increased; these cells are of varying size, with a population of large, almost mature Mk together with smaller forms, which are often found in clusters, especially in the spleen.[40] These morphological features, which resembled those observed in IM biopsies and in hematopoietic tissues from the TPO^{high} mice, prompted us to investigate whether these mice would develop myelofibrosis.

By analyzing a large cohort of GATA-1^{low} mice, we have been able to describe the natural history of myelofibrosis in these mice (Figure 73–3).[40,41] During their first year, the only overt hematological abnormality of these mice is thrombocytopenia and splenic enlargement due to the expansion of the Mks lineage; after the first month, they are no longer anemic, although a greater than normal degree of erythroid progenitor cell apoptosis persists, and they are able to mount a supraadequate response to anemia induction or EPO treatment.[42] From the first year of life, the first signs of MMM appear, with a progressive reduction (up to one-fifth the normal value) of the nucleated cell content in the BM cavity, the appearance of BM reticulin fibrosis that proceeds to collagen fiber deposition, and eventually osteosclerosis. The size of the spleen increases further (more than 5- to 10-fold that of the wild-type animals), and extramedullary hematopoiesis in the liver and less frequently in other organs can be detected. A moderate leukocytosis, with a few immature myeloid cells but no blasts, and dacryocytes with nucleated erythroblasts can be found in the PB. Thus, at 15–18 months of age, a full myelofibrotic phenotype is presented by the mice. However, unlike the mice overexpressing TPO, there is no leukemic terminal phase in the GATA-1^{low} animals, and the survival of the mice is not significantly reduced, since most die of old age at 20–24 months.[40] It is of interest that these genetically modified animal models have been made possible by their development in a CD1 background, since the high mortality rate in the original C57BL/6 strain would have likely precluded their recognition. Furthermore, when the mutation was introduced in the DBA/2 background, these mice showed severe anemia but did not express a full myelofibrotic phenotype, including extramedullary hematopoiesis and osteosclerosis. These observations point to the possible role of gene modifiers in the different strains, and might also configure a model to study the variability of the clinical phenotype of the disease in humans.[43] The GATA-1^{low} mice in the CD1 background are available from the Jackson Laboratories (at http://jaxmice.jax.org/, Strain Name: STOCK *Gata1^{tm2Sho}*, Stock Number 004655).

THE *JAK2*^{V617F} MODEL

The *JAK2*^{V617F} model of myelofibrosis was established during investigations trying to determine the exact role of the *JAK2*^{V617F} mutation recently identified in MPDs.[5–8] To analyze the consequences of this mutation for normal hematopoiesis, two groups studied the *in vivo* effects of *JAK2*^{V617F} expression in hematopoietic cells using an adoptive transfer in recipient mice of marrow cells transduced by a retrovirus expressing *JAK2*^{V617F}.[44,45] Both studies demonstrated that mice transplanted with HSC expressing *JAK2*^{V617F} develop a disease mimicking human PV, including its evolution toward the "spent" phase characterized by myelofibrosis.

In our study, we used a procedure similar to the one previously described for the TPO overexpressing model except that cocultures were carried out in the presence of IL-3, IL-6, SCF, and TPO.[44] Furthermore, virus-producing clones were generated from two infections of the GP + E86 cells with vesicular stomatitis virus (VSV)-G pseudotyped virus. Wernig *et al.* used transient transfections of 293T cells with the retroviral vector and the packaging plasmids to produce viral supernatants that were used to transduce 5FU-treated BM cells.[45] The infection procedure was carried out in the presence of IL-3, IL-6, and SCF and consisted of 1 day of prestimulation followed by 2 successive days of brief

exposure to the virus supernatant (90 min for 1800 × *g* centrifugations). Recipients were treated with two serial sets of irradiation (5.5 Gy each), instead of one (9.5 Gy) in our study, before injection of the transduced BM cells.[44] In both studies, bicistronic viruses carrying an IRESeGFP cassette were used with similar promoters [murine stem cell virus (MSCV) LTR derived].

During the 2–4 months of transplantation, using both strategies, C57BL/6 mice rapidly developed polycythemia (hematocrit: 60–90%) with reticulocytosis. Wernig *et al.* reported low EPO levels.[45] A mild leukocytosis was observed with an excess of polynuclear elements and rare immature forms. The platelet size was increased but platelet counts remained normal except in one of our low *JAK2*^{V617F} expresser groups, where transient mild thrombocytosis was observed. Myeloid hyperplasia of the marrow with Mk clusters was observed. Mild splenomegaly (2- to 3-fold) developed with expansion of the red pulp and hyperplasia of myeloid and erythroid cells (4- to 5-fold) and clusters of dysplastic and apoptotic Mks with neutrophil emperipolesis. Wernig *et al*. described decreased Mk ploidy and extramedulary hematopoiesis in the liver with myeloid, erythroid, and Mk cells.[45] The total number of myeloid and erythroid progenitor cells increased due to the expansion of splenic hematopoiesis. Endogenous erythroid colonies (growing without addition of EPO) developed from BM and spleen cells (around 30% of the total CFU-E) and constitutive activation of JAK2 downstream effectors (Stat5, ERK1/2) was detected in spleen and BM cells. No fibrosis was observed at this stage. In our study, mice were followed for 4 months after BMT.[44] During this late phase, the disease evolved to a very different phenotype. We observed abatement of polycythemia, abnormal red blood cell morphology, giant platelets as a sign of dysmegakaryopoiesis, and fibrosis in the BM and spleen. Ultimately, development of severe fibrosis (with reticulin and collagen deposition) in the BM and spleen was associated with anemia, thrombocytopenia, severe granulocytosis, marrow hypocellularity, and significant splenomegaly (6-fold). Mild osteosclerosis was observed in femurs. C57BL/6 mice usually survived over the 6-month survey; however, 3 out of 18 mice in Wernig's study[45] and 3 out of 65 mice in our study[44] prematurely died with very elevated white blood cell counts (58–102 × 10^9 cell/ml) with no sign of acute leukemia. The disease phenotype was not transplantable in sublethally irradiated mice but was transferable in lethally irradiated mice. Southern blots revealed oligoclonal retrovirally marked hematopoiesis early or late after transplantation.

Wernig *et al*. described a more dramatic phenotype in BALB/c than in C57B6 mice.[45] These mice develop marked leukocytosis (up to 17-fold), huge splenomegaly (10-fold), and fibrosis at early stages (1 month post-BMT), and had a short survival (from 50 to 95 days), suggesting that genetic modifiers are important in disease phenotype.[45]

In summary, these models demonstrated that high levels of *JAK2*^{V617F} expression induce a disease with features similar to those observed in PV patients, including evolution into a myelofibrosis-like disease. However, how a unique mutation can be involved in numerous diverse human disease phenotypes, such as in the MPD, is not explained by these models, and further work will be needed to establish the mechanisms leading to *JAK2*^{V617F}-positive pathologies that are not associated with erythrocytosis, especially as concerns MMM. Finally, this model offers a unique opportunity to assess novel therapeutic approaches for *JAK2*^{V617F}-positive PV.

THE *MPL*^{W515L} MODEL

Searching for novel mutations involving other components of the JAK-STAT signal transduction pathway in *JAK2*^{V617F}-negative MPD, a novel somatic mutation in the transmembrane region of MPL was identified, resulting in a tryptophan-to-leucine substitution at codon 515 (*MPL*^{W515L}).[9] This mutation is present in approximately 5–10% of *JAK2*^{V617F}-negative IM patients,[9,10] and results in constitutive activation of JAK-STAT signaling. Hematopoietic cells expressing *MPL*^{W515L} showed a selective proliferative advantage and a cytokine-independent growth when compared to wild-type cells.[9] With the aim to evaluate the relevance of this mutation in the pathogenesis of IM, a murine transplant assay was developed. Bone marrow cells were transduced with murine stem cell virus–internal ribosome entry site–enhanced green fluorescent protein (MSCV-IRES-EGFP) vectors containing *MPL*^{WT} or *MPL*^{W515L} and transplanted into lethally irradiated BALB/c mice. Only mice transplanted with *MPL*^{W515L}-transduced HSC developed, with a median latency of 18 days, a fully penetrant lethal myeloproliferative disease characterized by hepatomegaly and splenomegaly, leukocytosis, marked thrombocytosis, extramedullary hematopoiesis, and myelofibrosis.[9] Compared to *MPL*^{WT} mice, the BM of *MPL*^{W515L} animals showed a predominance of maturing myeloid cells and atypical and dysplastic Mks, sometime collected in clusters, that frequently exhibited the phenomenon of emperipolesis of neutrophils in their cytoplasm. Similar findings were reported in the spleen and the liver. When cultured *in vitro*, spleen cells derived from *MPL*^{W515L}-transduced mice demonstrated a marked increase of MK-CFUs that originated larger colonies as compared to those derived from BM cells.[9] In summary, this model offered a novel mechanism for activation of downstream signal transduction pathways in *JAK2*^{V617F}-negative MPD patients that results in myelofibrosis, and may represent a useful model for the study of drugs targeted to *MPL*^{W515L}-harboring cells.

INSIGHTS FROM MURINE MODELS INTO THE PATHOGENESIS OF THE STROMAL REACTIONS IN MYELOFIBROSIS

The stromal reaction observed in the BM microenvironment in MMM is characterized by fibrosis (excessive deposits of extracellular matrix proteins), osteosclerosis (new bone formation), and neoangiogenesis. This aberrant stromal reaction is known to be secondary to the stem cell disorder and is supposedly mediated by cytokines released by cells belonging to the abnormal clone, and especially from the Mks. Both the TPO^{high} and the GATA-1^{low} mouse model have provided new insight into the pathogenesis of the stromal reaction. The role of transforming growth factor-β1 (TGF-β1) and osteoprotegerin (OPG) in the promotion of BM fibrosis and osteosclerosis, respectively, has been elucidated. Additionally, a possible mechanism for release of cytokines in the BM microenvironment by abnormal Mks has been identified in the process of emperipolesis. Finally, the role of the monocyte/macrophage lineage in the promotion of the stromal reaction has been addressed in the TPO^{high} model. Thus, both TPO^{high} and GATA-1^{low} mouse models have proved to be useful tools with which to investigate both the cytokines and the cells involved in the modification of the BM microenvironment that occurs in MMM.

CYTOKINES INVOLVED IN THE STROMAL REACTION

Role of Transforming Growth Factor-β1 *In vivo* and *in vitro* studies have involved several cytokines in the development of myelofibrosis, such as TGF-β1, platelet-derived growth factor (PDGF), or basic fibroblast growth factor (bFGF). Among these, TGF-β1 has been the most likely candidate based on indirect observations. First, it potently stimulates the production of extracellular matrix components, by inducing fibroblasts to proliferate and secrete extracellular matrix and cell adhesion proteins, and prevents matrix degradation through the enhanced expression of protease that inhibits enzymes involved in the degradation of the extracellular matrix.[46] Second, TGF-β1 promotes fibrosis of a variety of nonhematopoietic tissues.[46] More recently, it has been shown to be directly involved in the pathogenesis of BM fibrosis in hairy cell leukemia.[49] Third, increased plasma levels of TGF-β1 have been reported both in patients with MMM and in TPO^{high} mice, and increased levels of TGF-β1 were found in extracellular fluids of BM and spleen in TPO^{high} and GATA-1^{low} mice.[25]

The prominent role of TGF-β1 in the promotion of BM fibrosis has been confirmed using the TPO^{high} model.[50] Lethally irradiated wild-type hosts (used because *TGF-β1*$^{-/-}$ mice die at weaning age from a multifocal inflammatory syndrome) were transplanted for long-term reconstitution with HSC from mice genetically deficient for *TGF-β1* (*TGF-β1*$^{-/-}$) or from wild-type (*TGF-β1*$^{+/+}$) mice infected with a retrovirus encoding the mouse TPO. Over the 4 months of follow-up, TPO levels in plasma were markedly elevated in both groups of mice and all animals typically developed a myeloproliferative syndrome characterized by thrombocytosis, leukocytosis, splenomegaly, increased numbers of progenitors in the PB, and extramedullary hematopoiesis. However, whereas prominent fibrosis was observed in BM and spleen from all mice engrafted with *TGF-β1*$^{+/+}$ cells, none of the mice repopulated with *TGF-β1*$^{-/-}$ cells showed deposition of reticulin or collagen fibers. In accordance with the development of fibrosis, latent TGF-β1 levels in plasma and extracellular fluids of the spleen from mice engrafted with *TGF-β1*$^{+/+}$ cells were increased 4- to 8-fold over baseline levels, whereas no increase was detected in hosts engrafted with *TGF-β1*$^{-/-}$ hematopoietic cells. Taken together, these data strongly supported the prominent role of TGF-β1 produced by hematopoietic cells in the pathogenesis of myelofibrosis induced by high TPO levels. Significantly, increased levels of TGF-β1 are contained in the extracellular fluids of BM and spleen in GATA-1^{low} mice, but they are 2- to 6-fold lower than those reported in the TPO^{high} mice; it has been suggested that the different disease evolution and morbidity in these two animal models might be correlated with the levels of TGF-β1 in the BM microenvironment.[25] However, other growth factors, such as PDGF or bFGF, might also contribute to the development of fibrosis, and would require investigation. Finally, another mechanism remains unknown; this concerns the fact that TGF-β1 has to be activated to exert its biological effect. In fact, even if increased plasma levels of latent TGF-β1 were detected in TPO^{high} mice, no increase in the active form of TGF-β1 was measured in the circulation.[50] Accordingly, no fibrotic lesions were identified in distant organs known to be targets of the fibrogenic effect of TGF-β1, such as lung or kidney. This indicates that critical regulatory mechanisms controlling TGF-β1 activation must take place within the hematopoietic environment at secretion sites. These mechanisms responsible for the local activation of TGF-β1 are not yet understood, but might involve potent *in vivo* activators of TGF-β1, such as thrombospondin-1 (TSP-1), integrins $\alpha_v\beta_6$, $\alpha_{IIb}\beta_3$, and $\alpha_v\beta_3$, or proteases. MKs and platelets synthesize and store TSP-1 in the same organelles as TGF-β1, and, moreover, they express integrins $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$. Thus, Mks may participate in the local activation of TGF-β1; additionally, monocytes/macrophages are sources of cytokines that can activate TGF-β1 *in vivo* as well.

Role of Osteoprotegerin The rapid development in TPO^{high} mice of osteosclerosis also offered a model to investigate the underlying causes of abnormal bone growth. Bone remodeling depends on the tightly integrated activity of two distinct cell types, the osteoblasts (the bone-forming cells) and the osteoclasts (the bone-resorbing cells). Osteoblasts derive from mesenchymal progenitors through the regulatory action of cell–cell and cell–matrix interactions and the actions of several growth factors such as TGF-β1, which could exert both stimulatory and inhibitory effects. Osteoclasts are monocyte-derived multinucleated cells. They require macrophage-colony-stimulating factor (M-CSF) for proliferation and receptor activation of nuclear factor-Kappa-ligand (RANK-L), via its binding to the receptor RANK expressed at the surface of osteoclast progenitors, for differentiation and maturation. OPG is a decoy soluble receptor that binds RANK-L and inhibits osteoclastogenesis.

The role of OPG in the development of osteosclerosis in TPO^{high} mice was demonstrated using OPG-deficient mice (*OPG*$^{-/-}$).[51] Because these animals are viable and develop normally, the four combinations of graft/host were performed, allowing the discrimination of the potential role of hematopoietic OPG (from donor cells) or stromal OPG (host cells). Regardless of the combination, all animals developed the expected myeloproliferative syndrome with BM fibrosis associated with increased TGF-β1 plasma levels. Osteosclerosis occurred only in *OPG*$^{+/+}$ hosts regardless of donor cell genotype with a marked elevation of OPG plasma levels. In contrast, only rare bone growth was observed in *OPG*$^{-/-}$ hosts with no OPG detectable in the circulation. These findings strongly suggest the role of the stromal OPG secreted by the host microenvironment in the promotion of osteosclerosis. The mechanism leading to stromal OPG upregulation remains unknown, but it is not mediated by increased TGF-β1 in TPO^{high} mice. Indeed, retrospective analysis of TPO^{high} mice engrafted with *TGF-β1*$^{-/-}$ donor cells showed no correlation between TGF-β1 levels and OPG levels.[51] All mice displayed similarly increased OPG plasma levels regardless of donor cell genotype (*TGF-β1*$^{-/-}$ or *TGF-β1*$^{+/+}$). However, TPO^{high} mice engrafted with *TGF-β1*$^{-/-}$ donor cells developed a delayed osteosclerosis compared to the control group, suggesting the involvement of TGF-β1 in this process, likely by stimulating osteoblasts proliferation. Furthermore, a recent study showed that TPO^{high} mice also displayed also high plasma levels of IL-1, which was demonstrated to originate in part from platelets.[27] This cytokine may be involved in stromal OPG upregulation as well. Osteosclerosis and increased bone mRNA levels for osteocalcin are also developed by GATA-1^{low} mice, starting around the sixth month of age. By crossing experiments, it has been observed that the extent of osteosclerosis is dependent on the strain employed, since bone marrow formation is maximal in C57BL/6 mice, very limited in DB/2 mice, and intermediate in the standard CD1 strain;[43] thus these models offer the opportunity to study novel factors implied in the process of osteosclerosis. Although GATA-1^{low} Mks are able to promote osteoblast proliferation *in vitro* by direct cell contact,[52] we failed to demonstrate an *in vivo* correlation between the

number of Mks in the BM of different mutated strains and the degree of osteosclerosis.[43]

CELLS INVOLVED IN THE STROMAL REACTION

Prominent Role of Megakaryocytes and the Process of Emperipolesis Several lines of evidence, obtained both from studies of patients with MMM and from murine models as described above, favor a crucial role of Mks in the development of the stromal reaction (Figure 73–4). First, Mks and platelets are the main source of TGF-β1. Second, hyperplasia and disturbed differentiation of Mks are observed in MMM patients and in both TPO^{high} and GATA-1^{low} mice. In addition, on BM biopsies, Mks are often found in close proximity to or surrounded by reticulin fibers, both in humans and mice. Third, BM fibrosis is associated with other diseases involving Mks, such as megakaryoblastic leukemia or gray platelets syndrome, and is also presented by other genetically modified animals (Table 73–1). TPO^{high} mice display Mk hyperplasia with dysmorphic Mks, suggesting that a long-lasting high production of TPO could affect Mk maturation. However, since GATA-1^{low} mice display normal levels of plasma TPO, notwithstanding their severe lifelong thrombocytopenia (likely because of TPO sequestration by the enlarged Mk mass), it seems unlikely that myelofibrosis in these mice is linked to TPO overstimulation. However, interestingly enough, Mks from mice treated with high TPO doses expressed low GATA-1 levels, positioning TPO/MPL and GATA-1 in a downstream relationship in the pathogenesis of the development of abnormal megakaryocytopoiesis and myelofibrosis.[25] How a high level of TPO can induce a dysmegakaryopoiesis remains unknown. One hypothesis is that a long-lasting TPO stimulation leads to MPL traffic defects and altered signaling (S. Constantinescu, unpublished data).

One possible mechanism for inappropriate cytokine release in MMM could be a pathological form of emperipolesis. This rare physiological process is defined by the random passage of different types of BM cells through the Mk cytoplasm without any important consequences for either the host or the invading cells. An increased frequency of neutrophil polymorphonuclear (PMN) cell emperipolesis within Mks is a common feature shared by the majority of patients suffering from extreme thrombocytosis (either reactive or myeloproliferative), but is not necessarily associated with BM fibrosis.[53] On the other hand, both in patients with MMM and in TPO^{high} and GATA-1^{low} mice, increased neutrophil and eosinophil PMN cell emperipolesis related to abnormal P-selectin localization on the DMS has been described.[54] The Mks from both these mice contain very few normal, mature α-granules; rather they have the appearance of large empty vacuoles derived from the Golgi apparatus and are almost devoid of normal constituents. In particular, P-selectin (GMP-140, CD62), a leukocyte receptor and a normal constituent of α-granules from which it is released during platelet activation, is found in small vacuolar structures scattered in the cytoplasm and on the membranes of DMS.[39] A model has been proposed by which the increased PMN emperipolesis in Mks, favored by the abnormal P-selectin localization on the DMS, would result in paraapoptosis of Mks due to the release of neutrophil enzymes in the cytoplasm; in fact, the cytoplasm of engulfed PMN is almost devoid of myeloperoxidase-positive granules, which conversely can be found in the Mk cytoplasm. This pathological and specific interaction between Mks and PMN cells could lead progressively to PMN-mediated Mk destruction, especially by causing α-granule lysis and the discharge of growth factors, including TGF-β1 normally contained in the granules, outside the Mk itself in the BM microenvironment through the DMS. This would finally result in the stimulation of reticulin and collagen synthesis and deposition by fibroblasts.[37]

Eventually, this same sequence of events might play a role in the constitutive mobilization of HSC in the circulation, which is

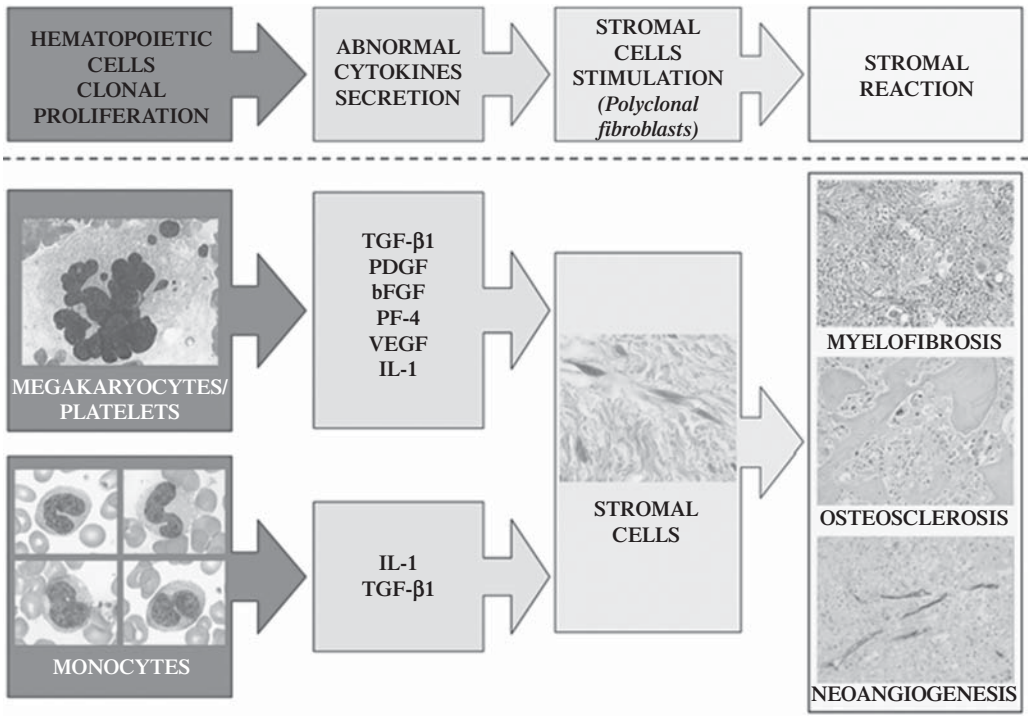

Figure 73–4. A pathogenetic model for the cytokine-mediated stromal reaction observed in MMM. (See color insert.)

characteristic of both the murine models and patients with MMM.[55–57] The PMN proteases released through the process of emperipolesis might result in the cleavage of adhesion receptors from the surface of the cells constituting the hematopoietic niche in the BM, as well as from the membrane of HSC, similar to what happens in the HSC mobilization induced by granulocyte-colony-stimulating factor (G-CSF).

Minor Role of Monocyte/Macrophage A central role for the changes occurring in the monocyte/macrophage lineage in the BM microenvironment in MMM has been supported by two different observations. First, Rameshwar *et al* reported that monocytes from patients with MMM were spontaneously activated and abnormally secreted TGF-β1.[58] Second, Frey *et al.* reported that TPO overexpression in SCID mice, but not in NOD/SCID mice, led to BM fibrosis, indicating a prominent role for the monocyte/macrophage lineage in the promotion of the stromal reaction.[19] However, a recent study demonstrated that NOD/SCID mice exposed to high TPO levels developed marrow fibrosis, strongly suggesting that fully functional monocytes are not required for the stromal reaction to occur, and pointing again to Mk as the key cell responsible for the pathogenesis of the changes in the BM microenvironment.[27]

RELEVANCE OF MURINE MODELS FOR HUMAN MYELOFIBROSIS

Since TPO^{high} models were first described, the role played by the TPO/MPL pathway in MMM has been elucidated. Recently two activating mutations of *MPL*, MPL^{W515L} and MPL^{W515K}, have been described in 10% of MMM patients and have been shown to induce fibrosis in mice.[9,10] Furthermore, the activating $JAK2^{V617F}$ mutation, found in 50% of MMM, also induces fibrosis in mice[59] and is directly linked to deregulated MPL signaling. On the other hand, although mutations in *GATA1* have not been reported to occur in MMM, the levels of GATA-1 in the MKs from MMM patients are significantly reduced, independent of *JAK2* mutational status, which points to a defect in the GATA-1-dependent pathway(s).[60] Thus, there is enough to suggest that the downstream relationship existing between the TPO^{high} and the $GATA\text{-}1^{low}$ animal models would mirror the situation in human disease. Furthermore, it is likely that the prominent role of TGF-β1 in fibrosis and of OPG in the promotion of osteosclerosis, shown with these models, will also be confirmed in the new animal models of MMM; of interest, abnormalities in OPG levels have already been described in human MMM.[61]

In conclusion, even though the newly discovered molecular lesions as a basis for MMM in humans appear to be different from those found in the animal models, these models have been shown to recapitulate the same cascade of events that culminate in the specific phenotypic abnormalities of the human disorder. Thus, these animal models are expected to further improve our understanding of the pathogenesis of MMM, with potential clinical implications, not to mention their usefulness for testing novel therapeutic agents to treat this incurable disease.[62–76]

74 Animal Models for Bone Tissue Engineering Purposes

Véronique Viateau, Delphine Logeart-Avramoglou, Geneviève Guillemin, and Hervé Petite

ABSTRACT

To assess the efficacy of engineered tissues, it is necessary to have (1) appropriate large animal models that mimic the clinical setting and (2) relevant methods of monitoring the biofuntionality of these tissues. However, developing these tissue constructs is a step-by-step process in which numerous variables such as scaffold design, source of stem cells and mode of growth factor application have to be optimized. After an *in vitro* optimization phase, the use of small animal models to optimize these various parameters and sort out any teething problems is recommended before launching into large animal models. Depending on the experimental aims, engineered tissues can be transplanted into either ectopic sites (subcutaneously or intramuscularly) or orthotopic sites. In all these experimental studies, non invasive imaging methods (X-ray, magnetic resonance, *in vivo* fluorescence, ultrasound imaging methods, etc.) as well as detailed quantitative molecular and histological analyses have been used to monitor the *in vivo* behavior of the engineered constructs. In this chapter we take stock of the present state of the art in this field.

Key Words: Bone, Bone healing, Tissue engineering, Stem cells, Growth factors, Biomechanics.

GENERAL CONSIDERATIONS

Tissue engineering and regenerative medicine are new research areas dealing with how to repair and regenerate organs and tissues using the natural signaling pathways and components of the organism. Basically, the three primary constituents of a tissue-engineering approach are (1) cells, (2) a scaffold for delivering and/or retaining cells, and (3) bioactive factors.[1]

The development of bioengineered bone constructs is a step-by-step process that begins with a preliminary but essential *in vitro* optimization step in which parameters such as scaffold design, cell proliferation, cell behavior on the material surface, cell osteogenic capability, and the kinetics of bioactive factor release are assessed.

After this necessary *in vitro* optimization phase, and because the ultimate goal of this approach is the reconstruction of a functional tissue that requires a complex biological and biomechanical *in vivo* environment, the use of animal models usually constitutes the next step of the bone construct developmental process before eventually performing human clinical trials. Animal models have therefore been consistently used to study and test the primary constituents separately, in various combinations, and lastly, within a defective bone site. Animal tests are a long and cumbersome stage in the bone construct developmental process because of the large number of biological and biomechanical variables that have to be assessed before it is possible to apply this engineering approach in the setting of human clinical practice.

CRITERIA FOR APPROPRIATE CHOICE OF ANIMAL MODELS IN BONE REPAIR

As previously stated by Einhorn,[2] "appropriate use of animal models in tissue-engineering research begins with careful consideration of the question asked."[2] Since many questions can potentially be asked in the field of tissue engineering, the answers are usually obtained using different animal models. The problem to be solved should therefore first be clearly identified in order to define the most appropriate experimental model. The complexity of the experimental design will depend on the criteria to be assessed (biochemical, molecular, mechanical testing, histology, functionality, etc.). It is worth noting that however carefully the experimental design and the equipment required are planned and however suitable the animal model selected may be, the results of studies involving no negative and positive control data that can be used to make comparisons will be useless, irrelevant, or worse still, misleading. Thus, determining the appropriateness of an animal model can be the most difficult and time-consuming aspect of the study design.

The focus of the study, especially whether it is biological, mechanical, or both, is a significant point. If biological issues are at stake, small, skeletally mature animals may be useful, and since these animals are inexpensive and give fast healing times, they can be used to set up large pools of data. Many biological tissue engineering questions can be answered using relatively simple small animal models. For instance, experiments in which construct is implanted into ectopic (subcutaneous or intramuscular) sites in small animals make it possible to easily determine the biocompatibility, biodegradability, osteointegration, osteoconductivity, and osteoinductive and osteogenic potential of the bone engineered construct *in vivo*. Larger, more expensive animals can be more suitable for studies that involve biomechanical issues because they simulate more closely the size and structure of human bones. Large animal models simulating the clinical situa-

tion as closely as possible are also usually preferred for preclinical trials.

The size of the defect in which the biomaterial will be tested, whether it is critical or noncritical (i.e., whether or not the defect will heal spontaneously during the animal's lifetime), its location (see below for various orthotopic implantations), as well as the mechanical environment (nonloaded or loaded models) are also critical factors. In addition, while the relevance of the model is of utmost importance, other parameters such as surgical feasibility and reproducibility, animal morbidity, and technical and financial constraints also have to be taken into account.

As far as bone tissue engineering is concerned, the main questions that arise tend to focus on the selection of the cell source, the scaffold material(s), the appropriate growth factor(s), the growth factor concentration required, and the mode of application (carrier systems and/or release mechanisms, for example).

CELL-RELATED CRITERIA Osteoprogenitor cells for the development of bioengineered bone have been isolated from a variety of tissues including periosteum, bone marrow, and adipose tissue, which are the most popular sources. The yield obtained in terms of the skeletal cell isolation rates and the osteogenic potential of material obtained from animal species shows some variability. For instance, harvested murine bone-marrow-derived stromal cells (BMSCs) are usually contaminated by the hematopoietic fraction,[3] isolation of rabbit BMSCs is weakly reproducible,[4] and sheep BMSCs show very weak levels of expression of alkaline phosphatase, an early marker of osteoblast differentiation. Cells can also be defined depending on their donor, which can determine the choice of animal model. Skeletal stem cells can be harvested from the animal into which they will be reimplanted (this is known as an autologous source), for instance. Although this autologous approach ensures the immunocompatibility of the cellular component, it has several drawbacks: (1) it is time consuming and cumbersome, since many animals are required to be able to perform statistically significant data analysis, (2) it is difficult to obtain cells showing a reproducible and consistent osteogenic potential from different animals, and (3) when using small animals, additional animals (from genetically identical animals, such as twins, clones, or highly inbred research animal models) have to be sacrificed to harvest a sufficiently large cellular sample. Last, for the sake of greater clinical relevance, skeletal stem cells are often harvested from human patients (xenogeneic source). However, the use of human cells involves implanting a hybrid construct into immunocompromised nude or severely combined immunodeficient (SCID) animals in which the humoral and cellular immune system is immature.[5] Only nude or SCID mice and nude rats are currently available for this purpose on the market, which drastically reduces the range of possible animal models when using human cellular components; in addition, the cost of these immunocompromised animals is usually 5- to 6-fold higher than that of their wild-type homologs. In specific cases in which it is necessary to assess the osteogenicity of xenogeneic cells grown *in vitro*, the diffusion chamber assay can be used. Cells are inoculated into a small chamber made of semipermeable membranes allowing the diffusion of gases and nutrients, while shielding xenogeneic cells from invading host cells.[6,7]

Some new cellular models have been recently developed using novel genetic methods developed for tissue-engineering applications. Genetically engineered cells that express (either constitutively or under the control of specific promoters) protein reporters such as enhanced green fluorescent protein (GFP) or luciferase were designed to track cells implanted *in vivo*.[8] Fluorescent and bioluminescent imaging methods provide a new noninvasive means of imaging the spatial patterns of marker gene expression. Several aspects of bone formation can thus be followed in individual animals from the time of implantation up to the moment when newly formed bone is remodeled and fully integrated.[9,10] While techniques of this kind open promising new perspectives, their use is nevertheless restricted to small-sized animal models.

SCAFFOLD-RELATED CRITERIA Scaffolds are mainly used for the delivery and retention of osteogenic cells in bone tissue engineering. Apart from serving as a mechanical substrate, scaffolds provide a favorable environment in which bone cells can migrate, proliferate, differentiate, and deposit bone matrix (i.e., they promote osteoconduction). Subcutaneous or intramuscular implantation is usually performed to test the biocompatibility and biodegradation/bioresorption of the scaffold, mostly in rats and lagomorphs for the sake of economy and technical simplicity. The size, shape (massive, granular, or even injectable), hardness, and chemical composition are the main parameters of the scaffold that have to be taken into consideration when choosing the animal species (small vs. large animals), the anatomical site (an intramembranous vs. endochondral bone site; a load-bearing vs. a non-load-bearing site), and the shape of the bone defect (a closed cavity vs. an open defect that will require additional fixing devices).

GROWTH FACTOR-RELATED CRITERIA Growth factors could be used to enhance the proliferation and differentiation of host or implanted osteoprogenitors as well as to promote local processes of angiogenesis. Strategies involving the use of bone morphogenetic proteins (BMPs), which induce differentiation of uncommitted progenitors into osteoblasts,[11] or angioinductive growth factors such as vascular endothelial growth factor (VEGF) or platelet-derived growth factor (PDGF)[12] seem to be particularly promising. Bioactive molecules are usually incorporated onto or into a three-dimensional scaffold. Simple tests can be performed on ectopic sites to assess the bioactivity of molecules. For instance, the osteoinductivity of BMPs is classically assessed by quantifying the rates of new bone formation after implanting BMPs at intramuscular or subcutaneous sites in rodents 3–4 weeks previously. When methods of this kind are used at orthopic sites, it is the features of the carrier material (see the previous section) rather than the type of growth factor applied that will determine the choice of animal model to be used.

The kinetics of growth factor release are of crucial importance, since the cellular response to biological stimuli will depend on the amount of biomolecule released and the time lapse of cell exposure. It is therefore essential to determine the *in vivo* pharmacokinetic profiles of the growth factors used in innovative delivery systems by tagging the protein before its implantation (for instance, using radioactive, fluorescent, biotinylated labels or Flag fusion protein production). Experiments along these lines could easily be performed ectopically or orthopically on small-sized animals.

Based on these considerations relating to the constituents of engineered bone constructs, in many cases the variables of interest can be tested using relatively simple models. However, most of the studies carried out so far on the monitoring of biological cues in the context of the whole organism have been restricted to the

use of rodent models. Small-sized animal models can therefore be used to optimize many of the steps involved, although the results obtained will have to be applicable to medium- and large-sized animal models in order to simulate human clinical settings more closely.

DECISION MAKING: ANIMAL MODELS CURRENTLY USED IN TISSUE ENGINEERED BONE CONSTRUCT ASSESSMENT

Whereas evaluation of tissue engineered bone construct (TEBC) biofunctionality is independent of its future field of application and is always performed in the same animal models, preclinical evaluations are performed in an animal model that reflects a specific human clinical setting.

PRELIMINARY ASSESSMENT OF THE BIOFUNCTIONALITY OF NEW TISSUE ENGINEERED BONE CONSTRUCTS

Heterotopic Implantation Subcutaneous or intramuscular implantation is the gold standard for testing the biocompatibility as well as the osteogenic and osteoinductive potential of bone constructs *in vivo*. These simple surgical procedures are mostly performed on rats and rabbits for financial reasons and because of their technical simplicity, but they have also been tested on larger species such as sheep[13] and goats[14] in cases involving larger, clinically sized implants where cell survival is a major concern. The TEBCs are usually directly implanted into the recipient bed. Alternatively, the fate of *in vitro* expanded cells can be monitored by inoculating them into diffusion chambers prior to their implantation. The nucleopore filters of the diffusion chambers prevent the invasion of implanted material by host cells, while allowing the diffusion of nutrients and cell contacts through the pores. Intraperitoneal implantation of these chambers is also being currently performed.[15–17]

Orthotopic Implantation Orthotopic implantation methods make it possible to assess the osteoconductivity and osteointegration of the implanted material as well as its biodegradability in a bone environment. Rat calvaria is the gold standard model used for orthotopic implantation purposes. Calvaria, which develops from a membrane precursor, has a poor blood supply and relatively little bone marrow. Calvarial defects therefore create a hostile environment for bone healing. Single midsagittal 8-mm circular lesions[18] and bilateral 5-mm parietal lesions[19] can be created in rats: both result in critical size defects (CSDs) as they give rise to a fibrous nonunion when bone loss is not replaced (Figure 74–1A). Craniotomies are easy to perform, have low morbidity rates, and are highly reproducible if performed with a circular trephine. Material of all kinds can be tested in that location, which is particularly well suited for assaying granular or paste-like materials. Moreover, a large number of animals can be operated on allowing significant statistical analysis. Laterally performed craniotomies have the advantage of allowing paired design and minimized morbidity while avoiding accidental damage to the midsagittal sinus. Yet the close vicinity of adjacent defects may allow substance diffusion and impair model relevance.[20]

Bone chamber models implanted in the diaphysis of long bones can be used to test some scaffold material in a reproducible loading or unloading environment. Bone chambers have been occasionally used at the femoral level in the rabbit and goat (1) to compare scaffolds loaded with various growth factor concentrations, (2) to study differences in scaffold processing, and (3) to assess the effects of loads on bone healing. The material to be tested is implanted in a titanium chamber where tissue ingrowth can occur. Depending on the type of chamber used, either single or repeated sampling procedures can be carried out. Repeated sampling is useful as it significantly reduces the number of animals to be operated on.

PRECLINICAL EVALUATIONS OF AUGMENTING BONE-HEALING PROPERTIES IN BONE REPLACEMENT PROCEDURES A relevant animal model for the preclinical evaluation of a TEBC will (1) mimic the surgical technique that is utilized

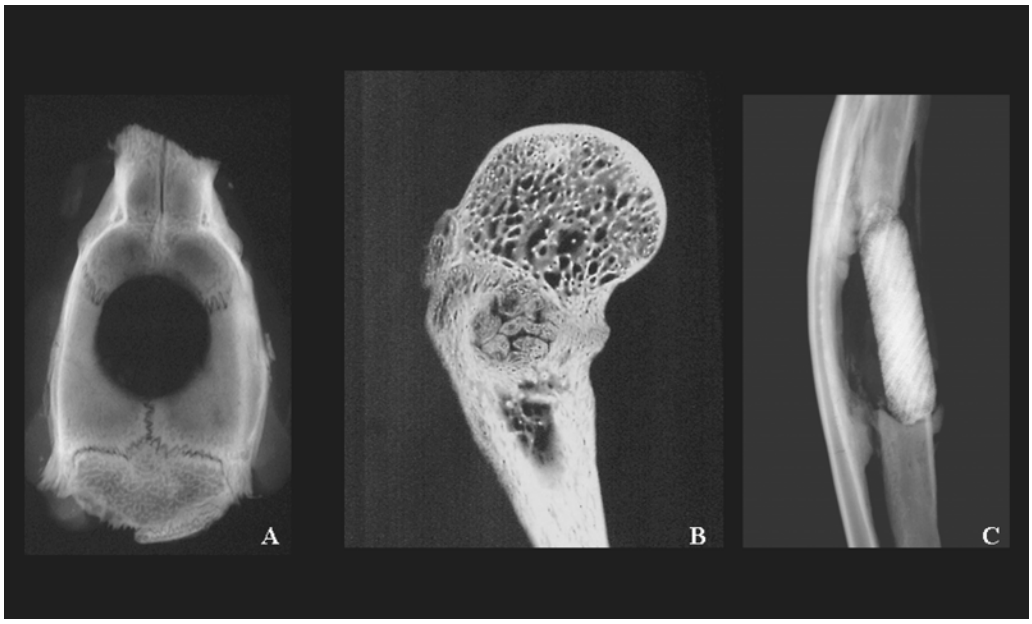

Figure 74–1. (A) Four-week postoperative rat calvaria bone defects left empty. (B) One-month postoperative microradiography of metaphyseal defects created in rabbit distal femoral condyles and filled with a TEBC. (C) Four-week postoperative rabbit ulnar defect filled with a TEBC.

in humans, (2) yield rates of nonunion similar to those observed in humans, (3) mimic the biomechanical environment present in humans, and (4) include animals receiving autografts (positive controls) as well as untreated animals (negative controls). The difficulty of inducing new bone formation depends partly on the anatomical location at which the construct is tested (metaphyseal or diaphyseal bone or spine, for example). The success of a TEBC performed at one anatomical site is therefore not predictive of its performances at another location.

Cranial Surgery Studies on calvarial, parietal, and skull defects have been performed on rabbit, dog, sheep, minipig, and nonhuman primate (NHP) (Table 74–1).[18,20–22] These lesions are easy to create, are highly reproducible, and involve low morbidity rates. The experimental designs used in these studies accurately reflect the clinical settings in which human cranioplasty is performed, although the calvarial regenerative capacity of animals is greater than that of humans, in whom the calvaria is devoid of muscle insertions. Several defects can be created in the same animal in order to compare different biomaterials and to obtain negative and positive control data on the same animal. Up to 12 22-mm lesions per animal have been created, for example, by Viljanen on sheep.[20]

MAXILLOFACIAL SURGERY

Filling Defects Filling defects in maxillofacial surgery often result from alveolar bone resorption at tooth extraction sites (Table 74–1). Suitable models have been developed in the dog by performing mandibular and maxillary premolar extractions.[23] Bone fillers have also recently been tested on unicortical or bicortical mandibular filling defects induced in dogs,[21] miniature pigs,[24] and sheep.[25] Mandibular defects have several advantages over periodontal wounds[25]: (1) they can be standardized in terms of their size and shape, (2) they involve a closed wound rather than an open wound, as occurs in the mouth, and (3) the only tissue regenerated is bone. Calvarial defects such as those described in rabbits, dogs, and NHPs are also currently used because of the anatomical similarities existing with the human mandible (two cortical plates with intervening cancellous bone).[18] Critical-sized nasal defects have been recently described in large Sprague–Dawley rats.[26] The advantage is that these defects involve an endochondral type of bone, whereas calvarial defects are induced in a membranous type of bone.

Segmental Bone Defects Mandibular discontinuity defects have been induced for experimental purposes to mimic the segmental bone resections that are currently performed in oncological maxillofacial surgery. These models partly reproduce the adverse clinical settings in which bone replacement usually takes place during maxillofacial surgery: (1) bone loading requires preventing segmental motion using bone fixation procedures when performing extensive bone resection, and (2) bone replacement is performed in the vicinity of a potentially highly contaminated site. Masticatory stresses differ, however, between humans and animals and vary from one species to another, depending on nutritional habits. Models have been described in the rat, rabbit, dog, sheep, and NHP.[21,27] As previously stated by Hollinger and Kleinschmidt,[21] mandibular bone is very thin in rodents and rabbits and ensuring the retention of implants is a challenging problem. We do not recommend the use of mandibular resection on these species: it is preferable to induce mandibular discontinuity defects in dogs, sheep, or NHPs, where they are easier to perform. Although there is little objective information available on the subject, Schmitz and Hollinger[18] have suggested that mandibular CSD can be as long as 40 mm in adult foxhounds and up to 25% of the total length of the mandible in NHPs. Mandibular resections are prone to postoperative infections, and when they are extensive, they are difficult to stabilize. Complications can be minimized by (1) performing preventive extraction of the teeth bordering the defect (including the maxillary teeth) 2 weeks before bone resection,[21] (2) using submandibular approaches to prevent intraoral perforation, and (3) ensuring mandibular bone fixation with bone plates.

Orbital wall defects have been performed in sheep.[28] The reproducibility of this model may be greater than in the case of mandibular defects and the morbidity may be lower, but as these defects are located in nonloaded bones, this model should be used only to test material to be used with unloaded bones.

ORTHOPEDIC SURGERY

Filling Defects Many TEBCs are used as "bone fillers" to deal with defects resulting from either bone sampling for grafting procedures, metaphyseal traumas, or surgical removal of benign or malignant tumors. Bone fillers are engineered as paste-like, granula, or massive (preset blocks) materials and experimental defects must be compatible with these specific presentations.[29–33]

Standardized metaphyseal defects have been induced in rabbit[34] and sheep[35] distal femoral condyles (Figure 74–1B) and in the dog proximal tibia.[36] These defects do not require any special additional immobilization and since they are highly reproducible, statistical analysis can be carried out on the histological data obtained. Defective lumens are sealed either with a bone flap or with methylmethacrylate cement to prevent the leakage of material. As they are located in loaded bones, these defects are more useful than the critical size ilial defect induced in the goat.[37]

TEBCs are also used as bone fillers in vertebroplasties to maintain or augment vertebral body volume in patients with bone loss resulting from osteoporosis or tumor removal. A sheep model for vertebral bone loss has been described[38] in which a defect is created surgically in the lumbar vertebral body, and either left intact (negative controls) or filled with coral (using an innovative technique) (Figure 74–2A) or with an autologous corticocancellous graft (positive controls).

Segmental Bone Defects According to Keys's hypothesis, under experimental conditions, a segmental long bone defect 1.5 times the size of the diaphyseal diameter will be beyond the regenerative capacities of bone in skeletally mature dogs and will result in nonunion when the missing bone is not replaced.[39] This hypothesis was also found to hold true in the case of feline tibia.[40] The length of the bone resections at which nonunion occurs is species and bone dependent and must therefore be established whenever a new model is developed (negative controls). Key's findings nevertheless roughly apply to many species (dogs, cats, pigs, sheep, NHPs) and can serve as guidelines for developing new models (Table 74–2). Rodents and rabbits are exceptions to this rule, however, as only much longer resections are associated with nonunion in these species.

As mentioned above, segmental defects must be kept in a perfectly stable biomechanical environment while healing occurs. Weight bearing is more difficult to prevent in animals than in humans; however. Achilles tenotomy is not a reliable adjunctive technique as it prevents weight bearing for only a short time.[41] Models in which bone fixation techniques (such as locked intramedullary nailing, bone plating) are used appropriately to neutralize any forces generated are therefore preferable to unlocked intramedullary nailing or external devices such as plaster casts, which do not neutralize the compression, traction, or rotation forces. Although external fixation methods may be satisfactory from the biomechanical point of view, they have several limitations: (1) the weight bearing pattern is irregular, and (2) bone lysis occurs around the pins with time, thus causing instability and reducing the reproducibility and relevance of the model.[42,43]

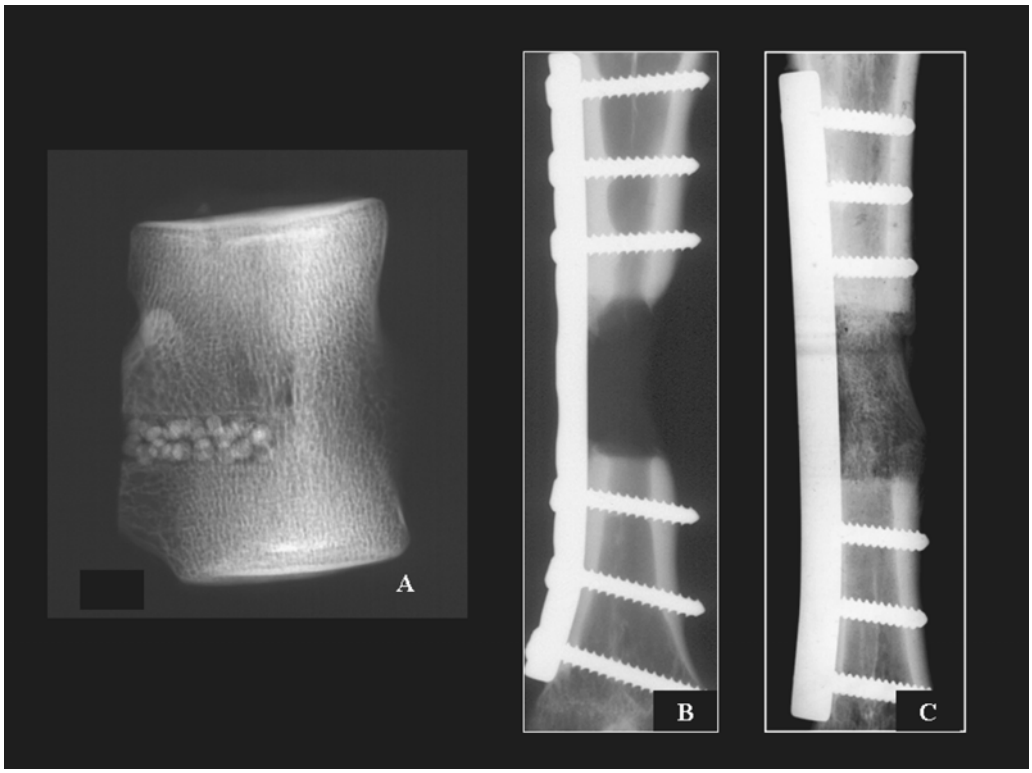

Figure 74–2. (A) Immediate postoperative radiograph of a surgically created vertebral defect filled with coral granules. Radiograph of a 16-week postoperative sheep metatarsal defects left empty (B) or filled with an autologous bone graft (C).

[a]BFT, bone fixation technique; CSD, critical size defects; IM, intramuscular; NHP, nonhuman primate.

Femoral resection has been performed on rats: 5- to 8-mm-long bone resections (20–25% of the femoral bone length) stabilized by custom-made bone plates[44] or external fixation devices[45] were found to result in nonunion after approximately 12 weeks.

The rabbit ulna is one of the most commonly used segmental long bone resection models.[46,47] In this case, remedial surgical procedures can be performed bilaterally,[48] they are easy to perform, and no internal fixation is normally required, as radioulnar synostosis makes for ulnar stability. The ulna is a weight-bearing bone with which implant loading is possible and the morbidity rate is low. This method has several limitations, however: (1) spontaneous bone healing occurs in 30% of the animals after 10-mm-long resections; since bone healing with 20-mm-long ostectomies has been observed, this is more of a model for delayed bone healing than for CSDs[49]; (2) bone curvature and synostosis make implant positioning and stabilization difficult to achieve when solid materials are used; and (3) individual variations in bone curvatures reduce the reproducibility of the procedures used to sample bone for histological analysis and biomechanical assays. Radial resections performed on rabbits suffer from the same disadvantages.[50] Tibial resections stabilized using unlocked intramedullary nailing methods have been reported to be associated with rotational instability and high rates of morbidity, which preclude their use.[51]

A highly reproducible CSD model has been developed based on the cat tibia.[40] Femoral,[46,52,53] tibial,[54] radial,[43] and ulnar[55] resections performed on dogs were stabilized using either bone plating[52,53] or external fixation methods.[43,54] Some of these models have shown spontaneous bone healing and are therefore not appropriate models for CSDs.[43] It was found that 25-mm-long ulnar resections performed on dogs have the same advantages and disadvantages as those described in the rabbit. Radial synostosis is nevertheless more strictly localized in dogs than in rabbits, which simplifies the positioning and stabilization of the implants.

Femoral resections stabilized by means of bone plates and tibial resections stabilized using either bone plates[56] or an intramedullary interlocking nail[57] have been performed in sheep. The recently described metatarsal resection method[58] has many advantages: (1) it is a true CSD, as fibrous nonunion was observed in 25-mm-long bone defects after a 4-month observation period, (2) it is performed in a straight bone lending itself to reproducible histomorphometric and biomechanical assays, and (3) it is associated with a low rate of morbidity (Figure 74–2B and C).

Postoperative handling of pigs is often difficult, and so is orthopedic surgery. A radial defect induced in the miniature pig was associated with very low rates of morbidity.[59] Femoral defects stabilized using either bone plate or external fixation methods have been described by Sendowski in Pitmann Moore minipigs and Large White pigs. High morbidity rates have been recorded with these models: external fixation devices have been unsuccessful in animals of both sizes and the use of bone plates has been satisfactory only with minipigs.[60]

Femoral, tibial, ulnar, and humeral resections have been performed on NHPs.[61–63] Although these models were developed in a species similar to humans as far as bone healing and biomechanical loading processes are concerned, they have some major drawbacks: (1) lack of negative controls[61–63] and (2) the excellent mechanical strength of the constructs used, which were solid metal implants.[62–71]

Spinal Arthrodesis (Fusion) As mentioned by Kruyt *et al*.,[14] spinal arthrodesis is one of the most challenging applications for TEBCs since even the use of autologous bone, the gold standard, is associated with relatively high failure rates. The objectives of spinal fusion differ from those of bone loss replacement: fusion is performed in order to create a mechanically optimum solution in a pathological spinal unit, and not to restore normal anatomy.[72] Regional differences in the spinal column can also significantly affect patients' healing potential.[73] The anterior spine is mainly cancellous and presents a large surface area for bone-healing purposes, thus providing greater opportunities for successful interbody fusion, whereas the posterior column has a greater proportion of cortical bone and a sublumbar healing environment, which have resulted in high failure rates among the attempts at fusion made at this location. Lastly, the fusion rates depend on (1) the number of vertebral units treated (the larger their numbers, the higher the risk of failure will be) and (2) the degree of mobility (left–right side comparisons can be misleading if appropriate instrumentation is lacking). TEBC methods must therefore be tested in an anatomical location similar to where it is to be applied, and the procedure used should be tested on a suitably large number of vertebral units.

Extensive critical reviews of the animal models used in preclinical spinal fusion trials[72–90] have been published by Schimandle and Boden,[91] Khan and Lane,[72] and Kruyt *et al.*[14] Interbody fusions obtained using either anterior or posterior surgical approaches as well as laminar, facet, and posterolateral intertransverse process fusion (PLF) techniques have been described in the rat,[90,92] rabbit,[93] dog,[74,94] pig,[9,95] sheep,[83,86,96] goat,[77,81,97,98] and NHP.[88–90] However, positive and negative controls have not always been included in these studies (Tables 74–3, 74–4, and 74–5).

Lumbar PLF performed on rabbits, which are the most extensively used animal models for spinal fusion, gives overall nonunion rates of 30–40%. These models can be used to make cost-effective comparisons between different osteoinductive constructs.[93] Dog models have also been extensively used. However, models developed on the basis of these small to medium sized species have several anatomical and biomechanical limitations: (1) the experimental fusion techniques used on animals can differ significantly from those performed on humans (the pedicle screw fixation method, which is currently used on humans to optimize biomechanical stability cannot be performed on rats, rabbits, or dogs), (2) implantable bone constructs designed for animals are necessarily smaller than those that can be used on the human spine, and (3) the loads exerted on the spine differ significantly between animals and humans.

[a]NHP, nonhuman primate.

Although models for spinal fusion developed in large animals do not simulate the graft-healing environment of humans any better than those involving smaller animals such as rabbits,[14] they do overcome some of the drawbacks encountered with small animal models: (1) implants such as cages and pedicle screws designed for human applications can also be used in the case of large animals, (2) some anatomical similarities with the human spine do exist [goat cervical anterior interbody fusion (AIF) models have gained popularity because this species has an erect cervical spine],[76] and (3) biomechanical trials can be more reliably performed on large-sized specimens.

NHP models undeniably recreate biological and biomechanical environments most similar to those described in humans. Failure to achieve posterolateral intertransverse fusion often occurs with NHPs, as with humans, despite decortication and the implantation of an autograft in the host bed/tissue/bone. Yet because of the low availability of animals and for ethical reasons, the use of NHP models is limited and only a few animals can usually be included in trials.

QUANTITATIVE ASSESSMENT OF BONE HEALING

Since bone exists in a variety of shapes and sizes, there are no established standards for assessing bone-healing processes. We will provide a brief overview of the techniques that are most commonly used to assess bone healing.

Table 74–5
Selected animal models for lumbar interbody fusion

[a]NHP, nonhuman primate.

CLINICAL ASSESSMENT OF UNION The limb should be examined with no cast for any persistent edema and tenderness at the operated site, which may suggest incomplete union. Persistent mobility at the operated site is a definite sign of incomplete union.

RADIOGRAPHIC ASSESSMENT

Plain X-Rays Since very little scientific information is available about the evolution of the bone repair process on the basis of radiographic evidence, radiographic assessments of bone repair depend largely on radiologists' experience. However, a number of characteristic features of bone repair (fracture gap widening, sclerosis at the fracture margin, periosteal reaction, the presence of callus, a callus density greater than cortex, bridging, periosteal reaction incorporation, remodeling) can be objectively observed on X-rays and some of them can be quantified. In addition, radiographic scales have been described for objectively assessing bone repair processes.

Dual X-Ray Absorptiometry and Computed Tomography Bone densitometric and morphological parameters can be measured quantitatively by dual X-ray absorptiometry (DXA) and volumetric quantitative computed tomography (vQCT).[99] vQCT is based on the scanning of the entire region of interest (i.e., the entire bone defect area) and a three-dimensional reconstruction of these data into anatomically relevant projections, using anatomical landmarks to define a system of coordinates. Techniques of this kind provide an accurate volumetric picture, making it possible to determine the bone mineral content (BMC) and bone mineral density (BMD) either of the entire region of interest or, by separate measurements, of the trabecular or cortical components. More sophisticated apparatuses [such as micro-computed tomography (CT)] are now being developed for three-dimensional *in vitro* analysis of small bone pieces. These methods yield images of a sufficiently good quality to be able to determine standard histomorphometric parameters such as trabecular thickness and separation. This information is useful as bone strength is only partly explained by BMD. The latest generation of micro-CTs collects three-dimensional data sets that provide a basis for finite-element modeling, which are then used for performing virtual biomechanical tests to predict mechanical properties.

HISTOMORPHOMETRY

Quantitative analysis of histological samples (histomorphometry) is based on the following measurements: (1) static bone development indices, (2) dynamic rates of bone formation and mineralization, and (3) microarchitectural properties of bone that contribute to ultimate bone strength. These measurements of skeletal parameters in tissue sections are performed with a bone-specific image analysis system and a microscope on stained sections. All the skeletal parameters used should be in compliance with and calculated according to the recommendations of the histomorphometry nomenclature committee of the American Society of Bone and Mineral Research.[100] In a recent review by Gerstenfeld *et al.*, it was recommended that the following parameters should be determined to study bone repair: callus diameter, total callus area, area of the cartilage, area of the fibrous tissue, area of the void, area of the total osseous tissues, and osteoclast and osteoblast volume density.[101] More specialized parameters that are also relevant to ongoing bone repair processes include the number of vessels per callus area, the number of apoptotic cells per cartilage area, and the total number of apoptotic cells per callus area. One rather critical issue arising in the quantitative analysis of histological samples is how to accurately sample such a heterogeneous tissue in order to obtain a set of statistically meaningful area measurements reflecting changes in the biomechanical and radiological properties. To address this issue, Gerstenfeld *et al.*[101] made the following specific technical recommendations: (1) adopt a transverse sectioning strategy rather than a longitudinal one, and (2) sections should be collected at fixed increments along the long axes of bone to ensure complete sampling across the entire volume of the bone defect and to obtain statistically valid measurements representative of all possible individual measurements of the total bone defect volume.

BIOMECHANICAL ANALYSIS

All treatments involving the use of an engineered bone are designed to regenerate a new bone that will withstand physiological loads in exactly the same way as a normal bone. It is therefore essential to be able to assess the mechanical properties of the newly formed bone in order to determine whether the new bone has been successfully or unsuccessfully engineered. Biomechanical tests can be performed on specimens machined from the bone piece to determine the intrinsic properties of the repaired tissue. Such measurements reflect the quality of newly formed bone but do not yield any information about the ability of the segment of newly formed bone to withstand physiological loads. Alternatively, tests can be carried out on whole segments of bone to determine the extrinsic structural properties of the bone segment. Tests of this kind can be used to predict the functional performances of the bone segment, but are rather prone to variations, as the mechanical properties of bone segments depend on parameters such as their size and their geometry.

Biomechanical studies are best performed on large animals that mimic the size and structure of human bone more closely than small animals. Tension, compression, torsion, and bending tests are routinely performed to assess the mechanical properties of bone. The choice of a specific test will depend on the question addressed and should, whenever possible, mimic the specific physiological loading conditions encountered in humans. Although no standardized procedures are available so far for assessing the mechanical properties of bone, detailed descriptions of biomechanical tests and recommendations on specimen preparation and preservation have been given.[102,103] In their tutorial, Turner and Burr[103] recommend (1) the use of sound testing methods, (2) validation of the testing procedure using material standards, and (3) the use of proper specimen preservation and preparation procedures.

One of the main drawbacks of biomechanical tests is that they are destructive and require a sufficiently large number of specimens for statistical analysis to be possible. Alternatively, ultrasonic methods involving sound velocity measurements through the bone structure can be used.[104] These methods are not destructive, but the bone strength is not measured directly and has to be inferred from the sound velocity data.

CONCLUSIONS

When testing a new TEBC, preliminary studies on biofunctionality (i.e., proof of the concept)[87] can be performed on mice and rats by carrying out subcutaneous or intramuscular implantation procedures (at ectopic sites) followed by rat calvarial CSD (at orthotopic sites).

Preclinical studies should ideally be performed first on a small animal model to assess the feasibility of the approach tested, and then on a large animal model to assess the efficacy. These models should be suited to the future field of application: (1) dogs or NHP mandibular CSDs if the construct is to be used for maxillofacial surgery, (2) rabbit ulnar CSDs followed by sheep metatarsal CSDs if it is to be used in orthopedic surgery for segmental long bone replacement purposes, and (3) rabbit then sheep lumbar PLF, or rabbit then goat or sheep cervical AIF, if the material is to be used to enhance spinal fusion in the lumbar and cervical spine, respectively.

The appropriate choice of experimental model is essential to obtaining relevant results. A complete review of the literature and a sharp critical analysis of previously validated models are essential preliminary steps. Ethical considerations must also be taken into consideration, and the animal model associated with the lowest morbidity rates and the least painful procedures should always be chosen. In some instances, custom-made experimental designs are required. Preliminary trials must first be performed on a few animals to assess the feasibility of the method tested and the resulting morbidity rates. Whichever model is chosen, all the results obtained must be interpreted strictly in the context of the experimental model used and great care should be taken about extrapolating these data to humans.

75 Markov Processes for Biomedical Data Analysis

RICARDO OCAÑA-RIOLA

ABSTRACT

Changes over time in a random variable make up a sequence of temporal values known as a stochastic process. Neuronal activity, depression status, and viral load are just a few examples of stochastic processes of interest in the field of biomedical research. Understanding the evolution and predicting the future status of the process under certain conditions both provide key information that is extremely useful in animal experimentation and in clinical and epidemiological studies in humans. A Markov process is a particular kind of stochastic process in which its future status will depend only on its present status, not on its past history. Since the Russian mathematician Andrei Andreyevich Markov (1856–1922) first defined this kind of process in 1906, there have been numerous applications in biomedical research. This chapter shows some of the Markov models that are currently the most widely used in the fields of biomedicine and the health sciences. The content has been drafted from an eminently practical standpoint, with particular emphasis on the main techniques for analysis, interpretation of results, the usefulness of the models, and the software available for applications. Interesting references have been included in the bibliography cited at the end of the chapter for any readers keen to learn more about the more theoretical aspects of this topic.

Key Words: Markov, Stochastic process, Probability, Autoregressive models, Biomedical research, Statistical analysis.

STOCHASTIC PROCESSES

Many of the variables used in biomedical research exhibit values that change over time. In rat breast cancer models, response to the carcinogen can be evaluated by recording the number of animals that have developed cancer on a monthly basis or by measuring tumour growth every week until the end of the experimental period.[1] In humans, blood pressure, the number of CD4 cells, or the status of patients during the course of their disease are all variables that show changing values over time giving rise to a time sequence of observations for each of them.

Generally speaking, the value of a variable X at time t is usually expressed as $X(t)$, such that $X(t_1), \ldots, X(t_k)$ form a sequence of values over time called a *stochastic process*.[2] The values that the variable may show are known as states and the process, as it develops over time, will be subject to changes in state and transitions between different states. In the usual terminology, *state space* refers to all possible values that the variable defining the process may take.

An analysis of stochastic processes will enable us to predict the state of a given process in the future, based on information available on its past states or values. The complexity of such predictions depends largely on the kind of process involved. However, the characteristics of some of these make them easier to analyze and interpret. The Markov process is a particularly well studied case, i.e., a stochastic process in which future status will depend solely on present status but not on past history.[3,4]

Since the Russian mathematician Andrei Andreyevich Markov (1856–1922) first defined this kind of process in 1906, there have been numerous applications in biomedical research. Both in animal experimentation[5–8] and in human studies,[9–12] the Markov models still prove to be effective today and remain the most widely used methods to study transitions between different states of a process and how these develop over time.

The methodology used for data analysis will differ according to the particular conditions set for each study. *Markov chains* are referred to when the values that the process may take are discrete, while the term *Markov process* is generally reserved for processes with a continuous state space. Although there is no standardized terminology, the general classification of Markov models can be outlined as shown in Table 75–1.

Many researchers today continue to explore new applications for stochastic processes in the field of biomedicine and the health sciences, giving rise to a major area of theoretical and applied research. Of all these processes, it is the Markov chains, both in discrete and continuous time, that are most widely used in biomedical research.[13] For this reason, these will be studied in greater detail in this chapter. Markov processes entail a greater mathematical complexity and their analysis falls beyond the scope of this chapter. However, the bibliography cited at the end of the chapter may be of interest to the keen reader.[2,14,15]

MARKOV CHAINS IN DISCRETE TIME

When the study variable can take only discrete values and observation is performed discontinuously over time, at discrete moments in time, the stochastic process can be represented by $X(1), X(2), X(3)$, where $X(n)$ is the value for the variable X in time n, where $n = 1, 2, 3. \ldots$

If this is a Markov chain, the future state will depend only on the present state and not on its past states or values. In this case, the probabilities of transition from one state to another are defined as

$$p_{ij}(n) = P[X(n+1) = j | X(n) = i] \; i,j = 1, \ldots, m$$

where $p_{ij}(n)$ is the probability that variable X will take value j at observation time $n+1$ if its value currently, at time n, is i. In other words, $p_{ij}(n)$ is the probability that the process will change from state i to state j at the time n.

The evolution of the Markov chain can be determined by ascertaining these probabilities that form the transition matrix $P(n)$:

$$P(n) = \begin{pmatrix} p_{11}(n) & p_{12}(n) & \cdots & p_{1m}(n) \\ p_{21}(n) & p_{22}(n) & \cdots & p_{2m}(n) \\ \vdots & \vdots & & \vdots \\ p_{m1}(n) & p_{m2}(n) & \cdots & p_{mm}(n) \end{pmatrix}$$

Since we are dealing with probabilities, all the components in the transition matrix must lie between 0 and 1, while the sum of the values in each row must equal 1. This is known as a *stochastic matrix*.

In the process described, the transition probabilities change over time, i.e., there is a distinct transition matrix for each observation time. This is what happens in viral epidemics such as chickenpox outbreaks where the probability of changing from being ill to being healthy will be almost zero on the first day of the infection and will approach 1 between 7 and 10 days after the onset of symptoms.[16] When this occurs, the discrete Markov chain will be *nonhomogeneous*.

When the transition probabilities do not change over time, the probability of passing from state i to state j will be the same at all times during the observation of the process. In this case, there will be a single transition probability p_{ij} that is constant over time such that $p_{ij} = p_{ij}(1) = p_{ij}(2) = \ldots = p_{ij}(n)$. Then the process will be a *homogeneous* or *stationary* Markov chain in discrete time, with a single transition matrix expressed as follows:

$$P = \begin{pmatrix} p_{11} & p_{12} & \cdots & p_{1m} \\ p_{21} & p_{22} & \cdots & p_{2m} \\ \vdots & \vdots & & \vdots \\ p_{m1} & p_{m2} & \cdots & p_{mm} \end{pmatrix}$$

ANALYSIS OF HOMOGENEOUS MARKOV CHAINS IN DISCRETE TIME Research related to the dynamics of populations exposed to infectious diseases is intended to shed light on the pattern of the epidemic when an infected subject enters the population, to study the rate of viral propagation, and to estimate the number of individuals who will be infected during the epidemic.

Since the early 1980s, AIDS has become one of the greatest pandemics of our time. Spain is currently one of the most severely affected Western European countries.[17] As a result, understanding the future developments of the epidemic has become a priority that should enable appropriate health policies to be implemented.

The following sections will describe how the HIV/AIDS epidemic in Spain can be analyzed based on Markov chains with yearly observation intervals.

Defining the States of the Process and Transition Mechanisms between Them One of the simplest models to study the AIDS epidemic establishes that each subject in the population may be in only one of the following states: susceptible (S), HIV-infected (HIV), with AIDS (AIDS), or died as a result of the disease (D).

The susceptible subject is not infected (state 1, S). After contact with an infected person, the subject will develop the infection and may infect other individuals in the population (state 2, HIV). An infected subject who develops the disease will become an AIDS case (state 3, AIDS), and may die as a result of the disease (state 4, D). Figure 75–1 shows the possible transitions between states together with the theoretical transition probabilities.

States "S," "HIV," and "AIDS" are called *transitory*, given that individuals will never go back to these states once they have gone on to another stage in the disease. State "D," however, is an *absorbent state,* as the subjects reaching this state remain in it and have no possibility of changing to another state.

This epidemic model is a variant of the SIR and Reed-Frost models that have been widely used to study dynamics in infectious processes in both human and nonhuman populations.[18,19]

Selection of the Most Suitable Markov Model to Study the Process Subjects are observed on a yearly basis so that both the states and the moments in time of the process are discrete. Moreover, the future state individuals may be in will depend only on their current state, not on their past history. As a result, the stochastic process is a discrete Markov chain.

If no changes are made to population health habits, HIV prevention policies, and treatment guidelines, both the incidence of HIV-AIDS and the mortality rate for AIDS cases will remain constant. As a result, there will no be change over time in

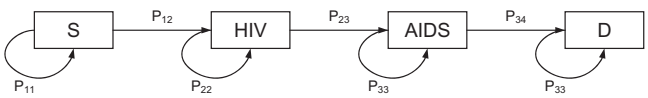

Figure 75–1. States in the HIV-AIDS epidemic.

transition probabilities. According to this idealistic hypothesis, the discrete Markov chain will also be homogeneous. In this case, this is the most appropriate Markov model to study how the epidemic will evolve.

Determining Transition Probabilities between States In human epidemics, the transition matrix is usually derived either from the data published on the population, incidence, prevalence, and mortality, or by means of specific purpose-designed research efforts, usually based on longitudinal studies. The most recent figures available for the HIV-AIDS epidemic in Spain date to 2004.[17] This information will be used to calculate the transition probabilities, starting at the first row of the matrix.

According to data published in Spain, the estimated number of new cases in 2004 was 2750 in a population of 43,197,684 inhabitants, i.e., a contagion rate of 64 cases per million inhabitants.[20] Consequently, $p_{12} = 0.000064$. Since a subject in a "susceptible" state cannot directly pass on to the "AIDS" or the "D" states, then $p_{13} = p_{14} = 0$. The sum of probabilities in a row of the transition matrix must be 1, giving $p_{11} = 1 - p_{12} - p_{13} - p_{14} = 0.999936$.

The second row of the matrix refers to the transitions that may occur from the HIV state. Thus, an infected individual will not revert to being susceptible, so $p_{21} = 0$. The incidence for AIDS in 2004 was 804 new cases[17] in a prevalent population estimated at 125,000 HIV-infected individuals,[21] giving $p_{23} = 0.006432$. An HIV$^+$ subject cannot go directly to state "D," so $p_{24} = 0$. Moreover, given that the values for the row must add up to 1, then $p_{22} = 1 - p_{21} - p_{23} - p_{24} = 0.993568$.

Those subjects who have developed AIDS will not return to either the "S" or "HIV" states, therefore $p_{31} = p_{32} = 0$. In 2004, there were 542 deaths from a total of 6609 AIDS cases,[17] which gives $p_{34} = 0.0082$. Finally,

$$p_{33} = 1 - p_{31} - p_{32} - p_{34} = 0.917991.$$

Since "D" is an absorbent state and the subjects remain in this state, then $p_{44} = 1$ and $p_{41} = p_{42} = p_{43} = 0$.

As a result, the transition matrix for the HIV-AIDS epidemic in Spain will be

$$P = \begin{array}{c} \\ S \\ HIV \\ AIDS \\ D \end{array} \begin{array}{c} \begin{array}{cccc} S & HIV & AIDS & D \end{array} \\ \begin{pmatrix} 0.999936 & 0.000064 & 0 & 0 \\ 0 & 0.993568 & 0.006432 & 0 \\ 0 & 0 & 0.917991 & 0.0082 \\ 0 & 0 & 0 & 1 \end{pmatrix} \end{array}$$

Analyzing the Evolution of the Epidemic over Time The transition matrix contains the probabilities for passing from one state to another in a single year, i.e., the probability that a susceptible subject is infected by the next year is 0.000064. However, to understand how the epidemic will evolve, it is necessary to calculate the probability that a subject who is susceptible today may be infected within 2 years. The Capman–Kolmogorov equations[3] enable these probabilities to be calculated by multiplying the transition matrix by itself, giving rise to a two-step transition matrix, i.e.,

$$P^{(2)} = P \times P \begin{pmatrix} 0.999872 & 0.000128 & 0.0000004 & 0 \\ 0 & 0.987177 & 0.012295 & 0.000053 \\ 0 & 0 & 0.842708 & 0.015728 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

Thus, the probability that a subject who is susceptible today may be infected within 2 years is 0.000128 or, in other words, there will be 128 *de novo* infections in 2 years. Similarly, the probability that individuals can change from their current state to another in 3 years can be calculated from the three-step transition matrix $P^{(3)} = P^{(2)} \times P$. Generally speaking, the transition matrix in n steps is merely the product of successive matrices, with n being a whole number greater than or equal to 2.

The course of developments in the epidemic over time will depend on the initial conditions present for the population under study vis-à-vis the virus, i.e., the current distribution of individuals in each of the disease states. In 2004 there were 43,065,533 susceptible subjects in Spain, 125,000 HIV infected and alive, 6609 AIDS cases, and 542 AIDS-related deaths. These figures make up the vector of initial prevalent cases that mark the starting point for the study of the future developments in the epidemic. This vector is represented by the sum of all its values, and must coincide with the overall population under study, taken as 43,197,684 inhabitants. The number of subjects that will be in each of the disease states within n years is derived from the product of the vector for initial prevalences and the transition matrix in n steps, i.e., $v \times P^{(n)}$.[2,13]

In 2006, 2 years after the latest recorded information, the number of subjects in each of the states will be $v \times P^{(2)} =$ (43 060 021, 128 892, 7124, 653). Thus, the number of infected cases in 2006 will have increased to 128,892, the number of AIDS cases will be 7124 and the AIDS-related deaths will amount to 653. The number of people susceptible to contagion will be 43,060,021.

The vector of initial prevalences may also be expressed in terms of probabilities or relative frequencies, dividing each component among the overall population. In this case, we would have $v = (0.99694, 0.002894, 0.000153, 0.000013)$ and $v \times P^{(2)}$ would result in the probability of being in one of the states 2 years after commencement of the study.

When studying population epidemics, the vector for initial prevalences is usually expressed as a number of cases per one million inhabitants. In this case, assuming an initial population of 1,000,000 people, there would be $v = (996940, 2894, 153, 13)$. Figure 75–2 shows the development of the epidemic using this vector as the starting point and calculating rates per million for each of the disease states up to 2024, i.e., 20 years after commencement of the study. For each year, the rate is derived from $v \times P^{(n)}$ with $n = 1, \ldots 20$.

If there is no change in the incidence and mortality for HIV-AIDS, the trend for HIV and AIDS cases will be on the increase. In 2024, the number of HIV infections will have risen to 3744 per million inhabitants, the number of people living with AIDS will amount to 248 per million inhabitants, while AIDS-related deaths will rise to 46 per million inhabitants. These figures mean that in 20 years, the number of *de novo* infections will have increased by 29%, AIDS cases will rise to 62%, and AIDS-related deaths will be 154% higher.

Different simulations for the hypothetical evolution of the epidemic in Spain can be derived by altering the vector for initial prevalences. Understanding what might happen in the future if the current situation were different provides a major source of information for decision-making purposes. This is one of the greatest contributions to biomedical research made by Markov models.

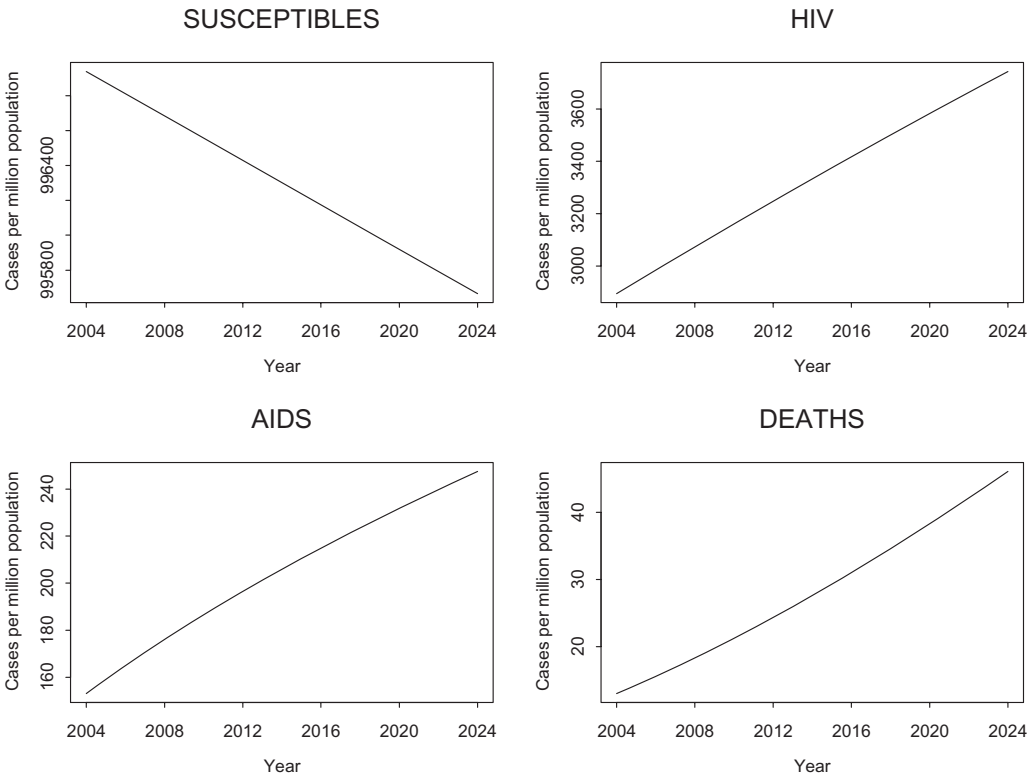

Figure 75–2. Predictions on the evolution of the HIV-AIDS epidemic in Spain.

ANALYSIS OF NONHOMOGENEOUS MARKOV CHAINS IN DISCRETE TIME Certain animal models for spatial learning in rats use a T-shaped maze with a single starting point and two exits placed on either side of the maze. Food or water is placed at one of these exits, such that the rat receives positive reinforcement every time it goes to this particular side of the maze.[22,23]

Let us suppose that the following experiment was repeated on five consecutive occasions with 20 adult rats. The side of the maze chosen by each rat was noted for each of the repetitions of the experiment, and recorded as correct (C) if this led to positive reinforcement or as incorrect (I) otherwise. The aim was to check whether the rats learned to go toward the side where the food was placed as well as to study the developments in the learning curve over time.

Definition of the States in the Process and Transition Mechanisms between States In the animal learning model, the space of states comprises two alternatives: choosing the right (state 1, C) or the wrong (state 2, I) side. Every time the experiment is repeated, the rat can choose either of the two options and can also repeat the same option several times consecutively. Figure 75–3 shows the possible transitions between both states called *recurrent*, since the rat, after selecting any of the states, could choose the same state again in later repetitions of the experiment.

Selection of the Most Suitable Markov Model to Study the Process The experiment is repeated five times consecutively, taking each repetition as an observation time. In this case, both the states and moments in time in the process are discrete. In addition, the side of the maze chosen by the rat in the following repetition will depend only on the current choice and not on past decisions. As a result, the stochastic process comprises a discrete Markov chain.

If the repetition of the experiment makes the animal learn to choose the right route, the probability of guessing correctly on the next repetition if the preceding choice had been wrong will be different at the beginning and at the end of the experiment. In line with this hypothesis, the probabilities of a transition between states will not be constant over time. As a result, the discrete Markov chain will also be nonhomogeneous. Consequently, there will be a transition matrix for each of the repetitions in the experiment.

Determination of the Probabilities of Transition between States In models of this kind, transition probabilities are usually estimated through longitudinal studies designed for this purpose. In this case, the experiment was conducted on 20 rats, 10 (50%) of which chose the right side of the maze at the first attempt (Table 75–2). All 10 received positive reinforcement.

When the experiment was repeated for the first time, 6 of the 10 rats that had initially chosen the right side of the maze chose this option again, thus $p_{11}(1) = 0.60$ $p_{11}(1) = 0.60$. Despite having chosen the right route initially, the remaining rats took the wrong route on the first repetition, such that $p_{12}(1) = 0.40$ $p_{12}(1) = 0.40$ (Table 75–2).

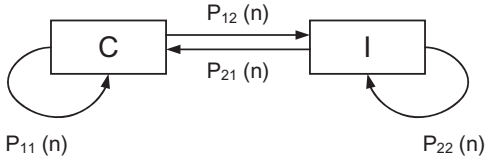

Figure 75–3. States in an animal learning model in rats.

Table 75–2
Transition matrices in an animal model for spatial learning in rats.[a]

Initial probabilities			*First repetition*			*Second repetition*			*Third repetition*			*Fourth repetition*		
			Time 1 P(1)			*Time 2 P(2)*			*Time 3 P(3)*			*Time 4 P(4)*		
C	*I*		*C*	*I*		*C*	*I*		*C*	*I*		*C*	*I*	
		C	6 (0.60)	4 (0.40)	10	6 (0.75)	2 (0.25)	8	9 (0.82)	2 (0.18)	11	14 (0.93)	1 (0.07)	15
		I	2 (0.20)	8 (0.80)	10	5 (0.42)	7 (0.58)	12	6 (0.67)	3 (0.33)	9	4 (0.80)	1 (0.20)	5
10 (0.50)	10 (0.50)	20	8	12	20	11	9	20	15	5	20	18	2	20

[a]Simulated data for didactic purposes. The cells of each matrix contain the number of rats that has gone from one state to another. In parentheses are the transition probabilities.

Of the 10 rats that originally took the wrong route, 2 changed their option in the repetition, thus $p_{21}(1) = 0.20$ $p_{21}(1) = 0.20$. As these are complementary, then $p_{22}(1) = 0.80$ $p_{22}(1) = 0.80$ (Table 75–2).

Analysis of Developments in Learning As in the case of the homogeneous Markov chains, the Chapman–Kolmogorov equations[3] enable the transition matrix in n times to be calculated, expressed by $P^{(n)}$, so that we can ascertain the probability of a rat choosing the right side of the maze on the nth repetition (time n) if it chose the wrong route on the first repetition. This transition matrix in n times is derived from the product of all the preceding transition matrices in time n, i.e., $P^{(n)} = P(1) \times P(2) \times \ldots \times P(n)$. Thus, the two-step transition matrix is expressed as

$$P^{(2)} = P(1) \times P(2) = \begin{pmatrix} 0.60 & 0.40 \\ 0.20 & 0.80 \end{pmatrix} \times \begin{pmatrix} 0.75 & 0.25 \\ 0.42 & 0.58 \end{pmatrix} = \begin{pmatrix} 0.62 & 0.38 \\ 0.49 & 0.51 \end{pmatrix}$$

such that if a rat chose the wrong route in the maze on the first repetition, the probability of choosing correctly on the second repetition is $p_{21}^{(2)} = 0.49$.

The three-step and four-step transition matrices will be $P^{(3)} = P^{(2)} \times P(3)$ and $P^{(4)} = P^{(3)} \times P(4)$, respectively. This concept is similar to that seen for homogeneous Markov chains. The only difference is that previously, as a homogeneous process, the transition matrices multiplied were identical given that they do not change over time.

The initial conditions for the process will set the learning curve for the rats, such that if 50% of the animals initially choose the right route in the maze and 50% the wrong route, the vector for initial probabilities is $v = (0.50, 0.50)$.

The probability of choosing the right or wrong route when the experiment has been repeated n times is the result of the product of the vector of initial probabilities and the transition matrix in n steps, i.e., $v \times P^{(n)}$ where $n = 1,2,3,4$.

Figure 75–4 shows the learning curve for the rats, where we can see the growing trend toward choosing the right route as the experiment is repeated again and again. After four repetitions, the probability that a rat will choose the route in the maze leading to the positive reinforcement is 0.90 and only 10% of the animals will choose the opposite option.

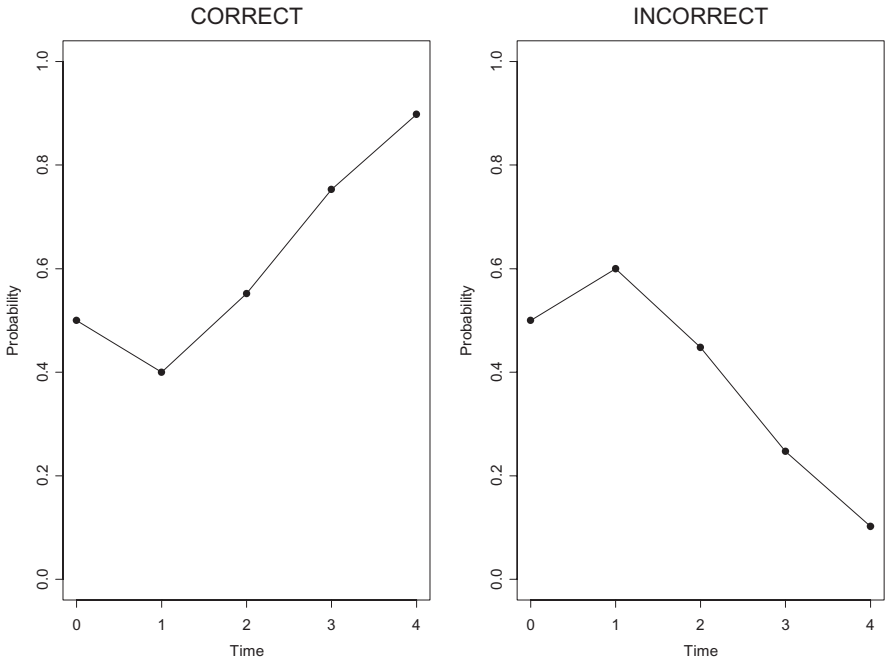

Figure 75–4. Learning curve in an experimental spatial learning model in rats.

MARKOV CHAINS IN CONTINUOUS TIME

Occasionally, changes in the status of a variable may arise at any time, and not only in discrete times. As a result, the stochastic process is represented by a succession of values $X(t)$ that represent the value for variable X at any moment in time t, where $t \geq 0$.

Similar to discrete Markov chains, if the process is Markovian, the probabilities of transition from one state to another are now defined as

$$p_{ij}\,(t,t+h) = P[X(t+h) = j | X(t) = i] \quad i,j = 1,2,\ldots,m$$

Thus, if in time t the variable is in state i, $p_{ij}(t,t+h)$ is the probability that a change in state j may occur between t and $t+h$, where h is a very small increase in time approaching zero. Indeed, these are *instant probabilities* of transition.

In the process described, the value of these transition probabilities depends on moment t when the change arises, i.e., the instant probability of going from state i to state j is different at time $t = 0$, $t = 1.72$, $t = 4.21$, etc. As a result, we will have a *nonhomogeneous* continuous Markov chain.

However, if the probabilities of transition between states do not depend on time, then we will have a *homogeneous* or *stationary* continuous Markov chain. In this case,

$$p_{ij}(h) = P[X(t+h) = j | X(t) = i] \quad i,j = 1,2,\ldots,m$$

Both homogeneous and nonhomogeneous types of model have been applied in genetic studies,[24,25] in research on viral load in HIV-positive patients,[26] or in variations in the status of asthmatic patients,[27,28] among other fields. However, it is not as straightforward to estimate the probabilities of transitions and to plot the graphs for evolution of the process over time as in discrete Markov chains, especially for nonhomogeneous models.

Over the past few decades, different techniques to analyze this kind of stochastic process have been proposed. Among these are the resolution of differential equations,[3,4] algorithms based on panel data,[29,30] parametric measurements, and nonparametric approaches.[31,32] Many of these methods are based on complex mathematical equations that are not included in the computer programs generally used to analyze biomedical data. For this reason, specific macros have been developed over the past few years enabling some of these models to be applied with less effort.[33]

Currently, both continuous time Markov chains and Markov processes with a continuous state space comprise major areas for research. Of particular interest is the development of new statistical methods and the implementation of specific software that can facilitate data analysis.

ADDITIONAL FEATURES OF MARKOV CHAIN ANALYSIS

Before the above-mentioned methods can be applied, we must first check that the process fulfils the Markov property. With the right parameterizations, any stochastic process can be expressed as an autoregressive generalized linear model in which past values act as variables accounting for the current state of the process.[34] To check whether the chain is Markovian, we need only to check that all the regression coefficients in the model are zero except the coefficient for the state of the process at the preceding moment in time. In this case, we will have an autoregressive model of the first order, equivalent to the Markov property. In general terms, stationary Markov chains are easier to model than nonhomogeneous ones. However, it is not good practice to assume the process is homogeneous without a prior check to guarantee the appropriate use of stationary models. The test proposed by Kalbfleisch and Lawless[29] is generally the most widely used to check this hypothesis. In this test, the number of transitions observed at each time interval is compared with the number of expected transitions according to the hypothesis of homogeneity. This gives a likelihood ratio statistic based on a chi-square distribution.

Any software that enables macros to be programmed can be used to analyze any kind of Markov chain. *SAS* (www.sas.com), *Stata* (www.stata.com), *SPLUS* (www.insightful.com), or *R* (www.r-project.org) are the most widely used programs for this purpose. The fact that specific routines have already been devised for some of these provides a further advantage for researchers.[2,33] In any case, basic computer programming skills are required to handle these programs, especially if we intend to implement new macros that have not yet been devised by other authors.

Other specific software, such as *Relex Markov* (www.relex.com), *DecisionPro* (www.vanguardsw.com), or *TreeAge Pro* (www.treeage.com) have been devised exclusively to analyze Markov chains. These are easy-to-use programs, although some are intended only for the analysis of Markov chains in discrete time and tend to pose certain limitations on the estimation of transition probabilities from a database with information from a longitudinal study.

Whether one software or another is used, be it specific for Markov chains analysis or for general statistics, will depend largely on the complexity of the study itself and the researcher's requirements.[35,36]

76 Software Tools for Modeling Biomedical Systems

KARL THOMASETH

ABSTRACT

Biomedical applications of computer modeling and simulation are manifold and range from virtual reality for training purposes to codification of knowledge of complex physiological systems to formulation and testing of hypotheses about biological phenomena. While development of complex simulation tools and comprehensive modeling requires considerable effort, the use of simple models can, even with minor investments, be useful to experimenters to organize ideas, analyze data efficiently, and plan experiments. Even for this restricted modeling framework, the variety of possible applications with different needs and the number of available software tools are very large. This chapter will therefore draw attention only to a few methodological issues and available software tools specific to biomedical modeling, in particular, model representation paradigms and statistical identification approaches. The intent is not to endorse the use of any particular modeling approach or software tool, but rather to delineate, with a few reference points, a broader modeling perspective that may be tailored to the needs of particular modeling studies on biomedical systems.

Key Words: Mathematical models, Physiologically based models, Minimal models, Parameter estimation, Statistical models, Hierarchical models.

INTRODUCTION

Computer simulation is used in all fields of scientific research to mimic the dynamic behavior of real systems under various operating conditions. This is accomplished by means of models that formally embed knowledge and hypotheses about the functioning of the systems. Simulation thus consists of reproducing real world behavior by operating on a model in a virtual environment, making it possible to test and to better understand the implications of beliefs about the actual system even in situations that would not be feasible in practice. Although simulation models are synthetic conceptual representations of reality, typically described in the form of mathematical equations, if they capture either explicitly or implicitly basic physical characteristics of actual systems they can produce valid predictions of their behavior even in broad ranges of testing situations. Because systems are in general entities that can be controlled and observed from the environment only through special inputs and outputs, the external validity of simulation models can be judged only in terms of the correspondence between simulated predictions and actual system responses observed under comparable input conditions. Nevertheless, confidence in simulation outcomes that cannot be readily verified in practice can still rely on the intrinsic validity of the assumptions embedded in the model. The formulation of simulation models is therefore simplified if the behavior of the system is governed by general physical or empirical laws that allow an accurate prediction of the system's response by means of mathematical equations. This approach is usually attainable and actually implemented with man-made systems, e.g., from simple products up to large industrial plants, enabling designers and users to predict the dynamic behavior of the assembly before its first use or even during the planning phase to identify and correct limitations and drawbacks. It is for this reason that early developments of computer simulation were made within space flight programs.

VIRTUAL REALITY Simulation is also useful to gain insight into the characteristics and limitations of physical systems that have to be manipulated or controlled by human operators. Simulators in biomedicine, e.g., for virtual surgery and clinical treatments,[1] may become tools that are as normal in the education of surgeons and medical staff as flight simulators currently are in the training of pilots. In these simulators, the analogy to reality is not only related to the accuracy of the model responses, but also to the mechanisms provided for interaction with the simulation system. Thus, the development of realistic human interfaces plays a major role in the design of such simulation systems.

KNOWLEDGE REPRESENTATION A different application of computerized models consists of the systematic collection and representation of knowledge about physical systems without the immediate goal of numerical simulation. An example is the bioinformatics Biological Systems Database resource (KEGG),[2] which provides access to a large amount of information, for instance, on the molecular structures of chemical compounds and drugs, and on the interactions of substrates, enzymes, and genes in metabolic pathways in different species. Available information in KEGG already makes it possible, for instance, to automatically generate by computer software mathematical equations of biochemical enzyme reactions, in particular metabolic pathways. However, to effectively simulate such reactions, numerical values should be assigned to substrates and to enzyme concentrations as well as to dissociation and rate constants appearing in the dynamic

equations. These are, however, mostly unavailable. Therefore, qualitative knowledge about the structure of a biological system, e.g., metabolic pathways, combined with general laws, e.g., mass action and enzyme kinetics, is sufficient to formulate a theoretical model and to write down its mathematical equations. However, additional quantitative information is required, e.g., on model parameters, to predict through computer simulation real life situations and to possibly validate the theoretical model against experimental data.

The most extensive undertaking for the integration of models of human physiology is the so-called Physiome Project, promoted by the International Union of Physiological Sciences.[3,4] The aim is the comprehensive codification, within a multiscale modeling framework, of current knowledge on biological structures and their functions at various levels of aggregation, ranging from molecules and cells, through tissues, organs, and body regions, up to the whole organism. The challenging computational modeling problems include the linking of properties of biological structures described in a hierarchical way at different levels of detail, and the integration of multidomain characteristics of biological material, e.g., mechanical, electrical, and biochemical, within time-varying, nonhomogeneous spatially distributed representations of substructures.

STRUCTURAL MODELING A more heuristic approach to describing the dynamic properties of generic systems is the so-called lumped-parameter modeling method, in which microscopic and regional aspects of materials and processes are not taken into consideration in favor of minimalistic representations. Typical biomedical examples are compartmental models that lump, in a finite number of state variables, substances distributed in anatomical regions and/or chemical binding states assuming that concentrations are homogeneous within the compartment's distribution volumes and that mixing, i.e., the equilibration of concentration after the supply or removal of the substance, occurs instantaneously. The seemingly oversimplification of the reality of lumped-parameter models is, however, fully compensated by their practical usefulness due to a higher level of abstraction that leads to simpler, more tractable mathematical model equations. This makes lumped-parameter models suitable for model identification, i.e., determination of a model that best fits experimental data, which can be a valuable complement to scientific research. In particular, if a model is structured consistently with knowledge or belief about the functioning of the system being studied, then estimated values of parameters provide quantitative information about particular functions of the system. This makes it possible, for instance, to assess and interpret the effects of external interventions, e.g., drug administration, by planning, carrying out, and model-based analysis of repeated experiments under different treatment conditions. More generally, if a particular structured model describes experimental data more accurately than similarly credible competing models, then even reasonable hypotheses can be put aside in favor of others. Mathematical models can therefore contribute to the advancement of knowledge in biomedical research insofar as they lead to the formulation and testing of hypotheses in conjunction with experimental observations.

In relation to this latter modeling framework, the following sections will first stress the importance of using structured models with physiological interpretation, then recall some graphic and textual conventions used in various software tools for specifying models of dynamic biomedical systems, and finally discuss principal statistical methods that should be provided by modeling tools designed for biomedical applications.

BIOMEDICAL SYSTEMS REPRESENTATIONS

EQUIVALENCE AND DISTINCTION OF MODELS Experiments consist in provoking with external inputs a response of a system to reveal internal characteristics that cannot be accessed or observed directly. Observations collected in dynamic, i.e., time-varying, conditions are clearly more informative about the system's structure than those collected at steady state, but require model-based calculations to extract quantitative information from the data. For this purpose a mathematical model of a given system-experiment pair can in general be expressed as a function of time

$$y(t) = f[t, u(t), p] \tag{76–1}$$

where, at the generic time instant t, $y(t)$ represents the array of all measurable quantities, $u(t)$ the array of all external, possibly time-varying, inputs and events that characterize that particular experiment, and p represents the array of model parameters. Actual measurements are in general noisy and possibly taken at discrete time points

$$z(t_s) = y(t_s) + e(t_s) \tag{76–2}$$

where $e(t_s)$ is measurement noise and the generic observation time point t_s belongs to the sampling set SS = $\{t_1, t_2, \ldots\}$.

Let us initially assume that model Eqs. (76–1) and (76–2) may correctly predict the outcome of experiments for any inputs $u(t)$ and sampling SS with particular values of parameters p, but without disclosing anything about the biological nature of the observed phenomenon. In this case the model would not be useful to interpret observed variations in the parameters p, e.g., between different subjects or following drug administration, because these would be meaningless without a physiological basis of the model. Mathematical models should therefore not only be able to fit experimental data but also be useful in explaining differences in responses observed under different experimental conditions. In this regard the structure of a model, from which the equations are derived, represents the main factor influencing the interpretation of results. For instance, Figure 76–1 shows two-compartmental models, which have clearly different meanings but that are equivalent from a dynamic viewpoint. That is, for any different system structure there exists a different mathematical expression of the type of Eq. (76–1), which can produce, with some restrictions on parameters, the same model output. Furthermore, from a mathematical point of view the dynamics of all models in Figure 76–1 can be summarized by the so-called impulse response function given by the sum of two exponential terms

$$h(t) = Ae^{-at} + Be^{-bt}, \quad t \geq 0; 0, \quad t < 0 \tag{76–3}$$

with $p = [A, a, B, b]$ in Eq. (76–1). The model output is then given as a convolution integral,

$$y(t) = \int_{-\infty}^{t} h(t-s)u(s)ds \tag{76–4}$$

The equivalence of the various models of Figure 76–1 relies on the fact that for admissible values of p there exist, for each model, parameter values $p_1, p_2, \ldots$ and nonlinear functions $g_1, g_2, \ldots$ that produce the same system output as in Eq. (76–4),

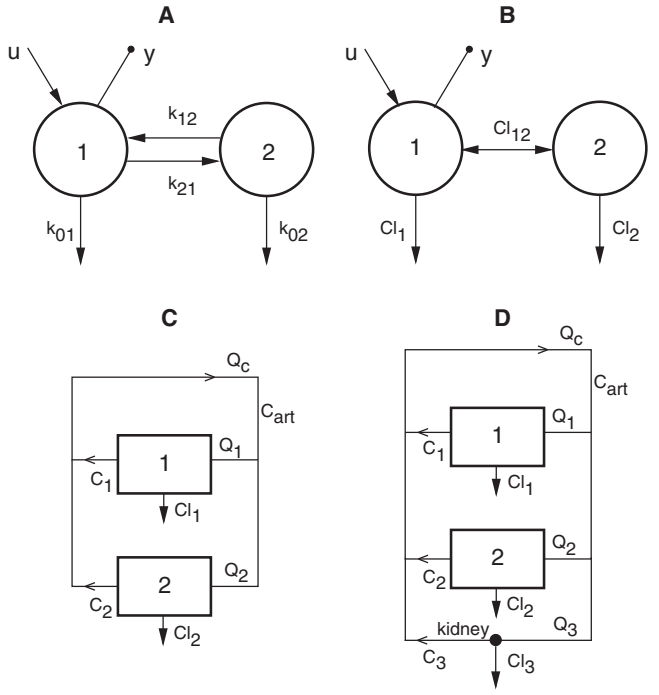

Figure 76–1. Different representations of two-compartment models exhibiting the same dynamic behavior under parameter constraints. (A) Traditional model with k_{ij} representing fractional clearances (time^{-1}), u input of material, and y concentration measurement. The distribution volume V_1 of compartment 1 must be assigned to relate concentration to mass. The model is not uniquely identifiable, unless either k_{01} or k_{02} is zero. (B) Physiological parameterization with Cls representing clearances (volume per time). The exchange of material between compartments depends, as in diffusion, on concentration differences, thus both compartmental volumes V_1 and V_2 must be assigned, giving a total number of parameters as in (A). (C) Physiologically based circulatory model with compartments interpreted typically as tissues with high and low perfusion and Qs and Cs representing blood flows and concentrations, respectively. Additional parameters (not shown) are distribution volumes and blood-tissue partition coefficients. The total number of parameters is thus considerably larger than for the minimal representations in (A) and (B). (D) The same as in (C) with additional elimination from the kidneys assumed having negligible blood volume.

i.e., with $p = g_1(p_1) = g_2(p_2)$. . . . Should the primary biological significance in parameter variations be provided by, say, p_1 then analysis of experimental data based on model Eq. (76–3) would show variability of p rather than p_1, i.e., useful information would be confused by the nonlinear function g_1. This can be extrapolated to the problem of comparing two competing models having both plausible physiological structures. One model may be preferred to another because of more realistic variations in parameters, e. g., in relationship to a disease or drug effect. The claim that the two-exponential function [Eq. (76–3)] is sufficient to describe a linear two-compartmental model is therefore at least misleading as regards the possible interpretations that can be given to between-subject variability of parameters.

Another advantage of adopting physiologically based structured modeling is the straightforward reutilization of already tested system structures to define new models, e.g., by adding compartments or introducing control actions on the transfer rates between compartments.

The concept of equivalence between models can be generalized to the so-called identifiability problem, which is often understated because it is difficult to solve. Let us assume, for example, that a real system's response may be accurately described through Eq. (76–4), i.e., by means of the four parameters in p, but that the experimenter may try to fit the data to a more complex model, i. e., with more than four parameters. In this case the equivalence $p = g_1(p_1)$ would be satisfied by multiple values of p_1 (maybe an infinite number), causing uncertainty in the results and making analyses on parameter variations meaningless. A more subtle situation is given with the same number of parameters but with multiple solutions for p_1 that satisfy the equation $p = g_1(p_1) = g_1(q_1)$, with p_1 different from q_1. To address these methodological issues at least one software tool has been developed.[5]

MODELING SOFTWARE TOOLS

A multitude of general purpose and specialized software tools exist for solving specific problems encountered in modeling and identification of biomedical systems. However, rarely can one software satisfy all the needs in a certain study. Fortunately, modern operating systems of desktop computers greatly facilitate exchange of data and information between different applications. Personal working environments are commonly tailored to individual attitudes and needs, e.g., from data entry through data analysis to final reporting. One should therefore consider also the possibility of utilizing different tools for organizing personalized modeling environments. In this way one could benefit from state-of-the-art, often free open-source, software developed in different disciplines for modeling, numerical simulation and statistical analysis, with added scientific, besides economic, value compared to all-in-one, usually niche commercial, software. Accessibility to a particular software is however often limited mainly by lack of human resources (trainee or expert user) or by the learning curves, that are usually the steeper the more flexible a particular software is. The choice of a software for pursuing a particular modeling project is therefore often suboptimal, and a weakness in the design of a chosen software can become a constraint in the study implementation. Thus, time investment in getting acquainted with more sophisticated and flexible software brings certainly advantages on the long run.

MODELING PARADIGMS Models of biomedical systems should be formulated as explicitly as possible to reveal and ensure coherence in the conceptualization of the actual systems. For instance, mass balance equations are often written implicitly in terms of dynamics of concentrations rather than masses to eliminate unknown distribution volumes viewed as "nuisance" parameters. This can cause trivial mistakes, such as implicitly assuming that a substance and its metabolites have the same distribution volume when they do not, e.g., extracellular versus total body water. Therefore, explicitly declaring even unknown parameters by setting them to conventional values may help to avoid oversights.

The mathematical equations that ultimately characterize the model itself are usually inadequate for a clear representation of systems, especially if documentation is scarce. The equations are typically described in terms of so-called ordinary differential equations (ODE) that can be efficiently solved numerically by computer algorithms. However, as a rule, ODE lose their clear relation to the underlying modeling assumptions and are commonly not self-explanatory except for modeling experts. The

feature of modeling software that mainly influences clarity and productivity is, therefore, in our view, the capability for domain-specific rather than equation-oriented modeling. In the traditional equation-oriented approach, mathematical equations that describe the dynamics of a system must be declared explicitly, such as in ACSL (Advanced Continuous Simulation Language) (e.g., www.aegistg.com), or coded in some programming language, such as Fortran or C, that requires specific mathematical modeling and programming skills. Moreover, deriving mathematical equations[6] from a system's concept can be an uncircumventable hurdle for most nonmathematicians. In this regard, to facilitate dissemination and reuse of models, a standard representation for coding mathematical models of biomedical systems, the CellML markup language, was devised at the University of Auckland (www.cellml.org).

In contrast to equation-based modeling, domain-specific modeling consists of declaring a system's structure by means of graphic or textual formalisms conventionally used in a particular discipline, e.g., representation of biochemical reactions or electrical circuit networks, leaving to the software the burden of generating the mathematical model equations or simulation code. Domain-specific modeling thus makes it possible to concentrate on the system's structure and modeling assumptions, reducing the risk of misspecifying model equations due to automated code generation. In the following a few domain-specific modeling paradigms of interest in biomedical research are discussed.

System Dynamics Modeling This modeling paradigm was introduced in the 1960s by J.W. Forrester at MIT to analyze the evolution of economical phenomena and is currently being promoted by the System Dynamics Society (www.systemdynamics.org). The modeling approach consists of a graphic specification of system structure in terms of so-called stock-and-flow diagrams, e.g., reservoirs and transfer of material, also depicting the relationship between variables, in particular, how flows between stocks are controlled by other variables. Thus, this kind of representation naturally fulfills conservation of mass. System dynamics modeling has been widely used in education and has been applied to social as well as physical and biological sciences.[7] Among various software that implement Forrester's System Dynamics paradigm the mostly used in biomedical research is STELLA (ISEE Systems, www.iseesystems.com). Another software historically associated with STELLA is Berkeley Madonna (www.berkeleymadonna.com), which used to lack a graphic model specification interface and relied on model files produced with STELLA. Now Madonna implements a simplified graphic interface based on the System Dynamics paradigm, as well as a textual interface for defining chemical reactions. A distinctive feature of Madonna is the implementation of tools to easily evaluate dependencies of simulation outcomes to parameters through sensitivity analysis and parameter estimation.

Compartmental Models Although the term "compartment" is often used to denote a distinct entity in a lumped-parameter representation of a distributed system, here it is understood in the more restricted sense of a pooled representation of a substance uniformly dissolved in a well-stirred volume of solvent (Figure 76–1). Compartmental models are completely specified by the initial quantity of material and distribution volume of each compartment and by the time-varying flow of material exchanged between compartments. This system representation is thus closely related to system dynamics modeling, but with a succinct graphic representation that evidences only compartments and direction of flows. A mathematically well-defined subclass, especially useful for modeling the kinetics of tracers, is represented by linear compartmental models, in which the flow rate between two compartments is proportional to the concentration in the source compartment (Figure 76–1A). Modern software that explicitly tackles this type of models is, for instance, SAAM II (http://depts.washington.edu/saam2).

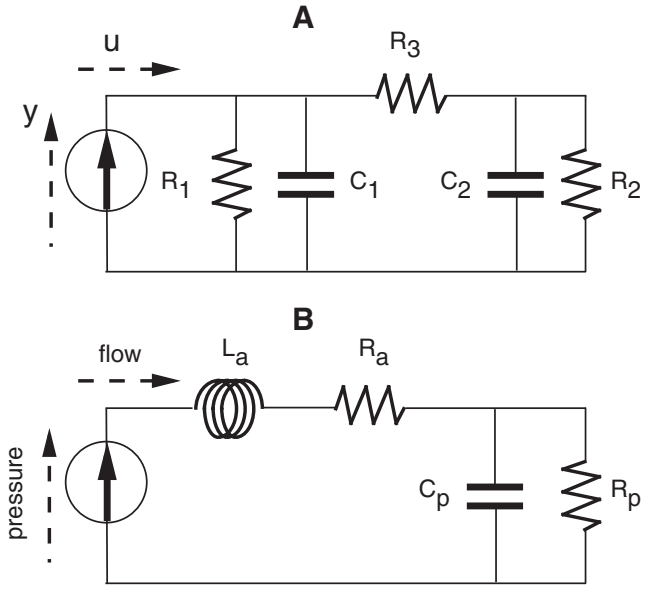

Figure 76–2. Simple electrical circuits with *R*, *C*, and *L* representing resistance, compliance, and inertia, respectively. (A) Dynamically equivalent circuit of the physiological compartment model of Figure 76–1B, if corresponding resistances are the inverses of clearances, i.e., $R = 1/Cl$, and capacitances are equal to distribution volumes. (B) Electrical analog of a respiratory model with forced ventilation. Subscripts a and p indicate airways and periphery, respectively. L_a accounts for inertia of air.

Electrical/Hydraulic Models Lumped-parameter models of the pressure–flow relationship in airways and blood vessels are conceptually equivalent to electrical circuit networks used, for instance, to model the membrane potential along the dendritic tree of a neuron. It is sufficient to equate pressure with potential and flow with current. Constitutive elements of such models are compliances (capacitors), inertial components (inductances), resistances, and sources of pressure (potential) or flow (current) (Figure 76–2). Conservation principles of mass (charge) and energy yield the so-called Kirchhoff's laws for electric circuits, which are useful for determining the pressures (potentials) at all junctions (nodes) and flows (currents) through each branch in a hydraulic (electric) network. It is worth noting that there are also analogies between electrical circuits and thermodynamic network models. The pioneering software used to simulate this kind of models is SPICE (Simulation Program with Integrated Circuits Emphasis) originally developed by L. Nagel and D. Pederson in the early 1970s at the University of California, Berkeley (http://bwrc.eecs.berkeley.edu/Classes/IcBook/SPICE/).

Signal Flow Diagrams Signal flow diagrams are mainly used in control engineering with blocks representing subcomponents of a system and with directed paths that link the outputs of components with the inputs of other ones (Figure 76–3). Addi-

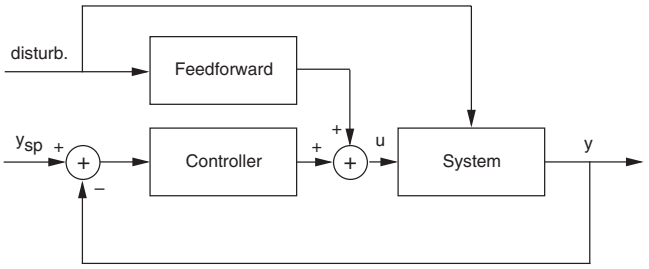

Figure 76–3. Example of a "homeostatic" control system with set point y_{sp}; y and u are controlled and control variable, respectively. The main controller produces its output dependent on the difference $y_{sp} - y$, and the so-called feedforward mechanism anticipates control actions in response to external disturbances of the system. The diagram can be viewed as a sketch of glucose regulation, where the pancreas is the main controller and gastrointestinal hormones are feedforward signals during meal ingestion.

tional graphic elements include summation and other mathematical operator blocks, which are important to specify closed control loops in the system. A fundamental concept of signal flow diagrams is that outputs of subsystems are only measures of some internal quantity and do not represent, e.g., a loss of material. Only inputs to subsystems affect the internal dynamics through their signaling action. This system representation well serves to clarify the control loops and signals in a system, but the implementation of conservation principles, e.g., of mass, can yield quite intricate representations. The software mostly used in implementing this modeling paradigm is Simulink, a graphic package that extends the numerical software Matlab (The MathWorks, www.mathworks.com). Incidentally, a recently developed Matlab extension of interest in biomedical research is named SimBiology, which provides tools for simulating and analyzing biochemical pathways. Nevertheless, other software tools exist for modeling biochemical reactions, such as the free program Gepasi (www.gepasi.org).

Bond Graphs Bond graphs were proposed in 1959 by H.M. Paynter to represent physical systems in terms of elements (ports) that store, dissipate, supply, and transform energy in various physical forms, and bonds that represent the exchange of power between these elements. Special components, so-called junctions, define the way components are connected, i.e., in series or in parallel. The power exchange paradigm naturally implements energy conservation across multiple energetic domains, e.g., mechanical, hydraulic, electrical, chemical, and thermodynamic. This makes bond graphs suited for specifying models of multidomain systems. The two factors whose product defines power, i.e., effort and flow in bond graph terminology, have different interpretations in different energetic domains, e.g., as described previously for hydraulic and electrical systems, but are treated consistently throughout the bond graph theory. The formalism is useful even if the product of effort and flow does not represent a power; in these cases we speak of pseudobond graphs. An important characteristic of bond graphs is that mathematical model equations can be derived symbolically from the graphic representation in a systematic, algorithmic way that can be implemented in computer software. This makes bond graphs intrinsically a multidomain-specific modeling approach suitable for generating model equations that can be easily exported for simulation to other software, e.g., Matlab or ACSL. The first bond graph modeling software developed in the early 1970s by R.C. Rosenberg, ENPORT, has been followed by many others, mainly oriented toward control engineering and industrial applications. The distinctive feature of bond graphs of algorithmic and symbolic derivation of mathematical model equations has pioneered the development of other multidisciplinary modeling languages, of which MODELICA (www.modelica.org) appears to be the most promising. The feasibility of multidisciplinary modeling software for biomedical systems has also been investigated.[8]

STATISTICAL SOFTWARE TOOLS

Statistical evaluation of the agreement between model predictions and experimental data for model identification and validation is a widespread and general issue in all experimental sciences. Biomedical systems modeling, as considered here, can largely take advantage of statistical methods implemented in general purpose statistical software. Only recently emerging modeling issues in postgenomic studies pose new challenging problems to statistical research that require new theoretical solutions and ad hoc software development, e.g., BioConductor (www.bioconductor.org). The integration of software specifically designed for modeling biomedical systems with general purpose statistical tools would therefore be a means to maximize quality and cost effectiveness in software design.

With regard to the more traditional statistical methods, of particular relevance for modeling dynamic biomedical systems are the so-called population pharmacokinetic methods that were pioneered in the early 1980s by L.B. Sheiner and others, which led to the development of established software such as NONMEM (www.globomaxservice.com). In the classical two-stage approach a model is first fitted to dynamic experimental data of each individual, and, in the second stage, model parameter distributions of the studied group and possible effects of covariates are analyzed. Population approaches aim instead at estimating simultaneously all parameters of a hierarchical model with different modeling levels. Typically, the dynamic system response of a single individual represents the first modeling level, and the statistical properties of model parameters and causal relationships between parameters and covariates are defined at the second or higher modeling levels.

The two mainstream population approaches are the Bayesian and the nonlinear mixed-effects modeling methods. Bayesian methods intrinsically use prior information to infer from experimental data the so-called posterior distribution of parameters in a single individual or in a group of subjects. That is, prior information available from previous studies or from the literature is updated, even with sparse experimental data, to obtain model parameter estimates in an individual or a group. Normally these estimates would not be obtainable from the same data without using prior information. For instance, in the extreme case of no availability of data, the estimates returned are simply the prior distributions. Bayesian methods thus have the substantial advantage of providing in any case model parameter estimates, which are more or less biased toward the a priori mean depending on the available information and data. This has clear implications for the design of complex studies in which one part of the experiment can provide prior information from a few individuals, and in the other part, sparse data are collected from many individuals to provide complementary information on between-subject variabil-

ity. General purpose Bayesian software tools are not very common because, on the one hand, the solution of inference problems typically requires ad hoc implementations, which are, on the other hand, easily put together by experienced statisticians due to powerful yet simple computational methods. Of note is the widespread software BUGS (Bayesian inference Using Gibbs Sampling) (www.mrc-bsu.cam.ac.uk/bugs) and the derived pharmacokinetic-oriented tool PKBUGS.

Nonlinear mixed effects (NLME) modeling methods are, in short, population approaches that view group data as one ensemble and distinguish between parameters that characterize the whole group, so-called fixed effects such as average value of model parameters and effect of treatment, and individual variations from these reference values, so-called random effects. NLME methods make efficient use of experimental data because fixed effects are estimated from the entire data set, making it possible not only to collect sparse data in individual experiments, but also to increase the success rate of model fitting over individual data fitting. Moreover, NLME are more robust than two-step approaches in disentangling between-individual variability of model parameters from statistical uncertainty related to residual errors. NLME estimation procedures are available, in addition to the aforementioned NONMEM, in most advanced statistical packages and data analysis environments. An extensively used software is the NLME package[9] provided with the free open-source statistical software R (www.r-project.org).

CONCLUSIONS

The study of biomedical systems, in a broad sense, involves different scientific disciplines that have historically evolved independently from each other with distinct conventional representations and heuristic mathematical laws used to describe specific physical phenomena. Developing mathematical models within a multidisciplinary context is, therefore, more difficult to accomplish than using software designed for a specific domain, especially if interacting phenomena belong to different domains and the software lacks a common specification dictionary. Unfortunately, no prevailing model description language has yet emerged to allow the exchange and reutilization of models across different simulation software—-not even bond graph modeling, which has been around for decades and presents unique characteristics as to the unifying representation of systems and the algorithmic approach to derive mathematical model equations. Perhaps modern object-oriented modeling languages adopted by different software developers and vendors, such as MODELICA, will fill this gap. An additional limitation of general purpose modeling software is usually the unavailability of robust statistical methods needed for model identification and testing of hypotheses that are indispensable in experimental research. At present, researchers interested in biomedical systems modeling therefore ought to select software tools that best meet their particular needs, either from biomedically oriented niche software that may exhibit adequate modeling and sufficient data analysis features, or from general purpose software tools that generally require integration and interface with other software to create advanced multipurpose modeling and simulation environments. To accomplish this, in addition to some programming skills, access to crucial information on data exchange formats and the like may be required, which is usually available only with nonproprietary software.

77 Developing Websites for Biomedical Research and Training

KRISHNA B. SINGH

ABSTRACT

The Internet and web technologies are changing rapidly, bringing a steady stream of exciting new applications and abilities to both the developer and the end user. Web-based applications have unique attributes to provide new and updated teaching materials in an interactive format. Websites designed for biomedical research and training provide rich contents with multiple hyperlinks and multimedia objects. Web-based tools for information exchange include forums, bulletin boards and discussion lists, chat rooms, videoconferencing, and webcasts using streaming technology. Regardless of the delivery format, the design of websites for biomedical research or training raises many issues such as selection of hardware and software authoring tools, collaborative design efforts, pedagogy, copyright or intellectual property issues, and concerns regarding security, privacy, and confidentiality. This chapter briefly reviews the client–server technology, and describes commercial tools for developing an academic website from personal experience. The challenges and motivators for creating websites for biomedical education and research are discussed.

Key Words: Information technology, Internet, World Wide Web, Website, Online education, Medical research, Biomedicine.

INTRODUCTION

Modern information technology (IT) and telecommunications through the Internet play a significant role in biomedical research and training across the globe. The Internet provides a repository of websites and databases on a variety of topics in biomedicine, and many more are constantly added and updated.[1,2] The web technology is changing rapidly, bringing a steady stream of exciting new applications and abilities to both the developer and the end user. Web-based applications have unique attributes to provide new and updated teaching materials in an interactive format. Websites designed for biomedical research and training provide rich contents with multiple hyperlinks and multimedia objects.

Several articles offer comprehensive reviews of website designs and implementation of web-based information.[3–5] Website designs involve distance delivery of print materials, graphics, animations, and audiovisual materials. Web-based tools for information exchange include forums, bulletin boards and discussion lists, chat rooms, videoconferencing, and webcasts using streaming technology.

This chapter briefly reviews the client–server technology, and describes commercial tools for developing an academic website from personal experience. The challenges and motivators for creating websites for biomedical education and research are discussed.

CLIENT–SERVER TECHNOLOGY

The Internet uses standard TCP/IP (transmission control protocol/Internet protocol) stack, which is a set of protocols for data communication over various computer networks. The protocols work together to allow computers using different operating systems and protocols to communicate with one another with a common language.

An intranet is a "private" network of connected computers used to share information within an institution, organization, company, and their affiliates and clients. The principal difference between an intranet and the Internet is that the intranet is not intended for public access. With privacy and security features installed, both Internet and intranets can be used to share a wide variety of media including text documents, graphics, animations, streaming audio and videos, and custom-designed applications.[6–9]

The methodology of website development involves composing web pages in standard hypertext markup language (HTML) and sending them over the Internet or intranet using a protocol called HTTP, which is an acronym for hypertext transfer protocol. However, other web authoring syntax and a variety of applications could also be used as needed. Software applications called a web browser such as Internet Explorer find information from websites and display them on computers connected to the Internet any time and from anywhere in the world. The web content resides on computers called web servers, and the client machine is any computer accessing that server's data.

HARDWARE REQUIREMENTS

In a typical institution or company, the IT personnel install and manage many computers using different operating systems, and hardware and software. The client workstations may include computers running Microsoft Windows, Apple Macintosh, and other

From: *Sourcebook of Models for Biomedical Research* (P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

platforms with different operating systems and applications. The servers and workstations are connected with an assortment of hardware and software, which might include Ethernet (10 megabits/second, Mbps), fast Ethernet (100 Mbps), and much higher speeds. In such environments, a local area network (LAN) and wide area network (WAN) of interconnected computers can be used for website development. Several routers and hubs are used for interconnectivity and traffic control.

The essential hardware and software for developing websites consist of a web server connected to a network of computers. In our department, the web server runs under a Windows 2003 operating system (Dell Computer Corporation, Round Rock, TX). The ancillary units consist of an automated tape backup, an uninterruptible power supply, and an antivirus program. Technicians from the Microcomputer Services of our institution installed and configured the hardware and software systems.

Based on our experience, the following routines are suggested to maximize the performance of a departmental network using the client–server technology:

1. The central processing unit of the server should be as fast as possible; multiple high-speed microprocessors may be needed for database and image intensive tasks.
2. Random access memory of 1–2 gigabytes or higher should be used.
3. Large hard drives with a capacity of 50–100 gigabytes or more are needed for storage of data and should be as fast as possible; redundant hard disk arrays will provide data backup and security.
4. Network adapters are required for networking. Most enterprise LANs and WANs are Ethernet based, where computers are connected by one of the network interface cards. The 10/100 Base-T card communicates at 10 or 100 Mbps, and higher speeds are becoming common at many academic institutions.
5. The network should offer domain name service, which converts easily remembered alphabetic addresses to the numeric IP address to find other computers over the Internet.

SOFTWARE REQUIREMENTS

Over the past few years, building web-based services and websites has become a popular way of sharing information for biomedical research projects.[1,2] The open source is a trustworthy mechanism for website deployment and distribution of information. Open source technology has become popular because it decreases duplicate efforts and produces rapid development of websites at participating institutions. Several custom software projects have been described that run using an open source model.[7,8] However, many universities are only beginning to draft policies regarding copyright issues for developing open source software.

The basic software needed for creating websites consists of one or more authoring tools and editing applications for texts, images, graphics, animations, simulations, and audio and video streams. Until recently, authoring web pages needed a working knowledge of HTML syntax, which, although not difficult to learn, can be tedious. Web pages can be authored using any text editor, and there are currently a variety of high-quality WYSIWYG (what you see is what you get) editors on the market that do not need any knowledge of HTML syntax. With these editors, anyone who can use a word processor can create static web pages. For a summary of website development tools, visit http://horton.com/tools.

For using database technologies, presenting live content and customization of websites, advanced computer skills are needed. These include a working knowledge of a scripting language such as JavaScript, and sophisticated programming languages such as Java and Perl. The ASP (Active Server Pages) technology was created by Microsoft to allow an easy combination of HTML, scripts (such as JavaScript and Microsoft's VBScript), and ActiveX. Another programming language called Extensible Markup Language or XML provides the foundation for many web services. Much like HTML, XML uses programming tags that define the properties of data on web pages. However, XML tags are far more versatile and can define precisely how data are displayed as well as contents.

Web-based data mining technology presents particular challenges to the standard HTTP protocol and website developers need to learn advanced skills. Webmasters should also have a working knowledge of at least one basic web-enabled database solution such as Microsoft Access. For database intensive tasks, SQL (Structured Query Language) is an example of a database management application that has become popular for querying and managing databases on websites. For skilled webmasters, other client and server-side programming and database creation solutions are available on the market.

CONTENT DEVELOPMENT

This section describes how the author used off-the-shelf commercial tools and created an educational website in the department of obstetrics and gynecology at Louisiana State University Health Sciences Center in Shreveport, Louisiana. The website was developed according to the guidelines of the American Medical Association.[10,11] The departmental faculty provided teaching materials and the authors independently edited the content for consistency and style before postings were done. The departmental website is located at http://obg.lsuhsc-s.edu/obgyn/index.html.

The website development tool automatically creates the web pages with standard HTML syntax (NetObjects Fusion, Website Pros, Inc., Jacksonville, FL). Slideshows were produced using Microsoft PowerPoint, and the training modules were created using Trainersoft software (San Diego, CA). Multiple-choice questions were written using Questionmark software (Stamford, CT). The training videos were edited using Camtasia Studio software (Okemos, MI). CodeCharge software (Utica, MI) was used to create backend databases for case studies on the intranet using Microsoft Access application. To encourage private discussions among the participants a bulletin board was created and hosted on the intranet, which is password protected.

Currently the departmental site includes 238 pages with 3771 links, including those found on external servers providing women's healthcare education. The website provides access to interactive lectures, computer-generated tests, quizzes, searchable databases, and a bulletin board for approved users. Various sections of the website provide links that include administrative and teaching materials. The Lessons and the Visiting Professors sections contain modular topics in reproductive medicine such as menstrual disorders, polycystic ovary syndrome, endometriosis, infertility, and laparoscopy. The Library section is an online source for educational materials in reproductive medicine (Figure 77–1). Table 77–1 provides the main goals and website addresses. Table 77–2 provides information on visitor profiles at the departmental sites from 1998 to 2004.

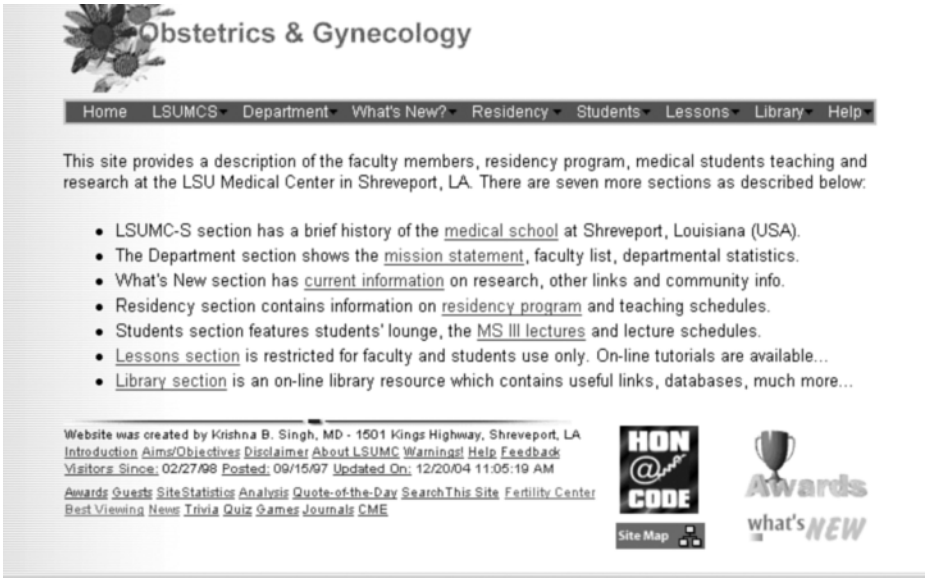

Figure 77–1. Screenshot of the home page at the departmental website showing the navigation bar and links for various sections.

DISCUSSION

Web-based virtual learning (also called electronic learning or e-learning) can be defined broadly as any use of the Internet and web technologies to create learning experiences. Web-based training (WBT) is individualized or group tutoring or mentoring delivered over public or private computer networks and displayed by a web browser. WBT is an example of on-demand interactive training stored in a server and accessed online across a network of computers.

Today many software tools for website development are available on the market, mostly at a low cost to individual users for professional website designs and publication. The Internet provides massive amounts of information including interactive tutorials on website development. Popular search engines provide addresses of websites for authoring as well as other website development tools. Online bookstores provide listings for hundreds of books on website development.

During the past decade, the virtual learning knowledge base has exploded, and increasing numbers of institutions and organizations are using innovative methods for online teaching and research.[12–17] To see some examples, visit the Association of Professors of Gynecology and Obstetrics website at http://www.apgo.org/members/index.cfm and review the reproductive medicine sites at several health sciences centers in the United States and Canada. The academic department's websites can also be searched using a tool provided at our departmental website (see Table 77–1).

Developing quality websites symbolizes an evolution that needs experienced website designers, surveys of the target audience, focus groups, and analysis of server data or a combination of these methods. However, posting of information on the web does not always undergo peer reviews or need some standard for publication. The design and implementation of websites need readily available technical support personnel and a variety of tools and techniques.[18,19] The collaboration of IT experts with content experts allows interactive websites to be developed that are cost effective and geared to end users needs. Our website is international in scope, collaborative, asynchronous in delivery, flexible, and responsive to learner needs.[16,17]

The websites designed for biomedical education and research can provide rich contents with many hyperlinks and multimedia objects. Web-based tools for information exchange include forums, bulletin boards and discussion lists, chat rooms, videoconferencing, and webcasting using streaming technology. Webcasting is a new instructional technology used to deliver audio and video presentations via the Internet, enabling learners to participate in a live class via a personal computer. Increasingly, scientific conferences are being webcast to extend the benefits of online education.[20,21]

Syndicated content delivery, known as Really Simple Syndication (RSS), is a popular way to deliver information from websites. Using RSS, a news site or a blog can automatically feed articles to a group of subscribers. Because RSS is still new, not all websites can publish using this medium. However, RSS feeds can be integrated on websites with relative ease to receive the latest information on a given subject.[22] This technology provides a speedy way of updating contents of academic websites.

Web logs, also known as "blogs," are an emerging tool that is easy to use, is web based, and can improve communication, collaboration, and information-gathering skills. Blog postings, typically updated daily, can include images, photos, links, video, audio, or simple text. The postings are archived by date and sometimes by category or by author. Another communication and reference tool called wiki is a hypertext-based collaborative software that enables authoring of documents collectively using a web browser.[23,24]

The blogs and wikis are web-based applications for collaborative knowledge warehouse. These tools have the potential to offer all the features of complex and expensive IT solutions for sharing and exchange of information (see wikipedia.org). An emerging technology called Web 2.0 refers to a second generation of services available on the web that lets people collaborate and share information online. In contrast to the first generation, Web 2.0 gives users an experience closer to desktop applications than the traditional static web pages. These collaboration tools can enable researchers to share knowledge and experience quickly using the available technologies.

Regardless of the delivery format, the design of websites for biomedical education and research raises many issues such as selection of hardware and software authoring tools, collaborative design efforts, pedagogy, and copyright or intellectual property issues. Significant concerns regarding the security, privacy, and confidentiality of consumers have also been raised. Motivating reasons for effective website development include team attributes such as strong leadership and judicious use of available resources. Barriers to development include administrative environments that do not yet fully integrate IT into educational vision and framework, lack of academic incentives for the faculty, and limited technical support staff.[25]

Recently many virtual communities for providing health education as well as support groups for patients have emerged. These cover a wide range of clinical specialties, technologies, and stakeholders. However, more research is needed to evaluate under which conditions and for whom electronic support groups are effective and how the effectiveness for delivering social support electronically can be assessed.[12,13] Chapter 78 (this volume) describes a variety of tools and techniques to build virtual communities for biomedical education and research.

CONCLUSIONS

Web-based applications have unique attributes that provide new and updated teaching materials in an interactive format. Websites designed for biomedical research and training provide rich contents with multiple hyperlinks and multimedia objects. Today many software packages for website development are available on the market, mostly at a low cost to individual users for professional website designs. The Internet and web technologies can promote online collaboration using forums, discussion groups, and content sharing. Newer technologies enable real-time collaboration in various forms. Properly designed websites can motivate, teach, and quickly update learners and teachers involved in biomedical education and research.

78 Building Virtual Research Communities Using Web Technology

KRISHNA B. SINGH

ABSTRACT

Exchanging information and building communication channels are critical ingredients of biomedical education and research. Collaboration tools can help researchers work in harmony and learn together at a distance. This category spans a wide variety of applications from simple text-based e-mail clients to complex online meeting tools. E-mail is the oldest, most widely used, and effective collaboration tool. Online discussions go by various formats and names such as discussion groups, bulletin boards, and discussion forums. The Internet and web technologies have the potential to increase the productivity of biomedical research. The Internet collaboratories can support expensive equipment to address complex problems, which can speed up discovery and innovation in research. Having the right tools and technology is a necessary foundation and building a community needs conscious effort among website designers, community promoters, and leaders. Integrating electronic collaborative tools into routine scientific practice can be successful but requires further research.

Key Words: Internet, World Wide Web, Online education, Biomedical research, Groupware, Collaboratory.

INTRODUCTION

Advances in Internet and web technologies over the past decade have resulted in increased opportunities for consumers and the medical community to become more innovative in biomedical research. These innovations have allowed instantaneous access to medical information at the point of need. Web-based applications have unique attributes to provide new and updated teaching materials in an interactive format. By capitalizing on technologies such as laptop or notebook computers, personal digital assistants, and web-based applications people have portable and remote access to biomedical information almost instantaneously. In the literature, several types of virtual collaboration tools have been described.[1–5] The use of electronic tools such as e-mail, bulletin boards, and web messaging for collaboration is also emerging in the medical practice and allied fields.[6–9]

This chapter explains the terminology and reviews potential uses of a wide range of Internet and web-based collaboration tools. Information on how some institutions have used the technology to develop large-scale collaborative research initiatives is also presented. Finally, how integrating information technology might harmonize biomedical education and research and its potential significance are discussed.

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

TERMINOLOGY

Many collaboration tools use the server–client architecture or its variants on a network of computers. In technical terms, a client is a computer system that accesses the service on another computer called a server using network connections. The client–server model is still used today on the Internet, where a user may connect to a service operating on a remote system through the Internet protocol suites. Web browsers are clients that connect to web servers and retrieve web pages for display. Most people use e-mail clients to retrieve their e-mail from their Internet service provider's mail storage servers. E-mail list servers are a popular Internet tool for online discussions. Instant messaging consists of instant communications between two or more people on the Internet. Instant messaging requires the use of a client program that hooks up an instant messaging service. An instant message differs from e-mail in that conversations happen in real time. Popular instant messaging services include Microsoft's MSN Messenger, AOL Instant Messenger, Yahoo! Messenger, Google Talk, and iChat for Apple computers. An older and still popular online chat medium is known as Internet Relay Chat or IRC. Technically, instant messaging typically boosts communication and allows easy collaboration among participants. Online chat can refer to any kind of communication over the Internet, but generally refers to a direct one-on-one chat in chat rooms, or using tools such as instant messenger applications (visit http://en.wikipedia.org).

Web-based virtual learning (also called electronic learning or e-Learning) can be defined broadly as any use of the Internet and web technologies to create teaching and learning experiences. Web-based training (WBT) is individualized or group tutoring or mentoring delivered over public or private computer networks and displayed by a web browser. WBT is an example of on-demand interactive online training stored in a server and accessed across a network of computers. WBT can be updated very rapidly, and the training provider administers access to the training. The phrase virtual community or online community is often hyped in different ways (visit http://en.wikipedia.org). The digital divide is a term that describes the differences between those who have access to the Internet and those who do not because of economic reasons, lack of computer competency or self-efficacy, or different knowledge management styles.

Table 78–1
Synchronous collaboration tools for real-time virtual meetings

Tool	*What it does*
Instant messaging/chat	Real-time one-to-one text messaging delivered over the Internet
Internet relay chat	Real-time many-to-many text messaging system delivered over the Internet
Whiteboarding/annotating	Real-time display screen that is shared and viewed by multiple users over the Internet and on which users can write or draw
Application and desktop sharing	Allows multiple users to view and share a computer desktop or application over the Internet
Audio conferencing	Allows multiple users to talk with each other in real time over the Internet
Video conferencing/video chat	Allows multiple users to see and hear each other in real time using streaming video and audio over the Internet
Interactive web collaboration tools	These tools combine many of the applications listed above and enable users to interact in a number of ways

Source: Roberts S. Choosing tools for real-time virtual meetings. Available at http://coe.sdsu.edu/eet/articles/sitools/index.htm.

Communication technologies can be broken down into two basic categories: (1) those that allow asynchronous collaboration in which communication does not occur in real time, and (2) those that allow synchronous collaboration in which communication takes place over networks in real time. Examples of asynchronous technologies include traditional correspondence courses, e-mail, database, and message boards. There are advantages to asynchronous learning when using the web-based technologies because hypermedia and hyperlinks can provide large amounts of information in distant locations. Examples of synchronous technologies include instant messaging and chat applications, Internet relay chat, whiteboarding, application sharing, and audioconferencing and videoconferencing using the streaming technology (Table 78–1). These media are expensive to buy or build but permit more collaborative work, brainstorming, learning, or tutoring in real time, and may also be more productive than asynchronous communications.[2–5]

Exchanging information and building communication channels are critical ingredients of biomedical education and research. Biomedical researchers face hard constraints for managing the vast amount of information produced during research projects. Collaboration tools can help researchers work in harmony and learn together at a distance. Most researchers desirous of creating a virtual space to share common experiences with colleagues can use the tools described below.

COLLABORATION TOOLS

This category spans a wide variety of applications from simple text-based e-mail clients to complex online meeting tools. The collaboration tools let participants share their ideas, and are essential for collaborative online learning and knowledge management initiatives. Providing a collaborative environment may require several separate tools using the Internet and web technologies.

E-mail is the oldest, most widely used, and effective collaborative tool preferred by patients and doctors alike.[6,7] The literature contains several articles in which the uses of bulletin boards and instant messaging have been described.[8,9] Online discussions go by various formats and names such as discussion groups, bulletin boards, and discussion forums. These applications are provided in a general-purpose server such as Microsoft Exchange Server. Alternatively, they can be part of an institution-wide virtual learning system such as Blackboard (blackboard.com). Simple bulletin boards and forums can also be integrated at websites using site development tools such as NetObjects Fusion (see Chapter 77, this volume).

With tools known as groupware, researchers can communicate easily with one another to perform difficult tasks even though they are remotely located or rarely overlap in time. There are several groupware applications such as Lotus Notes (IBM, Armonk, NY), eRoom (EMC Corporation, Pleasanton, CA), and Groove (Microsoft, Inc., Redmond, WA). Groove is a secure, peer-to-peer collaborative tool that integrates with a wide variety of applications such as file sharing, threaded discussions, web links, document review, and calendar into a single workspace. The product also integrates well with Microsoft Office suite. Because of its peer-to-peer architecture, the administrative overhead is much lower than that of some server-based applications such as Lotus Notes. For a list of groupware tools, visit http://www.grantbow.com/groupware.html.

With modern technology, research collaborations have advanced beyond simply providing shared access to documents on the Internet. Researchers engaged in complex initiatives have realized that running collaborative projects with great efficiency needs far more structure and organization than a basic shared network can manage. This problem is further compounded because research projects often span departments, divisions, and institutional boundaries on a global scale. Examples of newer and promising collaboration tools used in the medical and allied field include wikipedia, blogs, syndicated media, podcasting, and webcasting using streaming technologies.[10–15] Interactive tutorials on several tools and technologies for building virtual communities are available at http://www.imarkgroup.org/moduledescrC_en.asp. The next section describes custom-built collaborating systems, called collaboratories, and discusses what they are and what research domains they serve.

COLLABORATORY COMMUNITIES

The term collaboratory was first coined in the late 1980s to describe large-scale collaborations among researchers using the Internet infrastructure and tools. A collaboratory can be defined as an information technology large-scale infrastructure that supports cooperation among individuals, groups, or organizations in pursuit of a shared goal by simplifying communication and knowledge sharing.[16–18] Recently several collaboratories have been developed for online education and biomedical research. Using collaboratories, researchers can share access to large datasets and shared environments, support expensive equipment to address complex problems, and speed up discovery and innovation. They can also use an emerging class of advanced network-based applications referred to as "grid" computing. This approach

Table 78–2
Collaboratories in the United States and their domains of expertise

Name	*Purpose*	*Web reference*
Biomedical Informatics Research Network	Data sharing across neuroimaging databases in the United States	http://www.nbirn.net
Biological Collaborative Environment	Molecular modeling and simulation	http://www.ks.uiuc.edu/research/biocore
Molecular Modeling Collaboratory	Extensible, interactive molecular modeling software	http://www.cgl.ucsf.edu/research/collaboratory
National Laboratory for the Study of Rural Telemedicine	Established the first virtual hospital	http://www.vh.org
Visible Human Project	Three-dimensional representations of the normal male and female bodies	http://vhp.med.umich.edu
Environmental Molecular Sciences Laboratory	New communications technologies	http://collaboratory.emsl.pnl.gov

is flexible, secure, and provides coordinated resource sharing among many individuals and resources.

The Environmental Molecular Sciences Laboratory (EMSL) is a new national user facility housing various expensive scientific instruments. Development of the EMSL collaboratory is a symmetric collaboration between computer scientists, domain scientists (physical and biological sciences), and sociologists. The collaboratory relies on developing new communications technologies—shared computer displays, electronic notebooks, and virtual reality collaboration spaces with an integration of these technologies with videoconferencing and e-mail abilities. Table 78–2 provides a list of unique research projects incorporating collaboratory technologies in the United States.

DISCUSSION

The number of virtual communities that focus on healthcare topics has recently exploded. For example, Yahoo Groups (http://groups.yahoo.com) shows thousands of virtual communities related to healthcare and alternative medicine. Explosive growth of the Internet and web technologies at affordable costs plus consumer satisfaction with communities partly explain this phenomenon. The implications of rapidly growing health-related virtual communities need further research.[19–21]

Conducting online Internet-based research raises several ethical questions, especially about privacy and informed consent.[22–24] Researchers and peers from institutional review boards primarily decide whether research is intrusive and has the potential for harm, how confidentiality can be protected, and whether and how informed consent should be obtained.[21] Developing private intranet communities and websites internally provides administrative control and choices for leasing or buying hardware and software. However, it may be more proper to use the services of a community aggregator or application service provider depending on the aims of the project and available finances.

Application service providers can offer a rich collection of templates and tools to those who want to run their own online community. Internet service providers and major search engines also offer a wide range of collaborative tools at no extra cost to end users. For example, MSN provides different types of web-based e-mail servers, MSN messenger, chat rooms, and an application called spaces for creating weblogs or blogs.

The benefits of having an online community are real, but building a virtual community is not always straightforward. Having the right tools and technology is a necessary foundation, but does not guarantee that a community will work as expected. Building a community needs conscious effort among website designers, community promoters, and leaders. The builder of a virtual education and research community needs to determine what will hold it together as it expands with partnerships in the future.

Interactive websites for patient communication called patient portals may improve communication between patients and their clinics and physicians. In a randomized controlled trial, portal group patients demonstrated increased satisfaction with communication and overall care. Patients in the portal group particularly valued the portal's convenience, reduced communication barriers, and direct physician responses. More online messages from patients contained informational and psychosocial content compared to telephone calls, which may enhance the patient–physician relationship.[25] Institutions and organizations must promote cost-effective methods for researchers to communicate and collaborate efficiently with peers.

The major barriers to virtual networking include lack of time and motivation and negative attitudes to information technology among participants. Other factors for implementing virtual networks are related to technical and logistic issues. Integrating electronic collaborative tools into routine scientific practice can be successful, but requires further research on the technical, social, and behavioral factors influencing the adoption and use of collaboration tools.[18] Personal digital assistants, mobile telephones, fast services by direct mail, fax machines, and audioconferencing and videoconferencing are common tools for modern communication. For more demanding needs, researchers now have many choices for combining interactive tools with the traditional systems.

CONCLUSIONS

Web-based applications have unique attributes that provide new and updated teaching materials in an interactive format. Today many off-the-shelf communication tools for information gathering and biomedical research can be integrated at websites or used as stand-alone applications. With rapidly advancing information technology, the biomedical research community continues to harness trends in an emerging cyberspace infrastructure. These trends include collaborative scientific experiments and integration of resources from diversified fields. Developing a collaboratory empowers teamwork and collaborative approaches that support large-scale and information-rich biomedical investigations. Scientific research at regional and national collaboratories provides new insight into the biology of health as well as the prevention and cure of diseases.

Figure 8–1. Example of enrichment items for laboratory mice. The hut is tinted such that the mouse cannot see out, but human caretakers can see in. (Photo by Jill Rawlins.)

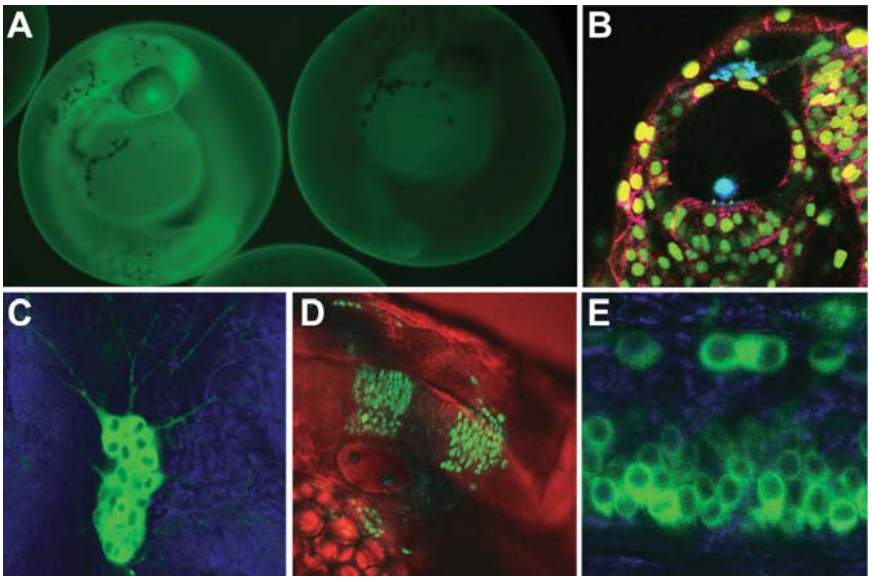

Figure 13–4. Imaging in live zebrafish embryos. (A) Whole embryos can be quickly imaged on a fluorescent dissecting microscope in their chorions to sort positive transgenics (left) from wild-type siblings (right). These embryos were not treated with PTU so the melanocytes are visible. (B–E) Confocal microscopy permits much higher resolution imaging. (B) A quick method for labeling is to inject RNA encoding fluorescent proteins, in this case a histone2B-EGFP fusion, and a membrane localized mCherry was used to image all the cells of the inner ear. (C) GFP transgenics can be used to image neuronal projections from the trigeminal ganglion as they extend. (D) GFP transgenics can mark specific populations of cells, in this case rhombomeres 3 and 5. (E) GFP fusion proteins can reveal the subcellular localization pattern of proteins, in this case a cytoplasmic protein in the Rohon-Beard and motor neurons of the spinal cord. (Images from S.G. Megason, L.A. Trinh, and S.E. Fraser, unpublished.)

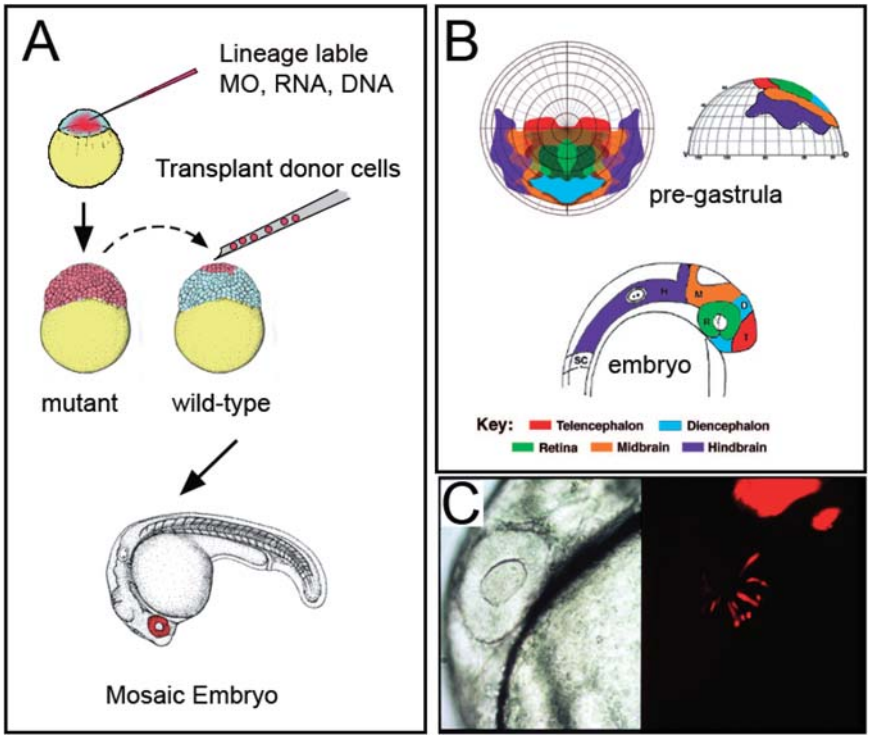

Figure 13–5. Creating genetic mosaics in zebrafish. (A) Donor cells are first lineage labeled with a tracer dye at the one-cell stage. Donor embryos can also be injected with morpholinos, RNA, or DNA. At the 1000-cell stage, totipotent blastula cells are transplanted into regions of the host embryo fated to give rise to specific structures. Donor and host embryos can be of either mutant or wild-type genotypes. Resultant chimeras are grown for subsequent analysis. (B) Fate-map of the pregastrula stage embryos. (Modified from Woo and Fraser, 1995.) (C) Mosaic embryo at 24 hpf showing bright-field (left) and fluorescent image (right) of rhodamine-dextran-labeled donor cells targeted to the eye and forebrain. (B.A. Link, unpublished.)

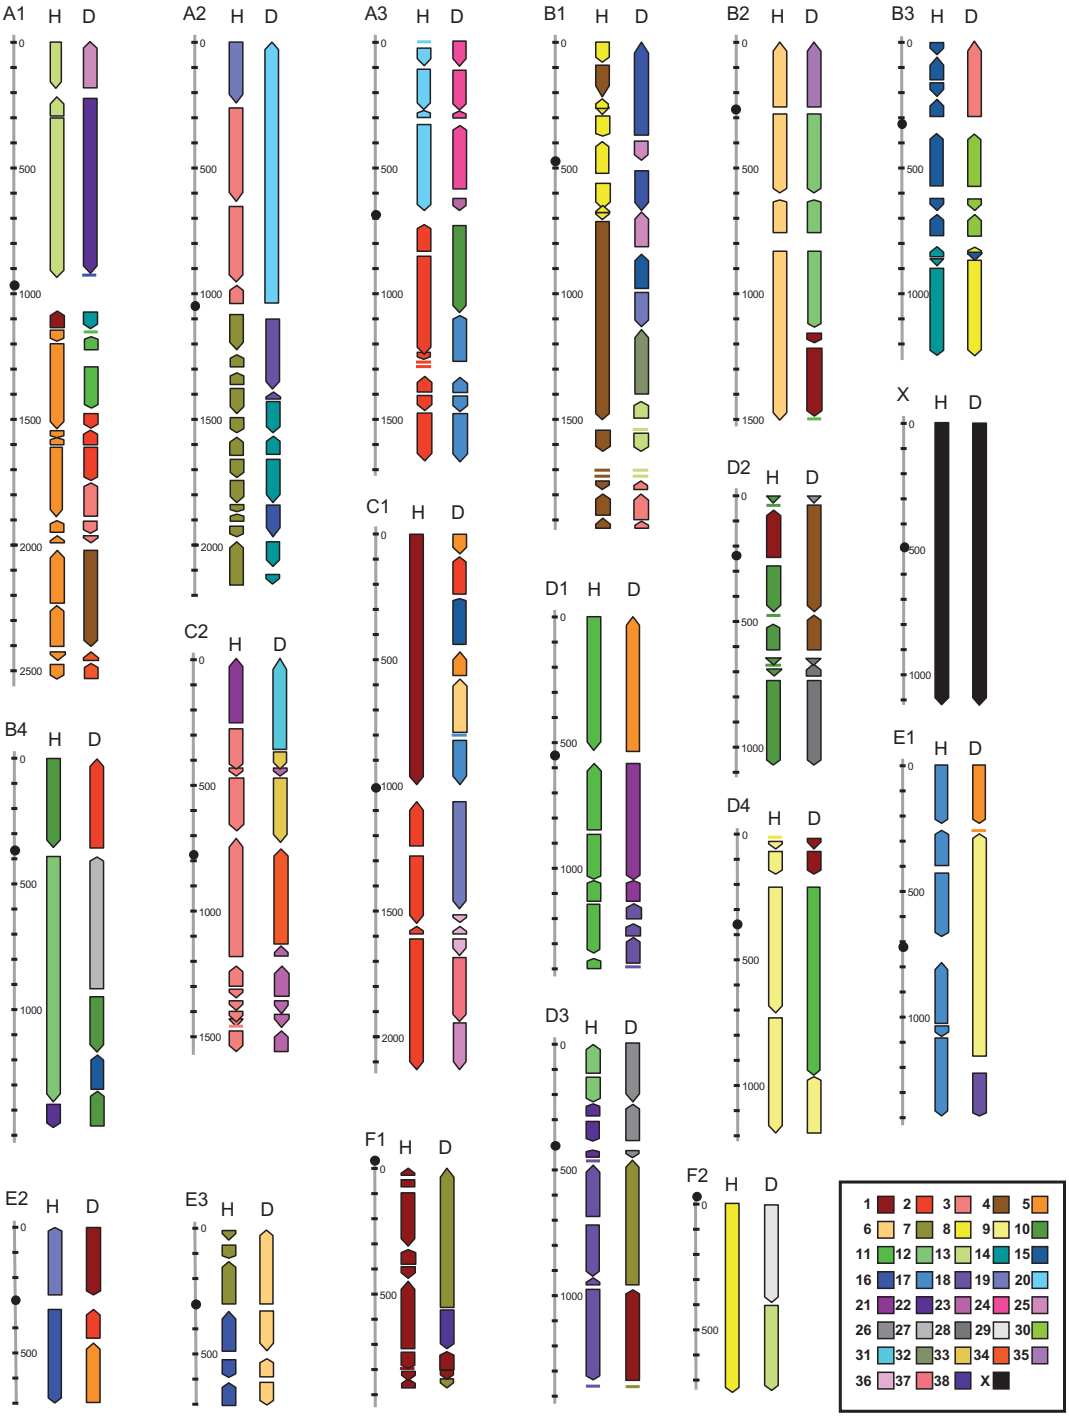

Figure 25–1. Feline chromosome maps (labeled at top) and homologous synteny blocks (HSBs) in the human (H) and dog (D) genomes. HSBs are shown to the right of each cat chromosome map (only the map scale is shown). The dark cross-marks on each cat chromosome correspond to 100-cR$_{5000}$ intervals. The inferred centromere positions are shown by dark circles. HSBs are color coded by human or dog chromosome, defined by the key in the bottom right corner. (Reprinted from Murphy *et al.*[7] Copyright 2007, with permission from Elsevier.)

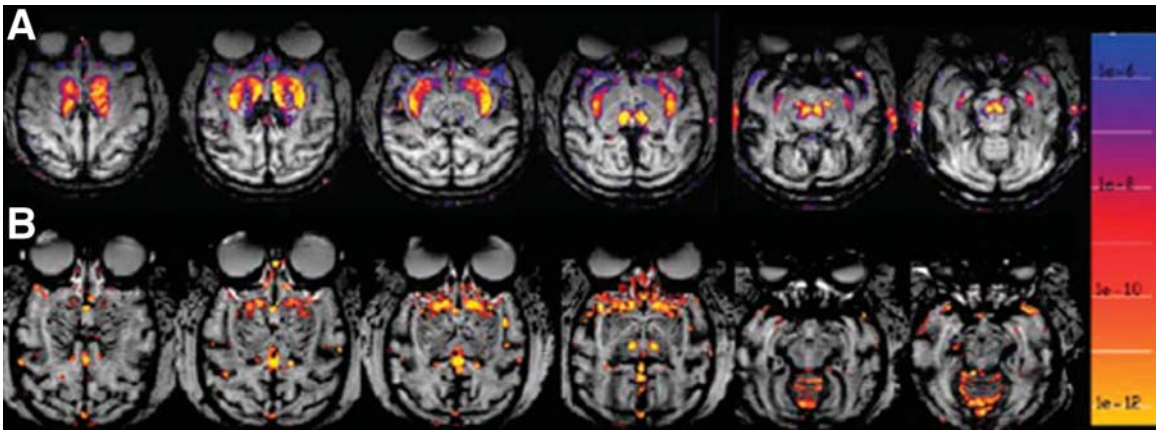

Figure 51–3. Changes in the CBV response to amphetamine (A) before and (B) 4 months after cessation of MPTP treatment in a cynomolgus monkey, showing an almost complete loss of amphetamine-induced CBV signal changes in dopaminergic regions. Parkinsonian primates had a prominent loss of response to amphetamine, with relative sparing of the nucleus accumbens and parafascicular thalamus. (Modified from Jenkins *et al.*[183] Copyright 2004 Society for Neurosciences.)

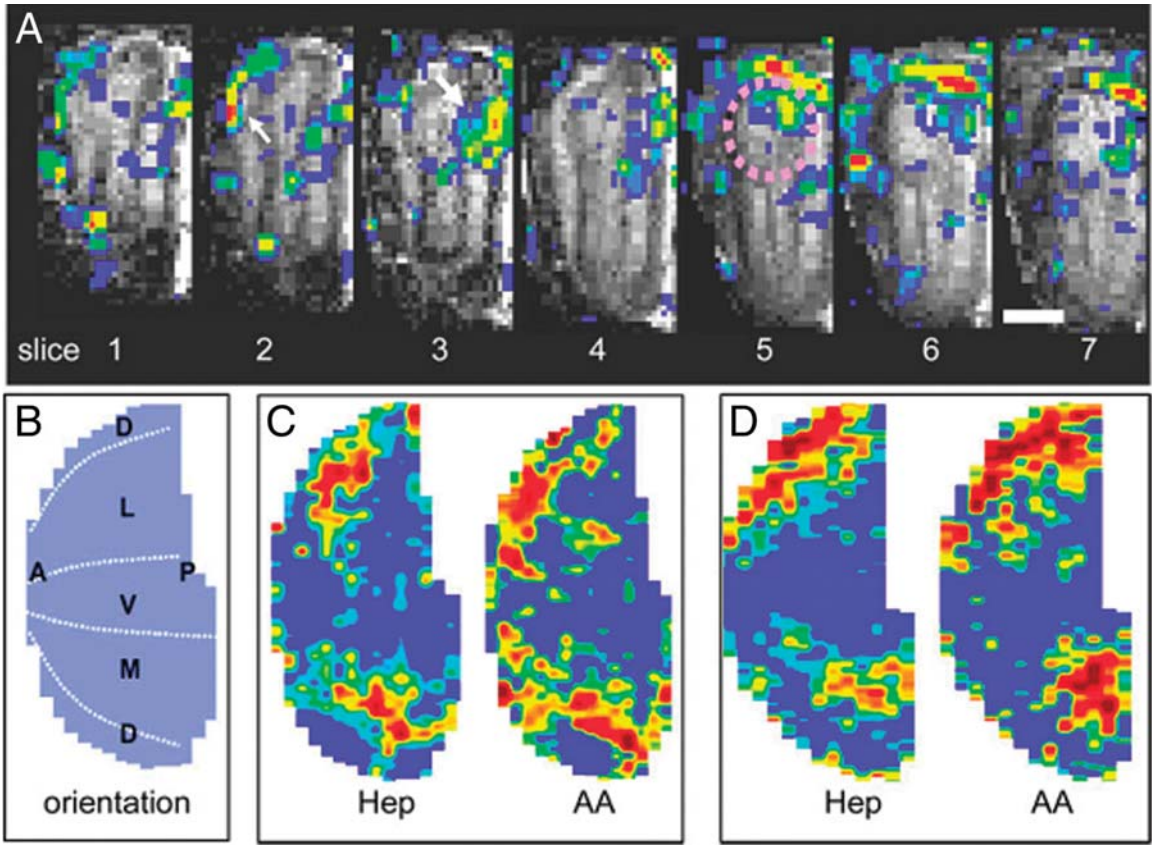

Figure 51–4. (A) Patterns of the fMRI response in the mouse main olfactory bulb (MOB) and accessory olfactory bulb (AOB, pink circle in slice 5) to the pheromone 2-heptanone, one of the urinary chemosignal compounds in mouse. The arrows point to two foci of activation suggestive of a pair of the nearly mirror projections of the receptor neuron subsets to the same MOB. Scale bar = 500 µm. (B) A flattened view of the olfactory bulb indicating the orientation of the odor maps shown in (C) and (D): A, anterior; D, dorsal; L, lateral; M, medial; P, posterior; V, ventral. (C, D) The odor maps of 2-heptanone (Hep) in two different mice show that this pheromone not only activates large regions of the MOB but also generates similar patterns across subjects. Interestingly, the odor map for amyl acetate (AA), a common odorant with an odor quality similar to that of 2-heptanone, was also similar to that of 2-heptanoneb. (Adapted from Xu *et al.*[217] Copyright 2005 Wiley-Liss, Inc.)

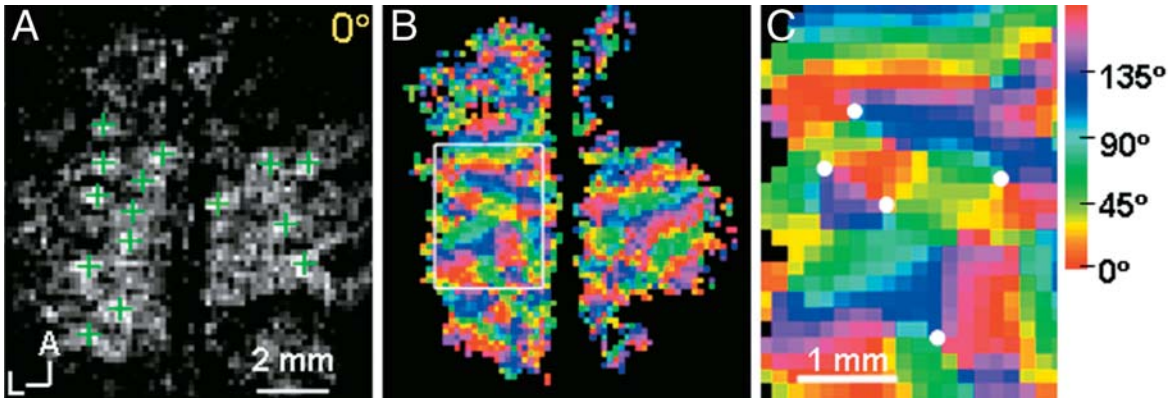

Figure 51–5. Signal changes in CBV-weighted fMRI obtained during stimulation of the cat visual cortex according to predetermined stimulus orientations. (A) Raw gray-scale functional map obtained by subtraction of images during 0º stimulation from prestimulus control. The center of each patch is marked with a green + sign. (B) Four different grating orientations (0º, 45º, 90º, and 135º) were presented in the study of one animal, enabling a composite angle map to be generated through pixel-by-pixel vector addition of the four single-condition maps. In the left hemisphere (marked by a white rectangular box), changes between pixels preferentially activated by a particular stimulus orientation were smoothed by a 3×3 Gaussian kernel. (C) A composite angle map was generated with the region indicated by the white ROI in (b). "Pinwheel" structures indicated by small white dots were observed where domains for all orientations converge. (Adapted from Zhao *et al.*[114] Copyright 2005 Elsevier.)

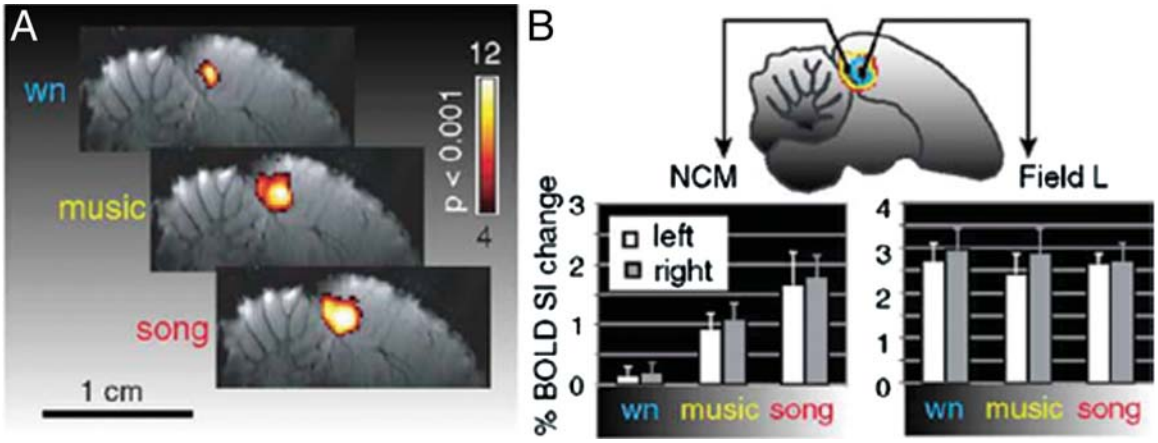

Figure 51–6. Auditory activation in the songbird telencephalon shows (A) statistical maps illustrating the localization of significant signal intensity changes during auditory stimulation consisting of white noise (wn), a concerto of Bach (music), and a stimulation with song from a male starling (song). (B) The location of the activated areas (top), together with the average BOLD response amplitude for each stimulus (bottom). (Adapted from Van Meir *et al.*[231] Copyright 2005 Elsevier.)

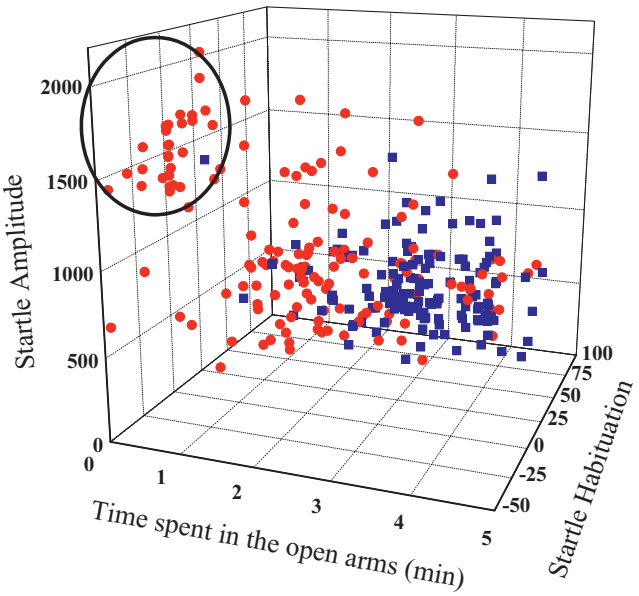

Figure 61–1. The effect of single PSS exposure versus unexposed control on rat anxiety-like behavior and acoustic startle response and habituation. The representation of the data from both paradigms (EPM and ASR) shows two obvious and rather distinct features. First, it is clear that PSS exposure alters the response of the majority of individuals to at least some degree. Second, the cluster of individuals that forms in the upper left hand corner of the graph (i.e., had the more extreme responses to exposure) is quite distinct from the majority of individuals.[36,48]

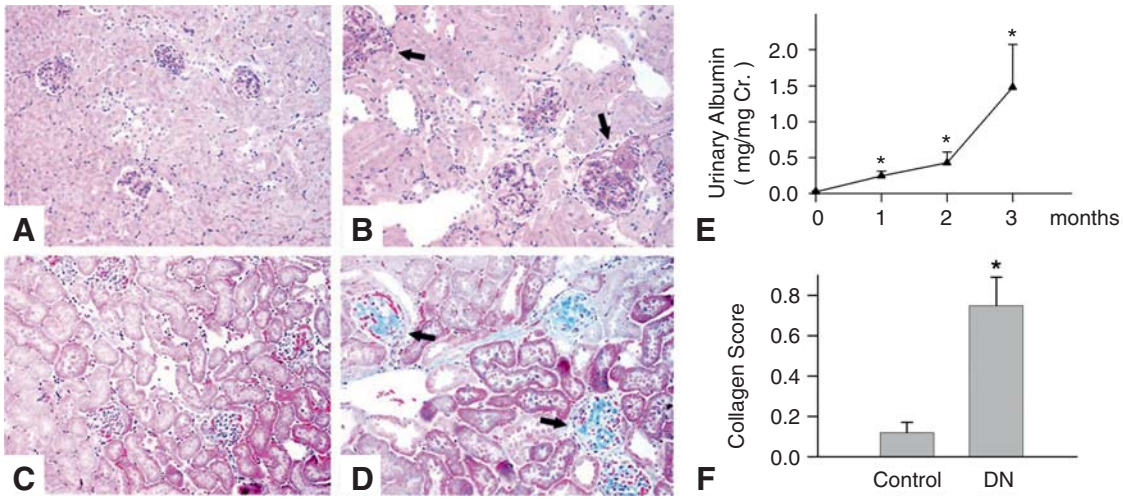

Figure 68–2. Diabetic nephropathy induced by streptozotocin (STZ) in uninephrectomized mice. One week after uninephrectomy, male CD1 mice received an intravenous injection of STZ. (A–D) Representative micrographs demonstrate glomerular enlargement, mesangial expansion, and segmental glomerulosclerosis (periodic acid–Schiff staining; A, B) and glomerular collagen deposition (Masson–Trichrome staining; C, D). (A and C) Normal control; (B and D) diabetic mice. Arrows indicate injured glomeruli. (E) Albuminuria develops in diabetic mice in a time-dependent manner. Data are presented as means ±SEM. *$p < 0.05$. (F) Glomerular collagen deposition score in diabetic and normal mice. *$p < 0.05$. (Adapted and modified from Dai *et al.*[46])

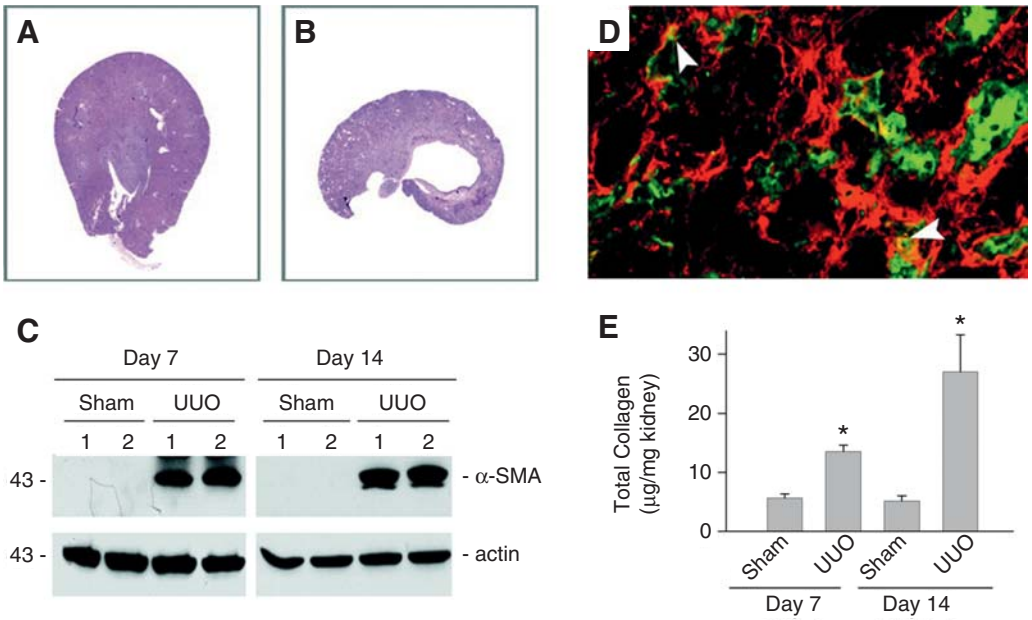

Figure 68–3. Interstitial fibrosis in the mouse model of obstructive nephropathy. (A, B) Representative micrographs show the cross sections and gross morphology of the obstructed kidneys at day 14 after ureteral ligation. (A) Sham control; (B) UUO. (C) Western blot analyses demonstrate a marked induction of α-smooth muscle actin (α-SMA), a molecular marker for myofibroblasts, in the obstructed kidney at day 14 after UUO. (D) Double immunofluorescence staining shows the α-SMA (red) and proximal tubular epithelial cell marker, fluorescein isothiocyanate (FITC)-conjugated lectin from *Tetragonolobus purpureas* (green). (E) Quantitative determination of total kidney collagen contents in sham and obstructed kidneys. Data are presented as means ±SEM. *$p < 0.01$. (Adapted and modified from Yang *et al.*[59]).

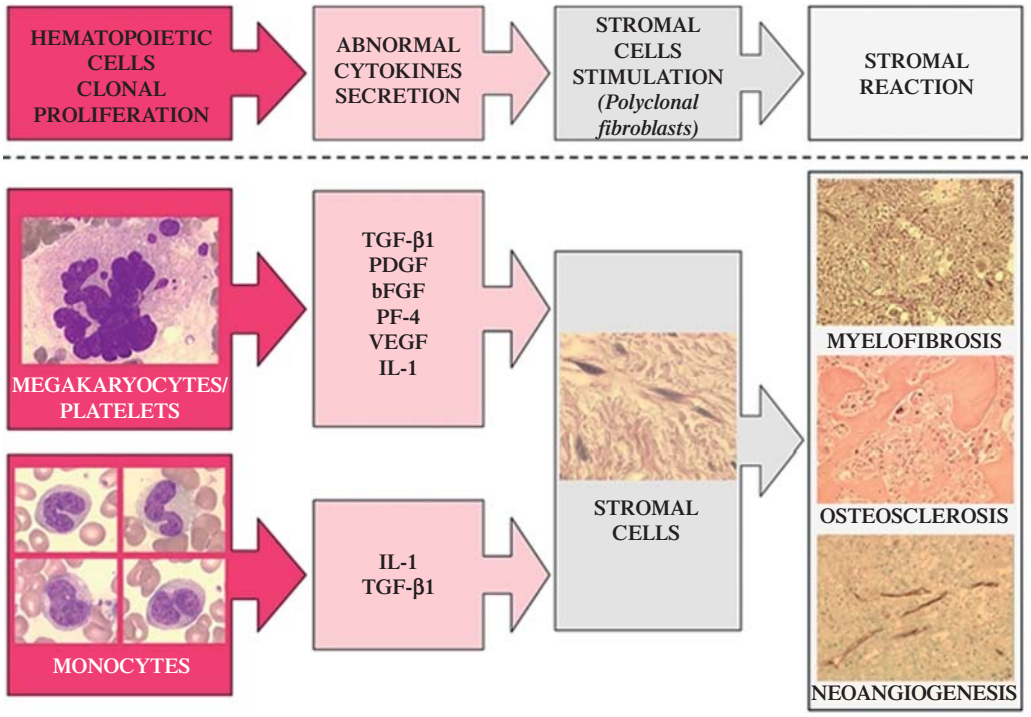

Figure 73–4. A pathogenetic model for the cytokine-mediated stromal reaction observed in MMM.
