Preface

The collection of systems represented in *Sourcebook of Models for Biomedical Research* is an effort to reflect the diversity and utility of models that are used in biomedicine. That utility is based on the consideration that observations made in particular organisms will provide insight into the workings of other, more complex, systems. Even the cell cycle in the simple yeast cell has similarities to that in humans and regulation with similar proteins occurs.

Some models have the advantage that the reproductive, mitotic, development or aging cycles are rapid compared with those in humans; others are utilized because individual proteins may be studied in an advantageous way and that have human homologs. Other organisms are facile to grow in laboratory settings or lend themselves to convenient analyses, have defined genomes or present especially good human models of human or animal disease.

We have made an effort not to be seduced into making the entire book homage to the remarkable success of the genomic programs, although this work is certainly well represented and indexed.

Some models have been omitted due to page limitations and we have encouraged the authors to use tables and figures to make comparisons of models so that observations not available in primary publications can become useful to the reader.

We thank Richard Lansing and the staff at Humana for guidance through the publication process.

As this book was entering production, we learned of the loss of Tom Lanigan, Sr. Tom was a leader and innovator in scientific publishing and a good friend and colleague to all in the exploratory enterprise. We dedicate this book to his memory. We will miss him greatly.

P. Michael Conn

List of Color Plates

Color plates to follow page 240.

Figure 8–1. Example of enrichment items for laboratory mice. The hut is tinted such that the mouse cannot see out, but human caretakers can see in. (Photo by Jill Rawlins.)

Figure 13–4. Imaging in live zebrafish embryos. (A) Whole embryos can be quickly imaged on a fluorescent dissecting microscope in their chorions to sort positive transgenics (left) from wild-type siblings (right). These embryos were not treated with PTU so the melanocytes are visible. (B–E) Confocal microscopy permits much higher resolution imaging. (B) A quick method for labeling is to inject RNA encoding fluorescent proteins, in this case a histone2B-EGFP fusion, and a membrane localized mCherry was used to image all the cells of the inner ear. (C) GFP transgenics can be used to image neuronal projections from the trigeminal ganglion as they extend. (D) GFP transgenics can mark specific populations of cells, in this case rhombomeres 3 and 5. (E) GFP fusion proteins can reveal the subcellular localization pattern of proteins, in this case a cytoplasmic protein in the Rohon-Beard and motor neurons of the spinal cord. (Images form S.G. Megason, L.A. Trinh, and S.E. Fraser, unpublished.)

Figure 13–5. Creating genetic mosaics in zebrafish. (A) Donor cells are first lineage labeled with a tracer dye at the one-cell stage. Donor embryos can also be injected with morpholinos, RNA, or DNA. At the 1000-cell stage, totipotent blastula cells are transplanted into regions of the host embryo fated to give rise to specific structures. Donor and host embryos can be of either mutant or wild-type genotypes. Resultant chimeras are grown for subsequent analysis. (B) Fate-map of the pregastrula stage embryos. (Modified from Woo and Fraser, 1995.) (C) Mosaic embryo at 24 hpf showing bright-field (left) and fluorescent image (right) of rhodamine-dextran-labeled donor cells targeted to the eye and forebrain. (B.A. Link, unpublished.)

Figure 25–1. Feline chromosome maps (labeled at top) and homologous synteny blocks (HSBs) in the human (H) and dog (D) genomes. HSBs are shown to the right of each cat chromosome map (only the map scale is shown). The dark cross-marks on each cat chromosome correspond to 100-cR_{5000} intervals. The inferred centromere positions are shown by dark circles. HSBs are color coded by human or dog chromosome, defined by the key in the bottom right corner. (Reprinted from Murphy *et al.*[7] Copyright 2007, with permission from Elsevier.)

Figure 51–3. Changes in the CBV response to amphetamine (A) before and (B) 4 months after cessation of MPTP treatment in a cynomolgus monkey, showing an almost complete loss of amphetamine-induced CBV signal changes in dopaminergic regions. Parkinsonian primates had a prominent loss of response to amphetamine, with relative sparing of the nucleus accumbens and parafascicular thalamus. (Modified from Jenkins *et al.*[183] Copyright 2004 Society for Neurosciences.)

Figure 51–4. (A) Patterns of the fMRI response in the mouse main olfactory bulb (MOB) and accessory olfactory bulb (AOB, pink circle in slice 5) to the pheromone 2-heptanone, one of the urinary chemosignal compounds in mouse. The arrows point to two foci of activation suggestive of a pair of the nearly mirror projections of the receptor neuron subsets to the same MOB. Scale bar = 500 μm. (B) A flattened view of the olfactory bulb indicating the orientation of the odor maps shown in (C) and (D): A, anterior; D, dorsal; L, lateral; M, medial; P, posterior, V, ventral. (C, D) The odor maps of 2-heptanone (Hep) in two different mice show that this pheromone not only activates large regions of the MOB but also generates similar patterns across subjects. Interestingly, the odor map for amyl acetate (AA), a common odorant with an odor quality similar to that of 2-heptanone, was also similar to that of 2-heptanoneb. (Adapted from Xu *et al.*[217] Copyright 2005 Wiley-Liss, Inc.)

Figure 51–5. Signal changes in CBV-weighted fMRI obtained during stimulation of the cat visual cortex according to predetermined stimulus orientations. (A) Raw gray-scale functional map obtained by subtraction of images during 0º stimulation from prestimulus control. The center of each patch is marked with a green + sign. (B) Four different grating orientations (0º, 45º, 90º, and 135º) were presented in the study of one animal, enabling a composite angle map to be generated through pixel-by-pixel vector addition of the four single-condition maps. In the left hemisphere (marked by a white rectangular box), changes between pixels preferentially activated by a particular stimulus orientation were smoothed by a 3×3 Gaussian Kernel. (C) A composite angle map was generated with the region indicated by the white ROI in (B) "Pinwheel" structures indicated by small white dots were observed where domains for all orientations converge. (Adapted from Zhao *et al.*[114] Copyright 2005 Elsevier.)

Figure 51–6. Auditory activation in the songbird telencephalon shows (A) statistical maps illustrating the localization of

significant signal intensity changes during auditory stimulation consisting of white noise (wn), a concerto of Bach (music), and a stimulation with song from a male starling (song). (B) The location of the activated areas (top), together with the average BOLD response amplitude for each stimulus (bottom). (Adapted from Van Meir *et al.*[231] Copyright 2005 Elsevier.)

Figure 61–1. The effect of single PSS exposure versus unexposed control on rat anxiety-like behavior and acoustic startle response and habituation. The representation of the data from both paradigms (EPM and ASR) shows two obvious and rather distinct features. First, it is clear that PSS exposure alters the response of the majority of individuals to at least some degree. Second, the cluster of individuals that forms in the upper left hand corner of the graph (i.e., had the more extreme responses to exposure) is quite distinct from the majority of individuals.[36,48]

Figure 68–2. Diabetic nephropathy induced by streptozotocin (STZ) in uninephrectomized mice. One week after uninephrectomy, male CD1 mice received an intravenous injection of STZ. (A–D) Representative micrographs demonstrate glomerular enlargement, mesangial expansion, and segmental glomerulosclerosis (periodic acid–Schiff staining; A, B) and glomerular collagen deposition (Masson–Trichrome staining; C, D) (A and C) Normal control; (B and D) diabetic mice. Arrows indicate injured glomeruli. (E) Albuminuria develops in diabetic mice in a time-dependent manner. Data are presented as means ± SEM. $*p < 0.05$. (F) Glomerular collagen deposition score in diabetic and normal mice. $*p < 0.05$. (Adapted and modified from Dai *et al.*[46])

Figure 68–3. Interstitial fibrosis in the mouse model of obstructive nephropathy. (A, B) Representative micrographs show the cross sections and gross morphology of the obstructed kidneys at day 14 after ureteral ligation. (A) Sham control; (B) UUO. (C) Western blot analyses demonstrate a marked induction of α-smooth muscle actin (α-SMA), a molecular marker for myofibroblasts, in the obstructed kidney at day 14 after UUO. (D) Double immunofluorescence staining shows the α-SMA (red) and proximal tubular epithelial cell marker, fluorescein isothiocyanate (FITC)-conjugated lectin from *Tetragonolobus purpureas* (green). (E) Quantitative determination of total kidney collagen contents in sham and obstructed kidneys. Data are presented as means ± SEM. $*p < 0.01$. (Adapted and modified from Yang *et al.*[59])

Figure 73–4. A pathogenetic model for the cytokine-mediated stromal reaction observed in MMM.

INTRODUCTION

1

1 Animal Models for Human Diseases

An Overview

JANN HAU

ABSTRACT

This chapter provides an introduction to the concept of laboratory animal models, focusing on a general classification of animal models for the study of human diseases. Animal models can be grouped into one of the following five categories: (1) induced (experimental) models, (2) spontaneous (genetic, mutant) models, (3) genetically modified models, (4) negative models, and (5) orphan models. This is followed by a discussion of how knowledge concerning human biology and pathobiology can be extrapolation from results obtained from studies of animals. Finally the chapter discusses how the difference in body size and metabolic rate between small laboratory animals and humans has an impact on the calculation of relevant doses for animals used as models for humans in experimental studies.

Key Words: Animal model concept, Induced animal model, Spontaneous animal model, Transgenic animal model, Negative animal model, Orphan animal model, Body size—scaling, Extrapolation, Laboratory animal science—definition.

INTRODUCTION

Throughout history ethical and religious considerations as well as social prohibitions have prevented experimental studies of human biology and pathobiology. Even studies of human anatomy were for long periods of time in history a criminal offense and thus not possible. Although impressive anatomical teaching theaters were established in many old European universities, postmortem dissection was often restricted exclusively to criminals executed for their offenses. In the more quiet corners of Europe the teaching theaters remained unused for decades. Consequently, most of our present basic knowledge of human biology, physiology, endocrinology, and pharmacology has been derived from initial studies of mechanisms in animal models.[1] Throughout history scientists have performed experiments on animals to obtain knowledge of animal and human biological structure and function.[2,3] Often such studies have not been conducted, and are not possible to conduct, in humans. This may not only be due to ethical or religious considerations. Often practical, economic, and scientific reasons make initial studies in animals the best solution for studies of a biological phenomenon.

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

Laboratory animal science may be defined as the study of the scientific, ethical, and legal use of animals in biomedical research, i.e., a multidisciplinary field encompassing comparative biological and pathobiological specialties for the optimal scientific use of animals as models for human or other species. Basic laboratory animal science is concerned with the quality of animals as sentient tools in biomedical research. It encompasses the comparative biology of laboratory animals, aspects of breeding, housing, and husbandry, anesthesia, euthanasia, and experimental techniques. For animal welfare reasons as well as for scientific reasons it is vital that scientists using animal models in their research are competent and have a good knowledge of basic laboratory animal science.

This sourcebook provides a thorough introduction to the use of animal models for human diseases. High quality animals combined with first class animal care ensure the highest possible health and welfare status of the animals and are a prerequisite for good science and public acceptance of the use of animals in research.

THE ANIMAL MODEL CONCEPT

A laboratory animal model describes a biological phenomenon that the species has in common with the target species. A key word for understanding the concept of animal models is "analogy."[4] A model should not be considered a claim of identity with what is being modeled, but a convergent set of several kinds of analogies between the "target" phenomenon to be understood and the system that is being studied as a substitute for the target phenomenon. A more comprehensive definition has been given by Held on the basis of Wessler's original definition[5]: "a living organism in which normative biology or behavior can be studied, or in which a spontaneous or induced pathological process can be investigated, and in which the phenomenon in one or more respects resembles the same phenomenon in humans or other species of animal."

What is generally understood by the term animal model is modeling humans. It is not the image of the used animal that is the focus of research but the analogy of the physiological behavior of this animal to our own (or another) species. It would thus perhaps be more correct to refer to animals as "man models" in this context. Laboratory animal science, comparative medicine, and animal experiments are indeed much more about humans than about any other animal species.[6]

The practice of studying biological phenomena and diseases in laboratory animals and transferring the findings into solutions

and treatments for improving human health and welfare has a long history and is well established in biomedical sciences. The significance and validity with respect to usefulness in terms of "extrapolatability" of results generated in an animal model depend on the selection of a suitable animal model. A good knowledge of comparative anatomy and physiology is an obvious advantage when developing an animal model. Animal models may be found throughout the animal kingdom, and knowledge about human physiology has been obtained from species far removed from humans in terms of taxonomy. A good example is the importance of the fruit fly for the original studies of basic genetics. Animal models are used in most fields of biomedical research as reflected in the respective chapters of this book.

CLASSIFICATION OF ANIMAL MODELS

A plethora of animal models has been used and is being used and developed for studies of biological structure and function in humans. The models may be "exploratory," aiming to understand a biological mechanism whether this is a mechanism operative in fundamental normal biology or a mechanism associated with an abnormal biological function. Models may also be developed and applied as so-called "explanatory" models, aiming to understand a more or less complex biological problem. Explanatory models need not necessarily be reliant on the use of animals but may also be physical or mathematical model systems developed to unravel complex mechanisms. A third important group of animal models is "predictive" models. These models are used to discover and quantify the impact of a treatment, whether this is to cure a disease or to assess toxicity of a chemical compound. The anatomy or morphology of the model structure of relevance to the studies may be of importance in all three of these model systems. The extent of resemblance of the biological structure in the animal to the corresponding structure in humans has been termed fidelity. A high fidelity model with close resemblance to humans may seem an obvious advantage when developing certain models. What is often more important, however, is the discriminating ability of the models, in particular the predictive models. When using models to assess the carcinogenicity of a substance it is essential that at least one of the model species chosen responds in a manner that is predictive of the human response to this substance. Thus the similarity between human and model species with respect to relevant biological mechanisms is often more important than the fidelity of the model. Often the two go hand in hand and high fidelity models offer the best opportunity to study a particular biological function.

An animal model may be considered homologous if the symptoms shown by the animal and the course of the condition are identical to those of humans.[7] Models fulfilling these requirements are relatively few, but an example is well-defined lesion syndromes in, e.g., neuroscience.[8] An animal model is considered isomorphic if the animal symptoms are similar, but the cause of the symptoms differs in humans and the model. However, most models are neither homologous nor isomorphic but may rather be termed partial. These models do not mimic the entire human disease, but may be used to study certain aspects or treatments of the human disease.[8]

CLASSIFICATION OF DISEASE MODELS

The majority of laboratory animal models are developed and used to study the cause, nature, and cure of human disorders. Disease models may conveniently be categorized in one of the following five groups, of which the three first are the numerically most important[9]:

1. Induced (experimental) models
2. Spontaneous (genetic, mutant) models
3. Genetically modified models
4. Negative models
5. Orphan models

INDUCED (EXPERIMENTAL) MODELS As the name implies, induced models involve healthy animals in which the condition to be investigated is experimentally induced, e.g., the induction of diabetes mellitus with encephalomyocarditis virus,[10] allergy against cow's milk through immunization with minute doses of protein,[11] or partial hepatectomy to study liver regeneration.[12] The induced model group is the only category that theoretically allows a free choice of species. Although it might be presumed that extrapolation from an animal species to the human species is better the closer this species resembles humans (high fidelity), phylogenetic closeness, as fulfilled by primate models, is not a guarantee of validity of extrapolation, as the unsuccessful chimpanzee models in AIDS research have demonstrated.[13] It is just as decisive that the pathology and outcome of an induced disease or disorder in the model species resemble the respective lesions of the target species. Feline immunodeficiency virus (FIV) infection in cats may therefore for many studies be a better model for human AIDS than HIV infection in simians. Although mice and rats have many biological characteristics in common, they do not necessarily serve equally well as models of human disease. For example, schistosomiasis (mansoni) infection may be studied in experimentally infected mice, but not in rats whose immune system is able to fight the infection effectively.[14]

Most induced models are partial or isomorphic because the etiology of a disease experimentally induced in an animal is often different from that of the corresponding disease in humans. Few induced models completely mimic the etiology, course, and pathology of the target disease in humans.

SPONTANEOUS ANIMAL MODELS These models of human disease utilize naturally occurring genetic variants (mutants). Many hundreds of strains/stocks with inherited disorders modeling similar conditions in humans have been characterized and conserved (see, e.g., www.jax.org). The best known spontaneous models include the athymic nude mouse,[15] the use of which represented a turning point in the study of heterotransplanted tumors and enabled the first description of natural killer cells. Some of these mutants were discovered almost a century ago, like the famous spontaneous model Snell's Dwarf mouse without a functional pituitary[16] and the curly tail mouse in which fetuses develop a whole range of neural tube defects.[17] Many of the mutants are available in inbred strains with corresponding coisogenic or congenic strains. This is very useful because the influence of just one affected gene or locus may then be studied against a reference strain with a genetic background similar to the mutant.

An extensive literature is available on spontaneous models and the majority of these involve mice and rat models, although a wide range of mutants in many different species has been described. A good example of the amount of information available is the publication of Migaki,[18] referencing more than 200 diseases in animals exclusively caused by inborn errors of metabolism.

The spontaneous models are often isomorphic displaying phenotypic similarity between the disease in the animal and the corresponding disease in man, the so-called face validity, e.g., type I diabetes in humans and insulin requiring diabetes in the BB rat. This phenotypic similarity often extends to similar reactions to treatment in the model animal and the human patient, and spontaneous models have been important in the development of treatment regimens for human diseases.

However, if the object of a project is to study the genetic causes and etiology of a particular disease then comparable genomic segments involved in the etiology of the disorder—construct validity—is normally a requirement. It should be remembered, however, that an impaired gene or sequence of genes very often results in activation of other genes and mobilization of compensating metabolic processes. These compensatory mechanisms may of course differ between humans and the animal model species.

GENETICALLY MODIFIED MODELS The rapid developments in genetic engineering and embryo manipulation technology during the past decade have made transgenic disease models the most important category—in terms of numbers—of animal disease models. The technology and ability to genetically modify mice resulted in a substantial increase in the numbers of laboratory animals used worldwide, which is a trend that seems to continue. A multitude of animal models for important diseases have been developed since this technology became available in the 1980s, and the number of models has increased quickly. Mice are by far the most important animals for transgenic research purposes, but farm animals and fish are also receiving considerable interest.

Many physiological functions are polygenic and controlled by more than one gene, and it will require considerable research activities to identify the contribution of multiple genes to normal as well as abnormal biological mechanisms. The insertion of DNA into the genome of animals, or the deletion of specific genes, gives rise to sometimes unpredictable outcomes in terms of scientific results as well as animal well-being in the first generations of animals produced. Thereafter transgenic lines can be selected and bred or cloned to avoid or select for a specific genotype. It is not an accurate science, although the methodology is constantly improving, with the aim of eliminating unwanted effects. The embryo manipulation procedures in themselves do not appear to affect the welfare of offspring in the mouse,[19] and the large offspring syndrome common in farm animals has so far not been reported in the literature for rodents, although it has been observed (Johannes Wilbertz, Karolinska Institute, personal communication).

Mutations induced by the use of mutagens like ethylnitrosourea is another approach to the generation of new mutants, which may serve as models of human disorders. In many aspects these mutants may be similar to spontaneous mutants and to the ones generated by transgenic embryo manipulation. The maintenance of a line raises issues for chemically induced genetic mutants similar to those for animals genetically modified through embryo manipulation.

The recent completion of the maps of the genomes of mouse (and other model animals) and humans will increase the research activities in functional genomics and proteomics, and using high density microarray DNA chip technology in human patients as well as in animals will make it possible to investigate which genes are switched on or off in different diseases.[20]

Having both the human and the mouse genome maps available, this new technology is expected to rapidly increase our knowledge on the genetic background and etiology of important diseases. This paves the way for a range of new homologous animal models with homology between animal and humans (construct validity) for genotype as well as for phenotype. This development may result in a change in animal use from models for the identification of causative genes to models for studying the effects of changes in genetic pathways, gene–gene interactions, and gene–environment interactions.[21] The characterization and application of genetically modified mouse models are slowed down by difficulties in phenotyping the animals. There is a need for accurate and reliable behavioral assessment, biotechnology development for physiological assessment, and analysis of complex data as well as training scientists in whole-organism research.[22]

NEGATIVE MODELS Negative model is the term used for species, strains, or breeds in which a certain disease does not develop, e.g., gonococcal infection in rabbits following an experimental treatment that induces the disease in other animal(s). Models of infectious diseases are often restricted to a limited number of susceptible species and the remaining unresponsive species may be regarded as negative models for this particular human pathogenic organism. Negative models thus include animals demonstrating a lack of reactivity to a particular stimulus. Their main application is studies on the mechanism of resistance to gain insight into its physiological basis. Occasionally negative models give rise to the characterization of new spontaneous (mutant) models. Examples are found in studies of infectious diseases and carcinogenicity where individuals exhibiting resistance to a treatment may be developed into new spontaneous models.[23]

ORPHAN MODELS An orphan model disease is the term used to describe a functional disorder that occurs naturally in a nonhuman species but has not yet been described in humans, and which is recognized when a similar human disease is later identified. Examples include Marek's disease, papillomatosis, and bovine spongiform encephalopathy (BSE), Visna virus in sheep, and feline leukemia virus. When discovering that humans may suffer from a disease similar to one that has already been described in animals the literature generated in veterinary medicine may be very useful.

EXTRAPOLATION FROM ANIMALS TO HUMANS

When experimental results have been generated in an animal model they have to be validated with respect to their applicability to the target species, which normally is the human. The term extrapolation is often used to describe how data obtained from animal studies reliably can be used to apply to humans. However, extrapolation is generally not performed in its mathematical sense where data fit a certain function that may be described graphically, and the graph extended beyond the highest or lowest sets of data to describe a situation outside the window of observation. Establishing toxicity data in animals and using these to determine safe levels of exposure for people is perhaps what comes closest to mathematical extrapolation in animal studies. However, most studies of animal structure and function are never extrapolated to be applicable to describing the corresponding features in humans; this is not relevant. What laboratory animal experimentation is about is very similar to other types of experiments. The scientists aim to obtain answers to specific questions. Hypotheses are being

tested and the answers obtained, analyzed, and published. As an example of this, we might question the possible health hazards of a new synthetic steroid and ask a number of relevant questions to be answered in animal studies before deciding on its potential usefulness as a human hormonal contraceptive: Does it exist in the same form in humans and animals? How does it affect the estrus cycle in rodents? How does it affect endogenous hormone levels in rodents and other species? How soon after withdrawal do the animals revert to normal cyclicity? Does it interfere with pregnancy in rodents and primates? Does it affect fetal development in rodents and primates? Is the frequency of fetal malformations in mice affected? Are puberty, the ovarian cycle, and pregnancy in rodent and dog offspring of mothers treated with the substance affected? Analyzing the data from experiments of this nature would provide information on the potential of the new synthetic steroid as a hormonal contraceptive in humans.

A large multinational pharmaceutical company survey analyzed data compiled from 150 compounds for the concordance between adverse findings in human clinical data with data that had been generated in preclinical tests in animals.[24] The concordance rate was found to be 71% for rodent and nonrodent species, with nonrodents alone being predictive for 63% of human toxicity (HT) and rodents alone for 43%. High concordance rates were found, e.g., for cardiovascular HTs (80%), hematological HTs (91%), and gastrointestinal HTs (85%). Lower concordance rates were observed, e.g., for the neurological group, because it is difficult to identify symptoms such as headache and dizziness in the animals studied. The only gastrointestinal HT that did not correlate with animal studies was, not surprisingly, nausea. One of the conclusions reached in this study was that the choice of species used might be subject to more thoughtful consideration. By tradition studies are often carried out using rats and dogs, without an open-minded consideration of whether alternative species might be more appropriate for testing a specific compound.

Although the predictive value of animal studies may seem high if they are conducted thoroughly and have included several species, uncritical reliance on the results of animal tests can be dangerously misleading and has resulted in damage to human health in several cases, including drugs developed by large pharmaceutical companies. What is noxious or ineffective in nonhuman species can be innocuous or effective in humans and vice versa. For example, penicillin is fatal for guinea pigs but generally well tolerated by humans; aspirin is teratogenic in cats, dogs, guinea pigs, rats, mice, and monkeys but obviously not in pregnant women despite frequent consumption.[25] Thalidomide, which crippled 10,000 children, does not cause birth defects in rats[26] or many other species,[27] but does so in primates. Close phylogenetic relationship or anatomical similarity is not a guarantee of identical biochemical mechanisms and parallel physiological response, although this is the case in many instances.

The validity of extrapolation may be further complicated by the question of which humans. As desirable as it often is to obtain results from a genetically defined and uniform animal model, the humans to whom the results are extrapolated are genetically highly variable, with cultural, dietary, and environmental differences. This may be of minor importance for many disease models but can become significant for pharmacological and toxicological models.

It is not possible to provide reliable general rules for the validity of extrapolation from one species to another. This has to be assessed individually for each experiment and can often be verified only after first trials in the target species. An extensive and useful overview on the problem of predictive anthropomorphization, especially in the field of toxicology research, is *Principles of Animal Extrapolation* by Calabrese.[28] The rationale behind extrapolating results to other species is based on the extensive homology and evolutionary similarity between morphological structures and physiological processes among different animal species and between animals and humans.[29]

MODEL BODY SIZE AND SCALING

The use of laboratory animals as models for humans is often based on the premise that animals are more or less similar with respect to many biological characteristics and thus can be compared. However, there is one striking difference between mouse and human, and that is body size. In proportion to their body size mammals generally often have very similar organ sizes expressed as percentage of body weight. Take the heart, for instance, which often constitutes 5 or 6 g/kg body weight, or blood, which is often approximately 7% of total body weight.

It is well known that the metabolic rate of small animals is much higher than that of large animals. It has also been demonstrated that capillary density in animals smaller than rabbits increases dramatically with decreasing body weight.[30] However, considering that most animals are similar in having heart weights just above 0.5% of their body weight and a blood volume corresponding to 7% of their body weight, it becomes obvious that in order to supply the tissues of small animals with sufficient oxygen for their high metabolic rate it is not sufficient to increase the stroke volume. The stroke volume is limited by the size of the heart and heart frequency is the only parameter to increase, which results in heart rates well over 500 per minute in the smallest mammals. Other physiological variables, like respiration and food intake, are similarly affected by the high metabolic rate of small mammals.

This means that scaling must be an object for some consideration when calculating dosages of drugs and other compounds administered to animals in experiments.

If the object is to achieve equal concentrations of a substance in the body fluids of animals of different body size then the doses should be calculated in simple proportion to their body weights. If the object is to achieve a given concentration in a particular organ over a certain time period the calculation of dosage becomes more complicated and other factors including the physicochemical properties of the drug become important. Drugs and toxins exert their effect on an organism because of the way they are metabolized, the way they and their metabolites are distributed and bound in the body tissues, and how and when they are finally excreted.

However, metabolism or detoxification and excretion of a drug are not directly correlated with body size, but more accurately with the metabolic rate of the animal (see Schmidt-Nielsen[30,31] for more details). Kleiber[32] in 1932 was the first to demonstrate that in a log–log plot of mammalian body weight to metabolism the graph forms a straight line with a slope of 0.75.

The metabolic rate of an animal as expressed by oxygen consumption per gram body weight per hour is related to body weight in the following manner:

$$M = 3.8 \times \mathrm{BW}^{-0.25}$$

where M is the metabolic rate (oxygen consumption in milliliter per gram body weight per hour) and BW is body weight in grams. This equation may be used to calculate dosages for animals of different body weights if the dose for one animal (or man) is known.[33]

$$\text{Dose}_1/\text{Dose}_2 = \text{BW}_1^{-0.25}/\text{BW}_2^{-0.25}$$

$$\text{Dose}_1 = \text{Dose}_2 \times \text{BW}_1^{-0.25}/\text{BW}_2^{-0.25}$$

These equations should be considered as assistance for calculating dosages, but caution should be exerted with respect to too broad a generalization of their use, and the 0.50 power of body weight should be employed when dealing with animals having body weights below 100 g.[34] Some species react with particular sensitivity toward certain drugs and marked variations in the reaction of animals within a species occur with respect to strain, pigmentation, nutritional state, time of day, stress level, type of bedding, ambient temperature, etc.[33]

CONCLUSIONS

The selection of an animal model depends on a number of factors relating to the hypothesis to be tested, but often more practical aspects associated with the project and with project staff and experimental facilities play a significant role. The usefulness of a laboratory animal model should be judged on how well it answers the specific questions it is being used to answer, rather than how well it mimics the human disease.[35]

Often a number of different models may advantageously be used in order to scrutinize a biological phenomenon and for major human diseases such as diabetes, a whole range of well-described induced models are available as are spontaneous models in both mouse and rat strains.

Most of the regulating authorities require two species in toxicology screening, one of which has to be nonrodent. This does not imply that excessive numbers of animals will be used because an uncritical use of one-species models may mean that experimental data retrospectively turn out to be invalid for extrapolation, representing a waste of animals. The appropriateness of any laboratory animal model will eventually be judged by its capacity to explain and predict the observed effects in the target species.[36]

The free choice of species when developing animal models is more or less restricted to the induced models making use of clinically healthy animals, in which a condition deviating from normality is experimentally induced. Although all laboratory animal species are in principle available for model development, it has been a clear trend during the past 30 years that the most popular species, the house mouse and the Norwegian rat, are increasing in popularity at the expense of farm animal species and pet species, while the use of nonhuman primates seems to remain stable.[37,38] The completion of the map of the mouse genome and the dominating position of mice in transgenic research seem to indicate that the dominance of the mouse as the most popular model for humans will increase even more in the future.

2 Selection of Biomedical Animal Models

MICHAEL S. RAND

ABSTRACT

Laboratory animals play a crucial role in research discovery and technological advances, and they will continue to take part in improving the lives of people and other animals. It is incumbent upon the researcher to know his subject well in order to provide relevant information to the scientific world. In an effort to assist the biomedical researcher in gaining this knowledge, this chapter provides the following key elements: definition of types of animal models, legislative and legal requirements, criteria for choosing a model, extrapolation validity recommendations, and descriptive features for publication.

Key Words: Animal models, Laboratory animal(s), Animal model types, Animal use criteria, Choosing animal model, Animal factors, Extrapolation, Animal description.

INTRODUCTION

Over the last one and one-half centuries, almost all medical knowledge, treatment regimes, and medical device development have involved research using animals. The key factor in using animals in research is in its extrapolatability of results to humans. Animals in research have been and still are essential in developing treatments for asthma, HIV/AIDS, cancer, birth defects, bioterrorism medical countermeasures, vaccines, antibiotics, high blood pressure, and much more. Additionally, they have been vital in the development of antibiotics, vaccines, and organ transplantation techniques.[1] As the rise in emerging infectious diseases (e.g., West Nile virus and avian influenza) continues, animals will be key and essential in the development of preventive and treatment modalities.

THE HISTORY OF ANIMAL USE IN RESEARCH

The use of animals to study human physiology and anatomy can be traced back to the second century AD in which Galen was a Greek physician and philosopher. His research was based almost exclusively on studies using apes and pigs. Unfortunately, this initiated many errors based on his accepted authority and the prohibition by the Church of using human cadavers for research purposes. Galen was later blamed for using incorrect methods in research when in truth it would be more accurate to say that he drew wrong conclusions based on uncritical interspecies extrapolation of data. That is, he assumed that all extracted information derived from his use of animals could be directly applied to humans. It was not until the late sixteenth century that this error began to be recognized.

Modern research principles can be attributed to three physiologists from the 1860s. In 1865, Claude Bernard, a French physiologist, published *An Introduction to the Study of Experimental Medicine*.[2] This book was intended to provide physicians with guidance in experimental research. It proposed the use of chemical and physical induction of disease in animals, thus becoming the first published book to advocate creating "induced animal models" for biomedical research. His peers of the time were Louis Pasteur in France and Robert Koch in Germany. Louis Pasteur and Robert Koch introduced the concept of specificity into medicine and the "germ theory of disease." The turning of the century saw the development and use of animal models for infectious diseases and screening and the evaluation of new antibacterial drugs based upon the work of these three researchers.

During the first quarter of the nineteenth century, animal studies were crucial for less than one-third of the major advances that occurred. With the contributions of Claude Bernard, Louis Pasteur, and Robert Koch, animal studies contributed to more than half of the significant discoveries made thereafter. Since 1901, two-thirds and 7 of the last 10 Nobel Prizes in medicine have relied at least in part on animal research.[3] Today, researchers rely on the identification and development of animal models to explore all avenues of medical science to include assessment of pathogenic mechanisms, diagnostic and therapeutic procedures, nutrition and metabolic diseases, and the efficacy of novel drug development.

THE CONCEPT OF ANIMAL MODELS

WHAT IS AN ANIMAL? Etymologically, the word "animal" derives from the Latin *animal* meaning soul/spirit, thus describing living organisms that are *animated.*

WHAT IS A MODEL? A model is an *object of imitation,* something that accurately resembles something else, a person or thing that is the likeness or *image* of another. The *Holy Bible* tells us that God said, "Let us make man in our image, in our likeness, so God created man in his own image, in the image of God he created him; male and female he created them." God created man out of the dust of the ground and then breathed into his nostrils the breath of life to animate him. Thus, humans are "animal models" of God.

Consequently, combining the two definitions, an "animal model" is an *animated object of imitation,* an "image of Man" (or other species), used to investigate a physiological or pathological circumstance in question.[4]

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

WHAT IS AN ANIMAL MODEL? The U.S. National Research Committee on Animal Models for Research on Aging attempted to define the term "laboratory animal model" as "an animal in which normative biology or behavior can be studied, or in which a spontaneous or induced pathological process can be investigated, and in which the phenomenon in one or more respects resembles the same phenomenon in humans or other species of animal."

Using the term animal model can be confusing because what is often meant by the term "animal model" is actually studying human conditions. In other words, it is not the image of the preferred animal that is the focus of research but the analogy of the physiological behavior of this animal to our own (or another) species. It would, thus, be more correct to speak of "human models" in this context. Indeed, although using animals in research can benefit other animals, it is much more focused on improving the human condition.

TYPES OF ANIMAL MODELS

When animals are used in research to study biological and functional systems in humans, they are broken down into the following categories:

1. **Exploratory.** Animals used in this category are used to gain an understanding of fundamental biological mechanisms, whether normal or abnormal. An example would be the use of a novel animal model of aging, particularly for identifying genes and biochemical pathways regulating longevity.

2. **Explanatory.** Animals used in this category are used to gain an understanding of complex biological problems. An example would be the use of cognitive and psychosocial animal models to provide an etiology for anorexia nervosa.[5]

3. **Predictive.** Animals used in this category are used to discover and quantify the impact of investigative treatments whether for diseases or chemical toxicities. Predictive animal testing models are important in improving the success of a drug or medical device in clinical trials and for generating new data in support of the ongoing marketing of existing products.

When animals are used in disease research, they are broken down into the following categories:

1. **Induced (or Experimental).** Induced models are ones in which normal animals are experimentally created either through surgical modifications, genetic modifications, or chemical injections. An example would be a myocardial infarction induced by coronary artery surgical ligation.

2. **Spontaneous.** Spontaneous models are genetic variants, which mimic the human condition. The variance occurs naturally through mutation and not by experimental induction. The *nu* mutation was first reported in 1966 in a closed stock of mice in a laboratory in Glasgow, Scotland. It was not until 1968, however, that it was discovered that the homozygous nude mouse also lacked a functional thymus, i.e., it was *athymic*. The mutation produces a hairless state, generating the name "nude." The other, unique defect of nude mice is the failure of the thymus to develop normally to maturity. The thymus remains rudimentary and produces reduced numbers of mature T cells. This means nude homozygotes (animals with identical mutant genes at corresponding chromosome loci) do not reject allografts and often do not reject xenografts (tissue from another species). The discovery that human neoplasms (tumors) could be grown in nude mice was immediately recognized as an important research tool. Thus, the spontaneous mutation of *nu* among laboratory mice was a serendipitous development that led to the nude mouse becoming the first animal model of a severe immunodeficiency. In the decades since, the nude mouse has been widely utilized by researchers studying factors regulating transplantable human tumor growth and cancer metastasis.[6]

3. **Transgenic.** Transgenic models are induced models in which DNA is inserted into or deleted (knockout) from the genome of the animal. The term "transgenic" was coined in 1981 by Gordon and Ruddle to describe an animal in which an exogenous gene was introduced into its genome. In the late 1980s, the term transgenic was extended to gene-targeting experimentation and the production of chimeric or "knockout" mice in which a gene (or genes) has been selectively removed from the host genome. Today, a transgenic animal can be defined as one having any specific, targeted genetic modification. Transgenic animals are most commonly produced through (1) germline modifications of gametes, (2) microinjection of DNA or gene constructs into zygotes (unicellular embryos), or (3) incorporating modified cells, including embryonic stem (ES) cells, into later stage embryos. After gamete or embryo modifications, the resultant embryos are matured to term in a recipient female.[7]

4. **Negative.** Negative models fail to react to a disease or chemical stimulus. Thus, their main use in biomedical research is for studies on the mechanism of disease resistance. A classic example is the failure of gonococcal infection to develop in rabbits after an experimental treatment that induces the disease in other animals. Negative animal models have become increasingly important with the advent of transgenic technology. For example, a novel transgenic mouse was created to study the lack of development of autoimmune thyroiditis with the injection of self-thyroglobulin. This strain of mice lacked certain surface epitopes to account for this negative reaction.[8]

5. **Orphan.** Orphan models are the opposite of negative models. Orphan models are animals in which a disease occurs but there is not a corresponding disease in humans. Orphan models may become induced models when a similar disease is recognized in humans later on. Historically, scrapie in sheep was such a model, but now is useful as a model for the human spongiform encephalopathies that are of so much concern (e.g., BSE, "mad cow disease," and CWD, chronic wasting disease in deer).

All categories above may be further subcategorized with the following divisions:

1. **Fidelity.** The extent a biological structure in an animal resembles that of a human. Thus, a high fidelity animal model gives a highly relevant biological closeness to the human structure. Model fidelity is best conceptualized as a continuous spectrum, ranging from low to high fidelity. Examples of low-fidelity models include bench models made of simple materials that often have little anatomical resemblance to reality. However, these models incorporate some of the key constructs of the simulated tasks. At the other end of the spectrum are high-fidelity models such as human or animal cadavers or the new array of virtual reality simulators. These simulators usually incorporate highly realistic visual and tactile cues in the midst of a highly interactive model. In between these two extremes, almost any kind of intermediate fidelity can exist.

2. **Homologous.** The symptoms shown in the animal are identical to those shown in the human. For instance, the recent discoveries of swine hepatitis E virus (HEV) from pigs and avian HEV from chickens afforded an opportunity to develop small homologous animal models for HEV.[9]

3. **Isomorphic.** The animal's symptoms or anatomy are similar to those in the human but the etiology or genetic character is different. For example, there is a set isomorphism between the human and mouse heart at the organ level and also at the organ part level: each species has a heart and a corresponding set of cardiac chambers (right and left atrium, right and left ventricle) and the wall of each chamber has a corresponding set of layers (epicardium, myocardium, endocardium).

4. **Partial.** These models do not mimic the entire human disease but enough similarities exist to allow their use in studying aspects of the disease or treatments. For instance, animal models of Alzheimer's disease can be created based on the accumulation of increased levels of amyloid-ß peptide in the brain and have many amyloid plaque deposits; however, they have only subtle behavioral and electrophysiological deficits, thus providing only a partial model of the human condition.[10]

5. **Face validity.** The degree to which there is a similar phenotypic display between the disease in the animal and the corresponding disease in the human. For example, it could be argued that the demonstration of drug effects in an animal model for depression after a period of chronic administration is important for establishing its face validity, but is not relevant to the model's predictiveness and therefore to its ability to serve as a screening test for treatments for the modeled disease.[11]

6. **Construct validity.** The degree to which there is a similar genetic display between the disease in the animal and the corresponding disease in the human. As an example of high construct validity, research was performed on three candidate dopaminergic genes (DRD2, DRD4, and DAT-1) that were sequenced in spontaneous hypertensive (SHR) and Wistar Kyoto (WKY) rats. No differences were found in DRD2 or DRD4 genes, but several variations were found in the DAT-1 gene that are of significance because several ADHD families show linkage to DAT-1. It also strengthened the validity of using WKY as a control for SHR, because their behavioral characteristics are similar to those of other rat strains.[12]

LEGISLATIVE AND LEGAL REQUIREMENTS FOR USING ANIMALS IN RESEARCH

Biomedical research is among the most regulated industries in the world. A comprehensive overview of global requirements can be found in the *Handbook of Laboratory Animal Science*, 2nd edition, Chapter 3.[13] Failure to comply with regulatory requirements can result in fines levied against the institution, suspension of authority to operate, permanent revocation of the facility's license, and withdrawal of public funding.

One newly regulated aspect of biomedical research not covered in this chapter occurred after the terrorist attack on September 11, 2001. The attack increased concerns in the United States for the possibility of bioterrorism using agents that would destroy human, animal, and plant life. This concern escalated the need for research that involved the development of therapeutic and preventive measures against such agents. In response, congress passed and President Bush signed into law the "Public Health Security and Bioterrorism Preparedness and Response Act of 2002" (Public Law 107–188) on June 12. The purpose of the act was to improve the capacity of the United States to prevent, prepare for, and respond to bioterrorism and other public health emergencies and to enhance the control of dangerous biological agents and toxins. The Centers for Disease Control and Prevention (CDC) is the agency with the primary responsibility for implementing the provisions of the Act with regard to human pathogens and toxins and the United States Department of Agriculture (USDA) with regard to animal and plant pathogens and toxins. The regulation provides for expanded regulatory oversight of select agents and toxins, and a process for limiting access to persons who have a legitimate need to possess, use, or store these agents. The regulation also establishes a requirement for a security risk assessment performed by the Federal Bureau of Investigation for those persons needing access to select agents and toxins. It also establishes and enforces safety and security procedures, including measures to ensure proper training and appropriate skills to handle agents and toxins; a requirement to designate an institutional Responsible Official to ensure compliance with the regulations; and a requirement to obtain a certificate of registration when there is a need to possess, use, or transfer select agents and toxins. Infectious agents labeled as "select" as determined by the CDC and USDA, registration forms, and other information concerning the Select Agents Program may be found at http://www.selectagents.gov.[14]

CHOOSING THE RIGHT MODEL

To quote the philosopher, Bernard Rollin, "The most brilliant design, the most elegant procedures, the purest reagents, along with investigator talent, public money, and animal life are all wasted if the choice of animal is incorrect." Once it has been determined that the use of laboratory animals is necessary, the most appropriate species, breed, and strain with the closest homology to humans must be chosen in order to give the research face and/or construct validity. Because new animal models are continually being identified and characterized and the field of biomedical research has become global in nature, the search for the appropriate animal model should start with a thorough literature search and a check of appropriate web sites (see Chapter 7). The Institute for Laboratory Animal Research maintains a very practical and useful search engine for this purpose.[15]

Selection of a species should not be based solely on availability, familiarity, or cost. Animals that meet these criteria may not provide the genetic, physiological, or psychological facets needed or wanted for the proposed project. It is almost impossible to give specific rules for the choice of the best animal model, because the many considerations that have to be made before an experiment can take place differ with each research project and its objectives. Nevertheless, some general rules can be given.

RESEARCH FACTORS

- Appropriateness as an analogue. Ensuring that the part or organ being studied has a function similar to the target species is vital in applying research-derived data from the chosen model.
- Transferability of information. The usual goal of research using an animal model is to define a process in a system with the hope of transferring the data gained to a more complex system. Traditionally, one-to-one modeling is

sought: modeling in one group of organisms that can be transferred to another group that has several analogous features of interest. This is especially helpful in modeling disease states. However, in modern research, many-to-many models are mainly used. This technique begins by analyzing the component parts of a process or disease, and then finding for each component analogous models in many taxa of living species.[16] This is especially helpful when a plurispecies approach is needed to gain approval for new medications or medical devices.

- Generalizability of the results. The ability to generalize results to the target species is important. Federal regulations prohibiting the unnecessary duplication of previous research highlights the importance of choosing an animal model in which testing results can be easily repeatable and verifiable on which to build new research. In May, 2006, the world was shocked when famed South Korean cloning scientist Dr. Hwang Woo-suk was charged with fraud and embezzlement when scientists could not verify his published data. In addition, if the ultimate target species is human, it is well known that this species is genetically highly variable, with cultural, dietary, and environmental differences. This may be of lesser importance in disease modeling since most diseases do not choose its victim based on genetic variability. However, this is now well known to be of importance in pharmacological and toxicological modeling and has opened up the new field of research in pharmacogenetics.
- Ethical implications. Certainly research must start with justification for using an animal at all. Federal regulations require the use of alternate methods if feasible. Alternate methods could consist of using cell lines, bacteria, computer models, or even human volunteers. The three Rs of Russell and Burch (replacement of existing experiments with animal-free alternatives, or reduction in the number of animals used, or refined methods to reduce animal suffering) help to meet the ethical concerns.[17]
- Numbers needed. Certainly consultation with a biostatistical analyst prior to submitting a proposal is highly recommended. Numbers needed to provide scientific validity, especially for publication, will impact many other factors such as cost and housing availability.
- Customary practice within a particular discipline. Caution must be displayed when using this criterion. Customary practices may not always mean that the most appropriate animal model has been used. The "customary" animal may not represent the most accurate genetic, microbiological, physiological, or psychological facets needed for the study. Historical evidence has revealed that using animal models just because others have has led to substandard results. However, customary practices when justified and supported by the other criteria listed can be a satisfactory and faster route of choosing the animal model needed.
- Existing body of knowledge of the problem under consideration. This criterion again emphasizes the need for a thorough literature search before forming the basis for the research project. The literature search will emphasize what is already known to prevent accidental duplication, but will also reveal what is not known. It will also make known published authorities in the discipline that may serve as a consultation source to prevent unnecessary and competitive research projects.
- Natural versus experimentally produced models. Unavailability of natural models will require the use of experimentally produced models. Depending on the objectives of the study, both may be needed.

ANIMAL CARE FACTORS

- Cost and availability. Certainly cost and availability are important factors when choosing an animal model, but they can be disastrous if the decision is based solely on cost and not the other listed factors. Cost also includes ongoing care not only for husbandry but also from experimental manipulations. Certainly, the best animal model can be in short supply as illustrated by the CNN news report on August 9, 2003. This report emphasized the increased demands in research due to public health crises such as AIDS and the threat of bioterrorism. The increased demands have led to a national shortage of rhesus macaques. In addition, the shortage has skyrocketed the cost per monkey.
- Housing availability. Another practical consideration in choosing the animal model is the accessibility of housing. Research animal housing requirements are stringent and may lessen the availability according to the species chosen. For instance, choosing a nonhuman primate may require the purchase of new caging and the hiring of additional personnel to provide specialized husbandry care, as opposed to choosing mice, which can be placed several to a cage and hundreds in a room.
- Husbandry expertise. Some models require not only special housing, but also special care.
- Stress factors. Stress sources from many different causes can affect the animal's physiology, biochemistry, and behavior. Sources of stress can be transportation, handling and manipulations, overcrowding, lack of environmental enrichment, and the research project itself.

PHYSICAL AND ENVIRONMENTAL FACTORS

- Ecological consequences. While the best animal model may be available only by capturing in the wild, ecological consequences must be considered in its removal. In addition, safety measures must be in place to prevent accidental escape from the research facility. A prime example is the *Xenopus* spp. frog. If it escapes, it can overrun local ponds and rivers endangering natural amphibian populations. Furthermore, care must be taken not to violate the Endangered Species Act (http://www.fws.gov/endangered/wildlife.html) or the Convention on International Trade in Endangered Species of Wild Fauna and Flora (http://www.cites.org).
- Hazardous components. Many research projects entail the use of chemicals, infectious agents, and radioisotopes. The uses of these components are highly regulated and the appropriate proper authority (Institutional Biosafety Committee, Radiation Safety Committee, Occupational Health and Safety Committee, Environmental Health and Safety Committee, and Institutional Animal Care and Use Committee) within each institution must give approval for

its use. In addition, all those who will be exposed, whether from the research side or the animal care side, must be notified.

- Environmental influences. Environmental aspects may be important to a particular animal species.[18] Environmental factors that fit into the broad categories of physical, chemical, biological, and social may impact the physiological and behavioral responses of animals. These factors include humidity, ventilation, light cycle and quality, noise, cage size and bedding materials, diet and water, and room temperature.[19] As an example, high temperature and humidity have been proven to impair memory in mice.[20]

ANIMAL-RELATED FACTORS

- Genetic aspects. Uniformity of organisms may be necessary where applicable. "This insidious evolution of the inbred genotype is known as genetic drift. It is capable of subverting the conclusions reached about comparable research results coming from different laboratories when each uses its own subline of the same inbred strain (Bailey DW, 1977)."[21] The importance and methods of preventing genetic drift in biomedical research can be found at http://jaxmice.jax.org/geneticquality/drift.html. In addition, it is important to remember that to be in compliance with the *National Institutes of Health's Guidelines*,[22] work with transgenic animals requires the approval of the Institutional Biosafety Committee as well as the Institutional Animal Care and Use Committee.
- Background knowledge of biological properties. Knowledge of biological properties such as generalized and specialized function of body components is needed in order to validate interspecies transfer of information. Certainly, a rat would not be the best choice in biliary studies due to the absence of a gallbladder. Knowing the biological properties also aids in the decision of whether the animal is a spontaneous model or must be experimentally induced.
- Ease of and adaptability to experimental manipulation. This is unquestionably a practical matter. Guinea pigs have highly inaccessible blood vessels and would be impractical in studies requiring repeated blood sampling. Prairie dogs and woodchucks can be vicious to handle; therefore, knowing the response to experimental manipulation may also influence the choice.
- Size of the animal. This item is important from several different aspects. The size of the animal impacts housing and husbandry availability. However, size is also important to consider when tissue sampling or blood collection is necessary. For instance, many proposals are rejected because the researcher failed to abide by published guidelines for removal of blood.[23] In addition, it is also important to incorporate the size of the animal into the decision-making apparatus when physiological or morphological properties such as joint strain or organ size must be identical to that of a human, especially when developing medical devices.
- Life span and age. Studies requiring components at different stages of life can certainly impact the species chosen. The average lifespan of a rat is 2.5–3.5 years, whereas it can be over 30 years for a rhesus monkey.
- Sex. The alternating cycle of hormonal production in the female gender and its influence on the data outcome must be considered when planning for the research project.
- Progeny needed. Female mice and rats can produce 5–10 progeny per month, whereas the rhesus monkeys only one or two per year. *Xenopus* sp. frogs produce thousands of ova during their lifetime, whereas mammals produce only dozens.
- Diseases or conditions that might complicate results. An excellent historical review on the struggle against pathogens in laboratory rodents can be found in Weisbroth.[24] The effects on research can be found in Baker.[25] Both publications emphasize the need for disease-free animals in research to prevent adverse effects on resultant data. Just as in human AIDS, the realm of disease-causing organisms changed with the advent of immune deficient models. Special caging and care procedures are fundamental in minimizing such infections.
- Special features of the animal such as unique responses or microflora. It is important to be familiar with unique anatomical or physiological features of the species you will be working with. The results could be quite unexpected otherwise. For example, in rabbits, the terminal portion of the ileum empties into an enlarged rounded viscus called the sacculus rotundus and not the colon as in humans. This unique feature of the rabbit is important to know when designing gastrointestinal studies.

Forming the above standards into a checklist will help to fulfill the criteria needed to choose the best model for the proposed research project. Model selection is the privilege of individual researchers, but they must be very cautious in their selection because in the end, it is up to them to convince the rest of the scientific community that they made the right choice.

Before choosing, consultations should occur with scientists who have already used the animal model. Just as with equipment purchase, communicating with previous users can be very helpful in learning unique features of the selected species, breed, and strain. Not all attributes (especially negative ones) are published, making it even more important to contact those who have experience with the animal model you choose.

Preparatory consultation should also occur with those who will be responsible for housing and maintaining the animals, as they will be the most familiar with the care of the animal and its physical and environmental needs. Preparatory consultation with the laboratory animal veterinary practitioner should also occur to discuss the animal-related factors.

EXTRAPOLATION FROM ANIMALS TO HUMANS

Extrapolation from animals to humans does not necessarily mean that biomedical research data obtained from using animals are then used to find a corollary in a human. Rather, a hypothesis is formed first based on human relevancy, and then tested on an animal. Answers are obtained, analyzed, and published based on the hypothesis. Although true in many cases, caution must be exerted in assuming that a close phylogenetic relationship or anatomical similarity guarantees an identical biochemical or physiological response in the animal. In addition, it must be realized that humans to whom the results are being extrapolated are genetically highly variable due to cultural, dietary, and environ-

mental differences. This is of minor importance when developing disease models but is highly important for pharmacological and toxicological models.

So, how can the validity of extrapolation be verified? Complete reliability cannot be guaranteed; however, following the following vital requirements will help to avoid several of the mistakes of the past and overcome problems of the future:

- *Taking a plurispecies approach*. Most of the regulating authorities require two species in toxicology screening, one of which has to be nonrodent. This does not necessarily imply that excessive numbers of animals will be used. The uncritical use of one-species models can mean that experimental data retrospectively turn out to be invalid for extrapolation, representing real and complete waste of animals. Using more than one species is, of course, no guarantee for successful extrapolation either.
- *Metabolic patterns and speed and body size must match between species.* The use of laboratory animals as models for humans is often based on the premise that animals are more or less similar with respect to many biological characteristics and thus can be compared with humans. However, there is one striking difference between mouse and human, and that is body size. In proportion to their body size, mammals generally have very similar organ sizes expressed as percentage of body weight. Take the heart for instance, which often constitutes 5 or 6 g per kilogram of body weight, or blood, which is often approximately 7% of total body weight. It is well known that the metabolic rate of small animals is much higher than that of large animals and, thus, provisions must be made to adjust the study accordingly. Drugs and toxins exert their effect on an organism not per se but because of the way that they are metabolized, the way that they and their metabolites are distributed and bound in the body tissues, and how and when they are finally excreted. Adjusted doses should include the following provisions:
  - If the object is to achieve equal concentrations of a substance in the body fluids of animals of different body size, then the doses should be calculated in simple proportion to the animals' body weights.
  - If the object is to achieve a given concentration in a particular organ over a certain time period, the calculation of dosage becomes more complicated, and other factors, including the physicochemical properties of the drug, become important.
  - Metabolism or detoxification and excretion of a drug are not directly correlated with body size but, more accurately, to the metabolic rate of the animal.
  - Some species react with particular sensitivity toward certain drugs, and marked variations in the reaction of animals within a species occur with respect to strain, pigmentation, nutritional state, stress level, type of bedding, ambient temperature, age, sex, route or time of administration and sampling, diurnal variation, and season of the year. As much as possible, these items must be controlled.[4]
- *Experimental design and the life situation of the target species must correspond.* A model cannot be separated from the experimental design itself. If the design inadequately represents the "normal" life conditions of the target species, inaccurate conclusions may be drawn, regardless of the value of the model itself.

DESCRIPTION OF ANIMAL MODELS[16]

Unlike the old days when the researcher could write in the materials and methods section "black mice were used in the study," modern obligations require an exact description of the model. The description should include the following.

- Genetic strain and substrain using correct international nomenclature.[26,27]
- Special genetic features.
- Microbial status of the animal.
- Age.
- Housing standards.
- Maintenance procedures.
- Diet.
- If used in infectious disease studies, the description should also include
  - Strain of the organism.
  - Method of inoculum preparation.
  - Route of inoculation.

CONCLUSIONS

Laboratory animals play a crucial role in research discovery and technological advances, and they will continue to take part in improving the lives of people and other animals. It is incumbent upon the researcher to know the subject well in order to provide relevant information to the scientific world. The final judgment in the choice of the animal model will always be in its ability to elucidate and predict the observed effects in the target species.

3 Improved Models for Animal Research

Rolf Sprengel, Leonid Eshkind, Jan Hengstler, and Ernesto Bockamp

ABSTRACT

Experimental animal models are critical to understand gene function and human disease. Many rodent models are presently available providing avenues to elucidate gene function and/or to recapitulate specific pathological conditions. To a large extent, successful translation of clinical evidence or analytical data into appropriate mouse models is possible through progress in transgenic or gene deletion technology. Despite these significant improvements, major limitations still exist in manipulating the mouse genome. For this reason and to maximize success, the design and planning of mouse models need good knowledge concerning the requirements and limitations of commonly used strategies and emerging technologies. The purpose of this chapter is to provide a current overview of strategies for manipulating the mouse genome.

Key Words: Transgenic mice, Knockout mice, Conditional mouse models, Cre and Flp recombinase, Tetracycline system, RNAi, Knockdown mice, Functional genomics.

INTRODUCTION

One of the central issues facing biomedical research is the need to transform *in vitro* data into knowledge about gene function in mice or humans. In this respect genetically engineered laboratory mice are an excellent tool for modeling genetic disorders, assigning function to genes, evaluating the action of drugs and toxins, and answering fundamental questions in basic science. Animal models account for factors such as age, stress, cell-to-cell communication, pathogen–host interaction, physiology, immune response, brain function, and other key issues, providing an advantage over *in vitro* assays or computer models. For example, tumor initiation, progression, and spreading cannot be recapitulated *in vitro* but can be addressed with animal models. Nevertheless, animal models represent only an experimental surrogate and results obtained from mouse experiments do not necessarily recapitulate the human situation.

Furthermore, introducing genetic changes to the germ line of the mouse may indeed identify gene function, but also might result in severe developmental consequences, complicating or preventing analysis. Embryonic lethal phenotypes, frequently associated with null alleles or compensatory pleiotropic gene expression, induced through the absence or increased gene expression, are examples that can prevent the generation of a useful animal model. To overcome these limitations and more precisely control gene expression or gene deletion in a tissue- and time-specific fashion, conditional mouse models are used and are becoming increasingly popular. Therefore, these second-generation models may significantly improve our ability to examine gene function *in vivo*.

In this chapter, we will discuss different conditional transgenic and gene-targeting techniques, as well as provide a brief overview regarding conventional mouse transgenesis and germ line gene targeting. In addition, we will examine the emerging technology to knock down gene expression *in vivo* through small interfering RNA (siRNA) methods. While this chapter is not intended to be comprehensive or to provide specific technical details, we encourage the interested reader to explore more focused reviews on this topic.[1–6]

STANDARD MOUSE TRANSGENESIS

Since the pioneering work from Gordon and colleagues reporting the successful generation of transgenic mice by microinjection of DNA into the pronucleus of one-cell embryos, the genetic manipulation of the mouse embryo has been extremely useful for creating thousands of murine models for biomedical research.[7] Today, two different methods are routinely used for generating genetically modified mice.

TRANSGENIC MICE

First there is microinjection of recombinant DNA into the pronuclei of fertilized mouse eggs or infection of germ cells/early embryos with viral vectors carrying the foreign gene.[3,8] With this technique the introduced DNA is more or less randomly inserted in one or multiple copies into the mouse genome. Typically, the recombinant constructs used for pronucleus injection are composed of a selected DNA sequence linked to a promoter or promoter/enhancer combination that determines the expression pattern and expression level of the selected DNA sequence in a given tissue or developmental stage. Using this approach, it has been possible to characterize the function of well-defined transgenic gene products, dominant negative or constitutively active gene mutations, or specifically designed proteins. Furthermore, *in vivo* suppression of a particular endogenous gene can be achieved by transgenic expression of antisense mRNA, ribozymes, and small hairpin (shRNAs) or micro-RNAs (miRNAs).[2,9–15] Besides gene products, transcriptional control elements as enhancers,

From: *Sourcebook of Models for Biomedical Research* (P. M. Conn, ed.),

silencers, promoters, or complete locus control regions can be studied using transgenic mice.[16–18]

One recurrent problem observed in transgenic mouse models are variegational position effects often disturbing or masking the specific function of the used transcriptional control elements. Theoretically, it might be assumed that after stable integration into the genome the recombinant DNA should readily manifest its predicted mission. However, many experiments reveal that the genetic surrounding of the inserted transgenic construct is modulating the expression pattern of the transgene itself.[19] Obvious reasons for positional variegation are that the injected DNA (1) integrates into or near an endogenous gene locus with strong transcriptional control activity, affecting in *cis* the promoter of the transgenic construct or (2) integrates in a chromatin structure prone to be inactivated during development, which would lead to silencing of the transgenic construct. To avoid this recurring issue, single-copy integration of transgenes into a selected target locus or the use of so-called insulator elements has been reported.[20,21] Alternatively, large recombinant constructs like bacterial artificial chromosomes (BACs) or yeast artificial chromosomes (YACs) can be used for generating position-independent transgenic mouse lines.[22,23] As one of the consequences of the genome sequencing projects, a collection of well-characterized BAC and YAC clones that cover nearly the entire human and mouse genomes is now available (for example, http://www.rzpd.de/products/clones; http://bacpac.chori.org; http://www.sanger.ac.uk). In addition to that, convenient methods for site-specific modification of BACs and YACs have been established.[24–27] However, it has to be emphasized that by the random chromosomal insertion of BAC or YAC constructs endogenous gene loci may be destroyed and also the expression of neighboring genes might be modified.[28] In case these endogenous genes will be indispensable to life, this will become obvious when the transgenic mouse variant can be maintained only as a heterozygous line.

For the above reasons, a correlation between phenotype and transgene function is obvious only when at least two independent transgenic mouse lines with identical BAC, YAC, or transgenic constructs show the same phenotype. If only one transgenic line is analyzed, it can never be completely excluded that the observed phenotype is not linked to the transgene itself but reflects the compromised expression of neighboring endogenous genes.

CONVENTIONAL GENE TARGETING

The second widely used method for the generation of gene manipulated mice makes use of pluripotent mouse embryonic stem (ES) cells. Targeted gene modification is built on the finding that mammalian cells have the enzymatic machinery for exact homologous recombination between identical (homologous) DNA sequences.[29–31] Thus precise predefined modifications of an endogenous gene are possible in cultivated mammalian cells including mouse ES cells. Genetically modified ES cells can then be used to generate gene "knockout" or "knockin" mice that carry the planned DNA modification.[32] Normally, pluripotent ES cells are injected in early mouse embryos at the blastula stage or aggregated with morula stage embryos. During embryonic development the ES cells participate in the formation of different tissues including the germ cells and as a result the embryo is composed of two different genetic backgrounds, derived either from the wild-type cells or the genetically modified ES cells. However, in case ES cells have contributed to the germ cells of the animal, offspring from these chimeric mice will harbor the desired genetic modification in the germline (germline transmission). To generate mice with a defined background, inbreeding with animals of the same genetic background as the original ES cell will produce genetically identical homozygous offspring. However, mice crossed to commonly used ES cell mouse backgrounds often poorly reproduce and are therefore difficult to expand. For this reason, for most experiments chimeric mice are crossed to mouse strains with good breeding efficiencies.

Typically, the targeting construct for homologous recombination is composed of a central core region flanked by two regions—the so-called homology arms—that are identical in sequence to the nucleotide sequence of the target region in the genome. The homology arms are required for correct site-specific integration or replacement of the endogenous gene segment by the DNA of the targeting vector. The core region of the targeting construct incorporates the planned genetic modification together with a positive selection cassette, conferring resistance to ES cells containing the targeting construct. Most of the genomic insertions of the targeting vector are random, somewhere in the genome. In a few cases a replacement of the gene segment by the targeting vector takes place. Therefore, enrichment strategies for correctly recombined ES cell clones have been developed. These enrichment strategies make use of negative selection cassettes such as the herpes simplex type 1 thymidine kinase gene or the gene for the diphtheria toxin α-chain. The negative selection cassettes are placed outside the homology arms and are lost during homologous recombination, whereas during random integration the entire targeting vector including the negative selection marker is inserted into the genome of the ES cell. This permits a counterselection against randomly integrated clones and leads to an enrichment of ES cell clones with correct trageting.[33–35] For complex multistep genome manipulations including large chromosomal deletions or translocations convenient combinations of different selection markers have been described.[34]

Most of the published gene targeted mice are summarized in several electronically searchable databases in the internet (see http://www.bioscience.org/knockout/knochome.htm, http://www.nih.gov/science/models/mouse/index.html, and http://www.informatics.jax.org/imsr/index.jsp). In addition to the already existing gene targeted mice, academic institutes and commercial companies have generated gene trapped ES cell libraries that can be used as a source for generating knockout mice. Each individual ES cell clone of such a library harbors a single integration of a viral construct, which in turn serves as a signpost for identification of the trapped gene. Recently, the major gene trapping groups have centralized the access to all publicly available gene trap ES cell lines.[36] In this portal (www.genetrap.org) a collection of at the time 45,000 well-characterized ES cell clones is available on a noncollaborative basis. In addition, gene-trap-derived gene-specific knockout ES cell clones are commercially obtainable (http://www.lexicon-genetics.com/discovery/omnibank_ebiology.htm).

Importantly, studies involving gene targeted mice have to consider the genetic background. Depending on the mouse strain that was used the *in vivo* function or loss of function of a particular gene can be very different.[37,38] For example, γ-protein kinase C knockout mice showed a considerable difference in sensitivity to ethanol that was completely dependent on the genetic background.[39] This example illustrates that the effect of a single genetic

alteration can be strongly affected by other genes and that the phenotype of a knockout mice is not a strict readout of the missing or destroyed gene but is the concerted action of the remaining genes. Therefore, in traditional genetics a phenotypic impairment of a gene knockout can be taken as just a hint for the function of a particular gene. The definitive proof is a rescue of the impaired phenotype of the knockout by, e.g., transgenic reexpression of the destroyed gene. However, the transgenic rescue of knockout mice is time consuming, expensive, and labor intensive. A simple shortcut strategy is usually applied to minimize the contribution of the individual genetic background. Knockout mice with the genetic origin of the 126SV mouse strain are crossed with C57BL6 or other inbred strains to generate F_1 hybrids that contain 50% 129SV and C57BL6 as genetic background. Next, the F_1 hybrids are intercrossed to generate knockout, heterozygous, and wild-type littermates. By analyzing knockout and control littermates from the F_1 hybrids, the influence of the genetic background is minimized since it will be very different from animal to animal. However, if this approach is used, the number of analyzed mice has to be high. As an alternative, the phenotype of the knockout can be analyzed in two very different genetic backgrounds, e.g., C57BL6 versus DBA. For this, C57BL6 and DBA congenic animals have to be generated. Congenic animals are genetically identical except for the modified region. However, 2–3 years of backcrossing to the defined mouse strain are necessary to achieve a statistically >99% homogeneous genetic background.[40] The Jackson Laboratory and the Center for Inherited Disease Research offer possible shortcuts for this time-consuming procedure that will approximately half the number of backcrosses (for more information about marker-assisted breeding see http://jaxmice.jax.org/services/speedcongenic.html and http://www.cidr.jhmi.edu/mouse/mouse_strp.html).

CONDITIONAL MOUSE MODELS

In conventional transgenic and gene knockout mice studies the clear-cut gene-function relation is hampered by several factors. Two of those factors were already discussed: the positional variegation and the genetic background. In addition, it has to be considered that the genetic manipulation is set in the early embryo at the one-cell stage. Therefore, the lack or malfunction of the manipulated gene can disturb the development. Consequently, the phenotype in adult mice might be caused by this abnormal development and not by the lack of proper gene function in adults. Likewise, the dysfunction of a particular gene can lead to the up- or downregulation of compensatory genes. Those pleiotropic compensatory effects would than mask a phenotype in adults.

A gene regulation system that permits the induction or deletion of a gene in a specific tissue or cell type at any given time would erase all the issues mentioned above. With a controlled gene switch it would be possible to study the function of a gene in a single animal before and after the gene is switched on or off. In an "off" and "on" state the genetic background and integration site are the same; the animal can develop normally since the gene switch can be turned after development and the time window for compensatory mechanism is narrow.

For this reason, it is obvious that the use of conditional mouse models is a much better choice than relying on conventional transgenic or knockout approaches. To decide which conditional animal model is most suitable, a detailed knowledge of the different established systems is essential. First, it is important to define the criteria that have to be met. The perfect regulatory system (1) should allow a tightly controlled regulation of the target gene without background activity, (2) should be reversible, (3) should be fast in induction kinetics, (4) should be effective in all target cells, and (5) should use a highly specific and nontoxic inducer.

Among the growing number of different conditional *in vivo* systems, the tetracycline (tet) regulated and the Cre-mediated site-specific recombination systems are most commonly used.[1,41,42] The scientific community has made a considerable effort to provide public resources comprising conditional mouse mutants (http://nagy.mshri.on.ca/PubLinks/indexmain.html and http://www.zmg.uni-mainz.de/tetmouse/index.htm). The activity of these initiatives provided the basis for sharing resources, valuable animal strains, and scientific information beyond the scientific scope of individual research projects. Taking a closer look at these resources prior the initiation of a conditional mouse project is therefore good practice and saves time and effort.

THE TET SYSTEM

Pioneering work from Gossen and Bujard established a general application of the *Escherichia coli* Tn10-derived tet resistance operon for regulating transgenic expression in mammalian cells.[43] In the TET system the tet repressor (TetR) is fused to the transcriptional transactivation domain VP16 of the herpes simplex virus, giving rise to the tet-controlled transactivator (tTA). In the absence of tetracycline [or other tetracycline derivatives like doxycycline (DOX), anhydrotetracycline, or 4-epidoxycycline], tTA specifically binds to the tTA-dependent promoter (Ptet) to initiate transcription of the Ptet-controlled transgene. Normally, Ptet is composed of seven copies of the tet operator consensus sequence (tetO) and a transcription initiation site (in most cases from the CMV immediate early promoter) that is placed close to the translational start codon of the Ptet transgene. If tetO7 is flanked by two transcription initiation sites (Ptet-bi), two genes can be regulated simultaneously by tTA.[44] Adding DOX to the system induces a conformational change of the transcriptional activator tTA, prevents its DNA binding, and at the Ptet promoter transcription is shut down. Thus the TET system requires two building blocks: as an effector the tet-dependant transactivator tTA and as responder a Ptet promoter-regulated gene.

The well-established pharmacological properties of tetracycline and its derivatives suggest that these compounds are safe and reliable regulators for tet-controlled gene function *in vivo*. The properties include predictable pharmacokinetics, good bioavailability and tissue distribution, known half-life times, lack of toxicity at the established working concentrations, and the ability to cross mammalian cell membranes, the blood–brain barrier, and the placenta. Until recently the only downside of using tetracycline or tetracycline derivatives in mice was a possible imbalance of the intestinal flora, which may result in diarrhea and to a less extent in colitis due to the antibiotic action of these compounds. In case unwanted antibiotic action of tetracycline or tetracycline derivatives poses a problem, 4-epidoxycycline, which is equally suitable for controlling tet on/off gene switches but lacks antibiotic activity, can be used instead.[45]

Almost immediately after the initial publication of the tTA "TET off" system in tissue culture experiments, the first report of a tet-responsive conditional mouse model provided evidence for the enormous potential of this system for reversibly controlling

gene expression *in vivo*.[46] Although this first tet-based mouse model sparked much enthusiasm, certain limitations of the TET system became obvious. Major problems included residual background activity of transgene expression in the off state, cellular toxicity of the original transactivator, low sensitivity to DOX in certain tissues, internal cryptic splice acceptors, suboptimal eukaryotic codon usage, and slow *in vivo* induction kinetics. During the last decade these problems have been addressed and an exquisite toolbox for the generation of tet-based conditional mouse models is available now.

The first major improvement of the TET system was the development of the reverse "TET on" transactivator (rtTA), which is activated and induces transcription of Ptet responder genes upon DOX administration.[47] Using the rtTA system in transgenic mice increased the speed of transgene induction, reaching in some tissues complete Ptet–gene activation in 1 h as compared to the slow activation kinetics of up to 1 week for tTA.[48,49] This marked difference in responsiveness between the tTA and rtTA system *in vivo* is explained by the metabolic half-life time of DOX in different tissues, i.e., by the fact that in certain tissues it will take some time before DOX is completely eliminated. This difference in induction kinetics can be a major determinant when designing tet-based mouse models. Using the tTA "TET off" system might permit fast shut down and slow induction kinetics contrasting with the rtTA "TET on" system suitable for immediate induction and slow extinction of tet-controlled transgene expression.

An additional initial drawback of the TET system was the occasionally observed leakiness leading to unwanted Ptet–gene expression. The Ptet leakiness was addressed by developing antagonistic repressors that silence any residual Ptet–gene expression in the noninduced state. The antagonistic repressors are heterologous fusions of a tet-responsive DNA-binding domain with a strong transcriptional repressor, capable of silencing the residual activity of a Ptet[50,50a]. This strategy uses an antagonistic combination of tTA and the repressor that—depending on the administration of DOX and either tTA or the repressor—exclusively binds to tetO7. One way to avoid leakiness of Ptet is the generation of a tet repressor mouse line that ubiquitously expresses the tet-responsive repressor and the crossbreeding of this Ptet silencer line to the leaky tet-responder mouse[51] (unpublished data from our laboratory). Alternatively, it is also possible to use constructs that express both a transactivator and an antagonizing repressor.[51–54] Finally, engineered responder cassettes containing repositioned TetO elements have also been reported to minimize leakiness of the TET regulatory system.[55,56]

High tTA and rtTA expression can lead to cytotoxicity, most probably due to pleiotropic effects of high levels of the VP16 transactivation domain.[57] Therefore, a second generation of tTAs and rtTAs was developed.[58–60] Remodeling tTA and rtTA improved several features of the TET system including increased DOX sensitivity, faster activation kinetics, improved codon usage, abrogation of cryptic splice sites, and extended DNA-binding and dimerization properties.[56,61,62] These remarkable advances helped to optimize the design of conditional mouse models and to adjust the experimental setup according to the specific needs of the planned experiment.

Since the first report of a tet-controlled transgenic mouse model, the TET system has become increasingly popular. Today the huge number of tet-based mouse models represent an invaluable resource for combinations of tissue-specific or generalized tTA (rtTA) expressing and Ptet responder mice. However, the scope of this chapter does not allow for a detailed description of already generated "tet on/off" mouse models. The reader is encouraged to visit the specialized electronic databases as an additional resource (http://www.zmg.uni-mainz.de and http://www.tetsystems.com).

Besides its fundamental appeal as an established conditional regulatory system in mice, the "TET on/off" system has attracted considerable interest because of its unique potential of reversible gene regulation. Consequently, the TET system will be an excellent choice for the study of gene function relationships, for example, in behavioral neuroscience.

SITE-SPECIFIC RECOMBINASES

The first site-specific recombination system that was used in the mouse was the Cre/loxP system.[63,64] Initially discovered in the filamentous P1 phage, the Cre/loxP system has become a valuable tool for the induction of site-specific DNA recombination *in vivo*.[65] Based on the enzymatic activity of Cre (for "causes recombination") and depending upon the position and orientation of loxP sites (for "locus of crossover P1"), mice carrying gene deletions, duplications, inversions, or chromosomal translocations can be generated.[66,67] In a similar way the *Saccharomyces cerevisiae* recombinase Flp can be used for site-specific recombination between FRT (for "Flp recombination target") sites in mice.[68] Both the Cre and Flp recombinases have been applied for the induction of ubiquitous or cell-specific recombination in mice.

The success of any recombinase-mediated conditional *in vivo* experiment depends on the "DELETER" strains that express the Cre recombinase. However, some of Cre expressing mouse lines are "leaky," with widespread instead of specific Cre-mediated recombination. Consequently, recombination will not be restricted to the anticipated cell type but will also take place elsewhere. In most cases this effect is due to the early developmental activity of the promoter driving Cre expression. Drug-inducible Cre recombinases can bypass unwanted Cre expression during development and can be used as conditional gene switches *in vivo*. This can be achieved by tTA-controlled Cre expression in triple transgenic mice. These mice harbor a tissue-specific tTA transgene, a PtetO controlled Cre, and the floxed target gene.[69,70] Another option is Cre recombinase fusions with mutant estrogen receptor binding domains that selectively bind 17β-estradiol analogues like tamoxifen.[41,71] In this scenario Cre–estrogen receptor fusion proteins are retained in the cytoplasm but are translocated to the nucleus upon addition of the synthetic ligand.

As in the TET system, protein engineering provided better recombinases including codon improved Cre and Flp enzymes, Flp recombinases with better *in vivo* activities in mammals, and modified recombinases recognizing novel target sites.[68,72–75] Again, before starting experiments, writing grants, and planning the generation of novel transgenic or knockout mice, it will be rewarding to have a closer look at already established resources (http://nagy.mshri.on.ca/PubLinks/indexmain.html).

The application of mouse lines with low Cre activity revealed that an incomplete rearrangement of the target sequence can also depend on the accessibility of the loxP sites in the target gene.[76] In addition, the observed recombination efficiencies at any given Cre indicator locus can be taken as only a first hint for the useful-

ness of a particular recombination system. Therefore, it is good practice to analyze the efficiency of the Cre-mediated recombination at the target gene for each series of experiments.

RNA INTERFERENCE

RNA interference (RNAi) is a sequence-specific eukaryotic surveillance mechanism initiated by double-stranded RNA that ultimately will result in the repression of specific target genes.[77,78] Building on the observation that in mammalian cells double-stranded RNAs (dsRNAs) of less than 30 bp will induce specific degradation of a target mRNA but will not trigger a general translational block or interferon response, RNAi knockdown technology has become very popular.[79]

In 2002 Hasuwa and colleagues reported the generation of knockdown mice and rats, thus providing direct evidence that RNAi technology can be used for studying the functional consequences of gene inactivation in animal models.[80] The relative simplicity, speed, and cost-effectiveness of using RNAi for studying gene function *in vivo* have sparked great expectations and have led to the development of an increasing number of novel tools.[2,81–84] However, there are several important issues to be considered. First, *in vivo* knockdown strategies might significantly deplete the mRNA levels of the targeted gene but might not be sufficient to abolish gene function. Second, in different tissues the level of knockdown might be variable, also being determined by the targeted sequence, copy number of the inserted RNAi transgene, and its particular integration site[85] (unpublished observations from our laboratory). Nevertheless, a partial knockdown of a gene function can be of advantage since "mild" phenotypes might in some cases be more suitable for uncovering gene function as compared to a knockout.[86] Third, an additional concern is specificity. Indeed, RNAi-mediated knockdown may not be limited to the selected target gene but instead may also affect the function of other genes, an effect known as off-targeting.[87] This issue is further compounded by the fact that our present general understanding of the different mechanisms involving short RNAs, like micro-RNAs (miRNAs) or repeat-associated short interfering RNAs (rasiRNAs), remains sketchy. For this reason, the possibility that a particular small RNA might inadvertently bring on unwanted gene regulatory effects other than the sequence-specific knockdown of the target gene cannot be excluded. For this reason, it will be essential to implement workable and standardized controls before interpreting and validating RNAi data.[88] Finally, high-level shRNA or miRNA expression might compete for limiting cellular factors and thus severely interfere with endogenous siRNA regulatory pathways.[89]

Two alternative strategies have been used for gene selective knockdown in mice: cytoplasmic delivery of synthetic short siRNA oligonucleotides mimicking the active intermediate of an endogenous RNAi mechanism or the stable expression of recombinant shRNAs or miRNAs . The first approach uses small molecules, expression constructs, or viral particles that are injected or infused in a more or less transient fashion.[90–96] Possible applications for transient knockdown experiments in mice are the testing of siRNAs as gene therapeutic tools for humans or their use in antiviral treatments.[82,97,98]

For many applications, however, the use of germ-line transmitting knockdown mice might be the preferred option. In this case the knockdown can be either mediated through ubiquitous expression of shRNAs using RNA polymerase III or tRNA promoters or, alternatively, through miRNA expression from housekeeping or tissue-restricted RNA polymerase II promoters. During the past years several groups have reported the generation of germline-transmitting knockdown mouse lines.[99–101] The methodology used for the generation of these mice is similar to the approaches discussed above including standard transgenesis or gene targeting. Likewise, conditional activation of shRNA or miRNA expression in mice has been demonstrated.[13,14,102–104] With conditional RNAi systems knockdown-induced lethality can be bypassed and loss of gene function can be studied during any given time window and/or in specific tissues.

At present, possible avenues for implementing conditional knockdown in mice either allow the permanent induction/extinction of the knockdown (Cre/loxP-based systems) or facilitate the reversible induction of a knockdown (tet on/off-based systems).

The first strategy reported for inducing conditional knockdown phenotypes in mice relied on Cre-mediated activation or extinction of shRNA expression.[14,102,103] In this situation a transcriptional and translational stop element (loxP-STOP-loxP) is placed between the shRNA transcription start site and the upstream regulatory elements, needed for shRNA expression. Upon removal of the loxP-STOP-loxP element by Cre, transcription of the shRNA or miRNA is set off and the knockdown is initiated. Conversely, this strategy also allows for conditionally removing an actively transcribing shRNA expression element and thus permanently extinguishing the knockdown.[14]

The alternative approach for generating conditional knockdown mice is to use drug-controlled systems. In this respect TET systems were applied for regulated shRNA and miRNA expression in mice. In a recent publication Szulc and colleagues demonstrated reversible silencing of an RNA polymerase III-transcribed shRNA by virtue of a DOX-dependent KRAB repressor.[13] Although RNA polymerase III promoter-based conditional strategies are normally efficient in all cell types and provide good knockdown levels, a limitation of these systems is their lack of tissue specificity. The development of RNA polymerase II promoter-mediated miRNA-based shRNA TET on/off systems overcomes this limitation and initial *in vivo* experiments demonstrated an application of this approach.[105] Similarly, recent documentation of second-generation shRNA- or miRNA-based libraries that cover most if not all predicted mouse genes provides an excellent resource for constructing conditional RNAi mouse models.[106,107]

CONCLUDING REMARKS

Within the last few years, researchers have expanded the toolbox to manipulate the expression of mouse genes by developing several novel techniques, including RNAi knock-down, improved tools for conditional gene regulation *in vivo*, and the ability to engineer large BAC clones by "recombineering". In addition, searchable databases, providing detailed information on established mouse lines, together with available collections of pre-characterized ES cell clones and libraries, will facilitate the use of genetically modified mice. Although, this chapter only provides a general overview on the use and limitations of mouse models, we hope the here provided information will serve as a primer illustrating the exciting possibilities and exquisite tools available for *in vivo* investigating gene function in mice.

General Considerations II

4 The Ethical Basis for Animal Use in Research

James Parker

ABSTRACT

The concern of biomedical researchers for the well-being of laboratory animals reflects a consensus that animals are conscious subjects. Partisans of the animal rights movement believe that researchers must go beyond the acknowledgment of consciousness and consequent attention to animal well-being. They should recognize just how similar human and animal consciousness are, and then address animal interests and animal rights. Consideration of these issues would challenge all uses, even painless uses, of animals. In any effort to identify the interests and rights of animals, even animal rights philosophers admit that the nature of consciousness and cognition—human and animal—matters. A theory of human consciousness and cognition developed by B.F.J. Lonergan is helpful in understanding and comparing human and animal consciousness. According to Lonergan, elemental wonder makes human consciousness and cognition a dynamic, self-assembling process moving from presentations given in experience through successive levels of understanding, judgment, and responsibility to the affirmation of values. Questioning sweeps humans across a divide between elementary knowing, which is shared with animals, and a type of knowing that is exclusively human. None of the animal behaviors catalogued by animal rights partisans reveals wonder and the drive to understand, affirm and decide. That drive is a single, restless activity generating successive levels of consciousness. If, as animal rights philosophers agree, animals are incapable of responsible behavior, it must also be that their cognitional feats are qualitatively different from those of humans. Absent questioning and the drive to understand, animals never emerge on the level of intelligent and rational, much less responsible, consciousness. Their cognitional achievements appear to fall within the province of elementary knowing, a realm in which they are accomplished associative learners—clever, to be sure, but not capable of the beginnings of full human knowing. Human consciousness and cognition differ enough from animal consciousness and cognition that humans claim rights while animals do not. So it is that even if we use animals in research, having vouched for their humane care, we use humans as experimental subjects only when they give informed consent. We safeguard the welfare of animals; we guarantee the rights of persons.

Key Words: Ethics, Consciousness, Animals, Biomedical, Research.

INTRODUCTION

If René Descartes (1596–1650) had not existed, animal rights philosophers would have had to invent him. They pillory this famous mathematician/philosopher for theorizing that animal operations are mechanical, not conscious—more like the movements of swans, propelled by water pressure, in the royal gardens of Versailles than like those of humans, directed by rational choices. Such a mechanistic understanding of animals, they assert, has provided justification for using them in biomedical research, even in painful experiments—something that we would never do to humans.

All philosophers today, however, are as certain as any pet owner that animals are endowed with consciousness. Except for viruses, bacteria, and, probably, insects and crustaceans, animals are aware of themselves and of the world around them that is made present by internal representations. Their movements and communication are more than the workings of mechanical stimulus and response.

Biomedical scientists are no less convinced about the existence of animal consciousness. In their professional organizations, in the laws and regulations they help draft, and in their laboratory deliberations they are keenly aware of issues about the humane treatment of research subjects that animal consciousness raises.[1] They follow and aid in advancing current "best practices" for ensuring animal well-being, keenly aware that in research institutions as well as in businesses or schools, there is always room for improving procedures.

On the topic of the existence of animal consciousness, Descartes has no contemporary disciples, philosophical or scientific. Instead, controversy swirls around the nature and degree of that consciousness. Several philosophers believe that we must go beyond an acknowledgment of consciousness and a concern for animal well-being and take into account the human-like nature of animal consciousness, address the issue of animal interests and animal rights, and challenge any use of animals, painless though it might be.

ANIMAL INTERESTS

The reputed father of the animal rights movement, Peter Singer, follows Jeremy Bentham (1748–1832), in positing that ethical reflection arises from our empathy with others in their pleasure or

pain.[2] When ethics is based on calculations of pleasure and pain it includes responsibilities not just to rational humans, but also to any creatures that experience pleasure and pain. Singer quotes a Bentham proclamation that has become "The Great Sentence" of the animal rights movement: "The question is not, Can they reason? nor Can they talk? but, Can they suffer?"[3]

Bentham proposed that we align ourselves with a hypothetical observer who is impartial, benevolent, and capable of discerning every consequence of a given action. From such a position we would be able to choose actions that achieve the greatest utility—defined as the maximum pleasure and minimum pain—for the greatest number of individuals. In our calculations, or course, "Each [individual] is to count for one and none for more than one."

Singer extends Bentham's method to animals. He does not claim that humans and animals are equal or demand that we treat them equally. He alleges that most members of the chromosomal species *Homo sapiens* are persons—they possess rationality and self-consciousness—but most animals are not. Conversely, some chromosomal humans, such as the mentally disadvantaged and senile, are not persons, while some animals such as chimpanzees clearly are.[4] Persons or not, all suffer. Consequently, even though we need not treat each sentient creature equally—it makes no sense to extend the vote to dogs—we must consider the potential pleasures and pains of each equally as we ponder how to treat them. If we give special consideration to certain individuals solely on the basis of their membership in the human species we act as "speciesists." Singer concludes:

> If the experimenter is not prepared to use an orphaned human infant, then his readiness to use non-humans is simple discrimination, since adult apes, cats, mice, and other mammals are more aware of what is happening to them, more self-directing and, so far as we can tell, at least as sensitive to pain, as any human infant.[5]

Is it permissible, then, to experiment on and/or kill anesthetized subjects? To answer this question, Singer expands Bentham's principle of pleasure and pain. He counsels us to consider not just the pleasures and pains, but also the interests and harms of those affected by any action. We can best determine interests and harms by taking account of what would be individuals' preferences. No sentient subject would prefer being experimented on and killed, no matter how painless the procedures.

Because human consciousness is more complex—human pleasures are fuller and human futures richer—the harm and the wrong involved in overriding preferences are usually greater with humans than with animals. Still, the mental life and interests of some human infants are on par with that of many animals. Consequently, we must, if we intend to experiment on and kill animals, be prepared to do the same to those babies.[6]

Singer's arguments have provoked several lines of response.[7] One contends that measuring potential pleasures and pains, interests and harms that might derive from certain actions cannot serve as a reliable guide to moral decision-making. There is a limit to how well scientists can peer into the future. Seldom can they see clearly the connection between a given experiment and a new treatment, or forecast with accuracy the number of its potential beneficiaries. Scientists are explorers, not clairvoyants.[8]

Fellow traveler in the animal rights movement, philosopher Tom Regan, makes a second critique, faulting Singer for the "morally callous" idea that the ends justify the means. When Singer proposed that some human/animal sexual acts might not be wrong—after all, they could be mutually satisfactory—a piqued Regan responded:

> "The end does not justify the means" is a moral truth that applies beyond the boundaries of our species . . . As a utilitarian, he [Singer] believes that right and wrong depend on how much satisfaction results from our actions, an outlook that leads him to accept many practices that advocates of animal rights reject.[9]

Regan also notes that because utilitarian ethics aggregates interests and harms—the total of harms weighed against the sum of interests—it is a rickety defense for small numbers of laboratory animals, whose harms might be outweighed by the benefits achieved for many humans.[10]

Still another response asks if Singer doesn't undermine his utilitarian starting point by allowing that the harm of killing humans is usually greater than that of killing animals. He makes it appear, after all, that even for him the nature of consciousness and cognition matters very much in ethical theory.

ANIMAL CONSCIOUSNESS AND RIGHTS

Consciousness and cognition matter. Regan and animal rights lawyer Steven Wise base their arguments on this conviction.[11] They hold that animals are conscious in a way that requires not only humane treatment but also respect for the right of never being used for food, companionship, entertainment, or research.

Wise argues that common law should treat chimpanzees and possibly other animal species not as property but as persons. As persons they would enjoy at least some of the same rights as young children or profoundly retarded adults. Among those rights is that of not being caged and not being subjected to medical research.

Rights, Wise asserts, must rest on something objective, and that something is the conscious mind that makes us capable of giving responsible direction to our lives:

> cognition is a very big deal because the fundamental legal right of animals, the least porous barrier against oppression and abuse that humans have ever devised, depends on it.[12]

Wise describes several apparent similarities between human and animal consciousness and cognition. Then, counseling us to take three aspirin before we read on, he presents his distillation of the "ten top theories of consciousness."[13] Evidently, he believes that if philosophers and neuroscientists are stymied in head-splitting disagreement about the nature of human consciousness, then there is little reason to deny it—whatever it may be—to animals.

There is no need for such abject surrender. Regan, for one, goes to great lengths to define consciousness and cognition. By consciousness he means the awareness that mammals have of their environment, and by self-consciousness he means the awareness of oneself. Regan claims self-consciousness for many species of animals because they act on beliefs and in fulfillment of desires, which requires that they experience themselves as identities in time and know the world in the continuum of time and space rather than as something always new and singular.

By beliefs and desires, Regan means certain mental states underlying animal behavior. When my dog Fatigué, for example, sees me standing at the door with his leash, he wags his tail and paws my leg. According to Regan, Fatigué both believes that we are going for a walk and desires to get going. He has internal

representations of the world around him, and can associate immediate representations (me at the door, leash in hand) to representations in his memory (previous walks). Moreover, his tail-wagging indicates that he has a welfare that matters to him. He is responding to more than a mindless physiological drive.

Fatigué's beliefs, Regan allows, are not as sophisticated as our concepts.[14] He may believe that a particular bone is good to gnaw on, whereas we can add the belief that the bone is part of a skeleton. Fatigué has few of the beliefs that make up a human concept. Still, he and other animals have beliefs, rudimentary as they may be.

Regan's contention requires that we inquire into animal consciousness and cognition. Is it so like ours that it can be said that animals possess rights and animal research is a moral wrong on par with experimentation on human subjects?

HUMAN CONSCIOUSNESS

The well-known philosopher of consciousness Daniel Dennett encourages us to "first devis[e] a theory [of consciousness] that concentrate[s] exclusively on *human* consciousness . . . and then look and see which features of that account apply to which animals, and why."[15] A good guide in the task of devising a theory of consciousness and cognition is the philosopher and theologian Bernard J.F. Lonergan.[16]

Lonergan begins by noting that conscious operations involve some sort of awareness that is missing in processes such as the growth of a beard. That awareness is immanent in cognitional and volitional acts: seeing, hearing, touching, feeling, smelling (all acts in the process of experiencing); imagining, thinking, conceiving (all acts in the process of understanding); reflecting, testing ideas, marshaling evidence, affirming and denying propositions (all acts in the process of judging); and taking stock of feelings, considering values, making decisions, committing ourselves (all acts in the process of willing). Unless we are in a dreamless sleep or coma, we are involved in these operations.

Each of these operations makes objects present to us. In other words, each is an act of knowing or willing objects, whether those objects are external stimuli or internal feelings. Because they make objects present (involving what Regan calls "consciousness"), Lonergan calls them intentional. Simultaneously and without any reflection or "bending back," each of these acts makes us present to ourselves. Because they make us present to ourselves (involving what Regan calls "self-consciousness"), Lonergan calls them conscious. It is because we—humans and animals alike—are present to ourselves (conscious) that objects can be present to us, or known.[17] Consciousness is the self-awareness that makes the knowledge and willing of objects possible.

Conscious and intentional operations (hereafter simply called conscious operations) are activities in a dynamic process that unfolds on four distinct but integrated levels. On the first level, we experience presentations that are given in acts of sensing and feeling—sounds and sights, odors, tastes, and feelings, both external and internal. All of these presentations, because they deliver objects, involve a type of knowing. We know the surroundings of sight, sound, smell, taste, and feel; of here, there, up, down, and over; of before and after; and of association ("A, then B"). While brewing the coffee, weaving in and out of traffic, or raking the leaves we know a taken-for-granted world.

It is obvious that animals share with humans this knowing that Lonergan calls elementary knowing. They, too, live in the taken-for-granted world, the world that is spontaneously and expected to be "out there" and real.[18] Elementary knowing allows animals to win sustenance, bear offspring, and stave off predators.

Due, however, to the spontaneous awakening of wonder, humans emerge from their habitat into the universe through a second type of knowing. What Lonergan terms full human knowing begins with questioning that transforms the presentations given in acts of sensing. Lonergan notes:

> if at moments I can slip into a lotus land in which mere presentations and representations are juxtaposed or successive, still that is not my normal state. The . . . world of mere impressions comes to me as a puzzle to be pieced together. I want to understand, to grasp intelligible unities and relations, to know what's up and where I stand.[19]

By virtue of a drive to find the cause and explain, solid, taken-for-granted surroundings are shot through with questions. We are puzzled by what might be causing that noise under the hood of the car, that ache in the back, that turmoil in the Middle East. Driven by the desire to understand we emerge on a second level of consciousness, the level that Lonergan designates as that of understanding. We continue attending to the objects perceived on the first level of consciousness, but we attend to them as questioners so that our consciousness is the awareness of a self that is puzzled, inquiring, and, at least sometimes, understanding. Figuring out a math problem, solving a crossword puzzle, or discovering clues in a murder mystery, we search for suggestive images and adopt a strategy of supposing ("What if . . . ?"). Then, suddenly—usually in a moment of rest after strenuous mental exertion but still with our suppositions—we generate a set of explanatory relationships, an understanding that is not present in sensations and feelings themselves. We relax in delight, "Ah, that's it!" Insight, or understanding, has occurred.

Notice that we can bend our native wonder back on itself in an effort to understand our own cognitive and emotional states. As we seek to understand the process of sensing, understanding, judging, and deciding, we make objects of these cognitional and volitional activities. All the while, of course, we remain aware of ourselves as inquiring, judging, and responsible subjects. We are introspectively conscious.

Insight, thrilling as it might be, is not the end point of human knowledge. The dynamic desire to know and decide—Lonergan calls it the eros of the human spirit—continues to unfold, impelling us next to check if our understanding is correct. On this third level of consciousness, what Lonergan calls rational consciousness, we ask, "Is this really so?" We marshal evidence for the concepts and hypotheses that formulate our insights. Scientists devise ways to test their hypotheses, and all of us draw up mental lists of conditions that have to be fulfilled before we can make ordinary judgments that something is true. Eventually our weighing of an idea leads to another insight when we discover that we have indeed fulfilled the conditions for saying, "This is so, this is true."

Most often we weigh conditions and come to insight about their fulfillment instantaneously—think of how quickly we are sure that we have gotten a joke. The rapidity of judgment can cause us to neglect how personal and significant is the act itself. In the act of judgment, as we satisfy ourselves that we are being neither rash nor indecisive, we take personal responsibility for the truth of an idea or the validity of a hypothesis. We realize that we are about to affirm or deny not only that something is true, but

also and simultaneously that we are authentic knowers, in touch with what is.

Full human knowing, which implicitly includes affirmation by the knower that he or she is indeed a knower, comes to term in judgment. But the heart remains restless; persistent questioning now turns into deliberation. It opens a gap between what we have affirmed to be and what might and what ought to be. Again, the capacity for introspection becomes crucial. We take stock of feelings about what is, seek to understand those feelings, and assess how those feelings should guide decisions and actions. We ask, "Whence this passion? What is the nature of this fear? Does this friendship call for truth telling or dictate discreet silence?" Our self-awareness becomes the awareness of a subject in the throes of deliberation. Questioning launches us from the domain of fact into the uneasy realm of values. Consciousness acquires the name of conscience.

Values, of course, do not already exist in an "out there" reality. It is we who generate values in the process of judging our insights into the data of inner and outer experience. Whether we can say with confidence that something is really true and then truly valuable depends on whether we have paid good attention to the data, made sense of the data in insight, and stand prepared to take responsibility for a judgment of fact about what *is* and then for a judgment of value about what *ought to be*.[20]

The fact that we generate values and attempt to direct our lives in accord with them is the source of the claims that we make on each other. The inescapable burden of having to choose reveals both my freedom and my responsibility. I must decide what to do, and I must decide that in relationship to others who appear to possess the same consciousness. My choice is both a claim on others and a response to their claim on me. These claims are what we call rights.

This account of the dynamic desire to know what is, determine what should be, and commit ourselves to what is truly worthwhile reveals the crucial importance of wonder. In questions that express wonder, humans strive to understand, wrestle with the difference between the real and the apparent, and ponder what is to be done or not done. Questioning makes human consciousness and cognition a dynamic, self-assembling process moving from presentations given in experience through successive levels of understanding, judgment, and responsibility to the affirmation of values. Along the way, questioning sweeps us across a divide between elementary knowing, which we share with animals, and a second type of knowing that Lonergan calls full human knowing.

A final comment on Lonergan's analysis of conscious cognition: in its basic structure, it is not revisable. We cannot deny or revise our account of the process without employing the very same operations that we have outlined—operations of sensing, understanding, judging (affirming/denying), and deciding.

HUMAN AND ANIMAL CONSCIOUSNESS COMPARED

Following Dennett's counsel, my present task is to "look and see which features of [the above] account apply to which animals, and why." I propose to do that in reverse order, beginning with consciousness on the fourth level, the level of conscience. Neither Singer, nor Regan, nor Wise claim responsible consciousness for animals. Instead, they claim that its absence in animals is no more significant, morally and legally speaking, than its absence in infants, or in senile or mentally exceptional humans. Singer believes that treating such marginal human beings any differently that animals constitutes "speciesism," and Regan argues that these exceptional persons—he calls them moral patients in contrast to moral agents—are possessors of rights.[21]

Even animal rights philosopher Mary Ann Warren objects to the ethical relevance of occasional conditions or exceptional cases.[22] Infancy, senility, and mental incompetence are conditions that all of us have experienced or will experience in our lifetimes. And, just as we know in a rough and ready sort of way the difference between being conscious and unconscious, so we also know the difference between a smart animal and an exceptional child. Unlike Fatigué, whose lack of moral agency is something expected, a child with a dog's mental capacity is received into the world as an unexpected cause for grief and extra care.[23]

If animals do not function on the level of responsible consciousness, do they operate on the level of rational consciousness and full human knowing? We can surmise that none of our philosophers of animal rights would argue that animals take responsibility for the truth by affirming or denying that something is or is not the case.

They might contend, however, that animals operate on the second level of intelligent consciousness and have "aha" moments. In fact, it is here that Regan and Wise, who offer several examples of animal cunning, attempt to blur any distinction between humans and animals. I will return to those examples presently, after drawing attention once again to Lonergan's distinction between elementary knowing, on the one hand, and full human knowing, on the other. It is certain that animals are conscious. And, to be sure, they know their surroundings and act smartly in their habitat. Still, we must ask if they do so with wonder and its expression in that imperious desire to know and to decide that both initiates full human knowing and grounds human rights.

Regan, unfortunately, gives us no account of the characteristic human activity of questioning. Understandable as such an omission is—people today tend to think of knowing in terms of information rather than activity—it skews the picture. Paying no attention to the activity of asking questions, Regan fails to notice how significant the difference is between existing as a sentient subject of a life on the one hand and existing as a sentient, understanding, rational, and responsible subject of a life on the other. It is only with the full human knowing and willing generated by questioning that we enter into the realm of responsibility, morality, and law.

What goes on in strictly elementary knowing—that is, what goes on in Fatigué's mind—can be inferred from behavior. Much behavior, human and animal, appears to be coded in genes that evolution has selected for survival. Weeds mimic plants, viruses trick the immune system, birds build nests, predators stalk their prey, and people react to threats with "fight" or "flight" instincts. Such behavior involves no conscious knowing.

Other behavior, although selected by blind evolution, is conscious and based on associative learning. Humans and animals connect behavior "A" with consequence "B," a fact that makes it possible for humans to train children as well as pets. Fatigué's behavior of standing ready at the door, wagging his tail, can be explained by his having connected a past walk to a present image of me with his leash. That association suffices to create expectation; he does not question the image of me with the leash, and

thus he will never say to himself, "He looks tired; maybe we ought to skip the walk tonight." As Stephen Budiansky comments:

> The intelligence of learned associations of this sort lies in part outside the animal's brain. It is not what is inside the head, but what the head is inside of—to use William Mace's felicitous phrase . . . the rationality of the world.[24]

Finally, some conscious behavior, still based on a capacity selected in evolution, entails not just associative learning, but also wonder and its products—insights, judgments, and values. Humans go beyond the givenness of presentations to develop theories, understand causation, reflect on thoughts and emotions, formulate values, and act to bring about our various visions of utopia.

Applying Occam's razor—one should choose the simplest adequate explanation of any phenomenon—we must ask if any of the many examples and stories of animal cunning require the insight, judgment, and responsible decision-making that are generated by questioning and characterize Lonergan's full human knowing. Fatigué's behavior tells us this much: in addition to undergoing vital processes such as the formation and nutrition of skeletal and muscular structures, he knows and desires things around him. Nevertheless, he probably does so in an elementary way. Curious as he may appear as he puts his nose to smells on his walk, he is not motivated by the drive to understand. When he has marked his territory, he goes on his way through a habitat that is anything but a world shot through with questions.

Is this supposition supported by observation? We can briefly review the fascinating literature of ethology by asking if any of four types of behavior manifests a type of knowing akin to full human knowing, which is initiated by questioning, or, rather, a type of knowing, which, however sophisticated, resembles elementary human knowing.

FEATS OF KNOWLEDGE Marian Dawkins explains that many vertebrates possess mental representations, carry around cognitive maps of food stores, retrieve hidden objects, sort and classify objects, count, and make and use tools.[25] Mice, to cite an example of tool making, use their excrement to plug vents carrying toxic cigarette smoke into their cages, probably acting on a learned association that we would express as "This (feces) here, then this (no smoke)." All such feats of knowledge and tool making remain within the scope of elementary knowing, in which animals associate "here" with "there," "before" to "after," "this means (a finger extended by a piece of straw) to that end (ants within the hill)."

SELF-REFLECTION Gordon Gallup reports that chimpanzees recognize themselves in mirrors and claims that this behavior proves their ability to reflect on themselves.[26] Dorothy Cheney and Robert Seyfarth, much more cautious, distinguish self-recognition—an ability to distinguish oneself from others that does not imply any awareness of doing so—from self-consciousness—a "meta-awareness" in which a subject can watch not just the mirror but himself looking into the mirror and thus have access to what is going on in his own mind. "There is ample evidence from studies of children . . . that many aspects of self-recognition do not require self-reflection."[27] Chimps not only know and reach for where they itch or feel pain but also recognize as part of themselves the hand they see in a mirror as it moves to the troubled site. Children rapidly acquire this same ability. In addition, however, and at about the time they begin asking questions, they begin to advance beyond such self-recognition to self-reflection as they turn the attention of inquiring intelligence upon their experience of such mental presentations. The different abilities of chimp and child correspond to the two types of knowledge, elementary and full human knowing.

ATTRIBUTION OF MENTAL LIFE The ability to attribute a mental life to others reveals the capacity for reflecting on one's own mental life. Humans come to such introspection by dint of questioning presentations of sense and feeling. If it were true that animals predict and attempt to change others' behavior because they understand that minds and intentions underlie that behavior, it would suggest that they can perform the introspection that we have claimed only for full human knowing.

Cheney and Seyfarth provide a careful analysis of the anecdotal and experimental evidence that chimpanzees possess a theory of mind. They conclude that even the most compelling examples of chimps acting as if they recognize that other individuals have beliefs—examples of apparent teaching and deceiving—can be explained in terms of animals' keen observation of behavior and their ability to follow associative ("A" then "B") rules to change that behavior.[28]

LANGUAGE To use a language is to employ signs or pictures or even words to fulfill a demand, obtain a reward, or achieve a desired end; to understand language is to employ the same instruments not just as means to ends, but also as conveyances of meaning. Computers can be programmed to use words. What they cannot do is understand themselves or understand the events of another's mind to which words point.[29]

Wise, who concedes that chimpanzees mostly employ signs as means of obtaining food or fulfilling human commands, is impressed that some chimps have demonstrated the use of more than 3000 words. But children at about the age of three years and without any specific training begin to go beyond the mere use of words to an understanding of thousands of words and the rules for joining them in an infinite number of novel combinations that express meaning in their minds and the minds of others.[30] For them, a word is a sign, or one thing standing for another, and also a symbol into which their minds and the minds of others can read significance.[31]

In summary, none of the animal behaviors catalogued by Wise reveals an underlying activity of asking questions or a basic capacity for wonder. All appear to fall within the province of elementary but not full human knowing. As chimpanzee researcher Daniel Povinelli notes, chimpanzees do not have an ambition to explain the world. Speculating about what would happen if he asked both a 3-year-old child and a chimpanzee why the chicken crossed the road, he concludes the following:

> For the three-year-old, the question is an opportunity to attribute feelings to the chicken and to make up a story—for example, the chicken must have missed its mommy and spotted her on the other side of the road. The chimpanzee has a much simpler answer: 'Yes.'[32]

It was Darwin who observed that the difference between human and animal consciousness is one of degree, not kind. It was also Darwin who noted that there is an enormous practical difference between humans and animals. Humans, he said, are the only "utopian animals."[33] It is the performance of asking questions that sweeps us into the realm of conscience and makes us "utopian animals." But that performance is a single, restless activity generating successive levels of consciousness. Just as it makes human

behavior responsible, it also makes some acts of knowing acts of understanding. If nonhuman animals are incapable of moral behavior, then, most likely, their cognitional feats are qualitatively different from ours. In the absence of questioning, they probably never emerge on the levels of intelligent, rational, and responsible consciousness. They are clever associative learners in elementary knowing, but probably not capable of the beginnings of full human knowing.

CONCLUSION: THE USE OF ANIMALS IN RESEARCH

Two overarching issues frame ethical reflections on the use of animals in research. The first is the issue of pain and suffering. The ground of the contemporary concern for animal pain—ground on which philosophers, scientists, and the general public stand together—is an unchallenged consensus that most vertebrate species are conscious. Scientists are morally and, ever since the Animal Welfare Act of 1966, legally bound to ensure the well-being of laboratory animals.[34]

The second issue is that of animal use. If animal consciousness is no different than that of humans, then any use of animals—as pets, as a source of food and clothing, as subjects of research, even when painless and certainly when it involves their death—is as morally reprehensible as the use of humans for the same purposes. The argument of this chapter is that human consciousness and cognition are evidently different enough from animal consciousness and cognition that humans can claim rights while animals cannot. So even if we use animals in research, having vouched for their humane care, we use each other as experimental subjects only when we give informed consent. We safeguard the welfare of animals; we guarantee the rights of persons.

8. Singer allows the use of animals when it is clear that small harm to few animals is outweighed by great benefits for many humans. Such cases, however, are very few. Biomedical research—especially basic research—does not proceed in a straight line from a handful of animals to certain specific persons. Ten years after declaring that the routine use of hundreds of thousands of laboratory animals in research "without the remotest prospect of significant benefits for human beings or any other animals" is ethically unacceptable, Singer heralded experiments in which experimentally damaged nervous systems of rats were repaired with stem cells derived from embryos. (Cf. Singer P. Sense and sentience: We might not need pig hearts if the ban on human embryo experiments were lifted. *Guardian* August 21, 1999:24.) Singer touted these experiments because they could lead to the practice of growing tissues for the repair or replacement of damaged organs, thus eliminating the need of temporary animal transplants for patients on human organ waiting lists. This research, however, depended on decades of basic research, much of it conducted with little understanding of its role in stem cell therapy and all of it involving the routine use of thousands of laboratory rats. None of it would have been approved if Singer's moral calculus had been used prospectively.

28. See Cheney D, Seyfarth RM.[27] Ever tentative, the two scientists leave open the possibility that chimpanzees possess a very limited theory

of mind. They may share another's feelings just as we spontaneously flinch at another's pain or grin at another's laugh, and they may be aware that feeling states such as pain underlie actions such as grimaces. Wise identifies such fellow-feeling as an "implicit theory of mind," while Lonergan names it the intersubjective and "potential meaning" of experience. Whatever it is called, it seems qualitatively different from an explicit theory of mind, which requires that one hold and compare two different states of mind, one's own and that of another. The ability to do that requires the introspection and active questioning of full human knowing.

29. So it is that the closest any language translation software has come to a meaningful alternative for "The spirit is willing, but the flesh is weak" is "The wine is good, but the meat is spoiled."
30. See Wise SM (2000, 221).[11] Cf. Trefil J. *Are We Unique?: A Scientist Explores the Unparalleled Intelligence of the Human Mind.* New York: John Wiley & Sons, Inc., 1997:55.

32. Wheeler D. With ingenious experiments, a psychologist studies the mental lives of chimps. *Chron Higher Ed* June 25, 1999:B2.
33. Cited in Budiansky 1998, xv. Compare contemporary philosopher Charles Hartshorne, cited in Derr TS. Animal rights, human rights. *First Things* 1992;20:23–30, who, although sympathetic to animal rights issues, notes that the human/animal difference is "so vast that for many purposes one can safely forget that it is a matter of degree."
34. What constitutes animal well-being, we should note, is not immediately obvious. Counterintuitive as it seems, rats, for example, may be put on edge by being placed in larger cages. Researchers have an ethical obligation to advance knowledge about animal well-being, asking ever-new questions that lead to new and sometimes revised judgments and gradually round out the picture of humane animal care.

5 Bibliographic Searching Tools on Disease Models to Locate Alternatives for Animals in Research

A Website Companion

Mary W. Wood and Lynette A. Hart

ABSTRACT

Nonvertebrate and vertebrate models are commonly used in research to study diseases that affect humans and animals and to clarify disease etiology and methods for disease prevention and treatment. The relevant information on models is published in a variety of resources and then indexed among free and proprietary databases. New searching tools specifically developed as a companion to this book can now be freely accessed at a designated website created as a companion for the *Sourcebook of Models for Biomedical Research*, where user-friendly searches can be executed at any time according to stored instructions, in a variety of databases pertaining to the relevant disease models. Some databases are freely available, such as PubMed, AGRICOLA, TOXLINE, and NCBI, as well as specialized resources such as FishBase and the JAX Mice Database. Other useful databases are proprietary, such as PsycInfo and Aquatic Sciences and Fisheries Abstracts. The website can be accessed: http://www.vetmed.ucdavis.edu/Animal_Alternatives/sourcebook.html.

Key Words: Animal models, Laboratory animal(s), Animal model types, Choosing animal model, Diseases, Alternatives, Disease models, Nonvertebrate, Vertebrate, Databases, Searching, Websites.

INTRODUCTION

Both nonvertebrate and vertebrate models are commonly used in research to study diseases that affect humans and animals and to clarify disease etiology and methods for disease prevention and treatment. A wide range of databases, both free and proprietary, are available to draw from when searching research literature on these topics.[1] Existing tools that use search filters in the PubMed database simplify identifying strains of mice as appropriate disease models.[2] In this chapter we describe other improved methods for effective literature searching for disease models, and present some new efficient strategies and tools for searching that are available in a new website companion for the *Sourcebook of Models for Biomedical Research*.

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

SEARCHING FOR A RANGE OF POTENTIAL MODELS Anyone can quickly become frustrated trying to monitor and locate the relevant information on published research concerning disease models. Following the current literature, which is so widely dispersed, can seem an overwhelming task. The pertinent information is published in numerous journals and books and then organized and indexed among a variety of databases, some of which are freely available and others that are proprietary. New searching tools are now available in a website specifically developed as a companion to this book. The searching tools can be freely accessed at a designated website, where user-friendly searches can be executed at any time according to stored instructions,[3,4] in a variety of databases pertaining to the disease models described in this volume. The databases include those freely available and linked on the website, such as PubMed, TOXNET, AGRICOLA, TOXLINE, and NCBI, as well as specialized resources such as FishBase and the JAX Mice Database. Proprietary databases available by subscription are also listed, such as ISI Web of Science, PsycInfo, and Aquatic Sciences and Fisheries Abstracts (ASFA). We have previously developed comprehensive search grids to facilitate bibliographic searching on topics related to alternatives for veterinary medical education.[5–7]

WEBSITE ON MODELS AND DISEASES As described below and covered extensively in the interactive website, a working list of topics addressed by searching tools (using a variety of databases and resources) has been selected from the following, including nonvertebrate and vertebrate animal models by species: sea urchin embryo; budding yeast; fungus; social amoebae; round worm; *Drosophila*; bees; *Xenopus*, fish, and other aquatic animals; mice; rats, guinea pigs, hamsters, rabbits, and ferrets; large and farm animals; exotics; cats and dogs; and nonhuman primates. Searching tools are also organized by disease, including aging, AIDS, alcoholism, Alzheimer's disease, atherosclerosis, diabetes, eye diseases, hearing disorders, lung cancer, multiple sclerosis, neurodegenerative diseases, obesity, acute and chronic pain, Parkinson's disease, posttraumatic stress, renal disease, sepsis, thrombosis, and wound healing. The website was developed as a companion to the *Sourcebook of Models for Biomedical Research* and can be accessed: http://www.vetmed.ucdavis.edu/Animal_Alternatives/sourcebook.html.

The website offers direct links to particularly relevant databases and other resources, and indicates which ones are likely to be especially useful for particular models or diseases. In addition, the website includes some stored searches in complimentary databases, termed embedded search templates, that can be launched at will. With these templates, users can use point-and-click technology to avail themselves of the currently available literature on a particular topic, and then make the search instruction more specific to their needs. The search templates generally draw on the high-speed, comprehensive PubMed database, or TOXLINE or NCBI; all are freely available to anyone.

RELEVANT LEGISLATION AND REGULATIONS REGARDING ALTERNATIVES For each use of animals, scientists are required by the USDA's Animal Welfare Act[8] and the related USDA Policy 11[9] and Policy 12[10] to complete animal use protocols that include questions on possible alternatives to procedures causing more than momentary pain or distress, whether in teaching, research, or testing. While researchers seeking improved methods or completing animal-use protocols often find it difficult to locate the relevant information, searching the literature regularly could result in identifying an improved animal (or even yeast or fungus) model for a particular disease. The regulations require that principal investigators provide a written narrative in the protocol concerning the availability of alternatives, including the methods and sources used to determine the availability of refinements, reductions, and replacements. USDA animal care Policy 11 provides a detailed description of painful and distressful procedures. Policy 12 offers detailed guidance on the investigator's description of the database search for alternatives, including the names of the databases searched, the date the search was performed, the period covered by the search, and the key words and/or the search strategy used. Considering the ongoing creation of new animal models and the development of new technologies, frequent searching and consideration of alternatives are appropriate so as to identify and consider new methods and models. This chapter addresses a gap facing scientists by presenting user-friendly searching tools that are targeted toward (1) locating animal models and (2) conducting effective bibliographic searches on animal models and diseases, as required for animal use protocols. These tools simplify searching by providing streamlined access to the resources being sought. Facilitating efficient and effective searching by users can improve the research and simplify compliance with USDA requirements.

REVIEWING DATABASES BY ANIMAL MODEL OR SPECIES

Browsing among the databases pertinent to animal models can be a useful place to begin, to gain familiarity with the array of resources. We have sorted the databases, including 20 complimentary databases, 10 other resources, and 10 proprietary databases listed here, so that users can quickly explore the topics of greatest interest, whether they be animals or diseases in general, or particular animal models or diseases.

POTENTIAL ANIMAL MODELS As shown in Figure 5–1, a large number of complimentary databases are available that pertain to animal models. Some of them have more specialized purposes. For example, ECOTOX, INVITTOX, and TOXNET pertain specifically to toxicology testing, indicating substances that may play an adverse role in certain diseases. FishBase and oneFISH deal with literature on fish. AGRICOLA covers the general literature on veterinary medicine, and PubMed covers the general literature on human medicine. DTIC and DoD Biomedical Research are sites developed in response to military needs, but have general applications for psychological stress and wound healing.

A variety of other complimentary resources are available that are useful in finding animal models. Of particular note are the resources dealing with mice, including the International Mouse Strain Resource, the Mouse Models of Human Cancers Consortium, and the NCI Mouse Models. Ensembl Genome Browser taps into the expanding genomic developments.

Other databases are available as proprietary products. Many institutions subscribe to some of these, so users may have ready access to them at their worksites. One of the most useful of these, ISI's Web of Science, offers web access to citation information, allowing a search for all papers that have cited an earlier work. This feature, previously known as *Citation Index*, offers a feed-forward in tracking papers that have cited a classic work to follow significant lines of research. PsycInfo has good coverage of the human psychological literature, and sometimes addresses pain and stress topics in more detail than PubMed, with an added value of going back to very early literature. CAB and Biosis offer more comprehensive coverage of the European literature and the biology literature than either PubMed or AGRICOLA. Zoological Record covers a broad base of literature on animal behavior of many species and goes back to the earliest references. Fish & Fisheries Worldwide is another database that is essential for people working with fish. ERIC is a database specialized for accessing the literature pertaining to education.

NONVERTEBRATE MODELS Identifying useful models for a study not involving mammals, or perhaps not even vertebrates, offers a potential for reducing the pain or distress that may result from interventive procedures. A growing number of such models are proving useful. Studies using these can be easily accessed, as indicated in Figure 5–2.

Sea Urchin Embryo Search templates offer point-and-click instantaneous searches of some topics where sea urchin embryos have been useful, including cellular activity, the role of metals in early development, and transcription. Other search templates launch TOXLINE or HSDB, two resources on toxicity that are less well known, retrieving studies pertaining to cellular mechanisms and substances with adverse impacts on cellular activity.

Yeast Yeast has proven useful in studies of drug design, glucose, and DNA, topics for which search templates are provided. The DNA search retrieves studies on DNA damage from exposure to toxic substances.

Fungus The use of nonanimal models, such as fungi, can be reviewed in search templates that reveal studies of circadian oscillations in fungi, as compared with other organisms.

Social Amoebas Specialized databases for the social amoebas include DictyBase and Dicty Workbench. Embedded searches focus on cytokinesis, signal transduction, and development.

Round Worm The round worm has become a preferred model for studies of aging that relates to studies of human mitochondria. The database, WormBase, is an important special resource for studies of *Caenorhabditis elegans.*

Fruit Fly *Drosophila* has longstanding importance as an animal model for genetic studies, as reflected in the special database, Homophila. Search templates here pertain to using the fruit

fly for studies of hearing, balance, neurodegenerative models, and aging.

Bees Studies of alcohol effects are conducted on nonvertebrates, bees. These studies are easily accessed in an embedded search.

VERTEBRATE MODELS A number of vertebrate species are familiar in laboratory studies, primarily the aquatic vertebrates and the small mammals. The fish, frogs, and other aquatic animals, and the mice, rats, and other small mammals are readily accessed as shown in Figure 5–3. Less commonly studied, but also used as models, are large and other farm animals, exotic animals, dogs and cats, and nonhuman primates; searching strategies for these species are presented in Figure 5–4.

Fish, Frog, and Other Aquatic Animals The use of fish has expanded in recent years, in many cases as a vertebrate replacement for mammals. Specialized resources are most appropriate

for searching on these species, including the complimentary FishBase, oneFISH, *Xenopus* Resources, Zebrafish Gene Collection, and ZFIN, and the proprietary ASFA and Fish and Fisheries Worldwide.

Mice Despite the growing number of nonvertebrate and fish models, mammals are essential for some studies. In mainstay models for studies in which a mammal is essential, the number of mice used far exceeds any other mammal. As examples, the search templates use mice as models for various diseases, for studies of Alzheimer's disease, and for studies of obesity. Specialized databases such as the JAX Mice Database and the Mouse Biology Program are important when searching for appropriate strains of mice. Specialized strategies for searching with search filters also can be employed.[2]

Rats, Guinea Pigs, Hamsters, Rabbits, and Ferrets Rats are frequently used as models in a wide range of studies where an animal larger than a mouse is needed. Other small mammals are used in specific research, such as ferrets in studies of *Helicobacter* and guinea pigs in hyperlipidemia. With these species, AGRICOLA provides coverage of some research that complements PubMed. The complimentary ANZCCART Fact Sheets provide practical information on basic parameters for working with small mammals.

Large and Other Farm Animals For agricultural animals, AGRICOLA invariably provides more comprehensive coverage of the research than PubMed. The FASS Guide is available at modest cost, providing another valuable resource on agricultural animals.

Exotic Animals Specialized databases are more effective when searching on exotic animals than PubMed, which is targeted specifically toward biomedical research and misses some important work utilizing exotic animals.

Dogs and Cats AGRICOLA is worthwhile for searching literature pertaining to dogs and cats, as is PubMed.

Nonhuman Primates Specialized databases are useful in locating literature on nonhuman primates, especially the complimentary PrimateLit, with research dating back to 1940.

REVIEWING DATABASES FOR ANIMAL MODELS BY DISEASE

Researchers face a dual challenge, to keep updated not only with regard to new animal models, but also concerning new work on the particular disease of interest.

DISEASES IN GENERAL As with animal models, a wide range of complimentary databases and resources is available for browsing, as indicated in Figure 5–5.

SPECIFIC DISEASES To provide useful examples of search strategies, four embedded search strategies are indicated in Figure 5–6 for each listed disease. For the embedded search templates stored concerning each of the specific conditions and diseases, two searches for each disease draw from PubMed, one focusing on a specific research strategy on a relevant topic for that disease and another addressing models for that disease. A third search for each disease draws from TOXLINE, the National Library of Medicine's bibliographic database for toxicology, covering the full range of effects of drugs and other chemicals, including biochemical, pharmacological, physiological, and toxicological effects. The fourth search for each disease uses NCBI (National Center for Biotechnology Information), offering an extended

- Sepsis
- Thrombosis
- Wound healing

CONCLUSIONS

A website companion for the *Sourcebook of Models for Biomedical Research* developed by the UC Center for Animal Alternatives offers streamlined access to information concerning animal models for disease. The site offers expeditious links to relevant databases and provides embedded stored search examples for effective searching for models. The site can be used as an instructional tool to demonstrate how to search in these

subject areas. The examples offer a starting point that a user can, with growing experience, use as a springboard for further searching.

ACKNOWLEDGMENTS

The extensive electronic library holdings of the University of California make it possible to explore, identify, and distinguish the unique features of the resources presented in these search grids. Hsin-Yi Weng creatively contributed to much of the developing technology offered in this chapter.

6 NIH Policies on Sharing of Model Organisms and Related Research Resources

J.P. Kim, Charlene Cho, and Norka Ruiz Bravo

ABSTRACT

The National Institutes of Health (NIH) has long recognized that the sharing of research materials and data is critically important to the progress of biomedical research. Effective sharing of research resources benefits the public by facilitating and promoting discovery across the full spectrum of the research community. In this spirit, the NIH Model Organism Sharing Policy builds upon extant NIH sharing policies to allow the NIH to continue to support and promote broad and enabling research effectively and efficiently. This chapter provides guidance, sample plans, approaches, and other resources for investigators considering how best to share model organisms and related research resources with the research community.

Key Words: Model, Organisms, Data, Federal, Funding, Grants, Sharing, Research, NIH, Policy.

INTRODUCTION

Model organisms have played a critical role in the history of biomedical research.[1] As tools of discovery and a means to demonstrate proof of concept, they have been pivotal in a broad range of seminal events, including among others, developing a vaccine against smallpox, testing the artificial heart, and discovering the genetic basis for lactose intolerance.[2] The sharing of research materials, including model organisms and associated data, has also been critically important in the progress of biomedical research.[3] Common use of model organisms by research laboratories has provided scientists with the opportunity to verify research results, explore previously unsuspected mechanisms of disease, and study complex biological questions using an integrative, holistic approach.[4]

As a public sponsor of biomedical research, the National Institutes of Health (NIH) is committed to supporting national and international efforts that encourage the sharing and dissemination of important research resources. This chapter will discuss the policies of the NIH on the sharing of model organisms and related research resources and its significance to biomedical research, as well as approaches and considerations of how such resources might most effectively be shared, consistent with NIH funding policies.

EVOLUTION OF NIH SHARING POLICIES

FROM PUBLICATION TO SHARING OF RESEARCH TOOLS TO DATA AND ORGANISMS The NIH is a part of the U.S. Department of Health and Human Services and is the primary federal agency responsible for conducting and supporting biomedical research in the United States. With a history dating back to 1887, the NIH has played a prominent role not only in biomedical research, but also in the dissemination of research results and materials to the research community.

As a steward of federal funds and in keeping with its mission, the NIH has formulated policies regarding the sharing of research resources made possible as a result of public funding (see Table 6–1). The concept of sharing research results has remained a constant element of NIH grants policies, including those related to unique research resources. An early Public Health Service (PHS) Grants Policy Statement set the stage by stating a seminal principle for federally funded research: "Project directors and principal investigators are encouraged to make the results and accomplishments of their activities available to the public."[5] A May 1980 Special Announcement was published in the NIH Guide for Grants and Contracts regarding the "NIH Policy Relating to Reporting and Distribution of Hybridomas Produced Under Grants and Contracts."[6] This was followed by additional announcements highlighting the importance of sharing.[7] The Bayh-Dole Act, P.L. 96-517, passed into law on December 1980 to stimulate research and development of government-funded research, prompted additional reminders about the importance and value to scientific research of sharing research resources.[8]

THE NIH POLICY ON SHARING OF MODEL ORGANISMS FOR BIOMEDICAL RESEARCH

After consultation with the research community, the NIH announced its Policy on Sharing of Model Organisms for Biomedical Research (NOT-OD-04-042) on May 7 2004.[9] Under this policy, NIH applications that result or may result in new, genetically modified variants of model organisms are expected to include a plan for sharing those organisms and related research resources. The policy is based on existing NIH Grants Policy [NIH Grants Policy Statements (http://grants.nih.gov/grants/policy/#gps)], including the NIH Research Tools Policy, and essentially serves as implementation guidelines for earlier policies.[10,11] As such, this

Table 6–1
Highlights in the evolution of NIH sharing policies

Year	*Policy*	*Publication*
Pre-1980s	Policy encouraging making the results and accomplishments of NIH funded activities available to the public	PHS Grants Policy Statement, October 1976
1980	Policy on reporting and distribution of hybridomas produced under grants and contracts	NIH Guide Supplement, May 1980
1984	Policy on reporting and distribution of unique biological materials produced with NIH funding	NIH Guide Notice, March 1984
1996	Biological materials policy: "Handling Non-Election of Title to Patentable Biological Materials"	NIH Guide Notice, May 1996
1999	NIH research tools policy: "Sharing of Research Resources: Principles and Guidelines for Recipients of NIH Research Grants and Contracts on Obtaining and Disseminating Biomedical Research Resources"	Federal Register Notice, December 1999
2003	2003 NIH data sharing policy: "Final NIH Statement on Sharing Research Data"	NIH Guide Notice, February 2003
2004	NIH model organism sharing policy: "NIH Policy on Sharing of Model Organisms for Biomedical Research"	NIH Guide Notice, May 2004

policy applies to extramural investigators and institutions that are funded by a variety of mechanisms (see below). Although this policy does not apply to NIH intramural investigators, the NIH intramural research program has guidelines that are consistent with those for the extramural community (for example, see http://www1.od.nih.gov/oir/sourcebook/ethic-conduct/resources.htm). Accordingly, the NIH advocates that investigators share such resources across the entire research community. The policy assumes that sharing will take place in a manner consistent with accepted practice. For example, new, genetically modified model organisms developed with NIH funding may be shared as mature organisms, sperm, eggs, embryos, or even the vectors used to generate transgenic or knockout organisms.

RATIONALE FOR THE SHARING POLICY The NIH Model Organism Sharing Policy contributes to scientific progress by making new resources available more quickly to a large number of people and obviates the need to use limited resources and investigator time to reproduce previously developed model organisms. With the Model Organism Sharing Policy, the NIH expects that new, genetically modified model organisms and related resources generated with NIH funding will be distributed and shared with the scientific community in a timely manner (i.e., at least upon publication of the primary results announcing the development of the genetically modified model organisms).

This expectation serves to fulfill the mission of the NIH: "Science in pursuit of fundamental knowledge about the nature and behavior of living systems and the application of that knowledge to extend healthy life and to reduce the burdens of illness and disability." Sharing of model organisms and related research resources allows the biomedical community, including students, postdoctoral fellows, and investigators, to engage in new scientific research and training opportunities, which can extend the scope of inquiry beyond that envisioned by the original creator of the animal strain. As a result, sharing research resources is likely to result in more rapid breakthroughs for the diagnosis, prevention, and treatment of disease than a single investigator could achieve alone.

Broad access and use of research resources also contribute to the many goals of the NIH, including "promoting the highest level of scientific integrity, public accountability, and social responsibility in the conduct of science." Sharing of model organisms allows investigators a chance to verify research results, reduces needless and costly duplication of effort, and serves as a form of insurance against unforeseeable loss of research resources (e.g., disasters such as floods, fires, and power outages that have resulted in the loss of valuable mouse strains and other resources). Thus, everyone benefits from the sharing of research resources, including investigators, the scientific community, and the public.

Indeed, sharing is good practice.[12] Journals such as *Proceedings of the National Academy of Sciences USA, Cell, Nature, Neuron, Immunity, The Journal of Immunology, The Journal of Neuroscience*, and *Science* require investigators to make unique resources available so that research results can be verified and additional research promoted. Both the Society for Neuroscience, with a membership of 29,000 scientists, and the Federation of American Societies for Experimental Biology (FASEB), consisting of 19 societies and a membership of 66,000 scientists, have taken positions that are consistent with the NIH policy. For example, the policy of the Society for Neuroscience is that "unique and propagatable research materials used in studies being reported must be made available to qualified scientists for bona fide research purposes"(see http://www.sfn.org/index.cfm?pagename=responsibleConduct_authorsOfResearchManuscripts and http://www.sfn.org/skins/main/pdf/Guidelines/ResponsibleConduct.pdf) under section 1.8 of "Guidelines: Responsible Conduct Regarding Scientific Communication," Society for Neuroscience, 1998.[13]

MODEL ORGANISMS DEFINED For purposes of the NIH Model Organisms Sharing Policy, the NIH uses the term "model organism" to describe both mammalian (e.g., mouse and rat) and nonmammalian models (e.g., budding yeast, social amoebas, roundworm, *Arabidopsis*, and frog). Genetically modified model organisms are those in which spontaneous mutations have occurred and/or those in which mutations have been induced by chemicals, irradiation, transposons, or transgenesis (e.g., knockouts and injection of DNA into blastocysts). Congenic or consomic strains are also considered genetically modified model organisms. Detailed information about model organisms can be found on the NIH Model Organism for Biomedical Research website (http://

www.nih.gov/science/models/). Publications and electronic databases as well as websites of stock centers and repositories that list available strains also make the identification of model organisms relatively easy.

SCOPE OF THE POLICY The policy covers both model organisms and related resources. Related resources include materials and data necessary for the production and understanding of model organisms, such as vectors, nonhuman embryonic stem cells, established cell lines, protocols for genetic and phenotypic screens, mutagenesis protocols, and genetic and phenotypic data for all mutant strains. As a matter of practice, genetic variants of viruses, bacteria, and other prokaryotic organisms should be made widely available. At this time, however, the NIH is not expecting the submission of a sharing plan from investigators who intend to develop noneukaryotic organisms.

It should be noted that this NIH sharing policy applies only to nonhuman model organisms. For example, human cells that are not commercially available would not be subject to this policy. For information on regulations, policies, and guidelines for human subject specimens, see http://grants2.nih.gov/grants/policy/hs/specimens.htm.

Unlike the related, but distinct, 2003 NIH Data Sharing Policy (http://grants2.nih.gov/grants/guide/notice-files/NOT-OD-03-032.html), which applies to projects requesting $500,000 or more in direct costs in any given year,[14] the NIH Model Organism Sharing Policy applies to all projects that produce or may produce model organisms or related resources. In other words, the NIH expects that all investigators pursuing projects that would or could result in model organisms and related resources will include a sharing plan in their applications, regardless of the requested budget amount or final amount awarded.

FUNDING MECHANISMS AFFECTED With respect to NIH grant mechanisms, this policy applies to all research project grants (R mechanisms) and Centers (P mechanisms) as well as to Small Business Innovation Research (SBIR) and Small Business Technology Transfer (STTR) awards. The policy also applies to individual Career Development awards (Ks) if the scope and aims of the project include the development of model organisms. By contrast, institutional training grants (Ts) or individual fellowships (Fs) are not subject to the policy, but sharing would be applicable to such grantees as the production of model organisms presumably would be covered under a mentor's research grant. This policy also applies to cooperative agreements and to contracts from the NIH that will generate model organisms and related resources as described above.

It should also be noted that this policy applies to all tiers of a funding agreement, including international collaborations and foreign grants. For example, if the U.S. institution is the primary grantee, then it would be the responsible for its subgrantee or subcontract arrangements and would be expected to ensure that this policy is adequately addressed in the application. In some cases, different subprojects will have different sharing plans, or only one or a few of the subprojects will need sharing plans. Regardless of how many parties are involved or who is designated as the primary grantee, it is important to state clearly in the application which party [e.g., Principal Investigator (PI) or head of the subproject] will be responsible for the implementation of the proposed sharing plan(s).

DEVELOPING SHARING PLANS When submitting sharing plans to the NIH under this policy, such plans should provide information to ensure that sharing will be meaningful for other investigators in the community. For example, the following information should be addressed.

How novel strains will be made available to the scientific community, including the following:

- The form in which the investigator/institution will provide the organisms (e.g., adults, embryos, sperm).
- Related research resources and data that the investigator/institution will provide.
- A reasonable time frame for periodic deposition of material and associated data.
- Whether the investigator/institution will share under its own auspices or use a repository, and, if a repository, which one.
- For vertebrate animals and for other species for which pathogens or contaminants are potentially serious problems, how the investigator/institution will maintain the strains to minimize the risks of infection or contamination.

How technology transfer and intellectual property issues will be addressed, including the following:

- How the institution plans to make such organisms and resources widely available to the research community.
- How the institution plans to make certain any rights or obligations to third parties are consistent with the terms and conditions of the NIH award to ensure appropriate dissemination of model organisms or related research resources under the NIH award.
- A description of the mechanisms that will be used to distribute organisms and related research resources [e.g., material transfer agreements (MTA)].

Sharing plans may vary, depending on the organism, the nature of the resources that will be shared, the extent of intellectual property issues involved, and plans for distributing the resource(s), as well as the particular programmatic goals. The actual content and level of detail included in a sharing plan will be affected by several factors, such as the status of the development of a model organism, the potential impact of intellectual property rights on the availability of the model organism, and the method of sharing. Therefore, the NIH recommends that the investigator contact the funding Institute or Center about the level of detail expected.

Samples of sharing plans for model organisms and related resources may be found at http://grants.nih.gov/grants/policy/modelorganism. These three sample plans have been provided below to assist the applicant community in responding to this policy when submitting a funding application to the NIH:

- A *simple plan* that may be appropriate for a project, which has the goal of producing a model organism but has not produced one (Organism Sharing Simple) (http://grants.nih.gov/grants/policy/model_organism/model_organ_simple_plan.doc).
- A plan for *sharing mice* (Organism Sharing Mouse) (http://grants.nih.gov/grants/policy/model_organism/model_organ_mouse_plan.doc).
- An example of a *complex plan* for sharing mice with IP held by various parties (Organism Sharing Complex) (http://grants.nih.gov/grants/policy/model_organism/model_organ_complex_plan.doc).

Sharing plans may also take into account practical limitations. For example, if a large genetic screen is conducted and thousands of lines are generated, only a few of them may display a phenotype that is of interest to laboratories. Generally, the investigator in such a case would not be required to maintain and distribute all the lines. Similarly, if knowledge of their existence is limited to a publication in which they were described as being used in a cross and do not demonstrate a specific phenotype, there would be no need to maintain or distribute those lines. However, if the collection of lines was generated with NIH funding and with the purpose of serving as a community resource, then there would be an obligation to share the lines.

There are certain instances in which sharing of a resource may not be appropriate. For example, an investigator would not be expected simply to redistribute a resource acquired from another source. However, if that resource is used to breed, construct, or generate another resource using NIH funds, there would be an obligation to share the derived resource. In any case, if no sharing plan is included in the NIH application, the applicant would be obligated to state why sharing would be restricted or not possible. Failure to provide an adequate sharing plan may affect the NIH's decision to make an award. Equally important, failure to comply with the submitted and accepted sharing plan may be considered in future funding decisions for the investigator and the investigator's institution.

GENERAL RESOURCES AND CONSIDERATIONS FOR THE DISTRIBUTION AND SHARING OF MODEL ORGANISMS AND RELATED RESOURCES Sharing of model organisms and related resources is not intended to be challenging for the research community, and yet depending on circumstances (e.g., demand or supply), responding to requests for model organisms can be costly and labor intensive. Also, there could be other considerations that may need to be taken into account when transferring materials.

To minimize administrative burdens and to help streamline the processing of such requests, the NIH recommends that developers deposit their model organisms with existing repositories, which would provide for ready, long-term access by the biomedical research community. Repositories such as the Mouse Models for Human Cancer Consortium (http://emice.nci.nih.gov/), the Mutant Mouse Regional Resource Centers (http://www.mmrrc.org/), the Rat Resource and Research Center (http://www.nrrrc.missouri.edu/), and the Zebrafish Information Network (http://zfin.org/) are among some of the examples of repositories funded by the NIH and should be viewed as valuable resources for the sharing of model organisms.

If submitting the model organisms with a repository is not an option, the NIH also offers funds for research resource sharing. Applicants may request funds in their applications for expenses associated with sharing model organisms and related research resources, including administrative supplements for unanticipated expenses associated with sharing.

Whether it is through a repository or through the auspices of the developer, distributing model organisms and related research resources developed with NIH funding should occur in a manner consistent with the NIH Research Tools Policy. The majority of unpatented transfers to not-for-profit entities should occur under terms no more restrictive than the Uniform Biological Materials Transfer Agreement (UBMTA) (http://www.autm.net/aboutTT/aboutTT_umbta.cfm) or the Simple Letter Agreement (SLA) (http://www.nhlbi.nih.gov/tt/docs/sla_mta.pdf). The provider may specify whether the model organism can be distributed to other parties. If the materials are patented or licensed to an exclusive provider, other arrangements may be used, but terms providing for commercialization option rights, royalty reach-through, or product reach-through rights back to the provider are inconsistent with the NIH Research Tools Policy.

When NIH-funded materials are being transferred to for-profit entities that intend to restrict their use internally, recipients should ensure that the materials are transferred with the fewest encumbrances possible. The SLA may be expanded for use in this instance, and internal-use license agreements with execution or annual use fees may be appropriate, depending on circumstances.

Ascertaining which type of agreement to use in transferring materials can present quite a challenge. It is important to keep in mind that if no agreement is used in obtaining a material, there may be no applicable restrictions. Consequently, it is best to confer with the technology transfer office of the investigator's institution for guidance on such matters.

CONSIDERATIONS FOR DEVELOPERS AND PROVIDERS OF MODEL ORGANISMS The NIH Model Organism Sharing Policy states that the NIH expects the submission of sharing plans from investigators whose projects will or could yield new, genetically modified model organisms or related resources. Further, if a given project unexpectedly results in new, genetically modified model organisms or research resources, it would be appropriate to share the model organisms, consistent with NIH grants policy. Consulting with the NIH program official and including a sharing plan in the next noncompeting application or in a separate letter would also be considered appropriate in such a situation.

Since sharing plans can be highly complex and can involve issues pertinent to intellectual property, these plans should be consistent with NIH guidelines and in consultation with individuals who have expertise in this area. These experts could be staff from an institution's sponsored research office, technology transfer office, or office of general counsel. Such consultation often will clarify a given institution's policies regarding sharing and distribution of research resources such as mutant mice as well as its policies regarding intellectual property. Parties developing and/or providing research resources should ensure that research use rights are retained for noncommercial research purposes, which are consistent with practices supported by the Association of University Technology Managers (AUTM) and the Council on Governmental Relations (COGR).

If sharing plans for NIH awards are in conflict with obligations (i.e., title to the invention) to third parties (e.g., company X), NIH-funded parties will need to revise any such agreements so that they are consistent with the terms and conditions of the NIH funding award. For guidance regarding this issue, see the 2003 NIH Grants Policy Statement,[15] as well as "Developing Sponsored Research Agreements: Considerations for Recipients of NIH Research Grants and Contracts"[16] and "Intellectual Property Reporting for NIH Grantees That Also Have Involvement with the Veterans Administration."[17] Nonprofit institutions that wish to waive or assign title of inventions developed under an NIH funding award to another party must obtain approval from the NIH, except where such an assignment is made to an organiza-

tion that has as one of its primary functions the management of inventions and are subject to the same provisions as the funding recipient.

As a term of award, it is the responsibility of the NIH-funded party to ensure that rights to inventions, such as model organisms and related research resources, arising out of NIH funding agreements are properly assigned to the institution. Failure to comply with NIH research resource sharing policies and the accepted plan may be considered by the NIH program staff in future funding decisions for the investigator and the investigator's institution.

An example of the Personal Benefits of Reserving Research Use Rights for the Research Community If the developer of a model organism reserves research use rights for at least noncommercial research purposes across the research community, this not only protects the nonprofit institutions, but it can also protect the developer of the mouse later on in his or her career. For example, in one scenario, a scientist is both an investigator at nonprofit institution A and the Chief Scientific Officer of for-profit X. While at nonprofit A, the investigator develops a model organism. The investigator does not want any competitors to have access to the resource, and therefore asks nonprofit A to license exclusively all rights for this resource to the investigator's for-profit X, while retaining a research use license only for nonprofit A. The investigator is terminated from both nonprofit A and for-profit X. The investigator moves to nonprofit B, hoping to continue the research, but can no longer access the resource because for-profit X refuses to provide access to the investigator and nonprofit A is not permitted to provide the resource to any third party. If a research use license had been retained for all nonprofit research institutions, the investigator would have been able to continue the research at nonprofit B unhindered.

CONSIDERATIONS FOR REQUESTORS AND RECIPIENTS OF MODEL ORGANISMS NIH sharing policies seek to ensure that research tools and results are made available to the biomedical community in a timely manner for furthering the research enterprise. Publications are the major medium by which the biomedical community learns of research results. When model organisms are reported in publications, users of the shared resource should acknowledge the source (repository and/or investigator) and reference the original citation describing the strains in their publications.

This citation helps identify the specific material used by identifying the source. Standard genetic nomenclature should be used to designate the strains. Scientific custom is to name providers of materials as authors if providers collaborate with recipients of organisms and contribute intellectually to the manuscript. Otherwise, it is appropriate for providers to be acknowledged as the source of research resources upon which the manuscript is based. This acknowledgment most appropriately appears in the Materials and Methods section of the publication.

As noted previously for developers and providers of model organisms, requestors and recipients of model organisms or related research resources produced with NIH funding should be mindful of the policies regarding inventions arising out of NIH funding agreements, including issues related to intellectual property. For example, if the recipient is employed by a not-for-profit institution (e.g., university) and conducts research with a model organism that results in a patentable invention, title to the invention must be properly assigned to the not-for-profit institution.

REVIEW AND EVALUATION OF SHARING PLANS When a sharing plan is submitted as part of the funding application, the Scientific Review Group, or study section, will comment on the adequacy of the sharing plan. Reviewers will be asked to describe their assessment of the sharing plan in an administrative note and, except in defined circumstances, will not include their assessment in the overall priority score. For some special initiatives, such as Funding Opportunity Announcements (FOAs) specifically directed to the development of model organisms, reviewers may be asked to integrate their evaluation of the sharing plan with other review criteria and factor their assessment into the overall evaluation of scientific merit. Any concerns must be resolved before an award can be made. Program staff, who will review sharing plans before making funding recommendations, should be the first point of contact for resolving sharing plan deficiencies.

Whether a sharing plan is reasonable can be determined by the reviewers on a case-by-case basis, taking into consideration the organism or related resource involved, the timeline, the applicant's decision to distribute the resource or deposit it in a repository, and other relevant considerations. For mechanisms other than special FOAs, the presence or adequacy of a plan should not enter into the scoring of the application. The sharing plan itself should be discussed after the application is scored and reviewer comments recorded in an administrative note. For special initiatives and research mechanisms, where the text of the announcement specifically includes the adequacy of a sharing plan as a review criterion, the adequacy of the plan will be discussed by the reviewers and will figure into the score. Finally, it should be noted that budget review would be part of the overall review consistent with usual NIH practice.

PROGRESS REPORTING AND MONITORING OF SHARING Grants management staff will ensure that an acceptable sharing plan is referenced in the Notice of Grant Award (NGA) either by the standard reference to the funded application or by specific reference to a revised plan. The NGA is a binding legal document. The terms and conditions incorporate, and the grantee accepts, the terms once funds are drawn to conduct the project. The Grants Management Officer works with the NIH program staff to complete this process and address enforcement if the plan is not followed. Recognizing that circumstances can change, grants management and program staff will work with grantees to renegotiate sharing plans as necessary. Each Institute or Center will determine an appropriate response, consistent with the NIH guidelines, if the terms and conditions of the award are violated.

Annual progress reports should report the number of sharing requests received and the number fulfilled when submitting a noncompeting renewal progress report, as well as the Final Progress Report.

As the expectations and tools available to facilitate model organism sharing continue to evolve, maximum flexibility is encouraged to allow for renegotiations during the project period at the request of either the Institute/Center or the funded institution in response to materially new and/or unforeseen information or developments. Sharing plans should be discussed with the appropriate NIH program contact who can work with the developer to modify the sharing plan accordingly.

It should also be noted that the sharing plan holds for the life of the grant. Accordingly, it should address how the institution

plans to make the model organism and related research resources available after the grant has expired, such as through cost-reimbursable charges or donation to a repository. As noted earlier, repository use is highly encouraged to provide for easy long-term access.

CONCLUSIONS

The sharing of research materials and data is critically important in the progress of biomedical research. Along these lines, the NIH Model Organism Sharing Policy builds upon extant NIH sharing policies to continue to fund and promote broad and enabling research effectively and efficiently.

This chapter provides sample plans, approaches, guidance, and resources for investigators to consider in how to share model organisms and related research resources with the research community.

When done effectively, such sharing of research resources moves research forward and enables additional research to benefit public health.

APPENDIX: EXAMPLES OF REPOSITORIES AND ASSOCIATED RESOURCES FOR SHARING OF MODEL ORGANISMS AND RELATED RESOURCES AND DATA

7 Databases for Biomedical Animal Resources

Richard L. Crawford and Tim Allen

ABSTRACT

Database searching for research involving warm-blooded animals is required by law in the United States and is also a requirement for performing animal research in many other countries. It is, therefore, necessary for the investigator/researcher to perform a reasonable database search before developing the research protocol.

Key Words: Databases, Searching, Websites, Animal models, Resources, Strategy, Protocol, Animal, Area of Study, Sources of Information.

INTRODUCTION

The United States (U.S.) Animal Welfare Act,[1] U.S. Department of Agriculture (USDA) animal welfare regulations,[2] and USDA-Animal Care Policy 12[3] require that the principal investigator, using warm-blooded animals in research, must ensure that pain and distress are minimized, that alternatives to the proposed procedure or protocol are not available, or if alternatives are available why they were not used, and that the research does not unnecessarily duplicate previous experiments. Also, many countries now have regulations that require researchers to document that they have conducted a search for possible alternatives when applying for permission to conduct animal research.

Database searching is the best method to find animal resources and to comply with the requirements of the Animal Welfare Act or similar regulations. It is important to become familiar with the database platform, the subjects covered in each database, and the sources of information for each database to perform an effective and reasonable search effort. An institution's librarian or information specialist can be of considerable help with database searching and should be consulted prior to developing the research protocol. Training of researchers in how to perform a proper database search is also recommended as the search strategy determines the type and quality of the information obtained.

DATABASES

While there are many papers discussing the utility of various bibliographic and specialty databases and information centers in the development of animal research protocols,[4–18] it is still useful to point out major providers/suppliers/repositories of animal models for biomedical research.

In the United States, the National Institutes of Health (NIH) is the primary resource for the development and funding of biomedical animal models. Their website—Model Organisms for Biomedical Research (http://www.nih.gov/science/models)—is a good starting point for information on various projects under development by the NIH, its grantees, and other national and international laboratories. Among the organisms listed are mammalian models, especially rat and transgenic mouse models, yeast, fungi, round worm, fruit fly, and frogs. Another excellent resource is the NIH, National Center for Research Resources, Division for Comparative Medicine. (http://www.ncrr.nih.gov/comparative_med.asp). The Division for Comparative Medicine provides access to laboratory-bred nonhuman primates including macaques, baboons, chimpanzees, owl monkeys, squirrel monkeys, and others. The Division also maintains an aquatic animal models program (zebrafish, *Xiphophorus*, cephalopods, and *Aplysia*) and has initiatives for invertebrates (*Drosophila*, *Caenorhabditis*, *Aplysia*, *Tetrahymena*, and cephalopods). The Institute for Laboratory Animal Research at the U.S. National Academies of Science has a unique search engine available that searches the websites of suppliers and repositories that sell or distribute experimental animals. It is available at http://dels.nas.edu/ilar_n/ilarhome/models.shtml.

The European Union (EU) maintains the European Mouse Mutant Archive (EMMA) (http://www.emma.rm.cnr.it/), which preserves and distributes relevant strains collected from repositories and laboratories throughout the EU. The EMMA Strain Database is accessible through an easy to use search utility and can be found at http://andy.emma.cnr.it/jEmma/list.utf8.html. In Japan, the Riken Bioresource Center was established by the government to serve as a global resource for biomaterials. The Center serves as the Japanese repository for an extensive collection of mouse strains. The searchable catalog provides a detailed description of the model, strain information, the developer, and pertinent journal references. The English version is available at http://www.brc.riken.jp/lab/animal/en/. Another excellent inter-

national source of information on animal models and their availability is through the Federation of International Mouse Resources (FIMRe). This 11 nation collaboration provides researchers with access to a searchable mutant mouse catalog, searchable database of mouse genome informatics, nomenclature guidelines, and links to repository sites for contributing new strains. It is available at http://www.fimre.org. These websites also provide numerous links to university collections, national laboratories, and commercial vendors.

Not surprisingly, commercial vendors also maintain extensive databases of useful animal models. The Jackson Laboratory (http://www.jax.org), which operates as a nonprofit institution, is one of the world's foremost repositories for unique mouse models and maintains a searchable database of available strains. This database, the International Mouse Strain Resource, contains information on global stocks of inbred, mutant, and engineered mice. It can be found at http://www.informatics.jax.org/imsr/index.jsp. Charles River Laboratories (http://www.criver.com) is a commercial vendor of rodents, rabbits, chickens, and chicken eggs. It maintains a database of disease models and transgenic models and provides access to the Deltagen repository of 900 knockout mouse lines. Taconic Farms (http://www.taconic.com), with its partner Lexicon Genetics, maintains a searchable database of genetically modified mice and has numerous other rodent models listed with detailed descriptions of their utility. Harlan (http://www.harlan.com) and Harlan Europe (http://www.harlaneurope.com), as the world's largest suppliers of laboratory animals, provide information resources on a variety of animal models and maintain an extensive catalog of rats, mice, hamsters, guinea pigs, cotton rats, gerbils, and rabbits. More vendor information can be found at http://guide.labanimal.com and http://www.lal.org.uk/breedersandsupp1.html. Table 7–1 summarizes the information listed above.

Large bibliographic databases such as the National Library of Medicine's Pubmed (http://www.pubmed.gov), Elsevier's EmBase (http://www.embase.com), and Thomson Scientific's BIOSIS (http://www.biosis.org) are catalogs of the world's peer-reviewed scientific publishing. As such they contain a wealth of information on different animal models and provide background information on these models. It is important to remember that while there is some overlap in coverage, each database contains unique information not found in the others. Not only does subject coverage vary but the sources of information are varied as well. For example, a search of Medline should also include EmBase, which includes monographs, reports, and other useful sources not included in Medline, which covers only journals. Several core databases, such as Medline, EmBase, and Biosis, should be searched in order to conduct a comprehensive literature search. Elsevier has made this somewhat easier by combining their EmBase with unique records from Medline to create EmBase.com containing more than 17 million biological and pharmacological records. Choosing databases pertinent to the protocol will provide the researcher with better information and more accurate resources for the study and will better comply with the laws and regulations pertaining to animal research.

The following tables list selected bibliographic databases for animal resources (Table 7–2), the subjects covered (Table 7–3), and the sources of information for the selected databases (Table 7–4). Table 7–5 lists web addresses for database vendors or portals to a variety of online databases.

WEB SEARCHING AND OTHER GENERAL DATABASES AVAILABLE ON THE WEB

Web searching is an information source that should not be ignored. There are many websites available and using the terminology "Animal Model" or "Animal Models" in any web search engine will bring up many websites concerning animal models. However, these will also include sites for animal replicas, sporting goods, top dog model, and other similar sites, and a lot of scrolling is required to locate pertinent and specific animal model sites. Consequently, it is necessary to choose your words wisely. Being specific will improve your results, i.e., use more than two or three words in your strategy. Remember, it is the World Wide Web, so consider international spelling, such as behavior, behaviour, tumor, tumour, estrogen, oestrogen, anesthetic, anasthetic, anaesthetic, and other words that may have several spellings. Enclosing a multiword phrase in quotation marks tells the search engine to list only sites that contain those words in that exact order. A plus (+) sign directly in front of a word indicates that the word or phrase must appear in the search results. A minus (–) sign indicates that the word or phrase should not be included in the search results.

By using proper searching strategies the results will be more accurate and meaningful to your protocol. In addition to the resources listed above, Table 7–6 lists other free resources that may provide useful information.

Because many countries require scientists using animals to consider alternative methods or to minimize pain and distress to those animals that are used, a listing of useful websites is provided below. Listed below are a few samples of websites for alternatives to animal use in research:

SPECIFIC ANIMAL MODEL DATABASES

As previously indicated, the Internet has a lot of useful information available through general searches using broad terms such as "animal models of disease." There are animal model suppliers and vendors, books on animal models, journal articles on animal models and their use, lists of animal models available, and links to useful information on animal models. A good web search combined with a good multiple database search should provide useful information to the researcher that is pertinent to the research protocol. Listed below is a sample of databases to be found from various institutions.

DATABASE SEARCH STRATEGY

Databases and web sites contain a great deal of useful research information, however, little pertinent information will be obtained without a proper search strategy to find the information desired. Listed below are pointers to keep in mind when preparing to do a database search.

1. What is the general area of study (drug testing, cardiology, toxicology, lipid metabolism, etc.)?
2. What is the type of protocol (research, teaching, testing, etc.)?
3. What is the proposed animal species?
4. Identify the systems or anatomy involved in the study.
5. List any drugs or compounds used in the procedure.
6. What are the objectives and end points of the protocol?
7. Use both American and European spelling.
8. List key words using terminology from your responses to the questions above.
9. If searching on a system that allows development of complex search strategies, keep your concepts separate and then combine them to obtain specific and pertinent information.
10. Choose databases that are appropriate to the area of study.

CONCLUSIONS

There is a tremendous amount of information available from databases and websites; however, it can be difficult to obtain the specific information desired if the proper databases are not searched and the terminology used is too broad or inappropriate to the protocol. Some databases, such as Agricola and Medline (PubMed), are available to search and download references for free. Other databases require subscriptions and the downloading references for a fee. If a facility is involved in a great deal of research, which necessitates database searching, a subscription to a database vendor would be helpful as multiple databases would be available for searching and those pertinent to the protocol or area of study could be utilized. Two, or more, databases should be searched and these databases should be pertinent to the protocol in both the subjects covered and the sources of information (not just journals). The search strategy, including databases used, key words used, and years searched, should be saved for use again when required or if changes are required in the protocol. Should the investigator not be familiar with database searching strategy, he or she should contact an institutional librarian or information specialist for assistance. Training in proper searching techniques is also very helpful to those who do not have librarians or information specialists available to them and are required to perform periodic database searches. Should neither of these options be available to the investigator, the Animal Welfare Information Center (U.S. Department of Agriculture, National Agricultural Library, Beltsville, MD; E-mail, awic@nal.usda.gov) is available for suggestions and assistance if desired.

8 Psychological Enrichment for Animals in Captivity

KRISTINE COLEMAN

ABSTRACT

Animal care in biomedical facilities has undergone a dramatic transformation in the area of psychological well-being and enrichment over the past two decades. Today, attending to the behavioral needs of research animals is considered an integral part of animal care. Enrichment is defined as environmental stimuli provided to research animals in an effort to improve well-being by increasing species-specific and decreasing abnormal behaviors. Such environmental enhancement can help alleviate some of the stress associated with living in captivity, and can thus produce a better research model. This chapter discusses some of the issues surrounding the provision of enrichment and details some basic enrichment strategies, with emphasis on rodents, dogs, and nonhuman primates.

Key Words: Environmental enrichment, Psychological well-being, Animal welfare, Laboratory animals, Animal behavior, Animal husbandry.

INTRODUCTION

Animal care in biomedical facilities has undergone a dramatic transformation in the area of psychological well-being and enrichment over the past two decades. In the early part of the twentieth century, the emotional welfare of laboratory animals was largely disregarded. This situation changed as people realized that like humans, animals have certain basic behavioral needs, which, if not met, can adversely affect the behavior and physical health of the individual.

Today, providing for the psychological requirements of research animals is accepted as an integral part of animal care.[1] Most institutions devote substantial resources to ensure that animals receive enrichment (items provided to animals beyond their basic food and housing needs) of various sorts. Many facilities, particularly those housing nonhuman primates, have entire units dedicated to providing psychological enrichment for subjects.[2] Furthermore, enrichment is now provided not only to mammals, but also to birds,[3] snakes,[4] and fish.[5]

This chapter discusses the psychological enrichment of laboratory animals. While it focuses on rodents, dogs, and nonhuman primates, most of the concepts are universal, and can be applied to other laboratory species as well.

WHAT IS PSYCHOLOGICAL ENRICHMENT? Environmental enrichment is "an animal husbandry principle that seeks to enhance the quality of captive animal care by identifying and providing the environmental stimuli necessary for optimal psychological and physiological well-being" (Shepherdson,[6] p. 1). In other words, it is a way to functionally simulate the natural environment of research animals, in an effort to increase the opportunity to express species-specific behaviors and decrease the occurrence of abnormal behaviors. The goals of providing psychological enrichment are to have animals that are in good physical condition, display a variety of species-typical behaviors, are resilient to stress, and easily recover (behaviorally and physiologically) from aversive stimuli.[7]

WHY PROVIDE ENRICHMENT?

ETHICAL CONCERNS The research community's views on the care of research animals reflect the significant change in attitude that has occurred in the general public over the past few decades. Much of this shift can be attributed to increases in scientific knowledge regarding the complex nature of animal behavior. Today, scientists and others using animals in research recognize that they have a responsibility to attend to the psychological well-being of their subjects.[8] In short, providing psychological enrichment, within experimental constraints, is generally considered the "right thing to do."

LEGAL OBLIGATIONS In most countries, including the United States, providing research animals with enrichment is not an option, but rather is required by various regulatory agencies. The Animal Welfare Act (AWA[9]) is the statute that safeguards laboratory animals in the United States. Nonhuman primates are afforded the greatest protection under the AWA, which mandates that research institutions housing nonhuman primates have in place a plan to ensure their psychological enrichment.[9] The AWA also calls for exercise for dogs used in research.[9] While the AWA does not contain provisions for mice, rats, or birds, scientists receiving federal funding from most U.S. funding agencies must adhere to the guidelines in the Public Health Service Policy On Humane Care And Use Of Laboratory Animals ["PHS Policy"; National Institutes of Health, Office of Laboratory Animal Welfare (OLAW)]. This policy covers all vertebrates and requires compliance with the AWA and the *Guide for the Care and Use of Laboratory Animals* ("*The Guide*"[8]). *The Guide* specifies that enrichment be provided for laboratory animals, including social housing when appropriate for the species and the use of objects and cage

complexities that "increase the opportunities for the expression of species-specific postures and activities and enhance the animals' well-being" (Council,[8] p. 37). It also sets the standards for voluntary accreditation through the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC), an organization that promotes the humane treatment of animals used in science.

ENRICHMENT CAN IMPROVE THE ANIMAL MODEL One of the most compelling reasons to provide enrichment is to reduce stress and improve well-being for laboratory subjects, thereby improving the animal model. Stress can adversely affect many physiological parameters including the reproductive axis,[10] immunological parameters,[11,12] and brain function.[13] Stressed animals are at a higher risk for becoming ill[14] or developing maladaptive behaviors such as self-directed aggressive behavior,[15] which can affect a variety of research outcomes. Reducing this kind of stress can result in more reliable research subjects, and improve the interpretation of research results.

Providing social housing to rhesus macaques is an example of how enrichment can improve the animal model. Macaques and other nonhuman primates are social animals, and have evolved to live in complex societies. Socially housing monkeys affords them the opportunity to engage in species-specific behaviors and to develop social and cognitive skills necessary for group living.[16] It also reduces potential confounding factors, which can directly affect research results. For example, singly and group-housed monkeys differ with respect to various immunological parameters, such as natural killer cell activity, cytokine production, and proliferation responses to mitogens.[17–19] These differences can affect the results obtained in a variety of studies. Thus, it can be argued that housing monkeys in a more natural condition produces a better model for human conditions.

EFFECTS OF ENRICHMENT

Environmental enrichment in rodents has been associated with a variety of behavioral, neural, and physiological parameters, including increased exploratory behavior,[20–22] decreased anxiety on the elevated plus maze,[23] improved learning ability,[24,25] increased brain size and weight,[26] increased number of synapses per neuron,[27] increased neurogenesis,[28] and decreased cell death.[26,29–32] Mice in an enriched environment also have higher natural killer (NK) cell activity than nonenriched mice, suggesting better immune function.[23] On the other hand, enriched rodents tend to consume more food[33] and ethanol[22,34] compared to nonenriched rats, an outcome that needs to be carefully considered in the study design.

While enrichment has been shown to decrease stress (as measured by serum levels of corticosteroid) in nonhuman primates,[35] several studies have shown that it can increase basal corticosteroid (CORT) levels and cause larger adrenal weights in male rats.[23,36,37] However, these studies also reported that the CORT levels of the enriched rats were still within normal limits and were not associated with pathology.[23] Furthermore, enriched animals also showed less fear and exhibited less response to other stressors, such as predators or experimental stressors, suggesting that enrichment can attenuate the stress response to aversive events.[23,25,36,38] This mitigating effect of enrichment on stress response has been found in other species as well, including birds[39] and snakes.[4] This ability to recover from stressful experiences is considered an important aspect of well-being.[7,40]

ENRICHMENT AND EXPERIMENTAL VARIABILITY The findings described in the previous section underscore the importance of considering enrichment as a potential variable in studies. Even small changes in enrichment practices can have dramatic effects on many experimental outcomes, leading to the potential for variability among laboratories.[41] It is important to carefully document the type of enrichment provided, as well as when and how it is implemented, and to report this information in scientific publications.

However, the absence of enrichment can also increase variability between laboratories.[42] Lack of enrichment may increase an animal's vulnerability to the stressors that are being investigated.[43] Furthermore, there can be vast differences in how individuals respond to stress.[44–46] Using enrichment to decrease stress associated with experimental procedures may reduce variability and the development of stress-related problems, thereby increasing the validity of experimental results.

IMPLEMENTING AN ENRICHMENT PLAN

There are many resources available for implementing an enrichment plan for various species,[1,47–49] including a special issue of the *Institute for Laboratory Animal Research* (*ILAR*) *Journal* (2005, Volume 46). Below are some general guidelines.

ENRICHMENT SHOULD BE SPECIES-SPECIFIC Each species has evolved under different environmental conditions, resulting in unique behavioral patterns. Successful enrichment programs must take these specific behaviors into account in an effort to increase the biological functioning of the captive environment.[50] For instance, while most rodents are social, golden hamsters are not. Even within a species, enrichment needs may also vary by strain[51] or gender.[43] The Animal Welfare Information Center, part of the United States Department of Agriculture, maintains a website (http://www.nal.usda.gov/) containing useful information regarding the behavior of various laboratory animal species.

CONSISTENCY IS IMPORTANT Because enrichment can affect many research outcomes, care must be taken to ensure enrichment is given uniformly, and not haphazardly. Enrichment should be considered an integral part of animal care, and not as something extra to be done "when there is time."[1] It is also important for caretakers and researchers to avoid providing extra enrichment to "favorite" subjects. Not only can this be an experimental confound, but it can also affect the well-being of the animals. We have found that if only one or two monkeys in a room get an enrichment device, they are sometimes threatened by other, presumably more dominant, individuals (personal observation), which can lead to self-biting or other behavioral problems.

INTEGRATE BEHAVIORAL NEEDS WITH EXPERIMENTAL NEEDS Successful enrichment programs integrate the needs of the animal with experimental constraints. Studies on feeding behavior may prohibit the intake of extra calories, but other enrichment options can be used in lieu of food enrichment. Macaques can be given foraging devices containing toys that can be manipulated (e.g., small cat toys) instead of food.[52] New enrichment options should be tested prior to their implementation, to see if they will affect experimental outcomes.

ENRICHMENT SHOULD BE RESULTS-BASED An important, but difficult, part of a successful enrichment program is assessment. Enrichment offerings should be periodically evaluated, and provisions that do not have a demonstrable effect upon

well-being of the animal should be reconsidered.[50] It is not always easy to decide whether or not a particular enrichment offering is effective. Parameters to be assessed should include behavior (enrichment items should increase species-typical and/or decrease abnormal behaviors) as well as physiological variables that indicate well-being (i.e., animals should be healthy, with few signs of chronic stress). It is also important to consider the cost and safety of enrichment items. Items that are difficult to clean may be fomites, increasing the risk of illness.[17]

Optimally, enrichment items directly affect the well-being of laboratory animals. However, there may be value in enrichment options that have only indirect effects on the animals for which they are designed. Televisions, for example, are often provided to nonhuman primate species, even though it is not part of the normal behavioral repertoire of wild monkeys. Still, because people like to watch television, they assume (rightly or wrongly) that animals would as well. In practice, most animals do not pay a lot of attention to TV enrichment, although some do. However, beyond the direct effects of TV enrichment on the animals (which may be small), it allows the caretakers to feel that they are doing something positive for the animals. This can increase their job satisfaction and improve the relationship between caretakers and the animals, which can, in turn, improve well-being for the primates.[53]

TYPES OF ENRICHMENT Enrichment can be broken down into five basic categories,[47,48] including social (housing gregarious species in groups or pairs), physical (perches, platforms, houses or platforms, toys, and other objects that can be explored or manipulated), food (novel food items, or objects that increase foraging time), sensory (televisions, radio), and occupational (physical and mental activity, including training). These enrichment options are not equally attractive to all species. Ideally, laboratory animals would receive multiple forms of enrichment.

ENRICHMENT FOR COMMONLY USED LABORATORY ANIMALS

RODENTS AND RABBITS Rodents and rabbits are among the most commonly used animals in biomedical research. Strikingly, although they have been bred in laboratories for centuries, they still maintain behaviors similar to wild counterparts,[54,55] including nest-building, burrowing, hiding, and foraging. Even knockout and genetically modified strains of mice and rats retain many behaviors of wild animals. A successful enrichment program should take species-typical behaviors into account.

Most rodents and rabbits are gregarious (although golden hamsters are not), and live in family groups.[56] Thus, social housing (in groups or pairs) should be one of the first considerations in implementing an enrichment program for these species. Such housing allows individuals to engage in many species-typical behaviors, including play and grooming.[55] Furthermore, having social companionship can buffer individuals against external stresses,[57] which, in turn, improves well-being.

However, social housing can lead to aggression in some species. Mice tend to be more aggressive than rats. Furthermore, both strain[58] and sex can affect aggression in mice. For example, female mice tend to fight less than males, particularly during the mating season. Providing additional enrichment can help ameliorate some of the negative consequences of social housing. Van Loo *et al.*[59] found that adding nesting material can reduce aggression in socially housed male mice.

In general, rodents and rabbits are prey species, which shapes much of their behavior. When confronted with an aversive or frightening stimulus, their first reaction is to hide or burrow. Providing the animals with shelter (e.g., tunnels or houses) or substrate in which to burrow affords them the ability to withdraw from aversive situations, which can alleviate fear and stress.[55] It also allows animals to exercise some control over their environment,[60–62] which itself reduces stress-related behaviors such as stereotypical behavior (defined as repetitive, invariant behavior patterns with no obvious goal or function).[37,57,63,64] These items, along with other forms of physical enrichment (e.g., platforms, nesting material, toys, and gnawing sticks), also increase exploration and manipulation and decrease abnormal behaviors in rodents and rabbits.[33,37,57,65–67] Many of these items (e.g., tunnels) can easily be made with commonly available materials, such as PVC tubing. Commercially available polycarbonate rodent huts provide shelter, but are tinted to allow observation of the animal by care staff (Figure 8–1).

In the wild, rodents and rabbits spend a great deal of their time foraging for food, and thus food enrichment is an important part of an enrichment program.[68] Indeed, rodents in the laboratory will work to obtain food, even when it is freely available.[69] Feeding enrichment can be as simple as hiding food in the substrate, which promotes foraging.

Exercise can also benefit rodents and should be included in an enrichment plan when possible, particularly if social housing is not an option. Exercise on a running wheel can mitigate some of the anxiety that occurs as a result of social isolation in mice.[70]

In addition to improving animal welfare, enrichment can also increase safety for humans. Providing enrichment can help to decrease the risk of bites and scratches, increasing safety for animal caretakers and researchers.[71] Van de Weerd *et al.*[33] found that mice from an enriched environment were easier to handle (e.g., showed more relaxed behavior) compared to mice in a standard environment.[33]

Providing enrichment is not without problems, however. The addition of objects can increase aggression among socially housed animals,[37] due to territoriality over particular items. Making more than one "favored item" available can help to reduce this aggression. Items must be carefully cleaned, to avoid causing illness.

Figure 8–1. Example of enrichment items for laboratory mice. The hut is tinted such that the mouse cannot see out, but human caretakers can see in. (See color insert.) (Photo by Jill Rawlins.)

And, care must be taken in deciding upon things to use. While nesting material is used without problem in many species, it can cause conjunctivitis in some genetically modified mice.[72] Therefore, enrichment options should be carefully researched prior to implementation, to ensure that they are appropriate for the species and strain being utilized.

DOGS Dogs are unique among laboratory animals in that they have evolved a well-developed bond with humans. Therefore, one of the best forms of enrichment for dogs is positive interactions with human handlers.[40] Socializing dogs with humans, particularly when they are puppies, allows them to learn appropriate social cues and behaviors.[73] Early socialization may also reduce stress for the dog and help to prevent behavior problems from starting.[74] Odendaal and Meintjes[75] demonstrated that simply petting a dog can increase affiliative neurotransmitters, including β-endorphins, for both the dog and the human. Working with socialized dogs is also safer for handlers. Dogs reared with human contact are more outgoing, easier to work with, and less likely to bite handlers compared to those without.[73,76]

Since the dog is a highly gregarious species, social housing, in pairs or groups, is important for their welfare. Social housing helps to increase species-specific behaviors, including play and exploration, and reduce abnormal behaviors such as stereotypies.[77] If social housing is precluded due to experimental constraints, dogs should be allowed to see conspecifics.[78]

Adding physical enrichment items such as beds, resting platforms, and toys can enhance the environment and improve the welfare of laboratory dogs.[73,77,79] It can also help increase learning in elderly dogs.[80] Providing dogs with a variety of objects from which to choose, including chew toys, can reduce boredom.[81]

Exercise is another important part of an enrichment plan for laboratory dogs. While exercise has not been shown to substantially improve welfare,[82] it is mandated by the Animal Welfare Act. Singly housed dogs must be given space to exercise.[9] However, simply giving the dog an area in which to play may not be enough to promote exercise. Dogs generally do not exercise unless they have stimulation from humans or other animals.[83] One way to ensure that dogs are getting exercise is to provide them with daily "play time" during which they can interact with other dogs. Another option is for handlers to take dogs for walks.

An effective way to improve welfare and refine common husbandry practices with dogs is to train them for various tasks using positive reinforcement training (PRT).[73] PRT techniques are a form of operant conditioning[84] in which the subject is presented with a stimulus (e.g., a verbal command), responds by performing a specific (i.e., target) behavior (e.g., present a body part for injection), and is provided with reinforcement (e.g., food treat). Training increases mental stimulation for the dogs.[73] It also makes dogs more obedient and easier to handle.[73] Bookstores are filled with resources on how to train dogs, including "Don't Shoot the Dog," [85] which provides an excellent introduction to PRT.

NONHUMAN PRIMATES Many species of nonhuman primates are used in biomedical research, although rhesus and other macaque species are among the most common. Unlike rodents or dogs, primates used in research have not been domesticated, and therefore have maintained even more of the behavioral repertoire of their wild counterparts than these other groups. Macaques and other nonhuman primates are social animals and live in complex societies, often with a strict dominance hierarchy. They form intricate social relationships in the wild, where they spend a great deal of time engaged in social behaviors such as grooming and huddling with other members of the troop. Thus, social housing is considered one of the best forms of enrichment for nonhuman primates.[16,86]

Options for social housing can vary from large outdoor enclosures to indoor cages, depending upon the constraints of the facility and the experimental design. For animals in cages, pair housing (i.e., housing two monkeys in a double cage with a removable slide) allows social contact between the partners, and as such is considered an acceptable form of social housing for several species of primates.[87,88] When full pair housing is not appropriate due to scientific reasons, the use of grooming contact slides[89] between adjacent cages should be considered. These slides are designed so that part of the slide is a solid panel while the other part consists of bars wide enough to permit grooming (Figure 8–2). They afford individuals privacy as well as increased social contact with the cage mate.[89]

Social housing increases the opportunity for animals to engage in many species-typical behaviors including play, feeding, and grooming.[90,91] It can also reduce abnormal behaviors such as stereotypical behavior and self-aggressive behavior,[92] although this is not always the case (personal observation). Social enrichment is, however, an important tool in preventing abnormal behaviors from occurring.[93] One of the main risk factors for the development of self-injurious behavior in macaques is having been reared without close social contact with conspecifics.[94] In addition, the presence of known companions can lessen the effects of various stressors,[95–97] and alter immune function,[18,19] which can improve well-being.

Social housing is not a panacea, however. It can result in injury if individuals are not compatible. Factors such as sex and age may affect how well individuals get along with each other. For macaques, males are generally harder to successfully pair house than females.[98] Temperament may also play a role in compatibility in pair-housed animals. In a study on female rhesus macaques (*Macaca mulatta*), we found that animals with similar temperaments (as measured by reaction to a novel object) were more likely to form successful pairs than those of different temperaments.[99]

Forming groups of monkeys is particularly challenging (see references 100–102 for strategies on group formation). Once formed, groups should remain stable. Introducing a new adult into an established group can result in injury or death to the newcomer. Even in the absence of overt aggression, social housing can be stressful, particularly in species with dominance hierarchies in which some animals have more access to resources than others. In these societies, individuals at the bottom of the hierarchy are more prone to stress and stress-related diseases than dominant individuals.[103,104]

The provision of physical enrichment is another important part of an enrichment plan for nonhuman primates. This type of enrichment, which includes toys, mirrors, wood, and other manipulatable objects, affords individuals the opportunity to express species-normative behaviors such as play and exploration.[35,105] Decisions regarding enrichment items should be based on the behavior of the species. For example, unlike macaques, owl monkeys (*Aotus* sp.) utilize nests in the wild, and should be provided with nest boxes in captivity. Macaques, on the other hand, utilize perches and other cage furniture.[86] Items such as toys should be rotated regularly to keep them novel and thus of interest

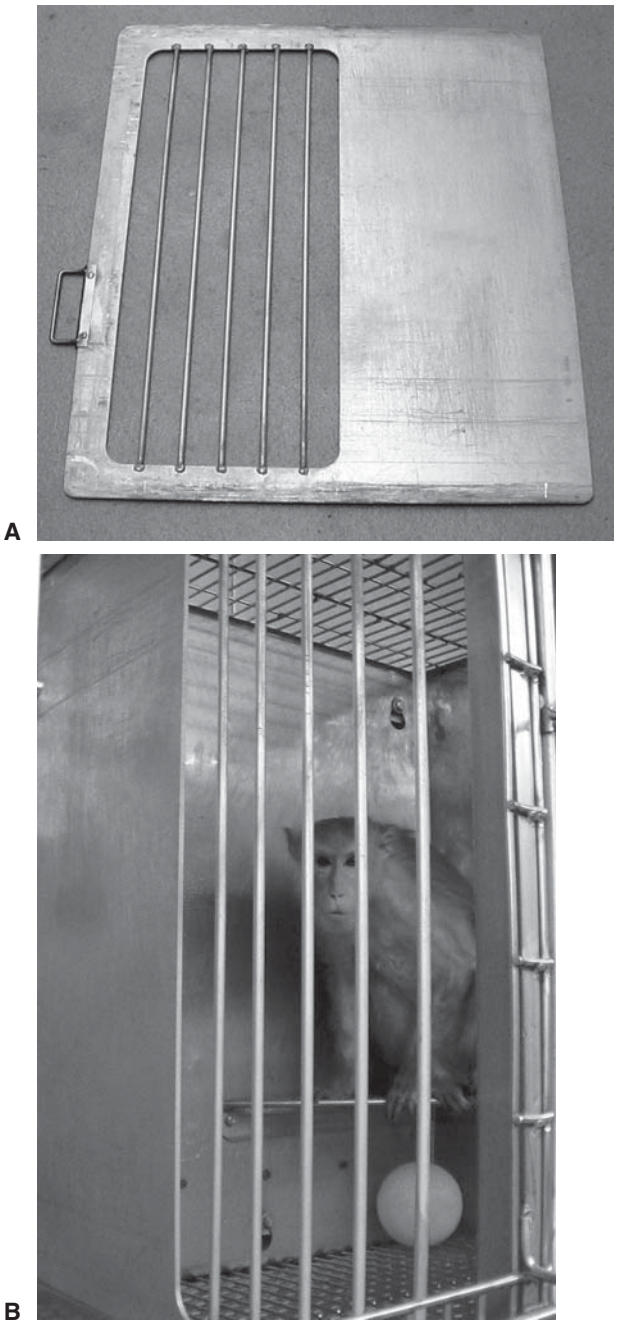

Figure 8–2. Grooming contact slide. The slide **(A)** is placed between two adjacent primate cages. The bars allow the partners to groom each other, while the solid part prevents full access to the other cage. **(B)** A slide within a cage (i.e., from the rhesus macaque's perspective). (Photos by Kevin Mueller.)

to the monkeys.[106–108] Specific enrichment devices, such as paint rollers or foraging boards covered with trail mix or other food items, are often provided to nonhuman primates in an effort to reduce the occurrence of abnormal behaviors such as stereotypy or overgrooming. There is debate as to the therapeutic value of such devices. While enrichment of this kind has been shown to decrease undesired behaviors in some studies,[105,109,110] others have found no discernable effect of the devices on abnormal behavior[111,112] or that the benefit was limited to the time the apparatus was present.[93]

Physical enrichment can increase the incidence of disease and injury for subjects. It is important to choose enrichment items that can be easily cleaned, to avoid spreading disease or illness.[17,113] Animals can injure themselves on certain types of hooks used to keep devices on the outside of cages (e.g., "S" hooks). Further, ropes and wire used to hang devices or swings should be covered with PVC tubing, to reduce the potential for strangulation.

Like rodents and rabbits, nonhuman primates spend much of their day foraging for food. This time is greatly reduced in a laboratory setting, where food is typically provided one or two times a day. Providing food enrichment can help functionally simulate the environment of nonhuman primate species.[50] Further, the USDA Draft Policy on Environmental Enhancement for Nonhuman Primates suggests that primates be provided with daily opportunities to forage. Devices have been developed to promote foraging and manipulation for the monkeys. These devices, which are typically put on the outside of cages and filled with trail mix and produce (depending on the species and dietary restrictions), provide monkeys with the challenge of obtaining food.[114] They have small holes through which the monkeys can forage for the treats. While these devices can be purchased commercially, they can also be made using materials such as PVC tubing (Figure 8–3). Handmade devices should be sturdy, so that they do not easily break. It is also important that devices can be thoroughly cleaned. Such enrichment devices have been found to decrease the occurrence of some undesirable behaviors, including stereotypies[112] and overgrooming,[105] when kept on the monkeys' cages continuously. However, these behaviors tend to return after time, likely due to increased boredom with devices that are kept on cages indefinitely. Rotating devices to keep them novel is recommended.[115] Adding a small toy to the device can also increase the amount of time they are utilized by the monkeys[52] (Figure 8–3).

Many facilities provide research primates with various forms of auditory and visual enrichment, including access to television, radio, brightly colored mobiles, or a window.[116] Computer screen savers can also be presented to the animals. Monkeys seem to watch the computer screens about the same amount as a television (personal observation). Television can be aversive if stressors, such as predators, appear on the screen. There is some evidence to suggest that sensory enrichment is beneficial to primates,[117] although there are contradictory results as well.[118] More work is needed to determine the benefits of this kind of enrichment.

Using positive reinforcement techniques to train monkeys to voluntarily cooperate with husbandry and/or research procedures is becoming recognized as an important tool in an effective enrichment program. PRT increases mental stimulation for subjects[119] and therefore is an effective form of psychological enrichment. Primates have been successfully trained to perform various tasks, such as presenting a body part for injection[120] or veterinary procedures,[121] taking oral medications,[122] and remaining stationary for blood samples.[120,123]

PRT can reduce the stress associated with common management procedures.[119,121,124] By allowing individuals to cooperate with the procedures, PRT may give primates an increased sense of control over their environment.[119] In addition, training can reduce abnormal behaviors in nonhuman primates. In a preliminary study,[125] we found that PRT reduced the occurrence of stereotypical behavior (e.g., pacing, rocking) in some, but not all, rhesus macaques. Furthermore, training primates to cooperate with research procedures can reduce the inherent risk of the

Figure 8–3. Foraging devices for nonhuman primates. **(A)** A device made by drilling extra holes into a wiffle ball. **(B)** A commercially available device (Crumble Disc Holder, Bio-Serv, Frenchtown, NJ), with a small cat toy added. (Photos by Jill Rawlins.)

procedures. It is clear that working with a cooperative animal is safer for caretakers and handlers than working with a highly stressed, and potentially reactive, animal.[126] While training is beneficial for the animal as well as the research, it can also involve a great deal of time. However, the time invested will likely be made up for by the decrease in time it takes to conduct procedures.[127]

CONCLUSIONS

In designing an enrichment program for an animal model it is essential to balance two equally important goals: the reduction of stress associated with the captive environment and the development of a model that (as closely as possible given the overriding need to care for the animal's physical and mental well-being) approximates the human condition. Life is as full of stressors for humans as it is for other animals.

Thus, it is not a realistic goal of any enrichment program to eliminate all stress. Not only is that goal unattainable, but it also is not necessarily in the animal's best interest. Stressors are not intrinsically detrimental,[7] and are a natural part of the behavioral repertoire of many animals.[16] Indeed, some can be adaptive, as they relieve boredom and help the animal learn to cope with environmental circumstances.[50] However, some stressors may not be adaptive, particularly if the animal has not evolved appropriate responses to them. These are the stressors that a successful enrichment program should address.

ACKNOWLEDGMENTS

I am grateful to Diana Gordon, Adriane Maier, Nicola DeBolt Robertson, Jill Rawlins, Greg Johnson, Kevin Mueller, and Victor Lucas for helpful comments on the manuscript and for their continued help and patience. I also thank Steve Schapiro for valuable conversations that have helped shape my thoughts on enrichment.

9 Integrated Network Modeling of Molecular and Genetic Interactions

GREGORY W. CARTER, VESTEINN THORSSON, AND TIMOTHY GALITSKI

ABSTRACT

In model organisms, systematic genetic perturbation and high-throughput data acquisition allow measurements of mutant phenotypes and detection of biomolecular interactions on a genome-wide scale. These data types are complementary in the sense that genetic interactions inferred from gene expression and other phenotype measurements can assign functional significance to the physical interactions between biomolecules. This chapter describes methods for the analysis of large-scale phenotype and expression data that employ genetic interactions to infer functional relationships between genes. Functional information is then used to direct the integration of physical interaction data to derive network models of cellular activity. These models, obtained from functional relationships but constrained by biochemistry, facilitate explicit and precise prediction of the effects of additional network perturbations.

Key Words: Genetic interaction, Network, Genomics, Cell differentiation.

INTRODUCTION

The identification of causal links between genetic variation and phenotype is central to the development of predictive, preventive, and personalized medicine. Many if not most phenotypes are determined by complex interactions among allelic variants and environmental factors. In biomedicine, these interacting elements are manifest as inherited and somatic genetic variants and polymorphisms, epigenetic effects on gene activity, environmental agents, and drug therapies including drug combinations. Development of new treatments for diseases with genetic susceptibilities will require not only the ability to genotype and classify patients on the basis of molecular fingerprints in tissues, but also an understanding of how genetic variants interact to affect clinical outcomes.

The large-scale study of how genotype contributes to the control of phenotype has been greatly aided by advances in methods to both systematically perturb genes and collect phenotype data on a genomic scale.[1–8] These high-throughput methods are designed to produce large quantitative data sets, requiring parallel development of computational and numerical modeling methods to interpret the output in terms of biological function. The primary objective of these methods is to identify functionally relevant genes and describe how they influence one another to produce cellular activity. In addition, this knowledge can be integrated with physical biochemistry to yield biomolecular models that carry out specific cellular functions. Such an integrated model facilitates validation of biological insights and identifies high-priority candidate genes for targeted therapeutic intervention.

One strategy to achieve this integration is to first infer functional interactions between trait genes, and then use these relationships to guide the selection of biochemical paths that are putatively responsible for the observed phenotypes. This provides a systematic framework for integrating two complementary data types: genetic interactions and physical interactions. Genetic interactions are inferred by observing how genetic perturbations interact to affect phenotypes, and encode functional relationships such as activation, repression, and information flow.[9] However, the biochemical interpretation of a genetic interaction is often ambiguous, frequently involving multiple molecular models and both direct and indirect mechanisms.[10,11] At the same time, the biochemical interactions plentifully generated through high-throughput methods are often lacking in functional interpretation.[12,13] Taking advantage of this complementarity by constraining the biochemical interpretation of genetic interactions by molecular wiring, we seek to construct biomolecular models that assign functional significance to physical interactions.

This chapter outlines steps toward such an analysis. First, we outline a systematic analysis and classification of genetic interactions on a large scale. Second, we discuss methods to integrate genomic expression data and physical interaction data to generate molecular hypotheses of functional organization. Finally, we outline a systematic method to extend the two analyses in a predictive model for the control of a biological response in yeast.

GENETIC INTERACTION NETWORKS

A genetic interaction is the phenotypic manifestation of how two alleles combine to jointly affect cellular activity. This classical method of analysis is based on comparing the phenotypes of strains with specific allelic variations, and thus is most readily performed using targeted perturbations in inbred strains of model organisms. Primary examples are the use of the deletion mutant library for *Saccharomyces cerevisiae*,[1] RNAi technology in *Candida elegans*[14] and *Drosophila melanogaster*,[15] as well as

curated data repositories such as FlyBase.[16] The properties and uses of genetic interactions learned with model organisms are of interest in the broader context of outbred populations that carry multiple alleles. The genetic basis of human disease susceptibility, in which polygenic interaction effects are often preeminent, is naturally the most urgent application.[17]

Genetic interactions are defined for a chosen phenotype in specific environmental conditions, so that the lone variables are the specific genetic perturbations (i.e., allele forms) carried by the strains being compared. The logic is as follows. Consider two genes, A and B, mutations of which yield observable phenotypes. Taking cell growth as an example phenotype, imagine a null mutation of A inhibits growth while a null mutation of B enhances growth. The growth rate of a double mutant, with null mutations on both A and B, is also observed to be inhibited. In this case the A mutant is said to be *epistatic* to the B mutant, as the A mutant phenotype does not change in the B-null background.* Such an interaction is often interpreted as evidence that A acts downstream of B, in that its knockout masks any modifications that occur further upstream of the phenotypic output.[9] So while this observation cannot, when taken alone, offer any biochemical explanation, it establishes a clear functional relationship between the two genes. Thus the genetic interaction can be considered as providing a comprehensive view of their coordinated activity, encompassing every step in cellular processing between genotype and phenotype.

Classical epistasis is one of many possible modes of genetic interaction. For instance, high-throughput screens in yeast have been developed to detect synthetic interactions,[2] which are manifest when a pair of genes that does not show phenotypic effects when mutated individually exhibits an altered phenotype when the mutations are combined in a single strain. With the proper experimental design, the modes of genetic interaction can be systematically analyzed and formally classified.[8] To this end, consider a genotype X, and its associated phenotype observation P_X. The phenotype could be a numerical measurement or any other observation that can be clearly compared across mutant genotypes (e.g., slow vs. standard vs. fast growth). If genotypes are labeled by mutant alleles, a set of four phenotype observations can be assembled that defines a genetic interaction: P_A and P_B for the A and B mutant alleles, P_{AB} for the AB double mutant, and P_{WT} for the wild type. The relationship between these four measurements defines a genetic interaction; for example, $P_{AB} = P_A < P_{WT} < P_B$ described an epistatic interaction while $P_{AB} < P_{WT} = P_A = P_B$ represents synthesis. It is immediately clear that some of these interactions are symmetric under an exchange of genes A and B (e.g., synthetic) while others are not (e.g., epistatic). There are a total of 75 distinct inequalities that can be constructed from four phenotypes.[8]

These inequalities were recently cataloged and classified as one of nine interaction modes, including epistasis and synthesis.[8] To test the applicability of this classification method over 1800 strains of systematic single and double gene perturbations were phenotyped for invasive growth, a cell differentiation response that occurs under specific environmental conditions. A software application called *PhenotypeGenetics*, created as a plugin for the *Cytoscape* software platform,[18,19] was used to systematically construct a genetic interaction network from the high-throughput, quantitative phenotype data. All nine interaction modes were found in significant numbers, illustrating that a spectrum of genetic interaction effects is present in complex biological systems. Specific alleles were found to interact in a particular mode with neighbor genes of coherent biological function, leading to hypotheses on regulatory and pathway organization. Large-scale patterns of mutual information were also extracted from the data set, and groups of genes with significant mutual information between them formed network cliques corresponding to physical pathways (Figure 9–1). The genetic interaction patterns represent the biological system as a map of information flow from specific genetic perturbations to quantifiable phenotype effects.

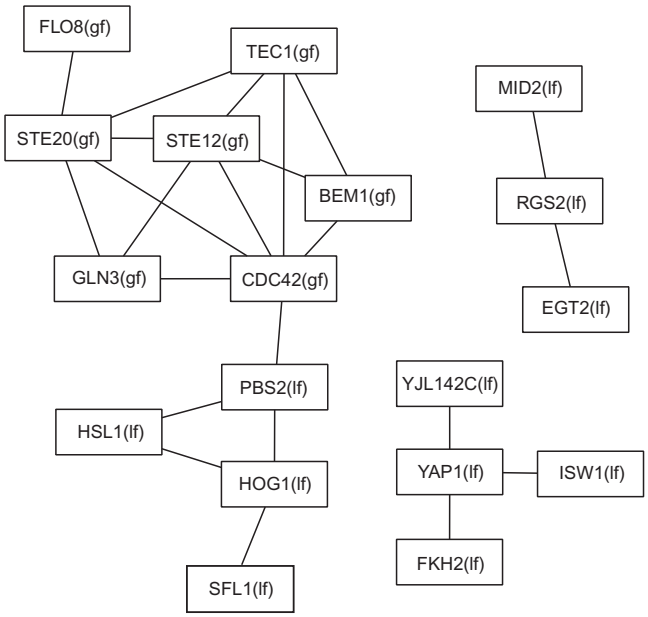

Figure 9–1. Networks of mutual information in patterns of genetic interaction show cliques. Nodes represent perturbed genes, gf indicates a gain-of-function allele, and lf indicates a loss-of-function allele. Edges connect gene pairs with significant mutual information in their patterns of genetic interaction. (Reprinted from Drees *et al.*[8])

DIRECTED DATA INTEGRATION

The invasive-growth network described in the previous section encodes functional information inferred from genetic interactions. We next consider a method to integrate these functional relationships with physical interactions in order to identify candidate molecular mechanisms that control cellular activity. In this section, we outline a strategy of data integration in which the analysis of genomic expression data directs the construction of regulatory networks.

By analyzing the effects of specific genetic perturbations on genomic expression, it is possible to identify specific genes that coordinate control of phenotypes at the transcriptional level. Moreover, gene expression can itself be viewed as a quantitative phenotype that is a suitable platform for studying complex phenomena such as genetic interactions.[20] Genomic expression measurements have many distinct advantages as a basis for quantitative

*The term epistasis is sometimes used as a generic term meaning genetic interaction. Here we use it in the narrow sense of one mutant completely masking the effect of another.

analysis. DNA microarray technology provides a well-established platform for systematic data collection and many statistical methods now exist that identify groups of coexpressed genes. Sets of genes obtained can be systematically queried for common function in increasingly comprehensive annotation databases such as Gene Ontology.[21] Furthermore, the perturbations and measurements of genes introduce a concrete, molecular basis for further analysis, and large-scale interaction databases now make it possible to place these biomolecules in a network context.

We took advantage of these resources in a study of the Ras-cAMP signaling pathway in yeast.[22] This pathway has been implicated in filamentous growth,[23] cell proliferation, and glycolysis.[24–26] In yeast, the pathway centers on the activation of adenylate cyclase (Cyr1) by GTP-bound Ras2 and Ras1 proteins, which in turn facilitates the synthesis of cAMP. We perturbed key pathway elements and collected genomic expression data, with the intent of tracing the observed expression responses to the perturbation(s) that caused them. Specifically, we created strains with exogenously controlled levels of cAMP, dominant-active and dominant-negative alleles of Ras2, and genetic perturbations of the GTPase activating proteins Ira1 and Ira2. The intent was to infer a detailed map of the activity of these pathway elements, ranging from shared effects resulting from multiple perturbations to highly specific effects resulting from one or two perturbations. We wanted to identify and classify signals regardless of global magnitude, detecting not only quantitatively large signals but also fainter (yet coherent) expression effects. These faint effects may be of particular biological interest, possibly identifying functional differences between multiple perturbations of a single gene or two near-homologous genes. Expression patterns specifically related to phenotypes can also be quantitatively minor.[27,28]

To disentangle signals in the data, we performed singular value decomposition (SVD) on the global data set to identify overlapping sets of coexpressed genes, each weighted by global significance.[29,30] To test the presumption that these genes were cofunctional and coregulated, we queried gene sets for statistical enrichment of annotated functions and enrichment in targets of known transcription factors. Both were found for the majority of gene sets. With SVD we were also able to identify the group of experimental perturbations (i.e., microarray conditions) that specifically caused the expression pattern shared by each set of genes. This provided both molecular origins (the perturbations) and targets (the enriched transcription factors and hence the coexpressed genes) of regulatory signals. By querying physical interaction databases, we linked the former to the latter via molecular-interaction paths. The resulting series of linked subnetworks maps multiple pathways of information flow through a dense signaling network to targets throughout the genome (Figure 9–2). They are explicit hypotheses of biomolecular mechanisms for signal transduction, obtained through data integration directed by functional relationships.

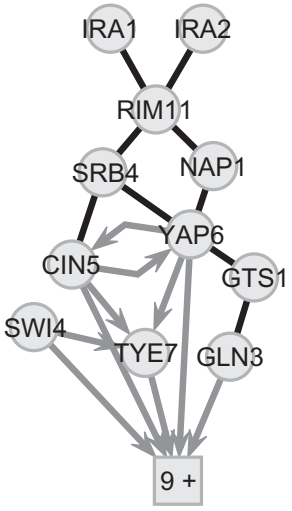

Figure 9–2. Regulatory network derived from perturbations of *IRA1* and *IRA2* genes, mapping putative biomolecular pathways for information flow to a set of genes sharing an expression component (box). The gene set, which is statistically enriched in Ty element transposons, is labeled "9+" to denote that it is the ninth SVD mode and the genes express the expression pattern with positive coefficients. Circular nodes represent individual proteins; black, nondirectional edges represent protein–protein interactions; gray, directional edges represent protein–DNA interactions. SYSTEM GENETICS

The functional information derived from genetic interaction analysis of phenotype is a powerful means of mapping relationships between genes in a pathway. However, many phenotypes are difficult to quantify and cannot yet be assayed with high throughput. This limits efforts to systematically exploit genetic interactions with quantitative methods. At the same time, we have demonstrated how analysis of microarray data for genetic perturbations can facilitate data integration and molecular network modeling. Thus we sought to combine genetic interactions analysis, numerical data decomposition, and functionally directed data integration to model the network control of gene expression and associated phenotypes.

We used a data-driven, linear decomposition of our expression data matrix to determine genetic influences from seed genes to genome-wide transcripts as well as cross-influences of the seed genes on one another's activity. Matrix decomposition methods such as singular value decomposition (SVD)[22,30] and generalized Network Component analysis (gNCA)[31] have proved successful in disentangling multiple overlapping quantitative signals in microarray data. The mathematical modeling was combined with physical interaction databases to infer (1) the degree to which certain transcription factors influence the expression level of every transcript in the genome, (2) the degree to which these transcription factors influence the regulatory activity of one another and hence cause genetic interactions, (3) the biochemical mechanisms that transmit these influences, and (4) how these biochemical mechanisms are organized into the biomolecular network that specifically controls the phenotype.

Our decomposition can be illustrated with the simplified case of two genes A and B, called seed genes since they are the starting point of the analysis, that influence the expression of two genes X and Y. For a strain background labeled with superscript *S*, consider a linear pair of equations for gene expression:

$$X^S = x_0 + x_A\, g_A^S + x_B\, g_B^S$$
$$Y^S = y_0 + y_A\, g_A^S + y_B\, g_B^S \qquad (9\text{–}1)$$

The parameters x_A, x_B, and x_0 represent contributions to the expression of X from the gene A, gene B, and the remainder of

the genetic background (similarly for gene Y). These are independent of the genotype. The coefficients g_A^S and g_B^S are the inferred activity levels of the seed genes A and B in the strain background *S*, and are independent of the transcript measurements. Influences between seed genes (observed as genetic interactions) can be systematically inferred from changes in activity levels of one in a strain in which the other has been deleted, e.g., in a deletion strain of gene B, $g_A^B < g_A^{WT}$ would evince a positive influence from gene B on the activity of gene A. Rather than substituting transcript level data for these activities (as in regression methods) these model-derived parameters conceptually include all levels of gene control from initiation of transcription to protein localization, modification, and degradation.

The system of equations can be expanded to model an arbitrary number of expression values and seed genes by systematically adding parameters. They can be cast in matrix form and the solution can be represented as a network of influences, as illustrated in Table 9–1. These matrices can be expanded to model numerous observables (expression of genes X, Y, Z, . . .) under single and pairwise perturbations of multiple genes (A, B, C, . . .), simply by adding appropriate matrix rows and columns. For example, three seed genes would be written as

$$\begin{pmatrix} X^{WT} & X^{A} & X^{B} & X^{C} & X^{AB} & X^{AC} & X^{BC} \\ Y^{WT} & Y^{A} & Y^{B} & Y^{C} & Y^{AB} & Y^{AC} & Y^{BC} \\ Z^{WT} & Z^{A} & Z^{B} & Z^{C} & Z^{AB} & Z^{AC} & Z^{BC} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \end{pmatrix} = \begin{pmatrix} x_0 & x_A & x_B & x_C \\ y_0 & y_A & y_B & y_C \\ z_0 & z_A & z_B & z_C \\ \vdots & \vdots & \vdots & \vdots \end{pmatrix} \bullet \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ g_A^{WT} & 0 & g_A^{B} & g_A^{C} & 0 & 0 & g_A^{BC} \\ g_B^{WT} & g_B^{A} & 0 & g_B^{C} & 0 & g_B^{AC} & 0 \\ g_C^{WT} & g_C^{A} & g_C^{B} & 0 & g_C^{AB} & 0 & 0 \end{pmatrix} \tag{9–2}$$

This procedure results in the decomposition of an expression data matrix **D** into two matrices: (1) an influence matrix, **X**, of coefficients for the influence of the seed genes on target genes and (2) a genotype matrix, **G**, of inferred activity levels for the

Table 9–1
Outline of mathematical modeling[a]

1. Model all possible influences (x_A, x_B, y_A, y_B) from genes A and B on the expression of genes X and Y	$X^{WT} = x_0 + x_A + x_B$ $Y^{WT} = y_0 + y_A + y_B$	2. Add coefficients (g_A, g_B) representing possible effects of A on activity of B, and vice versa	$X^{WT} = x_0 + x_A\, g_A^{WT} + x_B\, g_B^{WT}$ $Y^{WT} = y_0 + y_A\, g_A^{WT} + y_B\, g_B^{WT}$	3. Model effects of a deletion of gene A (similar for deletion of B); g_A becomes 0; g_B^A represents the activity of gene B in the A deletion strain; faded lines represent possible influences lost	$X^{A} = x_0 + x_B\, g_B^{A}$ $Y^{A} = y_0 + y_B\, g_B^{A}$	4. Model effects of double perturbation (deletion of genes A and B); faded lines represent possible influences lost	$X^{AB} = x_0$ $Y^{AB} = y_0$		Expression data	Influence matrix Genotype matrix
5. Rewrite equations as a matrix decomposition of the expression data	$\begin{pmatrix} X^{wt} & X^{A} & X^{B} & X^{AB} \\ Y^{wt} & Y^{A} & Y^{B} & Y^{AB} \end{pmatrix} = \begin{pmatrix} x_0 & x_A & x_B \\ y_0 & y_A & y_B \end{pmatrix} \bullet \begin{pmatrix} 1 & 1 & 1 & 1 \\ g_A^{WT} & 0 & g_A^{B} & 0 \\ g_B^{WT} & g_B^{A} & 0 & 0 \end{pmatrix}$	

[a]Modeling strategy illustrated for the simplified case of two seed genes (A and B) influencing the expression of two genes (X and Y).

seed genes in each genetic background. This is concisely written:

$$\mathbf{D} = \mathbf{X} \cdot \mathbf{G} \tag{9–3}$$

Thus, the more direct influences from the seed genes to target genes are separated quantitatively from the indirect effects that involve a second seed gene via a genetic interaction.

The structure of the genotype matrix [Eq. (9–2)] is fixed by the genetic composition of the laboratory strains. Activity levels of null alleles are fixed at zero and wild-type activity is set equal to one in all cases (gene-by-gene variation is encoded in the first column of the influence matrix). Other genotype matrix elements are unknown a priori. To set a scale for the inferred regulatory activities, we define the wild-type activities to be equal to one ($g_A = g_B = \ldots = 1$) and calculate the remaining activities as changes relative to wild type under perturbations of other seed genes (g_A^B, g_B^A, g_C^{AB}, etc.). The form of matrix **G** guarantees the existence of a unique best-fit solution due to the strict arrangement of ones and zeros required by the genotypes (i.e., the rows of matrix **G** are linearly independent and cannot be transformed to yield a similar format). In the decomposition of microarray data, the number of data points in Eq. (9–3) far exceeds the number of model parameters and a least-squares best-fit solution can be found.

From the genotype matrix **G** in Eq. (9–3), we can infer quantitative cross-influences between the seed genes that generate genetic interactions. These correspond to influences on inferred regulatory activity, rather than the gene expression influences encoded in the matrix **X**. They will allow us to make predictions for perturbations of path genes, with the modified influences experimentally manifest as altered genetic interactions. This is a further dimensional reduction of the genotype matrix **G**. Starting again with the case of two seed genes, A and B, we can write for their activity levels:

$$\begin{aligned} A &= A_0 + m_{AB}\, B \\ B &= B_0 + m_{BA}\, A \end{aligned} \tag{9–4}$$

The variables A and B define generalized activity levels of the seed genes, and the parameters A_0 and B_0 represent basal input not directly due to genes A or B. The m_{ij} account for influences between A and B. Self-influences, such as m_{AA}, are not included since they cannot be numerically distinguished from the basal input. The model can be readily generalized to the case of N perturbed genes. For a vector of gene activities, we replace $\{A, B\}$ with $\boldsymbol{g} = \{g_1, g_2, \ldots, g_N\}$ and write

$$g_i = g_{0i} + m_{ij}\, g_j \tag{9–5}$$

where $\boldsymbol{g}_0$ is a vector of base activity and the m_{ij} form is an $N \times N$ matrix encoding the influence of the ith gene on the jth gene. Equation (9–5) can be solved for the activities and we find the vector solution

$$\boldsymbol{g}^{WT} = (\mathbf{1} - \mathbf{m})^{-1} \cdot \boldsymbol{g}_0 \tag{9–6}$$

where **1** is the $N \times N$ identity matrix. The vector $\{1, \boldsymbol{g}^{WT}\}$ is the first column of the genotype matrix **G**.

In this formulation, the deletion of a seed gene requires setting both its base activity and its influences on other seed genes to zero. This corresponds to replacing the appropriate entry in $\boldsymbol{g}_0$ with zero and the appropriate column in **m** with zeros. This can be achieved by rewriting Eq. (9–6) in terms of a diagonal base activity matrix, $\mathbf{G_0}$, formed by placing the elements of the vector $\boldsymbol{g}_0$ along the diagonal, and a scaled influence matrix with elements $M_{ij} = m_{ij}/(g_0)_i$. Defining the vector $\mathbf{1} = \{1, 1, \ldots, 1, 1\}$ of length N, we then have

$$\boldsymbol{g}^{WT} = [(\mathbf{G_0})^{-1} - \mathbf{M}]^{-1} \cdot \mathbf{1} \tag{9–7}$$

In this form, a deletion of gene A is modeled by taking the limit as $(G_0)_{AA} \to 0$, which means setting the basal activity of that gene to zero. The resulting $\boldsymbol{g}^A$ (with a 1 prepended) corresponds to the second column of the matrix **G**. Multiple deletions are modeled by taking multiple zero limits for entries of the diagonal matrix $\mathbf{G_0}$. This effectively removes all traces of the deleted genes from the system. Note that by after fixing $\boldsymbol{g}^{WT} = \{1, 1, 1, \ldots, 1\}$ we can find a solution for the matrix elements of **M** and the base activities $\mathbf{G_0}$ using the matrix elements of the solution for **G** as described above. Since this is a further dimensional reduction, reducing $N^2(N-1)/2$ parameters to N^2, this generally requires a best fit solution.

To summarize, the linear influences decomposition assigns quantitative values to the influence of each seed gene on (1) the expression of every gene (encoded in **X**) and (2) the activity of the other seed genes (encoded in **M**). These influences amount to a global map of functional information flows of specified magnitude and sign (positive or negative).

A key use of the influence map is to serve as a template for integrating physical interaction data, in order to generate specific biomolecular hypotheses for regulatory activity. One strategy for this is to begin by selecting significant influences (i.e., the strongest ones). An example selection criterion is to use cross-validation to determine all influences that are highly unlikely to be nonzero.[28] Then, for each of these, a candidate molecular pathway is constructed that transmits the influence, using the integration of physical interaction data as previously described. In this way, networks can be constructed from physical interactions that were specifically selected based on the presence of numerical influences derived from the data. They propose specific biomolecular hypotheses of information flow in the network. Furthermore, perturbation of network elements predicts quantifiable changes in gene expression, since the corresponding numerical influence would be modified.

As a test of this modeling approach, we recently applied it to the control of filamentous growth in yeast. Certain strains of *S. cerevisiae* grow either as a round single-cell yeast form, or as a pathogenic, adhesive, invasive, filamentous form (also referred to as pseudohyphal development).[23] Many fungal pathogens of humans and plants exhibit similar dimorphism.[32] In response to environmental cues, the pathogenic chains of elongated cells adhere to host tissues, evade immune responses, and penetrate barriers. The invasive-growth phenotype previously discussed can be viewed as one part of this response. We chose five filamentation-related transcription factors as our seed genes and collected gene expression data for the 16 strains necessary to infer all genetic interactions between them: the wild type, 5 single knockouts, and 10 double knockouts. We then combined limited phenotype data with genomic expression data (thousands of measurements per strain) to infer a network that controls filamentous growth.

We identified a large set of genes with differential expression and performed the linear influences decomposition on the expression data (a 1863×16 data matrix). We then determined which

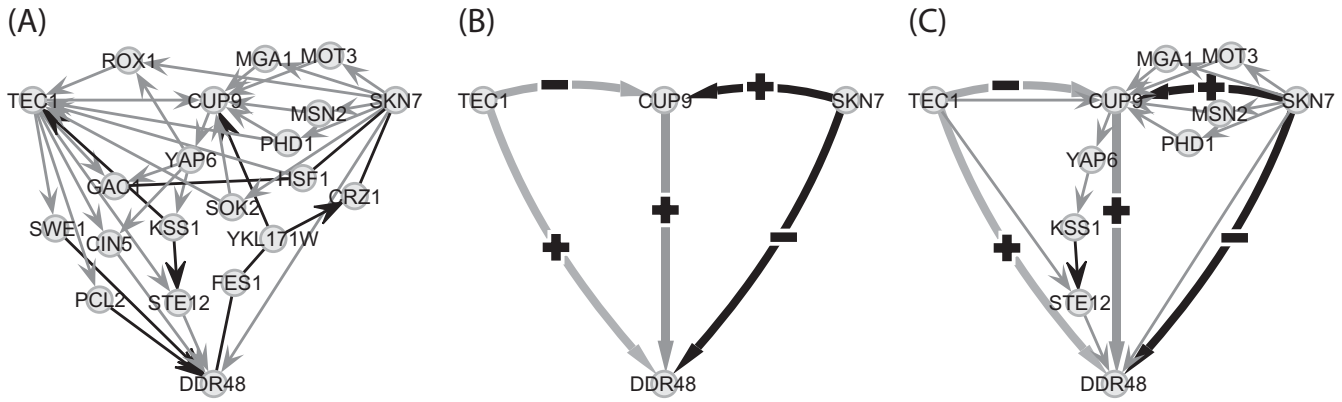

Figure 9–3. Data integration example: modeling how *TEC1*, *CUP9*, and *SKN7* control the expression of gene *DDR48*. (A) Network of physical interactions connecting the four genes from high-throughput data sets. This network is too dense and disorganized to identify functional pathways. Edges represent interactions as protein–protein (black, nondirectional), protein phosphorylation (black, directional), and protein–DNA (gray, directional). (B) Network of inferred influences using genetic influences decomposition. Bold edges indicate the direction of positive and negative influences (as labeled) and intensity indicates magnitude. (C) Integrated network constructed from the subset of physical pathways in (A) that are specific candidates for transmission of influences in (B). (Adapted from Carter *et al.*[28])

influences were significant and constructed putative biochemical networks controlling the expression of each gene. The strategy is illustrated in Figure 9–3 with a network for the transcriptional regulation of the gene *DDR48*, which encodes an ATPase involved in stress response, cell wall organization, and flocculation.[33]

We used the network model to predict genomic expression effects of additional genetic perturbations and tested these predictions by constructing additional combinatorial knockout strains and collecting microarray data. This served as a direct test of our genetic interaction modeling and data integration methods. We made predictions by removing (set to zero) numerical influences whenever the paths from influencer to influenced were broken under the downstream gene deletion. As a control, we made parallel predictions using a simpler linear model without genetic interactions. Our model provided a general improvement in fit across all genes. When assessed over thousands of expression measurements the improvement was highly significant, providing empirical evidence for both the importance of genetic interactions and the applicability of our modeling technique.[28]

In addition to microarray data, we also phenotyped each strain for filamentous growth. We then performed SVD on the genomic expression data[30] and identified a set of genes with an expression component correlated to the phenotype. The genes that strongly exhibit this expression component were a quantitative proxy for the phenotype, even though this component was quantitatively not the most dominant pattern in the data. These genes are statistically enriched in targets of eight transcription factors, of which six were known to have filamentous-growth-related phenotypes. Subsequently, we found that deletions of the other two have filamentation phenotypes.

We were able to determine which of our seed genes had strong expression influences on the phenotype-proxy gene set. By following the methods previously described to integrate physical interaction data, we connected these influencers to genes in the set in a biomolecular network. This constituted a candidate network for the regulation of filamentation, involving both known and novel regulators. Furthermore, from the topology of the network we were able to make systematic and precise predictions for the phenotypes of additional combinatorial perturbations. These predictions proved to be very accurate,[28] compared with predictions based a large training set of interactions.[8] We correctly predicted the phenotypes of all 13 of the novel double-knockout strains we constructed, compared to the training set expectation of seven correct predictions (significance of $p = 0.0002$). Furthermore, we were able to correctly predict the precise phenotype inequalities of six of the 13 strains, compared to an expectation of only two in the training set ($p = 0.009$).

DISCUSSION

The construction of predictive bionetworks has proved to be a substantial challenge due in part to the difficulty of extracting functionally relevant interactions from diverse high-throughput data types. With the increasing abundance of molecular interaction data, there are often numerous possible pathways of information flow between two genes.[34] Many recent works have sought to distill functionally important information by detecting systematic congruence in multiple large data sets.[10,35–39] These approaches have demonstrated substantial success in classifying genes according to functionality and identifying probable candidates for genetic interaction. In contrast, our goal was to infer functional relationships to drive network modeling. By using genetic influences decomposition of microarray data to guide data integration, our procedure assigned functional significance to specific physical interactions. This allowed us to make precise, testable predictions for novel combinatorial perturbations of specific genes.[28]

These models implicated new regulators and regulatory relationships. The network we obtained for the filamentous growth phenotype in yeast contained many genes known to be involved in filamentation, and the network also implicated new regulators of filamentation that were verified experimentally. In addition to implicating genes, our approach was often able to correctly infer relationships between the genes. The accuracy of the interaction network was evident in our broad success in predicting expression profiles and phenotypes for novel combinatorial perturbations.

A central concept in our approach was the assumption of linearity in quantitative relationships between genes. This allowed us to efficiently identify the effects of genetic interactions in the data and enabled systematic mapping of how the expression of

each gene is influenced by a genetic perturbation. Although the linear approach was sufficient to predict the effects of novel pairwise gene deletions, we note that it has the potential to oversimplify complicated regulatory mechanisms. In particular, the nonlinearity inherent in many posttranscriptional and feedback mechanisms often leads to behavior too complex to be adequately modeled with static linear relationships. In such cases, the networks obtained from our approach might best be used as a starting point for dynamic modeling. With relatively few network elements connected by quantitative relationships, these networks are ideally suited for ordinary differential equation (ODE) and stochastic modeling.[40]

10 The Sponge as a Model of Cellular Recognition

Xavier Fernàndez-Busquets

ABSTRACT

Sponges, the simplest extant Metazoans, have been traditionally used as models to study cell adhesion, since their abundant extracellular matrix allows a mild cell dissociation and the recovery of functionally active macromolecular structures. Dissociated sponge cells quickly reaggregate in a species-specific manner, differentiate, and reconstruct tissue, providing a simple model to investigate the molecular basis of animal intercellular recognition systems. Here, we review the application of sponges as biotools for the study of three cell recognition processes that are relevant for biomedical research. First, the species-specific association of sponge cells is discussed in the context of the role ascribed to carbohydrates in adhesion-related phenomena implicated, among other processes, in tumor metastasis. Second, we will summarize the current knowledge about a sponge proteoglycan that has been proposed as a model for the investigation of the mechanical properties of extracellular matrix proteoglycans in calcium-dependent cell adhesion events, whose impairment can lead to severe disorders such as Alzheimer's disease and Marfan syndrome. Finally, the self–nonself recognition reactions in sponges are presented as a window to the early period in the evolution of histocompatibility systems, and the corresponding molecular and cellular events will be compared with the processes and cells known to be involved in innate immunity and in placental implantation. Potential important applications of sponges in the search for new pharmaceuticals and in key biomedical areas such as stem cell research are just around the corner awaiting the development of sponge cell cultures.

Key Words: Cell adhesion, Extracellular matrix, Glycosaminoglycans, Invertebrate histocompatibility, Porifera, Proteoglycans, Self–nonself recognition, Single-molecule force spectroscopy.

SPECIES-SPECIFIC CELL ADHESION IN SPONGES AS A MODEL OF ORGAN-SPECIFIC CELL ADHESION

"Sponges grow spontaneously either attached to a rock or on sea-beaches, and they get their nutriment in slime: a proof of this statement is the fact that when they are first secured they are found to be full of slime." From Aristotle's History of Animals, 350 BC.[1]

AGGREGATION ASSAYS WITH CELLS AND SYNTHETIC BEADS Sponges are the most primitive present-day multicellular animals. They lack organs, but their bodies consist of a few classes of cells that are responsible for specialized functions such as food intake, epithelium formation, and self–nonself recognition, among others. In 1907, Wilson[2] pioneered the use of sponges as model animals for the study of cell adhesion, describing the existence of species-specific reaggregation of marine sponge cells that had previously been mechanically dissociated by passing them through a fine cloth. After disaggregation the cells slowly settled down and started moving; upon contact they generally adhered and larger aggregates were formed as new encounters continued to occur, eventually reorganizing functional miniature sponges.[3] When dissociated cells of differently colored sponge species were mixed and allowed to aggregate, the cells of one species combined with each other, but not with those from a different species. This phenomenon is analogous to the organ-specific cell adhesion events that represent the basis of clinically important processes such as cancer metastasis and graft rejection. Sponge cells associate species specifically through multivalent interactions of carbohydrate structures on a type of extracellular proteoglycan termed aggregation factor (AF),[4–6] the *slime* Aristotle was referring to. Based on their molecular structure, AFs have been related to hyalectans[5]: large, extracellular aggregating modular proteoglycans. But unlike hyalectans, aggregation factors do not possess any of the main glycosaminoglycan (GAG) types described in higher animals; instead, they have complex and repetitive acidic carbohydrate motifs different from those found in classical proteoglycans and mucins,[7] which include novel acid-resistant and acid-labile carbohydrate domains, large and branched pyruvylated oligosaccharides,[8] and other previously unknown structures.[6,9–11] In the marine sponge *Microciona prolifera* the proteoglycan molecule, *Microciona* AF (MAF), binds cell membrane receptors via Ca^{2+}-independent interactions of small 6-kDa glycans (g6). Larger 200-kDa glycans (g-200) self-interact through calcium-dependent associations (Figure 10–1C and D). This bifunctional structure is common to all sponge AFs studied so far and represents one of the first specific cell adhesion systems that were necessary for the evolution of Metazoans.

In aggregation assays performed with synthetic beads coupled to AFs purified from different sponge species,[12,13] the beads sorted out and associated only with those carrying AFs from the same species, providing conclusive evidence that AFs are the molecular entity responsible for species-specific cell aggregation.

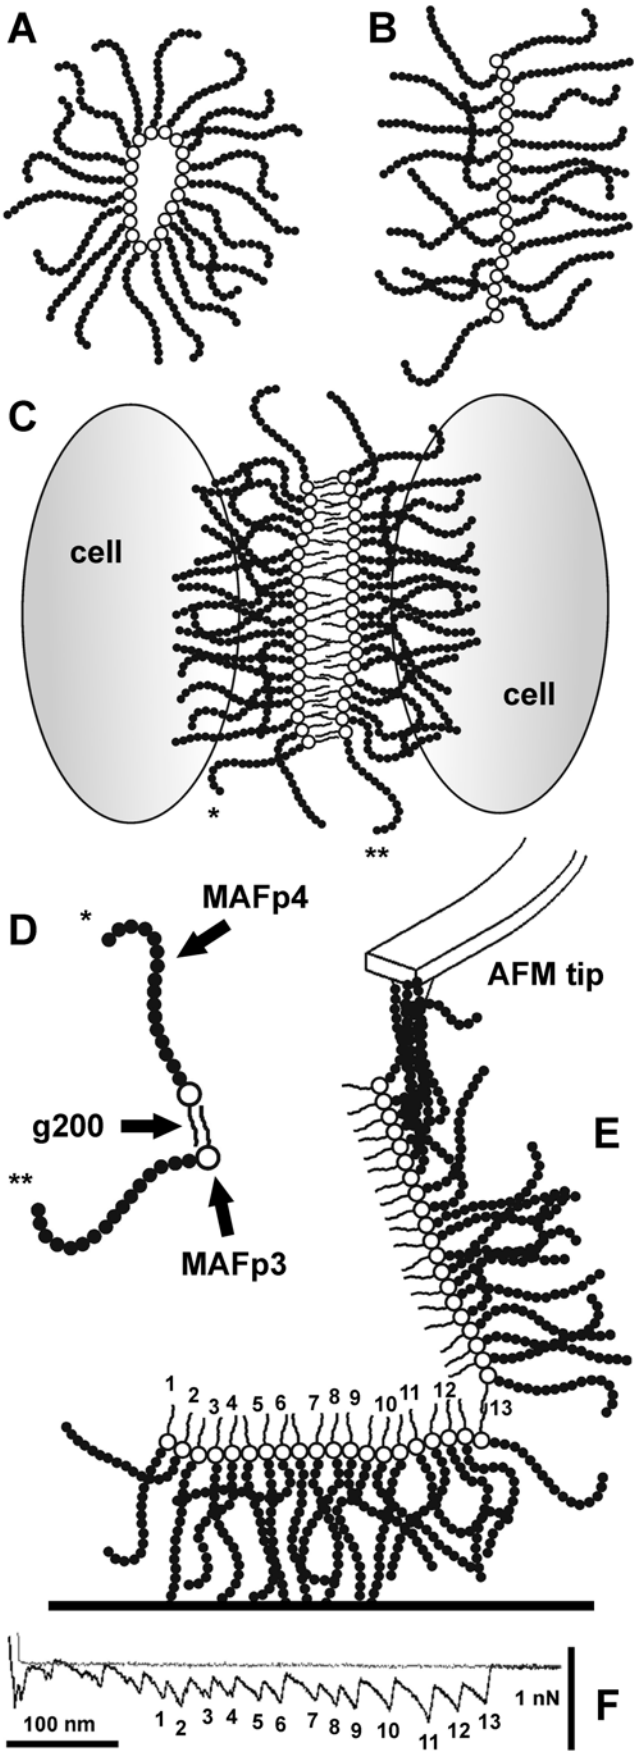

Figure 10–1. The aggregation factor of the marine sponge *M. prolifera* as a model for the study of proteoglycan structure–function relationships. (A) In its native form, MAF has the structure of a sunburst where the ring is formed by ~20 units of the MAFp3 protein (open circles), each noncovalently linked to a unit of the MAFp4 protein (an MAF "arm"). The solid circles forming MAFp4 represent repeated domains within the protein. (B) If the ring of MAF were open, the resulting structure is analogous to a classical proteoglycan, with MAFp3 and MAFp4 in place of link protein and proteoglycan monomer, respectively. (C) Model of the MAF interactions responsible for species specificity of cell adhesion: carbohydrates on MAFp4 bind receptors on the cell membrane, whereas the g-200 glycan on MAFp3 self-interacts in a calcium-dependent manner. For clarity, both MAF molecules are represented as linearized. (D) Detail of the interaction between the two subunits marked by asterisks (* and **) in (C). (E) Scheme of an SMFS experiment to study the adhesive interactions between two MAF molecules. For clarity, both molecules are represented as linearized. (F) Typical SMFS approach-retract curve obtained in experiments performed with native MAF, consistent with the representation from (E). The numbers from 1 to 13 correspond to the breaking of the individual g-200-g-200 interactions represented in (E) as the AFM tip is retracting from the surface. The 100-nm scale bar refers to parts (E) and (F) only. (Adapted from Garcia-Manyes *et al.*[18])

Glycoprotein subunits of MAF obtained through dissociative denaturing procedures bind *Microciona* cells, but with decreasing affinity correlating linearly with the decreasing size of the subunits,[14] suggesting polyvalency in the cell binding site. A small glycopeptide of 10 kDa obtained after trypsin digestion of MAF showed very little affinity for homotypic cells in its monomeric form, but reconstitution of binding affinity in the same order of magnitude as the native molecule could be obtained by polymerizing the glycopeptide fragment.[15] Eventually, both MAF–cell and MAF–MAF binding affinities were recovered upon chemical crosslinking of protein-free glycans isolated from the AF complex into large multivalent structures.[6,9,16] This indicated an active role for the carbohydrate moiety of MAF in the aggregation of sponge cells. In a final series of experiments it was shown that glycan-coated beads aggregated according to their species of origin, i.e., the same way as live sponge cells did.[17] Live cells also demonstrated species-selective binding to glycan-coated surfaces. These findings confirmed for the first time the existence of highly specific recognition between surface glycans, a process that may have significant implications in cellular interactions.

ROLE OF CARBOHYDRATES IN CELL ADHESION g-200 is not a common GAG, as suggested by its elevated fucose content and its resistance to usual GAG-digesting enzymes.[6] Preliminary nuclear magnetic resonance analyses performed with intact g-200 chains indicated such a structural diversity that the possible existence of a backbone containing a basic repetitive oligosaccharide unit could not be determined.[11] This complex structure of g-200, in contrast to the much simpler linear repetitive chains of chondroitin sulfate, heparan sulfate, or hyaluronan, can provide the basis for its highly selective adhesive properties in 10 mM Ca^{2+}, as illustrated by a strong intraspecies-specific binding,[18] weaker interspecies-specific interactions,[17] and very small adhesion forces with other unrelated GAGs.[18] Both the strength and the specificity of calcium-dependent carbohydrate–carbohydrate interactions might be guaranteed by polyvalency, by

compositional and architectural differences between carbohydrates, and by the arrangement of the carbohydrate chain in a three-dimensional context, where calcium ions provide not only electrostatic forces but can contribute via coordinative forces to glycan superstructures.[19]

Specific carbohydrate–carbohydrate interactions are rarely reported in biologically relevant situations such as cell recognition. However, carbohydrate structures have immense structural diversity, a ubiquitous distribution in vertebrate and invertebrate tissues, and are associated with the cell surface, as required of cell recognition molecules.[20] Carbohydrate–carbohydrate interactions are characterized by relatively weak forces that, when multimerized, can be easily potentiated by orders of magnitude, representing a highly versatile form of cell adhesion given the extraordinary plasticity of their structures.[21] Among the few known examples of carbohydrate self-recognition proposed to be specific in biological processes are the multivalent binding of Lewis^x epitopes involved in the first steps of embryogenesis[22] and in cancer metastasis,[23,24] glycolipid–glycolipid interactions controlling cell adhesion, spreading, and motility,[25,26] and self-interactions of the glycan portion of sponge proteoglycan carbohydrates leading to species-specific cell adhesion.[17,19]

The species specificity of cell recognition mediated by sponge proteoglycans can be a useful model to study other adhesion processes at structural levels above individual cells. Sponges do not have organs, and therefore the molecular machinery regulating the recognition between cells from different sponge species might be based on the same principles that rule the interactions between cells from different organs in higher animals. Adhesion molecules are essential to motility by interacting with bound and soluble substrates within the extracellular matrix (ECM). Proteoglycans bound to the plasma membrane mediate the polyvalent interaction of the cell with ECM constituents and with molecules from neighboring cell surfaces. Given their direct involvement in cell–cell and cell–ECM interactions, proteoglycans are likely to be implicated in the regulation of cell movement, but to what degree the carbohydrate moiety affects this process is only partially understood.

Cadherins are a family of Ca^{2+}-dependent adhesion molecules that bind cells via homophilic interactions, and cells expressing distinct cadherins aggregate separately when mixed in culture.[27] Cadherins are responsible for the cell sorting that is necessary to distribute different cell types to their proper positions during development. During embryogenesis, the expression of different cadherins is spatiotemporally regulated, and correlates with events that involve cell aggregation or disaggregation. Alterations in cadherin expression or function occur frequently during carcinogenesis and tumoral angiogenesis.[28,29] Another group of cell adhesion molecules includes those related to the immunoglobulin (Ig) superfamily, which generally have Ca^{2+}-independent heterophilic binding.[30] AF-promoted cell adhesion in sponges is based on carbohydrate structures with both Ca^{2+}-dependent homophilic binding and Ca^{2+}-independent heterophilic interactions with cell surface receptors, suggesting that proteoglycan-linked glycans can have important functions in cell adhesion and recognition, comparables to those assigned to cadherins and to molecules of the Ig superfamily.

Metastasis, the process by which a primary malignancy establishes distant and discontiguous disease, clearly involves carbohydrate-mediated cell adhesion.[31] Not all tumors are capable of metastasis, and those that succeed in it rely on a series of steps that involve cell dissociation, motility, and subsequent readhesion.[32] CD44 is a widely distributed cell surface glycoprotein that binds to ECM components containing hyaluronic acid (HA).[33] This permits tumor attachment and migration toward degraded areas rich in HA. CD44 expression is associated with aggressive melanomas and it is an indicator of poor prognosis.[34] As we will see below, antibodies raised against CD44 specifically target a sponge cell type of elevated motility.[35] Study of the essential role that carbohydrates play in sponge cell recognition, motility, and specific adhesion might contribute to understand the participation of carbohydrate structures in the complex processes leading to cancer spreading.

SPONGE AGGREGATION FACTORS AS A MODEL FOR THE STUDY OF PROTEOGLYCAN STRUCTURE–FUNCTION RELATIONSHIPS

The biological roles assigned to proteoglycans are highly diversified, ranging from relatively straightforward mechanical functions to effects on more dynamic processes such as cell adhesion and motility, to complex and still poorly understood tasks in cell differentiation and development.[36–39] Angiogenesis, axon guidance and synapse development, metastasis, and patterning events are just some examples of processes that require finely tuned interactions between cells or between cells and the ECM where proteoglycans are involved.[40–44] Efforts aimed at a better understanding of proteoglycan structure and function are often hampered by the difficulties in their isolation from vertebrate tissues. The purification of proteoglycans is often complicated by (1) limited source quantities, (2) the necessity of chaotropic solvents, proteases, and high temperatures for efficient extraction, (3) their large molecular size, and (4) a lack of defined functions to enable purity to be assessed.[45] Marine sponge proteoglycans are relatively small and can be extracted in considerable amounts while preserving their biological activity by following a mild protocol that essentially consists of dissociating the sponge tissue in calcium-free sea water and spinning down the cells and other debris. The resulting supernatant contains aggregation factor as the main component in such quantities and purity that it can be directly used for cell aggregation assays and other functional experiments. For structural determinations, this preparation has to be centrifuged at high speed to pellet the AF that is finally purified in a cesium chloride density gradient. Concentrated AF solutions (≥1 mg/ml) are highly resistant to proteolysis and can be stored at 4℃ for months without signifi cant loss in their specific cell aggregation capacity.

STRUCTURAL ANALYSES AND SINGLE MOLECULE FORCE SPECTROSCOPY STUDIES The supramolecular structure of MAF was elucidated by using immunochemical and electrophoretic procedures, combined with atomic force microscopy (AFM) imaging.[46] Twenty units from each of two N-glycosylated proteins, MAFp3 and MAFp4, form the central ring and radiating arms of MAF, respectively, stabilized by a hyaluronidase-sensitive component.[46] Each of the 20 arms is attached to one of the 20 globular structures in the ring in a 1:1 stoichiometry (Figure 10–1A), with an estimated molecular mass for the whole molecule of 2×10^7 Da.

Each MAFp3 ring unit carries on average one copy of the g-200 glycan involved in homologous self-interactions between

aggregation factor molecules (Figure 10–1C and D), whereas each MAFp4 unit carries about 50 copies of the g-6 glycan that binds cell surface receptors.[46] MAFp3 is a highly polymorphic 35-kDa protein, as deduced from direct cDNA sequencing of several different allelic forms and from restriction fragment length polymorphism analysis of genomic DNA isolated from different individual sponges.[47,48] MAFp4 has an estimated molecular mass of ~400 kDa,[48] is also polymorphic, contains putative transmembrane regions, and has a stretch sharing 30% homology with the cytoplasmic domain of the Na^+–Ca^{2+} exchanger,[49] a membrane protein responsible for the maintenance of low intracellular Ca^{2+} levels.

Both MAFp3 and MAFp4 contain abundant Ca^{2+}-binding sites and glycosylation motifs. If the MAF circular core were open, the resulting linear structure would be remarkably similar to hyalectans[50] (Figure 10–1A and B), although the building blocks of both molecules lack sequence homologies. MAFp4 is analogous to the glycosylated core protein of the proteoglycan monomer, and carries the N-linked g-6 glycan instead of O-linked GAGs. MAFp3 is the sponge counterpart of the link protein, both molecules having very similar sizes. Like link protein, MAFp3 is N-glycosylated and contains eight cysteines involved in disulfide bonds. Unlike link protein, though, MAFp3 does not contain an Ig-like domain.

During the past decade, single molecule force spectroscopy (SMFS) has developed into a highly sensitive tool for the investigation of single biomolecule interactions.[51] Most SMFS experiments use either optical tweezers or AFM to measure dissociation forces of single ligand–receptor complexes in the piconewton range. AFM-based SMFS has the capacity to detect interactions as weak as individual hydrogen bonds. The molecular binding partners are attached to the nanoscale force sensor and to a sample holder by covalent chemistry. A critical step in the design of an SMFS experiment is the crosslinking of biomolecules to surfaces, which can introduce undesired reactive groups or steric constraints resulting in the alteration of the biological interaction under study. In the particular case of AFs, their abundant sulfate groups provide a very strong quasicovalent binding to gold surfaces, thus allowing immobilization in the absence of chemical modification, and without affecting the binding sites.[18]

When the AFM sensor and holder are brought into close contact, a specific bond between the individual molecules can form. By increasing the distance between the two surfaces again, the molecular bond is loaded under an external force until it finally breaks, yielding the molecular dissociation force. Upon systematical variation of the externally applied load and monitoring the mechanistic elasticity of the complex, information about the kinetic reaction rates, the mean lifetime, the equilibrium rate of dissociation, dissociation length, and the energy landscape of the interaction can be derived. SMFS studies performed with sponge-derived proteoglycans of their calcium-dependent interactions[18] have revealed functional intermolecular domains (Figure 10–1E) that can contribute to many adhesive and elastic ECM interactions. The multiplicity of individual binding sites with a mean force of ~250 pN for each adhesion event (Figure 10–1E and F) confers a high degree of modulability as required in most biological interactions, in contrast to the higher stability of a single, strong bond. This modular elongation mechanism, be it intramolecular or intermolecular, has been proposed to be a general strategy for conveying toughness to natural fibers and adhesives.[52] Sponge proteoglycan extension curves, then, derive from the existence of intermolecular adhesion domains that through the summation of multiple single binding sites provide strong adhesion forces for the resulting polymer.[18] The cooperativity of abundant, relatively weak intermolecular carbohydrate adhesion domains provides a molecular basis for some of the functions of modular proteoglycans.

IMPLICATION OF PROTEOGLYCANS IN EXTRACELLULAR MATRIX-RELATED PATHOLOGIES Proteoglycans are among the first ECM constituents to be produced during embryonic development and are often aberrantly expressed in a variety of inherited and acquired disorders. One of the major pathological features of Alzheimer's disease is the presence of plaques composed of β-structured fibrils made up of amyloid-β peptide (Aβ).[53] Nucleation of Aβ can occur by self-assembly or by heterogeneous nucleation resulting from seeding Aβ onto non-Aβ elements present in the ECM, such as proteoglycans.[54]

One of the most common nonenzymatic posttranslational protein modifications is the reaction of reducing sugars (or of other carbohydrates resulting from the fragmentation of diverse polysaccharides) with nucleophilic amino acid side chains such as those found in arginine and lysine. Subsequent restructuring, oxidations, and dehydrations generate a group of heterogeneous compounds termed advanced glycation endproducts (AGEs).[55] AGEs have been found in pathological protein deposits such as the senile plaques characteristic of Alzheimer's disease or the β_2-microglobulin deposits in hemodialysis patients.[56] Given their participation in the regulation of diverse growth factors and cytokines through receptor-mediated mechanisms, it has been proposed that AGE-modified proteins are involved in the pathology of several age-related diseases.[57] *In vitro*, AGE formation accelerates the growth of β-amyloid aggregates through covalent crosslinking of Aβ monomers.[58] The extracellular accumulation of AGEs can be caused by an accelerated oxidation of glycosylated proteins and proteoglycans.[59] Glycosylated proteins and, especially, proteoglycans (whose carbohydrate content can be higher than 50%) produce an amount of radicals almost 50 times higher than that generated by nonglycosylated proteins. Proteoglycans are associated with and are likely play a fundamental role in the deposition of amyloid fibrils in all amyloid diseases.[60] Fibril formation and the lateral aggregation of Aβ *in vitro* are increased by GAGs,[61] in a pH-dependent effect.[62] Therefore the interaction of GAGs with amyloid fibrils might be based on electrostatic interactions similar to those involved in the calcium-mediated aggregation of AFs. MAF has been shown to induce a structural transition in Aβ from random coil toward highly stable fibrillar β-sheet structures as detected by circular dichroism spectroscopy,[63] and to increase Aβ-induced toxicity of nerve growth factor-differentiated PC-12 cells in the absence of Ca^{2+}. The addition of Ca^{2+} to MAF-Aβ aggregates resulted in a moderate attenuation of toxicity possibly due to a reduction in Aβ–cell interactions caused by extensive lateral aggregation of the MAF–Aβ complexes. Such aggregation might be seeded by the self-association of MAF triggered by calcium. These results indicate that Aβ is generally susceptible to proteoglycan-mediated aggregation and fibril formation. Sponge proteoglycans, thus, represent a simple model system that can be used to examine potential drugs for the treatment of amyloid-related disorders.

Microfibrils are evolutionarily ancient macromolecular assemblies of the ECM formed by the protein fibrillin. They have unique extensible properties that endow vascular and other tissues with long-range elasticity. In humans, mutations in the principal structural component of microfibrils, fibrillin-1, are linked to the inheritable disease Marfan syndrome, which is characterized by severe cardiovascular, skeletal, and ocular defects.[64] Fibrillin-1 is a calcium-binding protein and it has been found that variations in its calcium-binding properties may be important for microfibril assembly and for the biomechanical properties of microfibrils within tissues.[65] The fibrillin-1 domain with the highest recorded affinity for calcium is located in the region of the protein where mutations (including those that specifically disrupt calcium binding) cause the most severe form of disease, neonatal Marfan syndrome. Proteoglycans have important, but still poorly understood structural interactions with microfibrils, and they may contribute to their integration into the ECM.[66]

ALLOGENEIC RECOGNITION IN SPONGES AS MODEL OF HISTOINCOMPATIBILITY REACTIONS

GRAFTING EXPERIMENTS, IMMUNOCYTOCHEMICAL ANALYSES, AND GENETIC STUDIES When tissues from different individuals of a given sponge species are brought into contact, they either fuse or reject through cellular events similar to those observed in vertebrate grafts.[67] There is, though, a peculiarity of the sponge self–nonself recognition system that so far has not been described in other phyla, which is the possible involvement of proteoglycans in histoincompatibility reactions.

In *M. prolifera*, sponge fragments can be easily grafted, thus allowing the design of tissue histocompatibility experiments that yield important information about the cell types involved in the process.[35] In a typical grafting experiment, 2-cm-long sponge papillae are pushed together on a 0.5-mm-thick stainless steel insect pin, keeping the tissues under seawater at all times. The pins are finally stuck into the underside of a Styrofoam rack and left to float on a tank with running seawater at 20℃. As soon as 2 h after the graft set-up, massive cell migration toward the zone of contact is evident. The study of the sponge cell types involved in this phenomenon has shed new light on our understanding of the evolution of early histocompatibility systems.

Polyclonal antibodies raised against MAFp3 are specific markers for archeocytes, the sponge stem cells.[35] Archeocytes are mobilized upon allogeneic contact (between tissues from two individuals of the same species), and they accumulate in the contact zone. A second type of cell that also migrates profusely to allograft interfaces, the gray cells, is specifically recognized by monoclonal antibodies raised against the HA receptor CD44.[35] In allograft contact areas an observed decrease in the intensity of archeocyte staining is accompanied by an increase in the number of gray cells, which are the most adhesive cell type in *M. prolifera*.[68] A higher adhesion would slow down cell movement and aggregation, contributing to the nonfusion characteristic of allografts. Besides this cell adhesion-related role of gray cells in allograft interfaces, other evidence suggests a more direct immunological function for this cell type, which has been proposed to be the sponge immunocyte.[69,70] In contrast, the contact zone of sponge isografts (grafts made between genetically identical tissue fragments) does not accumulate cells. Here, the absence of a massive gray cell migration would permit the cell movements and aggregation necessary for the final outcome of isografts, which invariably end up in the fusion of the interacting tissues. This differential behavior implies the existence of a genetically based system of individual-specific cell signaling molecules. Although the precise nature of these self–nonself recognition markers has not been established yet, genetic studies point at MAF or MAF-related entities as one of the elements of the sponge histocompatibility system.[47,48]

Due to the presence in sponge tissue of a potent nuclease activity, a special protocol had to be devised for the purification of high-quality sponge genomic DNA[49]: 0.1 ml from a pellet of freshly dissociated sponge cells is added to a 2-ml tube to 0.9 ml of a buffer containing 4 M guanidinium thiocyanate, 25 mM sodium citrate, pH 7, 0.5% sarcosyl, and 0.1 M 2-mercaptoethanol, and gently mixed by immersion until the viscous solution becomes homogeneous. The proteins are then extracted with a 1:1 mixture of phenol/chloroform equilibrated with TE buffer (10 mM Tris–HCl, pH 8, 1 mM EDTA). After a second extraction with chloroform/isoamyl alcohol 24:1, the DNA contained in the water phase is ethanol precipitated and stored at 4℃ in TE, pH 7.5. Southern blot analysis of a significant number of sponges that were subjected to grafting experiments revealed that each genetically distinct sponge individual has a different set of genomic DNA coding sequences for MAFp3 and MAFp4.[47,48] Such inter-individual variability, also observed in the carbohydrate moiety of MAF,[18,47] matches the allelic complexity of the vertebrate major histocompatibility complex (MHC) and represents an early form of self-recognition. An evolutionary connection between cell adhesion and histocompatibility systems, however, has yet to be demonstrated. A prominent domain implicated in cell adhesion, the Ig domain, exists in several copies in the large basement membrane proteoglycan.[71] Similar domains are functionally important structures in most Ca^{2+}-independent adhesion molecules such as the neural cell adhesion molecule (NCAM),[72] the intercellular adhesion molecules (ICAMs),[73,74] and other neural or immune system-associated adhesion molecules. No obvious Ig-like domains have been identified in the cDNA-deduced MAF proteins, although the repeats found in MAFp4 exhibit interesting resemblances.[48]

SELF–NONSELF RECOGNITION IN SPONGES AS AN ANCESTOR OF IMMUNE SYSTEMS Natural killer (NK) cells are a subset of granular lymphocytes that express high levels of CD44 upon activation and mediate efficient MHC-unrestricted T cell receptor-independent lysis following binding of CD44.[33] The cross-reactivity of sponge gray cells with anti-CD44 antibodies, together with other morphological and functional similarities, suggests that deeper links between NK cells and sponge allogeneic reactions are possible. First, carbohydrates are crucial to the functions of NK cells[75]: NK cells can be identified and subdivided into functionally distinct subsets on the basis of the expression of lectin-like receptors.[76] Similarly, species-specific adhesion of sponge cells has a strict dependence on finely tuned carbohydrate interactions.[67] Second, NK cells are thought to be the remnants of a primeval immune system and are generally considered to be the evolutionary precursors of T cells.[77] In the human fetus, NK cells are the first lymphocyte lineage to appear,[78] followed by γδT cells

and αβT cells, in accordance with the controversial concept that ontogeny recapitulates phylogeny. NK-like cells have been suggested to exist in invertebrates like the snail,[79] a tunicate,[80] an earthworm,[81] and the leech.[82] Finally, in the allorecognition system of invertebrates no prior sensitization is necessary. The presence of self MHC class I molecules protects target cells from lysis mediated by NK cells,[75] verifying the "missing self" hypothesis that states that NK cell targets become susceptible to NK cell killing if they lack sufficient expression of self MHC molecules. Thus, unlike T cells, which recognize the presence of non-self, NK cells recognize the absence of self.[83] This observation prompted Burnet[84] to conclude that the primary mechanism of invertebrate allorecognition is based on self-recognition and any cell that lacks self antigens will be immediately recognized as foreign, a view that was later supported by investigations on the allogeneic responses of the colonial tunicate *Botryllus schlosseri*.[85] Some aspects of this invertebrate system appear to be retained in higher vertebrates.

There are many features of the immunology of allogeneic reactions in sponges that more closely resemble the immunological relationship between the animal fetus and its mother than between vertebrate allograft and host.[86] While contact with allogeneic cells in clinical transplantation is an artificial situation, in the crowded marine environment direct cellular contact among unrelated members of sessile invertebrate species occurs as naturally as the intermingling of allogeneic cells in placental implantation. In the latter case there is a well-defined boundary dividing invasive trophoblast and maternal decidua that mimics the collagen boundary separating two unrelated sponges, a situation very different from the extensive cell killing typical of vertebrate allograft rejection. In implantation, NK cells are the predominant cell type in deciduas and T cells are sparse; similarly, invertebrate allorecognition is mediated by NK-like cells, whereas vertebrate allorecognition is mediated by T and B cells. Finally, NK cells kill target cells deficient in MHC class I antigens, unlike vertebrate graft rejection where nonself antigens are detected; as mentioned above, current evidence suggests that sponge nonself recognition detects the absence of self antigens.[35] The development in early animals of the ability to discriminate self from nonself ensured the maintaining of individuality. It is possible that such a primitive form of allorecognition has been conserved to play a role in mammalian reproduction, which is the only natural situation in which allogeneic cells come into contact in vertebrates.

FUTURE PERSPECTIVES: DEVELOPMENT OF STABLE SPONGE CELL CULTURES, STEM CELL RESEARCH, AND BIODISCOVERY OF NEW PHARMACEUTICALS

Sponges possess totipotent cells, the archeocytes, that can differentiate into the rest of the cell types. Most important, other sponge cell types do spontaneously dedifferentiate into archeocytes, a phenomenon observed in naturally occurring processes such as tissue regression and remodeling, gemmule formation, and trauma induced by tissue removal.[87] Understanding the mechanism by which specialized sponge cells can return to an undifferentiated state will contribute to the quest for a reliable and ethically acceptable source of unlimited amounts of stem cells for therapeutic applications.

The main obstacle for the firm establishment of sponges as a generally accepted model laboratory animal is the current lack of stable sponge cell cultures. Interest in the development of sponge cell lines grew in parallel with the realization that sponges are an exceptional source of metabolites with potential pharmacological activities. Because of their longer evolutionary history, marine organisms have a greater molecular diversity than do their terrestrial counterparts. Among the numerous groups of marine invertebrates sponges rank first as the leading source of natural products in terms of the biogenetic diversity of secondary constituents and the sheer number of compounds isolated.[88] Furthermore, sponges have a high strike rate, especially for cytotoxic compounds: of the investigated marine sponge species, >10% has exhibited cytotoxic activity, suggesting production of potential medicinals. This percentage is considerably higher than that found for other marine animals (2%), terrestrial plants (<1%), or microorganisms (<1%).[89] Products with pharmacological activity identified in sponges include, among others, analgesics, antiinflammatory compounds, antitumorals, immunosuppressors, cardiovascular agents, neurosuppressors, muscle relaxants, antivirals, antimalarials, antibiotics, fungicides, and antifouling compounds.[90] Although many bioactives have been discovered in sponges, only a few of them have been commercialized.[91] Obtaining the necessary amounts of these metabolites requires quantities of sponge biomass that cannot be sustainably harvested from natural populations. Cultivation of sponge biomass in sea-based farms is feasible, but productivity is variable. Biomass production in controlled environments of aquariums has the potential to provide consistent yields, but many aspects of aquarium cultivation remain unknown for most sponges. In this context, the culture of sponge cells can become a future reliable source of metabolites.

However, sponge cell culture represents a unique purification challenge because, unlike higher Metazoans, there are no areas of a sponge from which a sterile primary culture can be obtained.[92] As an added complication, many sponges host endosymbionic microorganisms that may be released into an otherwise sterile culture if cells lyse. Control of microbial contamination is the most important obstacle to overcome in the establishment of primary sponge cell cultures. A combination of filtration, use of sterile media during cell dissociation, and selective sponge cell enrichment by density gradient separation has proven to be most effective. In addition, extended culture of dissociated sponge cells invariably requires the use of antibiotics to suppress bacterial contamination, especially in the rich media that are required. The antibiotic cocktails used do not inhibit fungal growth and proliferation of fungi is a recurring problem, and this at a cost that precludes any commercially sustainable metabolite production. As a result, current methodologies are at the stage of primary cultures without any significant progress toward a substantial increase in cell numbers or biomass due to cell proliferation.[93,94] The potential of sponges as model animals for the study of cellular recognition processes such as the ones described above will not be fully exploited until long-lasting cell cultures are successfully developed.

11 Sea Urchin Embryo

A Model System for Analyzing Cellular Activities During Early Development

TETSUYA KOMINAMI AND HIROMI TAKATA

ABSTRACT

Sea urchin embryos have long been used as ideal experimental materials. In this chapter, we describe research areas to which sea urchin embryos have contributed, and the potential fields for which they may serve as a model system. The most valuable feature of sea urchin embryos is the availability of a large amount of homogeneous material, which facilitates biochemical and molecular biological approaches. The ease of gamete handling enables detailed analysis of the mechanism of fertilization, and the transparency and synchrony of fertilized eggs facilitate investigations on cell division and the cell cycle. Sea urchin embryos are an ideal model system for signal transduction, because the number of constituent cells is small. The simple organization of the embryo simplifies the analysis of morphogenetic movements. Both primary and secondary mesenchyme cells are interesting populations for studying cell movement. Sea urchin embryos will continue to contribute to the analysis of various unsolved problems.

Key Words: Sea urchin embryo, Fertilization, Cell division, Cell cycle, Signal transduction, Specification, Gastrulation, Invagination, Morphogenesis, Cell movement.

HANDLING OF ANIMALS AND EMBRYOS

Sea urchins belong to the phylum Echinoidermata (echinoderms), which consists of six classes (Crinoidea, Asteroidea, Concentricyclodea, Ophiuroidea, Echinoidea, and Holothuroidea). At present, nearly 900 species of sea urchins (class Echinoidea)—divided into nine orders—are known. Most live in intertidal zones or shallow seas, and their distributions extend from equatorial regions through the North and South Poles. Embryos of sea urchins are frequently used in biological and medical research including those of *Strongylocentrotus purpuratus*, *Lytechinus variegatus*, *Lytechinus pictus*, *Arbacia punctulata* (North America), *Paracentrotus lividus* (Mediterranean Sea), *Psammechinus miliaris* (North Sea), *Hemicentrotus pulcherrimus*, and *Anthocidaris crassispina* (Japan). The whole genome of *S. purpuratus*, a well known species in North America, has already been sequenced (http://sugp.caltech.edu/). In the United States, some species are available from commercial suppliers such as Susan Decker (Davie, FL) or Marinus Scientific (Long Beach, CA). Some marine laboratories also supply these materials in several countries. Adult sea urchins are reared in a small aquarium equipped with a simple filtering system and maintained without feeding for a couple of months.

During the breeding season, fertilizable oocytes are shed following intracoelomic injection of 0.5 M KCl. In some species, more than a million eggs are obtained from a single female. Usually, the testis is directly excised from adult males, and the leaked semen is diluted with seawater immediately before use. Fertilized eggs are obtained by simply adding the diluted sperm to an egg suspension.

For embryo culture, natural seawater should be filtered to remove debris and microorganisms. If fertilized eggs are deprived of the fertilization envelope for manipulations, it is preferable to add antibiotics (e.g., streptomycin or penicillin). Commercially supplied artificial seawater (e.g., Instant Ocean) is also available. At an appropriate density, fertilized eggs developed into pluteus larvae within 2–3 days without any special care. Detailed handling of animals and embryos has been described previously.[1]

FERTILIZATION

The finding of the acrosome reaction in starfish spermatozoa[2] led to detailed analysis of fertilization processes, which was accompanied by improved electron microscopic and biochemical techniques. Many important concepts of fertilization (cortical reaction, activation, Ca^{2+} release, acid release, change in membrane potential, block to polyspermy, etc.) have come from numerous studies of sea urchin fertilization. The jelly coat of *A. punctulata* contains a chemoattractant for spermatozoa,[3] although this has not yet been proved in other sea urchin species. When a sperm head attaches to the jelly coat (Figure11–1A), the acrosomal vesicle breaks down and the acrosomal process forms. Proteolytic enzymes contained in the acrosomal vesicle digest the jelly coat and allow the spermatozoon to approach the egg. The first contact between sperm and egg is mediated by bindin on the acrosomal process and its receptor on microvilli extruded from the oocyte.[4] The binding of bindin and its receptor shows species specificity, and leads to the membrane fusion of both gametes.

(F) Sixty-cell stage. The four tiers of blastomeres are named an_1, an_2, veg_1, and veg_2 along the animal–vegetal axis. (G) Late blastula stage. (H) Fate map drawn in the median plane of the swimming blastula. (I) Pluteus larva (48 h after fertilization in *Hemicentrotus pulcherrimus*). (E–G) Positions of *Wnt8* and *Nodal* expressions are indicated in dark and light gray, respectively. (A–F) Frontal view. (G–I) Side view. Dotted lines in (G) indicate the boundaries of the veg_1 and veg_2 tiers. (H, I) Labels for SMCs (dark gray), foregut (reticulated), mid-gut (hatched), hind gut (dotted), and oral ectoderm (light gray) are common to Figure 11–2, which shows more details on stages between (H) and (I) of this figure. ap, animal pole; aoe, aboral ectoderm; cg, cortical granule; cr, contractile ring; fm, fertilization membrane; fp, female pronucleus; hl, hyaline layer; jc, jelly coat; ma, mitotic apparatus; mac, macromere; meso, mesomere; mic, micromere; mp, male pronucleus; oe, oral ectoderm; sp, spermatozoon; st, degenerating sperm tail; vm, vitelline membrane; vp, vegetal pole.

Following cell membrane fusion, the Na^+–K^+ ion channels of the egg act to elevate the intracellular Na^+ concentration and to depolarize the egg membrane. This electrical change is a rapid and transient block to polyspermy.[5] The influx of Ca^{2+} at the fusion site triggers the breakdown of cortical granules (cortical reaction), which is a typical Ca^{2+}-induced Ca^{2+} release reaction. The exocytosis of cortical granules propagates from the sperm entry point toward the opposite site concentrically. With cortical granule breakdown, the fertilization membrane is elevated (Figure 11–1B). This physical barrier is a late and permanent block to polyspermy. Molecules contained in the cortical granules cover the egg surface and form the hyaline layer (Figure 11–1B). Sea urchin fertilization is providing a model system for the analysis of intracellular signaling pathways for Ca^{2+} release from internal supplies.

After entry into the egg, the sperm head decondenses and becomes a male pronucleus. Centrioles brought into the egg with the sperm nucleus act as a microtubule-organizing center. The female pronucleus is pulled toward the centrioles along a ray of microtubules from the growing sperm monaster[6] and fuses with the male pronucleus. The transparency of the fertilized eggs enables us to observe these processes in detail.

CELL DIVISION AND THE CELL CYCLE

Fertilized sea urchin eggs have greatly contributed to the understanding of the mechanisms of cell division. This is due to the ease of handling and the transparency and synchrony of fertilized eggs. With differential interference contrast imaging or polarizing microscopy, dynamic changes in the mitotic apparatus—assembly and disassembly of microtubules—are observable (Figure 11–1C). Even the number of microtubules that constitutes the mitotic spindle can be estimated from the intensity of birefringence.[7]

By deforming fertilized eggs into various shapes, Rappaport has studied the spatial relationship between mitotic spindle and cleavage furrow.[8] It is now widely accepted that differences in the density of the microtubules that reach the egg cortex determine the position of the cleavage furrow (i.e., the position of the contractile ring), which exerts the main force for cytokinesis (Figure 11–1C). The existence of the contractile ring was first reported in fertilized sea urchin eggs.[9] To preserve this structure for electron microscopy, more than 500 combinations of buffers and fixatives were tested, but we can now detect microfilaments more easily using fluorescent phallacidins.

The fertilized eggs begin to cleave within 1.0–1.5 h after fertilization, and show radial and holoblastic cleavages. Up to the eight-cell stage, the cleavage pattern is typical (Figure 11–1D). In some species, blastomeres in the animal hemisphere are somewhat larger than those in the vegetal hemisphere. This is the first sign of the animal–vegetal axis. At the fourth cleavage, the animal blastomeres undergo meridional cleavage and give rise to eight blastomeres with the same volume (mesomeres). In the vegetal half, cleavage is horizontal and the cleavage plane shifts to the vegetal pole. As a result, four large blastomeres (macromeres) and small blastomeres (micromeres) are formed (Figure 11–1E). This formation of macromeres and micromeres is an excellent model for research of unequal cell division.

In most species, seven or eight rounds of synchronous cleavages occur at intervals of 0.5–1.0 h. The cell cycle then extends and the synchrony of division is lost. As is well known, the cell cycle is regulated by complexes of cyclin and Cdc(s) or Cdk(s). It is of note that cyclins were first found in sea urchin embryos.[10] By the stage of hatching, the fertilized eggs usually undergo 10 cleavages and develop into spherical and hollow blastulas (Figure 11–1H). The time required for development to the hatching stage is 10–12 h in most species. The hatched blastula develops into a pluteus larva through a series of morphogenetic movements and organogenesis within 2–3 days (Figure 11–1I). It is of note that each part of the larval body comprises a monolayered epithelium.

SIGNAL TRANSDUCTION AND GENE REGULATORY NETWORK

The double gradient theory has explained the results obtained from classical deletion and recombination experiments on sea urchin embryos.[11] Recent studies have revealed that micromeres and their descendants act as a signaling center for embryonic body patterning along the animal–vegetal axis. Briefly, β-catenin enters the nuclei of micromeres soon after their formation.[12] Then, *Wnt8*

expression begins in micromeres[13] (Figure 11–1E). By the 60-cell stage (after the sixth cleavage), its expression in micromere descendants disappears. Instead, expression is noted in the veg_2 tier of blastomeres (Figure 11–1F). Furthermore, expression of *Wnt8* shifts to the descendants of the veg_1 tier of blastomeres as the cleavage progresses (Figure 11–1G).

The delta-Notch signaling pathway is also involved in the specification of mesodermal cells.[14] This pathway also participates in defining the boundary between mesoderm and endoderm.[15] These upward signal transductions seem to last until the mesenchyme blastula stage. In the vegetal plate of the mesenchyme blastula, a number of nonciliated cells (probably the progeny of small micromeres) are positioned at the center of the vegetal plate, and prospective mesodermal and endodermal cells are positioned concentrically.[16] The detailed gene regulatory network for the specification of the endodermal–mesodermal lineage has been intensively studied and demonstrated in Davidson's laboratory (http://www.its.caltech.edu/~mirsky/index.htm).

For specification of the dorsoventral (oral–aboral) axis, Nodal, which is a secreting protein, seems to play a crucial role.[17] Expression of Nodal begins at the mid-to-late blastula stage (Figure 11–1G). This is followed by the expression of *goosecoid* and *Brachyury*, which are the target genes of Nodal. However, the earlier phases of the oral–aboral axis specification remain unclear. Although unequal distribution of mitochondria in unfertilized eggs is one of the factors that leads to Nodal expression,[18] it is also possible that some molecules colocalizing with mitochondria affect the specification of the oral–aboral axis. Furthermore, it remains unclear whether sperm entry leads to the displacement of a cytoplasmic component that affects the oral–aboral specification.

MORPHOGENESIS OF A MONOLAYERED EPITHELIUM

Gastrulation is the most prominent morphogenetic event in early development, resulting in the formation of three germ layers: ectoderm, mesoderm, and endoderm. To determine the mechanism of gastrulation, sea urchin embryos have long been used as a model system owing to their transparency, simple organization, and synchrony. The process of sea urchin gastrulation is composed of five steps.[19]

Step 1: After hatching, primary mesenchyme cells (PMCs), the descendants of micromeres, begin to migrate into the blastocoel (Figure 11–2A). PMC precursor cells embedded in the blastocoel wall retract the anchoring microvilli from the hyaline layer, lose their cilia and adhesion to neighboring cells, disrupting the basal lamina that coats the inner surface of the PMCs.[20] As a result, the PMCs become rounded and slip from the vegetal plate into the blastocoel. This step is a model for the epithelium–mesenchyme transition.[21]

Step 2: Once invagination has started, the thickened vegetal plate bends inward and gives rise to a short, stub-like gut rudiment within a rather short period of time (Figure 11–2C and D). This step is called primary invagination,[22] and has been intensively studied to determine the mechanism of invagination of a monolayered epithelium. As in amphibian embryos,[23] apical constriction of bottle cells triggers the onset of invagination.[24] However, the cellular basis of primary invagination cannot solely be ascribed to bottle cells, since invagination occurs even in bottle cell-depleted embryos despite a significant delay in invagination.[25] Several models are proposed to explain primary invagination.[26] Each model partly explains the change in shape of the invaginating gut rudiment. However, the kinds of forces operating during this simple morphogenetic movement are not fully understood. Other factors such as the force exerted by noninvaginating epithelium and changes in the turgor pressure of the blastocoel should be considered for further understanding of the mechanism of primary invagination.[19]

Step 3: After the primary invagination, a pause (for 1–2 h in most species) in the elongation of the gut rudiment is observed. During this period, secondary mesenchyme cells (SMCs) appear at the archenteron tip (Figure 11–2E). The SMCs extend long and thin filopodia toward the animal pole side, exploring the attachment site. With high-resolution Nomarski imaging, the presence of very thin filopodia (0.2–0.4 μm diameter) extending from SMC have been shown.[27] These thin filopodia provide a means by which cells can contact others several cell-diameters away. Target recognition by the SMC filopodia seems to be mediated by localized carbohydrate chains, since the mannose-specific lectin *Lens culinaris* agglutinin blocks the anchoring of the SMC filopodia to the prospective oral opening.[28]

Step 4: After this pause in archenteron elongation, the gut rudiment rapidly elongates until its tip reaches the inner surface of the apical plate (secondary invagination), resulting in a slender archenteron (Figure 11–2F). Several lines of evidence suggest that the filopodia connecting the archenteron tip and the apical plate pull the gut rudiment upward.[29] Dozens of cells are initially observed on cross sections of the gut rudiment, but the number

decreases to seven or eight after the completion of secondary invagination.[30] This explicitly indicates that the archenteron cells are rearranged during this morphogenetic process.

Step 5: It has long been thought that endodermal cells are exclusively derived from the veg_2 tier of blastomeres.[11] However, by labeling of veg_1 and veg_2 blastomeres with DiI, it was shown that the descendants of veg_1 blastomeres are also recruited into the archenteron.[31] Subsequent studies revealed that veg_1-derived cells are added to the archenteron after the completion of secondary invagination.[32] Cell trace experiments showed that cells that have been invaginated by the end of the secondary invagination differentiate into SMCs, esophagus, and the anterior half of stomach (Figure 11–2F). The posterior half of the stomach and the whole intestine are recruited into the archenteron during the prism stage (Figure 11–2G–I). This late invagination seems to be a typical convergence–extension movement.[33]

Thus, we can study various cellular activities involved in gastrulation using sea urchin embryos. The functions of various genes involved in the gastrulation process are becoming clearer.[34] With such knowledge, this model system may contribute to the further understanding of the morphogenesis of a monolayered epithelium.

CELL MOVEMENT

As described above, PMCs appear in the blastocoel after hatching. For a period of time, the PMCs stay at the bottom of the blastocoel (Figure 11–2A). Then they move about randomly on the inner surface (basal lamina) of the blastocoel wall (Figure 11–2B). Some PMCs move toward the animal pole side. After this phase, they begin to migrate toward the vegetal plate (Figure 11–2C) and form a ring pattern around the gut rudiment.[35] During these phases, the PMCs form very thin filopodia for locomotion and target recognition.[27] The migration pattern of PMCs seems to depend on changes in the composition of the basal lamina and the localization of some extracellular matrix (ECM) molecules.[36] After ring pattern formation, PMCs fuse with each other and form syncytial cytoplasmic cables in which skeletal spicules are deposited.[37] In transparent embryos with a large blastocoel, the behavior of individual PMCs can be traced with time-lapse video microscopy. In most species, a triradiate spicule rudiment appears in the ventrolateral cluster of PMCs at the end of secondary invagination (Figure 11–2F). Then, skeletal rods begin to elongate in three directions, and form the main frame of the larval skeleton (Figure 11–2G–I).

Micromeres formed in 16-cell embryos can be collected by centrifugation of dissociated blastomeres in a sucrose density gradient. The descendants derived from such isolated micromeres can differentiate autonomously into PMCs.[38] PMCs can also be isolated from mesenchyme blastulas using wheat germ agglutinin.[39] Using these materials, *in vitro* studies of the behavior of PMCs can be performed.

SMCs differentiate into four types of mesodermal cells: pigment cells, blastocoelar cells, coelomic pouch cells, and circum-esophageal muscles. Pigment cells may provide another model for analyzing cell movement.[40] In some species, pigment precursor cells leave the archenteron tip during gastrulation and enter the apical plate (Figure 11–2E-G). During this stage, they form long filopodia and move a considerable distance in the blastocoel. After entry into the apical plate, they begin to crawl in the ectodermal layer toward the vegetal pole side (Figure 11–2H). Thus, pigment cells change their manner of migration within a rather short time. Interestingly, pigment cells are distributed only in the aboral ectoderm (Figure 11–2I). Some ECM molecules, such as Ecto V expressed in the oral ectoderm[41] and arylsulfatase expressed in the aboral ectoderm,[42] are the candidates that cause this localization. However, the precise mechanism of pigment cell movement remains unknown. Pigment cells are another model for the analysis of cell–substrate interactions.

PHARMACOLOGY AND TOXICOLOGY

To now, the effects of various kinds of chemicals have been monitored using sea urchin embryos, because a large quantity of homogeneous material is available. With ryanodine receptor blockers, for example, it was found that sphingosine can activate the ryanodine receptor, resulting in transient Ca^{2+} release from thapsigargin-sensitive intracellular stores.[43] In this report, a homogenate of unfertilized sea urchin eggs was used as an assay system. Sea urchin fertilization is therefore an ideal model for the analysis of the intracellular signaling pathway of Ca^{2+} release, while other cellular activities are the targets of pharmacological investigations.

Toxicological effects are examined by immersing embryos in seawater containing the chemical to be tested. The effects are quickly and easily detected as delays in the development or malformation of embryos. For example, the interactive toxic effects of heavy metals at concentrations detected in mine effluents were examined. With various combinations of metals, it was found that zinc was one of the elements responsible for causing malformations (loss of the oral–aboral axis and diminution in size of the digestive tract), and its effects were intensified by the presence of other metals such as manganese, lead, iron, and copper.[44]

DISADVANTAGES IN BIOMEDICAL RESEARCH

Sea urchin embryos provide many models for the analysis of various cellular activities. However, they have some disadvantages. One is the limited breeding season. Full-grown and fertilizable oocytes that completed meiosis cannot be obtained from a single species throughout the year. Usually, two or three species of sea urchins with different breeding seasons are used in laboratories.

Creation of mutants is a powerful tool for analyzing the function of genes. Unfortunately, there is no established method for obtaining sea urchin mutants. This is due to difficulties in rearing metamorphosed juveniles. They change their source of nutrients as they grow. To our knowledge, there is no reported success in obtaining adult sea urchins under laboratory conditions. To analyze the function of genes, however, most of the methods used in other models (whole-mount *in situ* hybridization, overexpression of synthetic mRNAs, injection of dominant-negative mRNAs, or morpholino antisense oligonucleotides) are applicable to sea urchin embryos, although refined skill is necessary for the injection of synthetic mRNAs or nucleotides. There is no report of the use of RNAi in the analysis of gene functions in sea urchin embryos.

Micromanipulation is another powerful tool for analyzing the mechanisms that operate during early development. For this, the size of embryos is a critical factor. The diameter of sea urchin eggs, however, is around 100 μm in most available species. Sea urchin embryos are much more difficult to manipulate than amphibian embryos. While removal of a portion of embryonic

tissue is possible at later stages, marking, deletion, recombination, and transplantation of blastomeres are primarily limited to embryos at the early cleavage stage.

Echinoderm is a member of the Deuterostomata as well as the Chordata, and is considered to be the ancestors of chordates. The tool kit for regulation of gene expression is almost common between echinoderms and chordates. However, the usage of some genes differs from that of chordates. For example, Nodal, which is indispensable for the differentiation of endoderms and mesoderms in chordates, is expressed in the prospective oral ectoderm in sea urchin embryos.[17] *Brachyury*, the expression of which is limited to the notochord in chordates, is expressed in cells near the blastopore, in addition to the prospective oral region.[45] Furthermore, some downstream genes such as *SM30*, which encode a spicule matrix protein, are specific to sea urchins.[46] Therefore, molecular biological and physiological results obtained in sea urchin embryos are not necessarily applicable to chordates including mammals.

Despite the disadvantages mentioned above, sea urchin embryos should continue to serve as models for research in various biomedical studies, since they have many features that are unavailable in other animal embryos.

12 *Caenorhabditis elegans* Models of Human Neurodegenerative Diseases

A Powerful Tool to Identify Molecular Mechanisms and Novel Therapeutic Targets

Richard Nass and Lihsia Chen

ABSTRACT

Within the past decade it has become remarkably clear that the molecular components involved in basic cellular function and dysfunction are highly conserved across phyla from single cell organisms to humans. The high sequence similarities within eukaryotes and the advent of molecular technologies now allow us to utilize genetic models such as the nematode *C. elegans* to begin to elucidate the complex mechanisms involved in human neurodegenerative diseases. In this chapter we will briefly summarize recent advances using the nematode *C. elegans* to model a number of neurodegenerative diseases including Parkinson's disease, Alzheimer's disease, Huntington's disease, and hereditary spastic paraplegia, and describe how this relatively simple animal is being utilized to identify putative endogenous and exogenous molecules that may contribute to the disease. We also describe how this genetically tractable organism is amenable to high throughput technologies to identify novel drug targets and potential therapeutic leads to combat these devastating neurological disorders.

Key Words: Nematode, Genetics, *C. elegans*, Parkinson's Disease, Huntington's disease, Alzheimer's disease, Hereditary spastic paraplegia, 6-OHDA, High-throughput screens.

INTRODUCTION

The free-living soil nematode *Caenorhabditis elegans* was first introduced by Sydney Brenner in the mid-1960s as a model organism to dissect the genetic pathways that govern organ development, particularly of the nervous system, and behavior. Since then, the numerous advances resulting from the use of *C. elegans* have earned this simple animal a well-deserved reputation of a powerful genetic model system to elucidate cellular processes underlying normal development as well as disease. Indeed, the power of *C. elegans* was recognized some 35 years later when Sydney Brenner, Robert Horvitz, and John Sulston received the 2003 Nobel award for the establishment of the nematode *C. elegans* to explore organ development and programmed cell death.

It has become apparent in the past 15 years that the molecular pathways and mechanisms underlying basic biological processes are conserved between invertebrates and humans. Furthermore, the completion of the *C. elegans* genome and subsequently those of *Drosophila*, mouse, and human revealed genome conservation and revealed that the human genome contains only ~20% more genes than the *C. elegans* genome.[1,2] In addition to the genome, the worm's nervous system is highly conserved with mammals, and contains almost all of the known signaling and neurotransmitter systems found in the vertebrates.[3–7] These include enzymes and molecular pathways involved in the production of numerous neurotransmitters including acetylcholine, glutamate, α-aminobutyric acid, serotonin, and dopamine (DA), as well as neuropeptides and neurotransporters. Furthermore, most of the ion channels and components involved in mammalian synaptic neurotransmission are also present in the worm.[3,7] The similarity between worm and human nervous systems together with the conserved genomes and genetic pathways suggest that the knowledge and paradigms we gain by elucidating the molecular mechanisms involved in worm neurophysiology will have significant relevance to human physiology and disease.

In the present review, we discuss how *C. elegans* has allowed us to model several neurodegenerative diseases including Parkinson's, Alzheimer's, and Huntington's diseases, as well as hereditary spastic paraplegia, and how the opportunities presented by the worm will likely increase our understanding of the molecular basis of neurodegenerative disorders. We also describe how this genetically tractable system can be utilized to identify novel drug targets and potentially valuable therapeutic leads that can protect against cellular death.

CAENORHABDITIS ELEGANS AS A GENETIC MODEL

C. elegans is an anatomically simple organism containing under a thousand somatic cells. Its small size (1 mm long), large brood size (approximately 300–1000 progeny from a single hermaphrodite), short generation time (3.5 days), and ease of maintenance in the laboratory (tens of thousands can be grown on a 90-mm agar plate coated with bacteria) allow for inexpensive and rapid production of animals for experimental analysis.[8,9] In

addition, the worm is transparent, allowing for the visualization of cells and developmental processes such as cell migration or apoptosis in a living animal. The worm can also easily be grown in liquid medium in standard 384 or 96-well microtiter plates, facilitating high or medium throughput screening (HTS) of animals for particular behavioral phenotypes or optical properties.[10,11] In addition to studies on an organismal level, large-scale primary cultures first developed by Laird Bloom in 1993 provide the opportunity to investigate biological processes on a cellular level.[12–16] For example, electrical properties of different cells can be determined and compared in both whole animals and primary cultures. These primary cultures also are amendable to cell sorting and allow for the development of tissue-specific cDNA libraries.[17]

While the aforementioned properties facilitate the use of *C. elegans* as a model system to study biological processes, the power of *C. elegans* in fact resides in its accessibility to genetic manipulation (see also Chapter 72, this volume).[8,18] Forward genetic screens using chemical mutagens or γ-irradiation are a common way to identify genes involved in a particular cellular process. An advantage to this approach is that no a priori knowledge about gene function is needed in order to determine whether the gene plays a role in the particular behavioral phenotype or cellular process.

C. elegans is also amendable to reverse genetic approaches that make it possible to determine of the function of a particular gene. As with forward genetic screens, chemical mutagens can be used to induce deletions in the gene of interest to produce genetic nulls or hypomorphs. Genetic knockout animals can be screened and identified within as little as a week.[19] A federally funded *C. elegans* gene knockout consortium as well as the Japanese National Bioresource Project are two resources in which deletion mutations in *C. elegans* genes are being generated. These mutants as well as over 8000 genetic strains isolated from different laboratories around the world and stored in the *C. elegans* Genetic Stock Center are available upon request (see *Caenorhabditis elegans* WWW Server: http://elegans.swmed.edu/).[20]

The relatively recent discovery of RNA-interference (RNAi) by Andrew Fire and Craig Mello, for which both received the 2006 Nobel award in physiology or medicine, has greatly altered the way genetic screens are performed in *C. elegans*. RNAi is the evolutionarily conserved process of sequence-specific degradation of mRNAs induced by the introduction of double-stranded RNA (dsRNA) containing homologous sequence.[20,21] RNAi can thus be used as a convenient way to knock down expression of any gene. Such targeted gene knockdown by RNAi can be obtained in most cell types *in vivo* by introducing gene-specific dsRNA into animals by injection, soaking animals in the dsRNA, or feeding animals bacteria that express the dsRNA.[22,23] The ability to introduce dsRNA by feeding has allowed genome-wide genetic screens to be performed on a rather routine basis. Indeed, genes participating in different processes such as synapse function or the pathophysiology of Huntington's disease (see below) have been identified in such screens using a commercially available RNAi-feeding library, which contains over 18,000 *Escherichia coli* strains each containing dsRNA for a specific gene within the *C. elegans* genome (representing approximately 86% of the *C. elegans* genome).[24–27]

In addition to mutagenesis or RNAi screens, the worm can be genetically manipulated with the introduction of transgenes. The ease and relatively short amount of time for generating transgenic animals have enabled functional studies to be performed routinely. These studies include the expression of green fluorescent protein (GFP) reporter or rescue constructs (about 4 days), which greatly facilitate spatial and temporal protein expression pattern studies as well as structure–functional analyses.[28–30]

The *C. elegans* nervous system has been reconstructed previously on the ultrastructural level. As such, the physical connections (axon targeting, as well as electrical and chemical synapses) of the 302 neurons that make up the *C. elegans* nervous system have been mapped.[31] Together with the accessible genetics and ease of high-throughput approaches, *C. elegans* provides a powerful tool to model neurodegenerative diseases to better dissect the molecular and cellular processes underlying the diseases.

MODELING PARKINSON'S DISEASE AND DOPAMINE NEURON CELL DEATH

Parkinson's disease (PD) is the second most prevalent neurodegenerative disease and results from the loss of over 80% of the DA neurons within the substantia nigra pars compacta (SNpc).[32,33] The disorder also results in the formation of protein aggregates called Lewy bodies (LBs) in a significant number of the surviving neurons.[34–36] The degradation of the DA neurons confers the classic triad of PD symptoms, including tremors, rigidity, and bradykinesia. Although the molecular basis of this disorder has not been identified, etiological and pathological data suggest that there is both a genetic and environmental component that causes oxidative damage, and proteosome and mitochondrial dysfunction.[33,37–39]

One of the most common mechanisms to model Parkinson's disease in vertebrates is through exposure of the animals to a DA neuron targeted toxin. Several weeks following exposure to the toxin, most of the animals display a Parkinsonian-like syndrome. The most common neurotoxins used are 6-hydroxydopamine (6-OHDA), 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), 1-methyl-4-phenylpyridinium ion [MPP^+ (the active metabolite of MPTP)], or the insecticide rotenone.[40–43] 6-OHDA and MPP^+ are transported into the cell by the high affinity dopamine transporter, DAT, which is also the target of drugs of abuse including cocaine and amphetamine.[41,43,44]

Genetic and epidemiological studies indicate that the etiology of PD likely involves specific molecular pathways involved in protein aggregation, degradation, oxidative stress, and mitochondria function. To date, at least seven genes have been independently identified that are associated with rare, familial forms of PD, including α-synuclein, parkin, DJ-1, UCH-1, NURR1, PINK-1, and LRRK2.[39,45–51] α-Synuclein, the first PD-associated gene identified, is a presynaptic protein that appears to interact with synaptic vesicles and could be involved in the regulation of both dopamine biosynthesis and dopamine transporter function.[52] α-Synuclein coding mutations A30P and A53T alter the structure of α-synuclein and affect DA neuron viability *in vitro* and *in vivo*.[34–36] Another mutation, α-synuclein K46E, has been recently identified and as with the other α-synuclein mutations, may interfere with the proteosomal degradation pathway.[51]

Toxin-induced and genetic *C. elegans* PD models that recapitulate many aspects of PD have been developed. We generated the first *C. elegans* PD model with a transgenic strain that expresses the GFP in all eight DA neurons that are thus visible under a fluorescent microscope.[53,54] When we briefly exposed (0.5–1 h) the animals to 6-OHDA, we find a time- and concentration-dependent

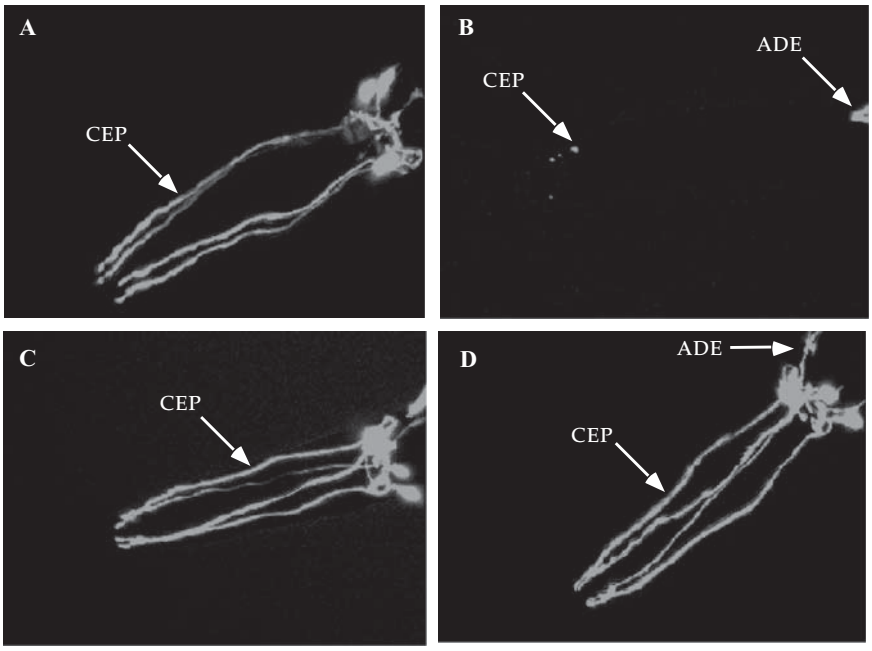

Figure 12–1. Suppression of 6-OHDA sensitivity of DA neurons in *C. elegans*. (A) $P_{dat\text{-}1}$::GFP animals exposed to vehicle; (B) $P_{dat\text{-}1}$::GFP worms exposed to 6-OHDA; (C) $P_{dat\text{-}1}$::GFP, *dat-1* (ΔDAT-1 worms) exposed to vehicle; (D) $P_{dat\text{-}1}$::GFP, dat-1 worms exposed to 6-OHDA. See Nass *et al.*[54] for details. (Reproduced with permission from Nass *et al.*[54])

loss of DA neuron integrity.[54] Consistent with the vertebrate PD models, the 6-OHDA-induced effects require the presence of the DAT, and can be completely blocked by coincubation with DAT agonist (e.g., amphetamine) or antagonist (e.g., cocaine) (Figure 12–1, data not shown).[54] MPP^+, the vertebrate mitochondrial complex I inhibitor, also causes loss of GFP in the DA neurons and likely DA neuron cell death, although no ultrastructural studies were performed to confirm degeneration (R. Nass, unpublished data).[55] We subsequently performed a forward genetic screen to identify suppressors of the 6-OHDA-induced cell death.[56] In our initial efforts we identified three novel *dat-1* alleles conferring complete tolerance to 6-OHDA, as well as additional mutants that confer partial tolerance. These studies provide proof of concept for the ability to identify specific toxin suppressors. Overall, our results as well as those from other groups mimic several significant aspects of vertebrate PD models. Thus the *C. elegans* PD model provides a powerful way to identify and characterize endogenous and exogenous molecules that may contribute to PD neurodegeneration.[32,55–57]

C. elegans does not contain an apparent homolog to the PD-associated protein α-synuclein, but the lack of an endogenous molecule can aid studies in dissecting potential interacting molecules, without concern for compensatory effects. In collaboration with Garry Wong at Kuopio University in Kuopio, Finland, we generated transgenic animals expressing either human wild-type (WT) or mutant A53T α-synuclein in the DA neurons within the worm.[58] We found that both synucleins confer DA neuron cell death. Motor deficits were also observed when α-synuclein was expressed pan-neuronally, and α-synuclein-containing inclusion bodies are seen in some of the DA neurons.[58] In a study by Kuwahara and colleagues, the expression of human A30P (and A53T) also appears to cause DA neurodegeneration, abnormal locomotion in response to food, and a loss of DA neuronal content, and importantly the addition of exogenous DA ameliorates the behavior defects.[59] Recently, Cooper and colleagues identified a Rab GTPase in a yeast plasmid overexpression screen that suppresses the α-synuclein toxicity in yeast.[60] Overexpression of the GTPase, which plays a role in Golgi vesicle docking and endoplasmic reticulum (ER) to Golgi vesicular transport, also rescues DA neuron cell death in both the fly and the worm, suggesting that PD-associated α-synuclein pathology may disrupt normal function of RabGTPase or the pathways involved in vesicle trafficking *in vivo*.[60] Furthermore, Wong and colleagues have recently shown significant gene expression changes in genes associated with the ubiquitin-proteasomal and mitochondrial systems in animals expressing α-synuclein, further supporting the role of these systems in PD-associated cell death.[61] The above studies suggest that the α-synuclein-induced toxicities observed in *C. elegans* may occur through pathways similar to those observed in vertebrate systems and that the worm could be a powerful model to explore human synucleopathies.

Two other genes associated with recessive PD have also been explored in *C. elegans*. *Parkin* encodes for an E3 ubiquitin ligase, one of a number of proteins that ubiquinate substrate proteins and mark them for degradation by the proteosome.[47] DJ, a protein of largely unknown function, may serve as a chaperone, and protect against neuronal oxidative stress and apoptosis.[48] *C. elegans* contains homologues for both parkin and DJ-1. Parkin mutations confer increased sensitivity to ER stress and aggregation, and result in lethality when coexpressed with human A53T α-synuclein in the worm.[62] Deletion of parkin or knockdown of DJ-1 increases the sensitivity to mitochondrial complex I inhibitors and can be partially rescued by compounds that improve mitochondrial function.[63] We have also found that the deletion of parkin renders the worms almost 2-fold more sensitive to 6-OHDA (R. Nass, unpublished data). Overall, these results support a strong role of the PD-associated proteins affecting proteosomal and mitochondrial function, and suggest that *C. elegans* is a viable model for PD-associated DA neuron dysfunction and cell death.

MODELING ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is a heterogeneous neurodegenerative disorder that is the most common cause of dementia.[64] Patients exhibit cognitive decline such as impaired judgment and orienta-

tion, progressive memory loss, and personality changes. In the severe stages of the disease, patients lose their ability to function in daily activities and are generally bedridden and dependent on caregivers. Postmortem analysis of AD brains reveals extracellular senile plaques and intraneuronal neurofibrillary tangles (NFT), which are now considered hallmarks of AD. In addition to these structural changes, there is extensive neuron loss. The remaining neurons in the AD brain show morphological changes that include dystrophic neuritis and reduced synapses.

The major component of senile plaques is aggregated β-amyloid$_{1–42}$ (A$\beta_{1–42}$), a cleaved product of the amyloid precursor protein (APP).[65,66] Mutations in the APP gene as well as genes encoding presenilin 1 and 2 (PSEN1 and PSEN2) are associated with some familial forms of AD (FAD), in which an overproduction of A$\beta_{1–42}$ is seen.[67–69] Presenilins are active components of the intramembranous protease complex, γ-secretase, which processes APP. These discoveries led to the amyloid cascade hypothesis, which holds that altered amyloid processing and aggregation are the key pathogenic causes of AD.[70]

Several transgenic animal models have been established to test the amyloid hypothesis. These include mouse, *Drosophila*, and *C. elegans* transgenic animals that overexpressed either A$\beta_{1–42}$ or mutated APP that would result in increased levels of A$\beta_{1–42}$.[71] While none of these models recapitulates all aspects of AD, each presents facilities to dissect the molecular and cellular pathogenesis of AD with respect to the amyloid hypothesis.[72]

APP and presenilins are conserved in *C. elegans*. The worm APP homologue, encoded by the *apl-1* gene, interestingly lacks the A$\beta_{1–42}$ sequence, as is the case for the *Drosophila* APP homologue.[73,74] RNAi knockdown of the worm APP homologue leads to an uncoordinated phenotype, while a genetic deletion in the gene results in lethality, indicating an essential function of the worm APP.[26,75] Genetic analysis of one of the worm presenilins, SEL-12, reveals a function in the notch signaling pathway in vulval development.[76] SEL-12 in the notch signaling can functionally be replaced by HOP-1, the second worm presenilin, and by WT human presenilins, indicating functional conservation of the homologues In contrast, human presenilins containing FAD mutations display reduced ability to replace *sel-12*.[77–79] The presence of these homologues in *C. elegans* not only makes it possible to determine the biological function of these proteins, but also to identify genetically interacting proteins in the pathway. Indeed, in a previous *C. elegans* screen for proteins involved in signaling of a notch-like protein, GLP-1, the *aph-2* gene was identified.[80] The human orthologue of APH-2, known as nicastrin, was independently identified as a protein that coimmunoprecipitates with presenilin 1 and has a role in APP processing.[81]

To create a *C. elegans* AD model, transgenic animals expressing human A$\beta_{1–42}$ in body wall muscles were generated.[82–83] These transgenic animals exhibit progressive paralysis and amyloid-like plaques in the muscles and shortened life spans, phenotypes that parallel those observed in AD patients. Although this model system limits expression of human A$\beta_{1–42}$ to body wall muscles, it has been useful in assaying for both molecular and cellular responses to the presence of human A$\beta_{1–42}$. For example, these *C. elegans* transgenic animals show signs of oxidation stress, as indicated by increased levels of carbonyl, a key marker for protein oxidation.[84] Similarly, AD brains and cultured hippocampal neurons exposed to exogenous synthetic A$\beta_{1–42}$ show increased levels of carbonyl and signs of oxidation stress. The *C. elegans* AD model has also been useful in testing the toxicity of fibrillar deposits of A$\beta_{1–42}$ and its role in AD progression. Using transgenic animals that had a temperature-inducible expression system of A$\beta_{1–42}$, it was determined that paralysis and increased levels of carbonyl were induced upon expression of A$\beta_{1–42}$, but prior to any detection of amyloid plaques.[85] This result indicates that fibrillar amyloid deposition does not correlate with gross pathology and protein oxidation in *C. elegans*.

Techniques to detect global changes in protein and gene expression as well as screens can easily be employed on the *C. elegans* AD model. For example, to better understand how A$\beta_{1–42}$ induces protein oxidation, proteomic techniques were used to identify proteins that are specifically oxidated in the *C. elegans* transgenic AD animals.[86] In addition, microarray analysis of gene expression in the *C. elegans* transgenic AD animals was performed to identify global gene expression changes induced by A$\beta_{1–42}$. Identified in this screen was heat shock protein 16 (HSP16), which was also shown to colocalize with A$\beta_{1–42}$, in *C. elegans* AD model.[87] These screens have thus been valuable in identifying candidate amyloid-induced protiens that participate in AD. Drug screening and genetic modifier screens can also be performed easily on the *C. elegans* to identify potential therapeutic reagents and molecular pathogenesis of the A$\beta_{1–42}$ in AD. For example, ginkgo biloba leaf extract (EGb761), was shown in clinical trials to be effective against AD forms of degenerative dementia.[88] Supporting these results is the recent discovery that EGb761 reduces the oxidative effects of A$\beta_{1–42}$ in the *C. elegans* transgenic AD strains.[88,89]

Another feature of AD is NFTs, which are composed of fibrillar aggregates of hyperphosphorylated forms of tau, a microtubule-binding protein (MAP) that promotes microtubule assembly and stability.[64] It is unclear if or how NFTs and tau may be involved in AD progression. One hypothesis holds that tau aggregates are toxic to neurons. Another hypothesis posits hyperphosphorylated tau sequesters normal tau and other MAPs, leading to microtubule disassembly and thus disrupting axonal transport.

To dissect the molecular and cellular pathogenesis of NFTs and tau in AD in a simpler model system, a *C. elegans* model for tauopathy was established with the creation of transgenic animals expressing normal human tau in the nervous system.[90] These animals showed progressively uncoordinated locomotion that was accompanied by progressive accumulation of insoluble phosphorylated human tau, neurodegeneration, and reduced cholinergic neurotransmission; these phenotypes are much more severe with the expression of mutant tau containing pathogenic mutations that cause frontotemporal dementia and parkinsonism (FTDP-17).[91] Thus, these animals recapitulate many traits present in human tauopathies.

With a *C. elegans* model for tauopathy established, assays and screens similar to those done with the *C. elegans* model for amyloid-induced pathogenesis can be performed to better understand pathogenic mechanisms of tau and NFTs. In a recent genome-wide screen, RNAi on 16,757 genes was performed on the tau-expressing transgenic animals for altered uncoordinated phenotype as a means to identify players in this tau-induced phenotype.[92] Sixty genes that specifically enhanced the tau-induced phenotype were identified; these include stress-response proteins as well as kinases and phosphatases that could affect tau phosphorylation. Some of these genes, such as GSK3β, have previously been implicated in human tauopathies. [93]

The relative ease of culturing large numbers of animals, together with straightforward genetic manipulation, has allowed for screens and analysis on a global scale; this has led to the identification of participants in both amyloid- and tau-induced phenotypes, suggesting many advantages that *C. elegans* has to offer in elucidating the molecular basis of cell death in AD. With the establishment of *C. elegans* models for AD and tauopathies, it will be possible to study the relationship between amyloid and tau in the pathogenesis of AD, and identify novel therapeutic targets to inhibit neurodegeneration.

MODELING TRINUCLEOTIDE REPEATS OR HUNTINGTON'S DISEASE

Huntington's disease (HD) is a progressive autosomal dominant neurodegenerative disease that is characterized by abnormal movements, emotional disturbances, and cognitive decline. The disease is one of at least eight other diseases that are caused by the abnormal expansion of a CAG repeat encoding the poly-(Q) tract in a protein.[94] In HD the poly-Q tract is located within the N-terminus of the protein huntingtin.[95] Other poly-Q-related diseases include the X-linked motorneuron disease spinobulbar muscular atrophy (SBMA), which affects the androgen receptor, and spinocerebellar ataxia.[94] HD occurs when the poly-Q repeat is generally greater than 40 residues (individuals without the propensity to develop the disease have between 10 and 29 repeats), and there is an inverse relationship between the number of residues and the age of onset. The duration of the illness following onset is typically 15–20 years and the illness eventually results in death.

The molecular mechanisms underlying HD is not well understood, although current beliefs include both a gain- and loss-of-function of the huntingtin protein.[94,96,97] Huntingtin is ubiquitously expressed in the cytoplasm and is associated with vesicle membranes and vesicle trafficking proteins, and may contribute to neurogenesis.[98–100] Although the pathology is found throughout the central nervous system, the striatum appears to be particularly vulnerable. The expansion of the poly-Q causes insoluble granular and fibrous deposits and these aggregates may be responsible for the pathogenesis, including proteosomal impairment, transcriptional dysregulation, excitotoxicity, and loss of glutamate and dopamine receptors.[101–103] Mouse models indicate that HD-associated phenotypes become apparent before there is cell death. Furthermore, increases in the cleaved huntingtin fragment during pathogenesis causes a depletion of WT huntingtin, suggesting a loss of function, and may contribute to the oxidative stress and mitochondrial impairment seen in HD. Finally, the poly-Q-containing protein inclusions found in HD have also been proposed to be neuroprotective by decreasing the levels of mutant huntingtin in the cell, and limiting the amounts of the globular and protofibrillar intermediates that have been thought to contribute to neurotoxicity.[104]

Several *C. elegans* models of HD have been developed to explore the molecular basis of the toxicity. Overexpression of the expanded poly-Q fused with the huntingtin fragment in sensory and other neurons causes cellular dysfunction and protein aggregation.[105–107] As in vertebrate studies, the severity of the aggregation is dependent on the length of the poly-Q, and the aggregation is preceded by neuronal dysfunction, although the aggregation does not always lead to cell death. Poly-Q expression in muscle cells is also toxic, and the severity increases with the number of the glutamine repeats.[108,109] Furthermore, the aggregation threshold decreases as the animals aged. In an elegant follow-up study, Brignull, Morimoto, and colleagues show that poly-Q length correlates with apparent toxicity and neuronal dysfunction, but that the solubility and aggregate formation is neuron specific.[107] Furthermore, the development of protein inclusions does not always increase with animal age. Overall, these results suggest that aggregate formation is not the sole cause of cellular dysfunction, and suggest an intrinsic property of the poly-Q expansion confers the significant pathology.

C. elegans models of HD have been developed to identify potential modifiers of the toxicity. Poly-Q aggregate formation and toxicity can be reversed by overexpression of the yeast chaperone Hsp104, providing further support that misfolded protein(s) may be the toxic moiety.[108] RNAi of several small endogenously expressed Hsps within the worm accelerated the onset of poly-Q aggregation, suggesting that these proteins may act to protect cells from aggregation-induced toxicities.[110] Tor-2, a putative chaperone and a protein found to colocalize with α-synuclein in PD Lewy bodies, also inhibits the formation of aggregates.[111] Although a homologue in humans has not been identified, overexpression of *pqe-1* suppresses poly-Q-mediated toxicity in worms, while loss-of-function mutations enhances it.[105] Recently Wang and colleagues have overexpressed the endogenous ubiquilin, a protein found to interact with presenilins in AD and found in neuropathological inclusions in HD and PD, in muscle cells in *C. elegans*. Overexpression prevents and rescues the motility defect associated with expression of the huntingtin poly-Q fusion in muscles. Furthermore, RNAi of the endogenous protein exacerbates the toxic effect. Although the molecular basis for the neuroprotection is not clear, it may modulate the ubiquitin–proteosome system or act as a molecular chaperone.[94]

Finally genome-wide RNAi screening has identified modulators of poly-Q aggregation. Nollen *et al.*[112] expressed poly-Q residues fused to the yellow fluorescent protein (YFP) in muscle cells and grew the worms on bacteria expressing dsRNA with the goal of identifying genes that could be involved in the aggregate formation. The investigators reported almost 200 proteins that result in the premature appearance of the aggregates, and include those involved in protein synthesis, folding and transport, and degradation. The screen also identified a number of proteins involved in RNA synthesis and processing, and although it is not clear how these genes could affect the propensity of poly-Q to aggregate, they may be involved in the regulation of the proteosome. This screen demonstrates the power of RNAi screening in *C. elegans* to identify novel proteins that could be involved in poly-Q aggregation.

HEREDITARY SPASTIC PARAPLEGIA

Hereditary spastic paraplegias (HSP) are heterogeneous neurodegenerative syndromes that are clinically marked by progressive spastic paralysis in the lower limbs, the onset of which can occur as early as infancy.[113] While teenage or later onset of the disease is typically accompanied by marked progression of limb weakness so that canes and wheelchairs are often required, there is generally little worsening of symptoms in early childhood or infancy onset of the disease. HSP syndromes can be classified clinically as uncomplicated if symptoms are limited to progressive spastic weakness in the legs, or complicated if the disorder is accompanied by other neurological abnormalities such as mental

retardation. Histopathological studies of uncomplicated HSP generally show the terminal ends of axons associated with cortical motor neurons slowly degenerating in a "dying-back" fashion; i.e., degeneration begins at the distal end of the axon in a retrograde direction.[114]

Genetic mapping has placed HSP to at least 29 loci (SPG1–29), of which 11 genes have been identified.[115] The identified genes encode proteins that participate in extremely diverse processes. While much is still not known about many of these genes, current studies are just beginning to reveal how their loss or impaired function may result in HSP. These genes can be grouped into two classifications: (1) genes that participate in corticospinal tract development and (2) genes that are required to maintain the health of corticospinal tract axons. Genes of the latter classification can further be grouped into mitochondrial and axonal trafficking genes.[113,115]

L1 is a cell adhesion molecule (CAM) that belongs to the immunoglobulin (Ig) superfamily. Mutations in the SPG1 gene encoding L1 can result in X-linked HSP that is often complicated by mental retardation, adducted thumbs, and hydrocephalus.[116] Interestingly, manifestation of these symptoms is quite variable even with the same mutation in the L1 gene within the same family.[117] A striking observation in these patients is an absent or reduced size of the medullary pyramids, suggesting abnormal development of the corticospinal tract.[118] Mutations disrupting L1 function in mice produce phenotypes very similar to those observed in human patients. Indeed, these mice exhibit hind limb weakness and show hypoplasia of the corticospinal tract.[119] Together, these results suggest that abnormal development of the corticospinal tract may be responsible for the spastic paraplegia exhibited in the patients.

Because L1 is expressed in multiple tissues, including the nervous system, it is not surprising that L1 has both neuronal and nonneuronal functions.[117] In the nervous system, there is increasing evidence that L1 functions in axon guidance and fasciculation, efficient initiation and propagation of action potentials, and synapse function. Numerous studies have revealed multiple interacting proteins that help mediate L1 function; these include L1 itself, other Ig family proteins, integrins, neuropilin, and ankyrin. However, how impaired function of L1 results in corticospinal tract hypoplasia or the manifestation of the additional symptoms is not clear. Besides L1, the L1 CAM family consists of three additional genes that have apparent overlapping expression and function, complicating the dissection of L1 functions and mechanisms; they include NrCAM, neuroglian, and CHL1.

L1 CAMs are conserved in *C. elegans* in the form of two genes, *sax-7* and *lad-2*.[120,121] The SAX-7 protein is a single transmembrane protein that contains many hallmarks of the vertebrate L1 CAM family that include six Ig and five fibronectin type III repeats in the extracellular domain, a transmembrane domain, and a short but highly conserved cytoplasmic tail that contains an ankyrin-binding motif and a consensus PDZ-binding motif.[120] Like L1, SAX-7 is highly expressed in the nervous system as well as multiple nonneuronal tissues. The most striking phenotype exhibited in animals with reduced or loss of SAX-7 function is the position of neurons and their axons that are initially normally positioned become progressively displaced as the animals mature and age.[122,123] This displacement is reduced in animals that do not move as robustly as wild-type animals.[122] Together, these results indicate SAX-7 plays a maintenance role to ensure proper attachment of the neurons and axons against mechanical forces exerted by the environment and animals themselves.

LAD-2 is a noncanonical L1 CAM that is expressed only in a handful of neurons in *C. elegans* (X. Wang and L. Chen, unpublished data).[124] While the LAD-2 extracellular domain contains the conserved six Ig and five FNIII repeats, the LAD-2 cytoplasmic tail is much shorter and divergent and lacks the ankyrin-binding motif conserved in SAX-7 and vertebrate L1CAMs.[121] Reduced *lad-2* function results in axon guidance defects in the LAD-2-expressing axons (see Figure 12–2; X. Wang and L. Chen, unpublished data). This phenotype indicates that LAD-2 plays a developmental role to ensure proper axon pathfinding. Axon guidance defects have also been reported in L1 mouse knockouts and mutants of the sole *Drosophila* L1 homologue, neuroglian.[119,125]

These studies in *C. elegans* have revealed both a developmental and maintenance role in the nervous system for L1CAMs. Perhaps a combination of axon guidance defects and impaired positional maintenance of axons leads to hypoplasia of corticospinal tract, which leads to early onset of HSP in patients with impaired L1 function.

In neurons, axonal transport is heavily reliant on kinesins and dyneins, molecular motors that transport vesicles, membrane, and membranous organelles along microtubule tracks in an anterograde and retrograde fashion, respectively.[126] Several genes that are associated with HSP appear to participate in axonal transport. Indeed, SPG10, which is associated with dominant uncomplicated HSP, was identified as encoding KIF5A, a neuronal-specific kinesin heavy chain.[127] Pathogenic mutations are localized to the motor as well as the microtubule-binding domains. Mutations in the SPG4 gene encoding spastin are responsible for 40% of the autosomal dominant uncomplicated HSP.[128] Spastin is an AAA (ATPase associated with diverse cellular activities) ATPase that shares sequence homology with the microtubule

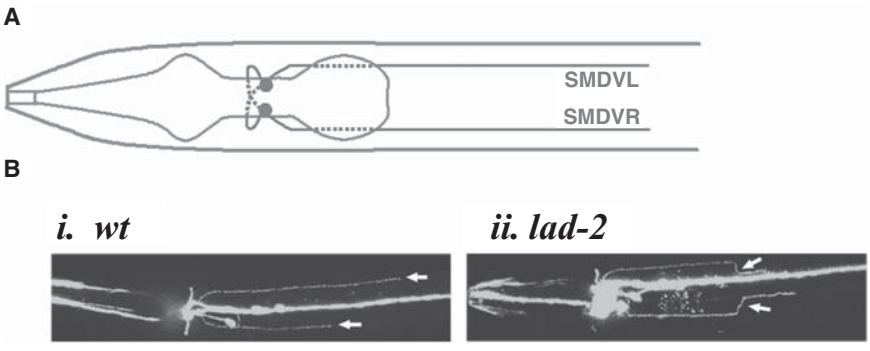

Figure 12–2. A schematic of the SMDL and SMDR axons is shown (A). Using the Pglr-1::GFP as a marker for SMDL and SMDR neurons and associated axons, *lad-2* mutant animals exhibit axon guidance defects for both neurons (arrows point to the point of deviation) (see Bii). The wild-type positions of both axons are shown (Bi).

severing protein, p60 katanin. Like many proteins that are involved in membrane trafficking, spastin contains a microtubule interacting and trafficking (MIT) domain. While microtubule binding and severing activity have recently been reported for spastin, its putative trafficking roles have yet to be confirmed.[129] A single spastin homologue is conserved in *C. elegans* and is encoded by the *spas-1* gene.[130] Like vertebrate spastin, the SPAS-1 protein is expressed in multiple tissues and can bind microtubules. Consistent with the broad expression of *spas-1*, *spas-1* genetic mutant animals exhibit pleiotropic phenotypes (Y. Matsushita and T. Ogura, personal communication). Detailed analysis of these phenotypes is necessary to dissect the mechanistic roles of SPAS-1 which in turn will reveal insight into how impaired or loss of spastin leads to HSP.

Consistent with a possible trafficking role for spastin is the recent discovery that spastin interacts with atlastin, a member of the dynamin family of GTPases that participates in vesicle trafficking and the dispersion of mitochondria. Atlastin, which is encoded by the SPG3A gene, is associated with 10% of autosomal dominant uncomplicated HSP.[131,132] Interestingly, a pathogenic mutation in atlastin has been shown to abolish interaction with spastin underscoring the functional importance of this protein interaction in healthy axons.[131]

While the function of KIF5A and its role in trafficking are uncontroversial, the functions of spastin and atlastin and their roles in the cellular pathogenesis of HSP are not clear. Based on the hypothesis that these proteins are indeed involved in trafficking, perhaps the less-than-efficient transport of proteins, membranes, and organelles such as the mitochondria, to the ends of the axons is detrimental to the health of the axon, resulting in the degeneration of axons that occurs in a distal–proximal fashion that is typical in HSP.[113]

In addition to trafficking proteins, there is increasing evidence that mitochondrial proteins are associated with HSP. Spartin, encoded by the SPG20 gene, is associated with recessive HSP complicated by distal muscle wasting.[133] Like spastin, spartin contains an MIT domain, suggesting microtubule-binding activity as well as intracellular trafficking.[134] Indeed spartin was recently shown to associate with microtubules and be localized to intracellular structures that include mitochondria and synaptic vesicles.[135,136] Moreover, a pathogenic mutation in spartin was shown to abolish its localization to the mitochondria, linking mitochondria to HSP.[135]

The SPG7 gene encodes for paraplegin, a nuclear-encoded mitochondrial metalloprotease belonging to the AAA family of proteins that has chaperon and proteolytic functions in the mitochondrial inner membrane. In addition to autosomal recessive HSP, patients with mutations in SPG7 exhibit structural and functional abnormalities in their muscles indicative of defects in mitochondrial oxidative phosphorylation.[137] *Spg7* knockout mice similarly exhibited degenerating axons that contain enlarged and structurally abnormal mitochondria clustered in synaptic terminals as well as inefficient retrograde axonal transport, suggesting that loss of paraplegin affects axonal transport.[138]

Like *SPG7* knockout mice, reduction of the sole *C. elegans* paraplegin homologue, SPG-7, by RNAi causes mitochondrial defects and premature lethality (T. Ogura, personal communication). The cause of this lethality has not been determined, but may be a result of defective mitochondria caused perhaps by an accumulation of abnormal proteins in the mitochondria. Indeed, *spg-7*(RNAi) results in increased levels of abnormally processed mitochondrial marker (GFP that contains a mitochondria import signal), indicating a role for SPG-7 in protein quality control. Furthermore, *spg-7*(RNAi) also activated the mitochondrial chaperone heat shock genes, *hsp-60* and *hsp-6*, homologues of the respective vertebrate HSP60 and HSP70 chaperones.[139] HSP60 is also associated with HSP although its role in the disease is not clear.[140] Together, these studies support a hypothesis that accumulation of abnormal mitochondrial proteins resulting from impaired paraplegin function leads to mitochondrial respiratory dysfunction, which in turn directly causes axon degeneration. Alternatively or additionally, the progressively abnormal mitochondria are less efficiently replaced, leading to a clogging of the transport system in the axon, which consequently degenerates due to inefficient axonal trafficking.[116]

NIP1A, a gene coding for unknown function, has also been implicated in causing juvenile onset HSP in at least six families.[141,142] Kindred studies suggest that the identified mutations within the putative integral membrane protein are pathogenic through a dominant negative mechanism. Expression studies involving the *C. elegans* NIP1A homologue show significant expression in the worm neurons, consistent with strong NIP1A expression in neuronal tissues within the human brain.[143] Overexpression of the wild-type NIP1A in *C. elegans* does not impair worm mobility; in contrast expression of NIP1A containing the corresponding pathogenic human mutations results in complete paralysis. This striking effect of pathogenic NIP1A in *C. elegans* reveals a valuable tool to dissect the functions and mechanisms of NIP1A to reveal participation of NIP1A in HSP. Taken together with the aforementioned *C. elegans* studies, the nematode is revealed as a powerful genetic model to dissect the molecular basis of the complex array of proteins involved in HSP and motor neuron dysfunction.

PERSPECTIVES AND FUTURE DIRECTIONS

The use of the nematode *C. elegans* in biomedical studies provides remarkable opportunities to identify and characterize potential human disease genes and proteins *in vivo*. The high similarities on the molecular level between the worm and humans suggest that the paradigms discovered using these systems are highly relevant to mammalian neurodegenerative diseases. Mammalian proteins that are associated with neurodegenerative diseases can complement and recapitulate many aspects of their pathology in worms. The ease of performing forward and reverse genetic screens will also very likely assist in the identification of novel molecules and pathways involved in neurodegeneration.

C. elegans is also easily amen able to chemical genetic screens to identify novel therapeutic drug leads, therapeutic targets, and the molecular pathway involved in the drug's efficacy. The worm is sensitive to a wide range of human neuroactive drugs, and has been utilized to screen for mutant proteins that have altered function in the presence of the drugs.[32,144,145,146] These screens also have the potential to identify molecular pathways not thought to play a role in the disease, or off-target sites of drugs that have not been previously identified.[5,147] For example, since *C. elegans* can

easily be grown in liquid medium in 96-well microtiter plates, we could grow our DA neuron reporter line expressing α-synuclein in solution in the wells each containing a different compound from our small compound library. The plate can then be analyzed in a fluorescent plate reader, and those wells in which the DA neurons still fluoresce would contain a compound that has the potential to be neuroprotective in mammalian systems. Once a therapeutic has been identified, we can perform suppressor chemical screens to identify the molecules and interacting partners involved in the compound-mediated protection of the DA neurons. We would simply mutate the animals and screen for worms in which the DA neurons are *not* protected by the drug. Using standard *C. elegan*s genetics and molecular biology, we could then quickly identify the drug targets and pathways involved in the drug's efficacy.

The high conservation of biological processes within the nervous system between *C. elegans* and humans and the strength and ease of incorporating forward and reverse genetics to identify and characterize novel components involved in cell dysfunction and death *in vivo* make this relatively simple animal a powerful and formidable tool in our arsenal in elucidating the molecules and their interactions that are involved in human neurodegenerative diseases. The strength and ease of incorporating the worm into high-throughput screening assays to identify novel compounds, therapeutic targets, and molecular pathways involved in neuroprotection are just beginning to be realized. It remains to be seen if the mighty worm will provide the therapeutic insight that has so far eluded us into combating the devastating effects of neurological diseases.

13 Zebrafish as a Model for Development

Brian A. Link and Sean G. Megason

ABSTRACT

The zebrafish model has recently emerged as a significant experimental system for developmental biology studies. In this review, we provide an introduction to the zebrafish model system by overviewing set-up and husbandry requirements, the genome, and associated bioinformatics infrastructure. We then detail the utility of zebrafish for forward, reverse, and chemical genetic studies of development. We also discuss using zebrafish for live cell imaging experiments. Finally, we provide an overview of zebrafish community resources.

Key Words: Vertebrate, Genetics, Chemical-genetics, Time-lapse imaging, Organogenesis, Mutant analysis.

INTRODUCTION

Zebrafish, *Danio rerio*, are small freshwater teleosts that were insightfully selected as an experimental model based on several practical criteria as well as their genetic amenabilities. During the 1980s, the pioneering work of the late geneticist George Streisinger and his colleagues at the University of Oregon established the groundwork for utilizing zebrafish as an experimental system. This organism has now emerged as a significant model for developmental biology studies, acting as a segue between the genetic power of invertebrates and the relevance of rodents (Table 13–1).

Adult zebrafish are approximately 1.0–1.5 inches in length and can be housed inexpensively with modest space requirements (Figure 13–1). Sexual maturity is reached reliably at 3 months, but under optimal growth conditions this time can be reduced to 2 months. Females can produce 100–200 embryos per week. Fertilization occurs externally and initial development is completely transparent. Development through larval stages can also be rendered transparent with the use of melanin synthesis inhibitors.

Another attraction of zebrafish for developmental studies is the rapid ontogeny. Blastulas enter gastrulation at approximately 5 h postfertilization (hpf). Somitigenesis begins just before 10 hpf and by 24 hpf the major subdivisions within the nervous system are in place, as are the rudiments of the primary organs. For example, the heart primordium initiates rhythmic beating within the first day. Embryos begin to break from their protective chorion envelope around 60 hpf, although this nonessential shell can be manually removed at earlier times. By 72 hpf, organogenesis is well underway and embryos exhibit touch responses and swimming behaviors. Visually evoked behaviors are present by day 4. For the first 5 days of development, embryos feed endogenously from their yolk material. Specific stages of zebrafish embryonic development have been described in detail by Kimmel *et al.*[1] After day 5, larval zebrafish need to be fed externally and a brief discussion of zebrafish husbandry is provided next.

ZEBRAFISH HUSBANDY

In addition to the embryological advantages of zebrafish, their ease in care is another attraction as an experimental model. When starting a zebrafish colony, the typical researcher contacts one of several companies that specialize in the construction and installation of multitank systems. These systems can vary from accommodating 10 tanks to well over 1000 (Figure 13–1B). For laboratories that just need a small supply of embryos, individual 10-gallon tanks will suffice. Water quality is a key parameter in keeping and raising zebrafish. Zebrafish require slightly brackish water for proper osmoregulation (400–800 µS). Appropriate salinity is achieved by addition of balanced salt preparations, which are available commercially. The pH should be maintained around 7.0 and the temperature at approximately 28℃. One major concern with recirculating fish systems is the maintenance of the nitrogen cycle. Nitrogenous compounds are found in several forms as by-products of fish metabolism: ammonia (NH_3) and nitrite (NO_2^-) are toxic to fish and need to be converted to the third nontoxic form of nitrate (NO_3^-). Larger zebrafish systems rely on biological (microbial) filtration to maintain the nitrogen cycle. Smaller individual tank systems can also be maintained with chemical filtration. Appropriate pH is maintained by addition of sodium bicarbonate or calcium carbonate to raise pH and hydrochloric acid to decrease pH. Additional water quality details can be obtained from the system supplier.

Circadian cycles are also import for healthy fish. Most researchers use a 14-h on/10-h off lighting cycle. Feedings should also occur at consistent times. In general, fish are fed two or three times daily with a vitamin-enriched dry food and freshly hatched brine shrimp. Live brine shrimp can easily be prepared in the laboratory by hatching purchased brine shrimp eggs or cysts using commercially available hatchers. To prevent fouling the tank with uneaten food, no more food should be given than can be consumed by the fish in the tank within 10 min.

Raising larvae to adulthood can be challenging for new fish researchers. The critical factors are having high-quality water slowly flowing through the tanks as soon as feeding begins, ensuring that the larvae cannot escape or get washed out of the tanks,

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

and feeding a proper larval diet. Larvae can be fed a variety of foods including fresh *Paramecium*, rotifers, or dry food of the appropriate particle size. Live *Paramecium* can be ordered from the Zebrafish International Resource Center (Eugene, OR) and can then be propagated in the laboratory. High success rates in raising larvae can also be achieved with powdered foods designed especially for larvae (e.g., Hatchfry Encapsulon Grade I, Argent Labs). Larvae begin consuming live brine shrimp ~2 weeks postfertilization.

Embryos can be obtained by either pairwise or group crosses. Fish are netted from their housing tank and placed into breeding tanks the night before embryos are to be collected. Zebrafish typically breed at "dawn" when the lights turn on. Breeding tanks contain a porous insert sleeve, allowing the fertilized eggs to slip though to the bottom, where they are protected from cannibalization by the adult fish. Embryos can then easily be collected and used for microinjections or other experimentation and observation.

THE ZEBRAFISH GENOME

The zebrafish genome is diploid, is composed of 25 paired chromosomes, and is estimated at 1700 Mb, about half the size of the human genome.[2,3] A working draft of the assembled genome is available from the Sanger Centre (http://www.sanger.ac.uk/Projects/D_rerio/). Comparative mapping has shown extensive conservation in synteny (the ordering of genes along the chromosome) between zebrafish and humans. In fact, the local synteny between zebrafish and humans is even greater than between mouse and humans, as the mouse appears to have undergone substantially more chromosome rearrangements.[4] Analysis of the zebrafish genome, along with that from other bony fishes, has revealed an ancient genome duplication prior to the dramatic speciation of the teleosts followed by massive gene loss. In practical terms, this has resulted in the duplicate representation of approximately 30% of the zebrafish genes as compared to mammalian orthologs.[5] This has implications for both genome assemblies and gene functional studies. Having two loci for essentially the same gene can be viewed either as an advantage or a disadvantage, depending on the question at hand. For the majority of duplicated genes studied in zebrafish, the divergence between the two genes is most dramatic within regions that control expression. The prevailing view is that while duplicated genes have subpartitioned their expression domains, they are often functionally equivalent. Of course this assumption warrants experimental validation. For forward genetic studies, gene duplication can be perceived as advantageous, as mutations potentially will yield more specific phenotypes than mutations in other vertebrate species. However, when both paired genes retain expression in any given domain, the disadvantages of genetic compensation can complicate experimental interpretation. Indeed, redundancy and compensation might prevent the isolation of mutations in particular genes because no measurable phenotype would be induced. From an experimental perspective, it is important to know whether the gene being investigated is duplicated. In the following sections, we next describe the most common techniques and utilities of zebrafish for studies in developmental biology.

Table 13–1
Advantages and disadvantages of popular animal models[a]

Cell culture	+	+	+	+++	+++
Relevance to human health	++	++	+	+	+++

[a]This table is a rough guide for comparing the most commonly used model systems. It should serve as a general introduction as it summarizes complex comparisons that will not hold true for every situation. See the text for more details.

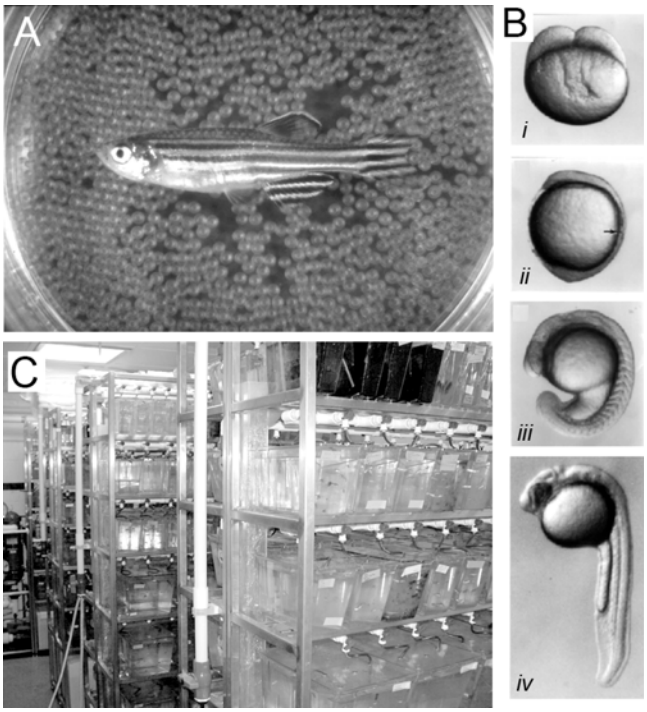

Figure 13–1. Adult and embryonic zebrafish. (A) Single female adult zebrafish in a 10-cm culture dish with newly fertilized embryos within their chorions. (B) Embryo morphology (chorions removed): (i) 2 cell (~45 min); (ii) 1 somite stage (arrow, ~10.5 h); (iii) 18 somite stage (18 h); (iv) 24-h embryo. (C) Typical multirack circulating system. In this system, each rack has 6 shelves of 6–12 tanks, depending on the size of the tanks. [Images in (B) modified from Kimmel *et al.*, 1995.]

FORWARD GENETICS

MUTANT SCREENS Forward genetics refers to phenotype-based analysis followed by identification and characterization of the mutation in the causative gene (Figure 13–2). Mutant screens exemplify this phenotype-to-genotype approach. There is no doubt that forward genetics put zebrafish on the experimental systems map. Several large-scale mutagenesis screens have been conducted and others are currently underway. The first large-scale screens were done in tandem in the laboratories of C. Nusslien-

Volhard (Tübingen) and W. Driever (Boston/Freiburg) in the mid-1990s. Ethylnitrosourea (ENU) was used as the mutagen, which largely produces point mutations. The initial descriptions of these screens were published in a special issue of *Development* in 1996.[6] With chemically induced mutations, the causative gene mutation is usually isolated by combining positional cloning and candidate gene analysis techniques. Isolation of chemically induced mutations can be laborious, but the continued refinement of the zebrafish genome assembly greatly aids in such efforts.

Alternative approaches to ENU-induced mutagenesis are also possible. Shortly following the ENU screens, the Hopkins laboratory (MIT) conducted a retroviral-insertion screen.[7,8] The advantage of this strategy is that the phenotype-causing genes could be easily identified by simple inverse-polymerase chain reaction (PCR) assays. The disadvantage was that the mutagenesis was less efficient and the kinds of mutations created by large insertions, in principle, are more limited than point mutations. In addition, specialized expertise and facilities are required for the generation of high-titer pseudotyped viruses.

One variation on the more time and cost consuming *de novo* genetic screen is the shelf screen. Shelf screens refer to reanalysis of an existing collection of mutants for the phenotype of interest and several shelf screens have been successfully conducted.[9–12] For example, Neuhauss and colleagues screened for visual behavior deficits, identifying subtle ocular phenotypes in mutants that had been previously characterized for other defects.[10]

There are several important issues to consider with regard to mutational analysis in zebrafish. As with any genetic screen the assay for the phenotype of interest should be fast and robust. Most of the initial developmental genetic screens in zebrafish were morphology based. However, it is now more typical to screen for mutations that affect the expression of specific genes, antigens, or transgenes that express green fluorescent protein (GFP). Most screens for developmental anomalies require matings through several generations in order to bring recessive mutations to homozygosity (Figure 13–2). Dominant mutations can be selected in the F_1 generation, but the phenotype must be nonlethal in order to preserve the carrier. With zebrafish, when studying developmental phenotypes, the role of maternal mRNA and protein must be carefully considered. The large ooplasm of zebrafish contains very large supplies of maternally derived (wild-type) mature transcripts and proteins. This "start-up package" for the newly fertilized embryo can mask the early function of mutated genes. The degradation of specific mRNA and proteins is variable, but some maternal products have been shown to remain in zebrafish embryos for over 7 days, a relatively late developmental time point. The masking of early phenotypes by maternal products can be prevented through the use of maternal-zygotic (MZ) mutants in which both the mother and embryo are homozygous mutant. Excellent reviews on the logistics and further considerations of genetic screens in zebrafish are available.[6,13–15]

CHEMICAL GENETICS One other approach to phenotype-based study of developmental biology (as well as other biological phenomena) is termed chemical genetics. In 2000, R. Peterson and colleagues published a paper describing the use of combinatorial small molecule chemical libraries to induce phenotypes in developing zebrafish.[16] Once identified, small molecule compounds that disrupt developmental processes can be applied at different times. These agents, therefore, can be used similarly as conditional genetic alleles. In addition to allowing for time-specific disruptions, another advantage of chemical genetic screens is that founding generation embryos can be used. There is no need to progress through several generations of inbreeding as there is for genetic mutant screens. The major challenge with chemical genetics is target identification. What protein(s) and/or other cellular components does the compound affect? Traditional biochemical purification approaches are most common in target identification. More recently, chemical genetics has been used in tandem with genetic mutagenesis to identify potential small molecule targets as well as to conduct suppressor/enhancer screens. With this approach, mutagenized zebrafish embryos are screened in parallel with and without a phenotype-inducing small molecule. Those mutations that suppress or enhance the phenotype are strong candidates to disrupt genes that function in the same biological pathway as the small molecule. Excellent reviews on using zebrafish for chemical–genetic studies have been published.[17–19]

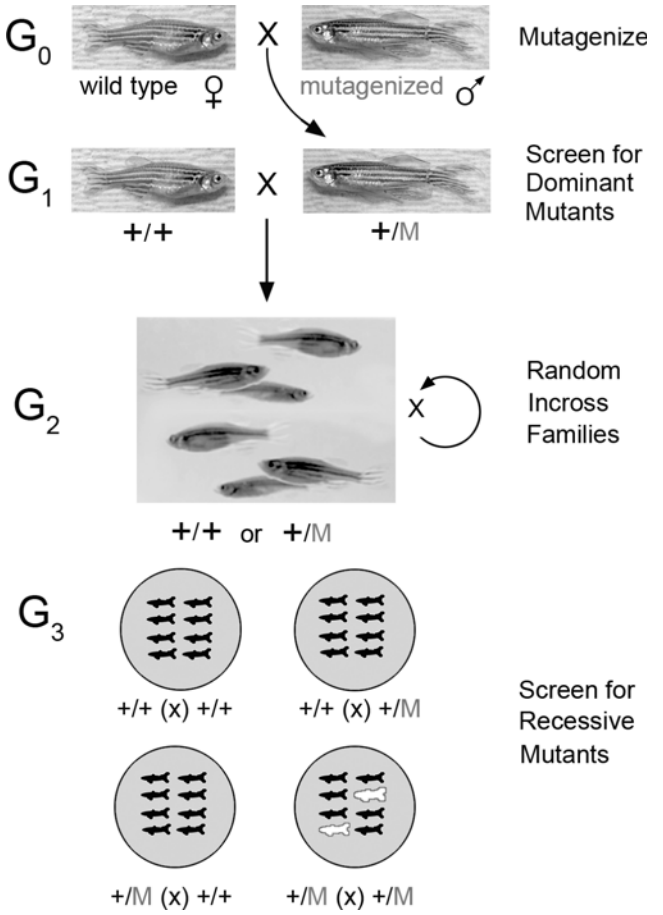

Figure 13–2. Classical three-generation screen for recessive mutants. In the founding G_0 generation, male spermatagonia are mutagenized. Resulting fish carry random mutations. This G_1 generation can be screened for nonlethal dominant mutations. To identify recessive mutations, G_1 fish are outcrossed again and the resulting G_2 families are incrossed. G_3 embryos will then show recessive phenotypes.

REVERSE GENETICS

In addition to being a superb system for phenotype-driven, forward genetic approaches, the zebrafish is also an excellent

model for a variety of gene-driven techniques collectively referred to here as "reverse genetics." With reverse genetics, the investigator starts with a gene and tries to characterize its function as opposed to forward genetics in which the investigator starts with a function (i.e., phenotype) and tries to characterize the genes involved. For zebrafish, there are multiple and diverse techniques available for characterizing the function of a gene.

The primary advantage of zebrafish over other model systems is the ease with which reverse genetic approaches can be done and the wide array of available methods (see Table 13–1). The main reason that these techniques are easy to do in fish is that zebrafish eggs can be readily collected and injected in large numbers. In a typical experiment, a researcher would set up several pair matings the evening before, collect fertilized eggs from each pair in the morning (typically 50–250 eggs per pair), and inject 100–1000 eggs in a few hours. Injections are done under a dissecting microscope using a pressure injector and micromanipulator as detailed previously (http://zfin.org/zf_info/zfbook/chapt5/5.1.html). Most people learn how to be proficient at injections within a few sessions. It is best to do injections at the one-cell (zygote) stage to ensure an even distribution of the reagent. The initial divisions of zebrafish are meroblastic (incomplete cytokinesis), meaning that reagents can transfer between all the cells until the 16-cell stage.[20] Injections can also be done at later stages intentionally to achieve a mosaic distribution.

DNA/RNA INJECTIONS One of the most common ways to characterize a gene in zebrafish is simply to inject DNA or RNA based on the gene into eggs and assess the resulting phenotype of the embryos. The injected construct, for example, can be full length, dominant negative, or encode other mutant and truncated forms for structure–function analysis. Stabilized, capped RNA can be made using commercially available *in vitro* transcription kits from plasmid DNA templates. RNA can be injected into the yolk at the one- to four-cell stage and typically results in high-level, uniform expression. It is good practice to monitor the expression level and distribution of injected RNA by coinjecting RNA for a fluorescent protein [e.g., enhanced green fluorescent protein (EGFP)] or better yet using a fluorescent fusion protein construct. This allows properly injected embryos to be quickly sorted on a fluorescent dissecting microscope while still living. RNA typically starts expression within 4–5 h postfertilization and degrades within 2–4 days postfertilization, so injections are useful for studying developmental stages only within that window.

DNA injections should be done into the blastoderm rather than the yolk to improve expression, but they still typically result in mosaic expression even when done at the one-cell stage. Use of the Tol2 transposon system can substantially improve the distribution of expression.[21] The advantage of DNA injection over RNA is that DNA allows the use of enhancers to control when and where expression occurs and can result in more sustained expression. DNA injection is also how transgenic lines are made as described below.

MORPOLINO/SIRNA INJECTIONS DNA and RNA injections are typically used for gain-of-function studies. Injecting dominant-negative constructs can provide some insight into loss-of-function, but there are a number of caveats with this approach concerning the specificity and efficacy of the reagents. Traditionally the preferred method for doing loss-of-function studies was through the use of genetic null mutants, which with a reverse-genetic approach are often not available. Within the last several years, however, two methods, morpholinos and RNAi/siRNA, have become available to efficiently and specifically generate loss-of-function phenotypes in a number of organisms with morpholinos being much more popular for zebrafish.[22] Morpholinos are 18- to 25-bp synthetic oligonucleotides with a modified backbone that is resistant to enzymatic cleavage yet still base pairs with high affinity and specificity. They are designed to be antisense to the gene of interest such that they base pair near the start codon in the mature mRNA to block translation or across a splice junction in the pre-mRNA to block splicing. Both approaches can work well, but splice site morpholinos have the advantage that their efficacy can be assessed using reverse transcriptase (RT)-PCR. Morpholinos may not completely abolish expression, so the term "knockdown" rather than "knockout" is used to refer to their activity and "morphant" rather than "mutant" is used to refer to the affected embryos. When using morpholinos, it is essential to do controls to monitor the efficacy of knockdown (e.g., antibody staining) and specificity (e.g., rescue by coinjection of an RNA that lacks the target sequence). Morpholinos can be ordered through Gene Tools or Open Biosystems.

RNAi and the related technology of siRNA have worked well in a number of other systems, but in fish they have not yet been shown to work as robustly as morpholinos. Simple injection of dsRNA as is used for RNAi in worms and flies results in nonspecific effects in zebrafish.[23] siRNA is widely used in mammals and has the potential benefits of being cheaper and being able to be delivered genetically, but has received only minor use in zebrafish.[24,25]

TRANSGENIC MISEXPRESSION SYSTEMS The above methods take advantage of the ease of injecting zebrafish eggs to do transient assays. It is also useful to take advantage of the genetics of zebrafish to do transgenic-based studies to characterize a gene's function. This powerful ability to do both injection-based and stable transgenic-based approaches for reverse genetics is unique to fish (Table 13–1). Compared with injection, transgenic approaches are more labor intensive, but they allow more precise control.

A transgenic organism is an organism that contains an exogenous piece of DNA called a transgene. The term is most often used for stable transgenics in which the transgene is integrated into the genome and stably inherited from generation to generation. There are several ways to make transgenics in zebrafish.[26] The first approach is to simply inject DNA for a transgene into fertilized eggs, raise the embryos to adulthood, and screen for founders that pass on the transgene to their progeny. This method is not terribly efficient on a per embryo basis but since injecting and screening are easy in fish, transgenics are routinely made this way. Generally, around 5% of injected animals will become founders and they will pass the transgene on to around 5% of their progeny since the founders are mosaic. These numbers can vary depending on a number of factors including the construct, amount of DNA injected, and the skill of the person injecting. The transgene will follow normal Mendellian inheritance in subsequent generations. Since several hundred eggs can be injected in a few hour session, the injections do not require much work. The labor in generating transgenics is in raising the eggs to adulthood and screening to identify founders. Screening can be done visually for fluorescent protein (e.g., EGFP) transgenics but may require PCR for other constructs. Transgenics made by simple DNA injection

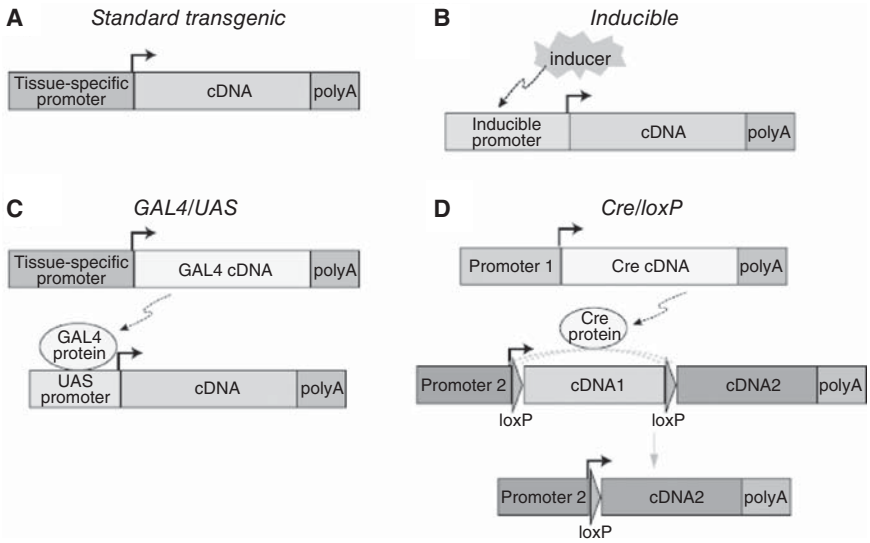

Figure 13–3. Transgenic misexpression systems. (A) For standard misexpression, a transgene contains an enhancer/promoter (typically tissue-specific) driving expression of a cDNA of interest. To ensure optimal expression it is important to include an intron (not shown) and a polyadenylation signal. (B) Inducible transgenics contain a single transgene containing a promoter that is activated in response to an outside factor such as heat or a drug. (C) In the GAL4/UAS system, two different transgenics are used that when separate have no effect. When combined (e.g., by crossing or coinjection), GAL4 made from one transgene will activate expression of the other transgene through binding the UAS sequence resulting in the cDNA being expressed in a domain determined by the tissue-specific promoter. (D) The Cre/loxP system also typically makes use of more than one transgene, although there are many variations on its use. In the example shown, Cre recombinase is expressed from one transgene and causes recombination between IoxP sites on a second transgene. The end result is that cDNA1 is expressed in cells that express promoter 2 and have *never* expressed promoter 2 and cDNA2 is expressed in cells that express promoter 2 and expressed promoter 1 at *any* time in their past. Such a system can be used for genetic fate mapping if visible markers are used or for controlled misexpression similar to GAL4, but with an important distinction caused by the irreversible nature of the loxP recombination.

often contain multiple tandem copies of the transgene. Multicopy transgenics can provide higher expression levels, but sometimes it is important to have single copy insertions (e.g., loxP reporters, gene trapping). Two transposon systems, Tol2[21] and Sleeping Beauty,[27] have recently been developed that generate single copy insertions and also integrate more efficiently than simple DNA injections. These transposons can be used for insertional screens as described above, but they can also be used to increase the efficiency of making specific transgenics. A final method for generating single copy insertions with improved efficiency is through the use of the meganuclease I-SceI.[28]

A common problem in using transgenics for studying the function of a gene is that the transgene can cause a dominant lethal phenotype, precluding the establishment of stable transgenic lines. There are several ways around this problem including inducible and binary systems. Inducible systems consist of a single transgene that is silent until expression is turned on by some outside factor. The promoter for the zebrafish heat shock protein (Hsp) 70 has only minimal activity in all tissues (except the lens) at 28.5℃, the normal temperature for raising embryos. Ubiquitous expression from Hsp70 can be induced by heat shocking the embryos for 1 h at 37℃ (Figure 13–1A). Localized expression from Hsp70 can also be induced by local heating using a focused laser.[29] Inducible expression has also been achieved is zebrafish using the steroid glucocorticoid.[30] Binary systems use two separate transgenes to provide regulated expression. In the GAL4/UAS system, one transgenic fish expresses the yeast transcription factor GAL4 under a tissue-specific promoter.[30,31] A separate transgenic fish contains the gene of interest behind a minimal promoter containing UAS sites (Figure 13–1B). The UAS transgene is normally silent, but when crossed with the GAL4 line, it is turned on by GAL4 binding the UAS sequence and activating transcription in a pattern determined by the promoter regulating the GAL4 transgene. Once GAL4 and UAS lines have been established, a variety of experiments can be done simply by crossing different GAL4 and UAS lines. Another versatile binary system consists of the site-specific recombinase Cre and its recognition sequence loxP.[32] As shown in Figure 13–3, a transgene can be made to express one gene prior to recombination and a second gene after recombination. This transition can be controlled by combing the "loxP transgenic" with a second transgenic that expresses Cre tissue specifically. Numerous variations on this theme are possible using Cre/loxP and the analogous recombinase system FLP/FRT.

LOCUS-SPECIFIC MUTAGENESIS Although morpholinos can provide valuable loss-of-function data for a gene of interest, the cleanest and the traditional method is to have a genetic mutation for the gene. Until a few years ago obtaining mutants for any specific gene could be done with mouse only through the use of homologous recombination in embryonic stem cells. Recently, however, a new method called TILLING (Target-Induced Local Lesions IN Genomes) has been developed that uses a bank of mutagenized sperm and brute force molecular methods to detect sperm samples with mutations in the gene of interest.[33–35] These sperm samples are then used for *in vitro* fertilization to recover and analyze mutant animals. A review comparing various forward and reverse genetic techniques was recently published.[15]

Mutations found with TILLING are still random, point mutations and small deletions, but it may soon be possible to achieve the exquisite precision of genetic engineering possible with mouse

ES cells in zebrafish. Zebrafish have been produced from cultured cells through somatic cell nuclear transfer (i.e., cloning).[36] If these cells can be manipulated in culture through gene targeting as is done with mouse ES cells, then it may soon be possible to construct zebrafish mutants with any desired DNA sequence (e.g., conditional alleles, GFP fusions). Work is also being done to establish zebrafish ES cells. Germline chimeras have been made from ES-like cells after short-term culture[37] and these cells have been targeted using homologous recombination,[38] but to date these techniques have not been successfully combined.

IMAGING

ADVANTAGES One of the most compelling reasons for the use of zebrafish today and its choice by George Streisinger as a model organism over three decades ago is its superb suitability for imaging. Streisinger's choice is even more clairvoyant in light of the incredible technological revolutions in both fluorescent proteins and confocal/two-photon imaging during the past decade. A number of attributes make zebrafish ideal for imaging. Zebrafish are largely transparent for much of their development allowing excellent light penetration for optical microscopy. From fertilization to 24 h postfertilization, zebrafish embryos are remarkably transparent. The embryo proper (as opposed to the yolk ball) has no color and extremely low autofluorescence. Shortly after fertilization (0–1 hpf) the yolk scatters moderately due to cytoplasmic streaming, but subsequently it is also transparent. Although transparent, it is best to avoid imaging through the yolk when possible, because it has a slight yellowish tinge and a higher refractive index. The yolk is also moderately autofluorescent. Zebrafish contain three types of pigment cells that begin to differentiate on the second day of development and can interfere with imaging. Melanocytes are the first and most obvious pigment cell (Figure 13–4A), but production of the dark melanin pigment from these cells can be easily blocked by adding phenylthiourea to the media. The other two cell types, xanthophores and iridophores, begin to appear around 48 hpf. Xanthophores produce a light yellow pigment and are slightly autofluorescent, while iridophores produce crystals of purine that are highly reflective but small. While these pigment cells make imaging some tissues difficult (such as the eye), most tissues in zebrafish can be readily imaged throughout their development in the embryonic and early larval stages. The egg shell or chorion of zebrafish embryos is also transparent. For routine imaging on a dissecting microscope, the chorion does not present a problem (Figure 13–4A), but for high-resolution imaging on a compound microscope, it is best to remove the chorion (Figure 13–4B–E).

Zebrafish embryos are externally fertilized and develop freely in an aquatic media meaning that they are accessible to imaging throughout their development and easy to keep alive during time-lapse imaging. Another important advantage for time-lapse imaging is the rapid development of zebrafish, which allows equivalent developmental processes to be imaged with shorter movies in fish and thus much easier. Zebrafish embryos are also a nice size for imaging. They are small enough to fit completely within the working distance of many high-end objectives yet are not so small that the details of their development are beyond the resolution available with optical microscopy. Zebrafish embryos are easy to label at high levels through injection of RNAs for fluorescent proteins (Figure 13–4B) or soaking in fluorescent dyes. Achieving high-level labeling is important in order to capture high signal-to-noise images quickly with minimal photodamage.

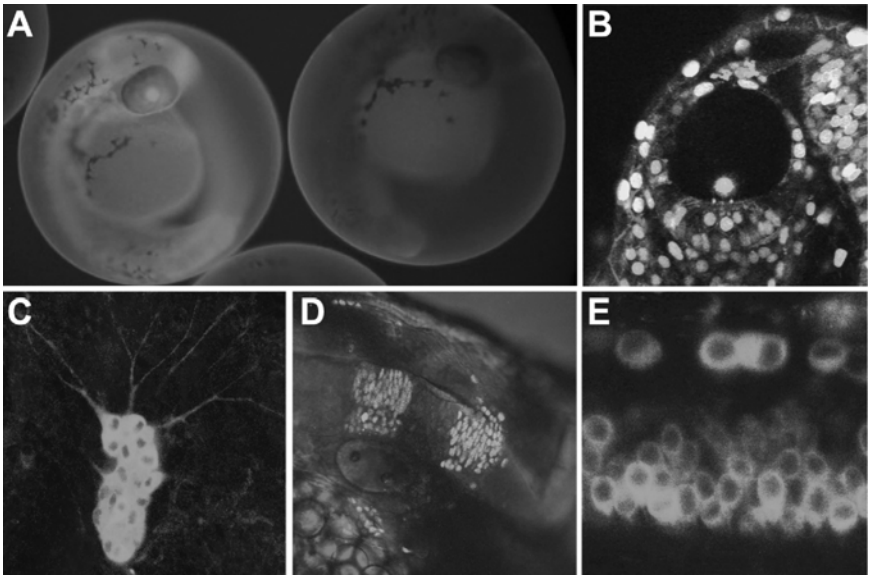

Figure 13–4. Imaging in live zebrafish embryos. (A) Whole embryos can be quickly imaged on a fluorescent dissecting microscope in their chorions to sort positive transgenics (left) from wild-type siblings (right). These embryos were not treated with PTU so the melanocytes are visible. (B–E) Confocal microscopy permits much higher resolution imaging. (B) A quick method for labeling is to inject RNA encoding fluorescent proteins, in this case a histone2B-EGFP fusion, and a membrane localized mCherry was used to image all the cells of the inner ear. (C) GFP transgenics can be used to image neuronal projections from the trigeminal ganglion as they extend. (D) GFP transgenics can mark specific populations of cells, in this case rhombomeres 3 and 5. (E) GFP fusion proteins can reveal the subcellular localization pattern of proteins, in this case a cytoplasmic protein in the Rohon-Beard and motor neurons of the spinal cord. (Images from S.G. Megason, L.A. Trinh, and S.E. Fraser, unpublished.) (See color insert.)

MICROSCOPES For quick, routine imaging, zebrafish embryos can be imaged on a dissecting or stereo microscope in a Petri dish full of egg water (Figure 13–2A). Most popular manufacturers now produce dissecting microscopes equipped for fluorescence that allow live zebrafish embryos expressing fluorescent proteins to be screened and sorted quickly. After 24 hpf, movement of the embryos can be a problem. Embryos can be anesthetized by adding a few milliliters of 0.1% tricaine to the Petri dish (0.010–0.015% final concentration). Embryos can be recovered from anesthesia with no ill effect by transferring to fresh egg water.

For high-resolution imaging a compound or better yet a confocal or two-photon microscope should be used (Figure 13–4B–E). Confocal and two-photon microscopy is advantageous because both approaches can eliminate out of focus light, which can be a problem unless only a small minority of cells is labeled. Tricaine should be used be used to prevent movement. At the proper concentration tricaine can be used to immobilize embryos for at least 48 h for time-lapse imaging while maintaining proper development (S.G. Megason and S.E. Fraser, unpublished observations). Careful mounting of embryos in the proper orientation and close to the coverslip is essential for high-resolution imaging. A fast and easy method for still images (not time-lapse) is to place the embryos in a drop of 2% methyl cellulose and cover with a coverslip supported by tape or vacuum grease. For time-lapse imaging it is essential to prevent the embryos from drifting during the time lapse. This can be accomplished by simply embedding the embryos in a dilute solution of low-melting temperature agarose. This method works well for imaging many parts of the body for moderate lengths of time (~12 h), but the rigidity of the agarose affects many aspects of morphogenesis such as tail extension. For more reproducible mounting and longer term time lapses of normal development, specially designed, micromachined templates can be used to cast agarose mounts to hold embryos in place for imaging (S.G. Megason and S.E. Fraser, unpublished observations).

LABELS For simple transmitted or reflected light microscopy, zebrafish can be stained using enzymatic markers with chromogenic substrates. This is routinely done with *in situ* hybridization to reveal RNA expression patterns and is also done using lacZ transgenics.[39] These techniques require the embryos to be fixed so time-lapse imaging cannot be done and are difficult to capture in three dimensions.

The true power of imaging zebrafish is through the use of fluorescent microscopy. Fluorescent imaging opens up two important dimensions (t and z): it allows molecular imaging to be done in real time on living embryos *and* it permits the use of confocal and two-photon microscopy to capture high-resolution volumetric images. Organic dyes can be used to label embryos such as bodipy ceramide to label membranes[40] or calcium indicators to monitor Ca^{2+} currents in neurons.[41] Fluorescent proteins such as GFP offer a number of advantages over organic dyes. They can be expressed in a spatial and temporal-specific manner through the use of transgenics.[26] Fluorescent proteins also come in a wide spectral range and are typically more photostable than organic dyes allowing for multicolor imaging (Figure 13–4B). Fluorescent proteins can also be engineered using standard techniques of molecular biology to act as reporters for a number of activities. At the simplest, they can serve as a coexpression marker—e.g., when making a transgenic to analyze the function of another gene, an internal ribosome entry site (IRES)-GFP cassette can be added to monitor the expression of the gene of interest. GFP transgenics can also be used to mark a particular cell type for analyzing mutant phenotypes or to simplify screening for new mutations involved in the development of that cell type (Figure 13–4C and D). Fluorescent protein transgenics can serve as markers for gene expression patterns. Once a transgenic line is available, it is often easier to use it to look at gene expression than performing *in situ* hybridization. GFP fusion proteins can also be used as "functional reporters." Fusions of GFP to a protein of interest can be used to monitor the subcellular localization of that protein, which often relates to its functional state (Figure 13–4E). For neuroscience, voltage, pH, and Ca^{2+}-sensitive versions of fluorescent proteins are available[42–44] as well as versions that can travel across synapses. For monitoring protein–protein interaction *in vivo*, fluorescent resonant energy transfer (FRET)[45] and bimolecular fluorescent complementation (BiFC)[46] can be used.

EMBRYOLOGICAL EXPERIMENTATION

While the genetic and imaging capabilities of zebrafish are the model's strengths, embryonic cell manipulation techniques have also been established for zebrafish. In this section we will introduce the most common "embryology" techniques used for zebrafish.

CELL AND TISSUE CULTURE To complement much of the *in vivo* analyses using zebrafish, there has been an increasing need to conduct cell biological experiments in culture. The use of zebrafish for this purpose is just in its beginning and no well-established zebrafish lines exist. However, protocols for primary cell culture are available for a variety of cell types.[47,48] In addition, cultures from blastula stage embryos have been shown to be mulitpotent and can be targeted for DNA transfections.[49,50] An area of active research and great promise is the use of these embryonic stem-like cells for targeted gene manipulation through homologous recombination.[38] The culture of whole tissue explants has also been developed and used for assessing inductive events as well as monitoring cell behaviors.[51,52]

LINEAGE LABELING AND FATE MAPPING One of the central questions in developmental biology is how progenitor cells distribute their progeny among various cell types. The ability to lineage label and fate map is essential for the utility of a model organism in developmental biology studies. In zebrafish, several strategies can be employed to label individual cells. The most common technique currently in use for labeling individual or small groups of cells relies on photolysis of caged fluorescein or other fluorescent labels.[53] With this technique, newly fertilized embryos are injected with the caged fluorescent compound. At later times, the individual cells can be labeled by "uncaging" the compound using a focused laser of the appropriate wavelength. The labeled cell is documented and its descendents can then be followed over time in a dynamic fashion or assessed at one particular time of interest. In a variation of this technique, fish with the *hsp70* promoter upstream of GFP (*hsp70*:GFP) can be used to photolabel cells in a similar manner.[29] In both techniques, the fluorescent label is diluted with each round of cell division. To permanently label cells, transgenic zebrafish have been established that contain *hsp70*:cre recombinase and lox{stop codon}lox-GFP.[54] The activation of cre recombinase will then catalyze the excision of the stop codon in front of the GFP transgene, permanently marking the heat-activated cells.

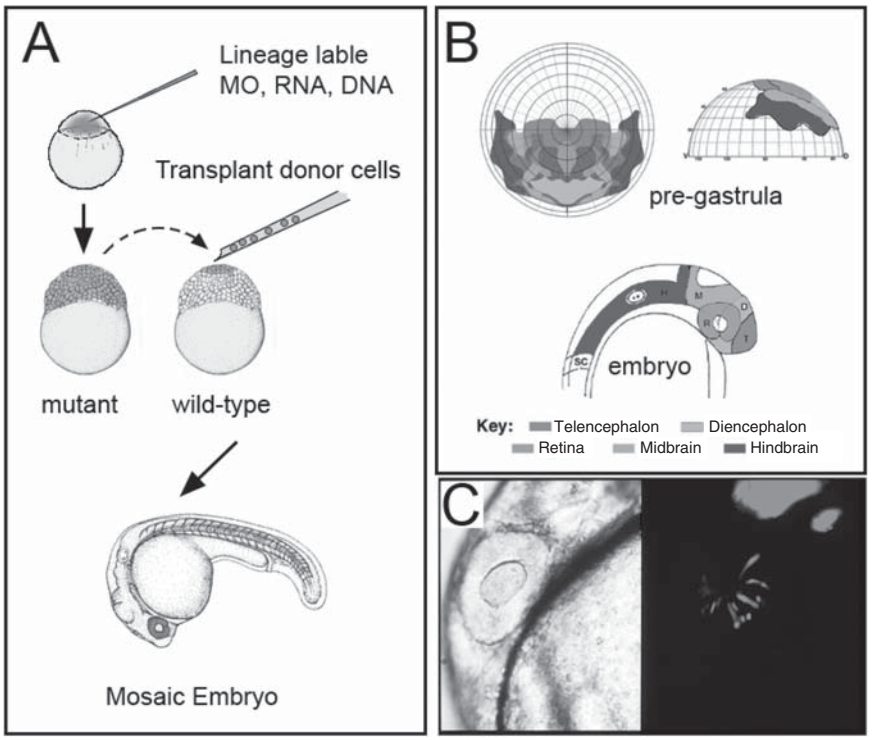

Figure 13–5. Creating genetic mosaics in zebrafish. (A) Donor cells are first lineage labeled with a tracer dye at the one-cell stage. Donor embryos can also be injected with morpholinos, RNA, or DNA. At the 1000-cell stage, totipotent blastula cells are transplanted into regions of the host embryo fated to give rise to specific structures. Donor and host embryos can be of either mutant or wild-type genotypes. Resultant chimeras are grown for subsequent analysis. (B) Fate-map of the pregastrula stage embryos. (Modified from Woo and Fraser, 1995.) (C) Mosaic embryo at 24 hpf showing bright-field (left) and fluorescent image (right) of rhodamine-dextran-labeled donor cells targeted to the eye and forebrain. (B.A. Link, unpublished.) (See color insert.)

In addition, focal labeling can be achieved through electroporation strategies. Protocols for labeling single cells[55] and larger fields of cells[56] have been established. With electroporation, localized electrical current carries small charged molecules across the plasma membrane into cells. For lineage marking, either labeled dextrans or plasmid DNA for GFP or other genetically encoded reporters can be delivered. Electroporation can also be used to manipulate gene expression as morpholinos or DNA for dominant negative/active proteins can be electroporated.

The described techniques have been used to establish several types of fate maps for the zebrafish embryo.[57–60] However, the need remains to assess cell fate determination with loss or gain of function of specific gene products, as well as at later times of development.

CELL AND TISSUE TRANSPLANTATION Zebrafish, like other *ex utero* organisms, are excellent specimens to conduct cell and tissue transplantation studies during development. The small size and tough epidermis of the zebrafish embryo, however, do pose problems for these types of experiments. In general, the approaches used for cell and tissue transplantation in other species such as chick and frog also apply to zebrafish.[61] Typically, the donor and host embryos are embedded adjacently in a low percent agarose gel or methyl cellulose. The fish are anesthetized using Tricane. Donor embryos are either labeled genetically with a fluorescent transgene or by injecting a tracer at the one-cell stage. For individual cell transplants, polished glass electrode pipettes are used to remove and expel cells. The positive and negative pressure needed to do this is created by a manual syringe driver. The details of this apparatus and technique have been described by J. Eisen (Westerfield, 1995; http://zfin.org/zf_info/zfbook/zfbk.html). For whole tissue transplants, sharpened tungsten needles or pulled glass electrodes are used to dissect and manipulate the tissue of interest. For ages over 1 day, the epidermis is thick but can be focally weakened by applying a small drop of mineral oil. Specific protocols for ocular tissue transplantation have been published.[62,63]

GENETIC MOSAIC ANALYSIS Genetic mosaic analysis is an elegant way to probe where and how specific genes function during development. Genetic mosaic embryos consist of cells of more than one genotype. In zebrafish, genetic mosaics are created by cell transplantation in early embryos, usually at the blastula or gastrula stages (Figure 13–5).[64,65] Because detailed fate maps exist for most tissue types in the early embryo, donor cells can be targeted to areas that will normally contribute to specific structures (Figure 13–5B and C). By transplanting genetically mutant cells into wild-type hosts and visa versa, the cellular autonomy of phenotypes associated with the mutation can be determined. As with other cell transplantation techniques, donor cells are labeled with a stable tracer at the one-cell stage or by utilizing transgenes. Excellent reviews of this technique and the analysis of genetic mosaics have been published.[66,67]

COMMUNITY RESOURCES

Although having grown tremendously in the past decade, the zebrafish community still has a well-organized infrastructure and strong community resources. The main website for all things zebrafish is ZFIN, the Zebrafish Information Network at http://zfin.org. It is maintained at the University of Oregon by Monte Westerfield and colleagues as the "official" NIH-supported, model organism database for zebrafish. ZFIN contains a wealth of information on genes, alleles (including mutants and transgenics), expression patterns, and anatomical atlases. ZFIN also contains an online copy of "The Zebrafish Book" by Monte Westerfield, which is essential reading for those new to using zebrafish in their research (http://zfin.org/zf_info/zfbook/zfbk.html). Other important resources for genomic information are NCBI GenBank

(http://www.ncbi.nlm.nih.gov/) and the Sanger Institute (http://www.sanger.ac.uk/). The Sanger Institute is currently sequencing the zebrafish genome using a combined 10 × whole genome shotgun and BAC sequencing approach (http://www.sanger.ac.uk/Projects/D_rerio/). As of September 2006, 64% of the genome is at finished quality and most of the remainder is covered as "unfinished" quality. The principal stock centers for zebrafish mutants and transgenics are ZIRC (the Zebrafish International Resource Center, http://zfin.org/zirc/) at the University of Oregon and the Tübingen Stock Center (http://www3.eb.tuebingen.mpg.de/core-facilities/zebrafish-stockcenter/tubingen-zebrafish-stockcenter) in Tübingen, Germany. A large variety of zebrafish strains can be requested from these stock centers for a nominal fee. The ZIRC also provides cDNAs/ESTs, anitibodies, and pathology services. The zebrafish community follows a standardized nomenclature for mutant and transgenic alleles. Each individual strain of fish is given an allele number such as b109. The initial letter designates the university or laboratory that identified the allele and the number is a unique number that specifically identifies that allele. A detailed description of the nomenclature guidelines can be found at ZFIN (http://zfin.org/zf_info/nomen.html). The most common companies for providing recirculating zebrafish systems are Aquatic Habitats, Aquaneering, and Marine Biotech in the United States and Aqua Schwarz in Germany. All of these companies as well as a number of other useful zebrafish-related companies are listed on the ZFIN company directory (http://mirror.zfin.org/cgi-bin/webdriver?MIval=aa-companyselect.apg). The zebrafish community holds an international conference on development and genetics every 2 years in the summer currently in Madison, WI. On alternating summers there is a large meeting in Europe, which rotates in its location. There are also a number of regional zebrafish meetings. Information on all these meetings is at ZFIN (http://zfin.org/zf_info/news/mtgs.html). There is a 2-week course on zebrafish at the Marine Biological Laboratory at Woods Hole, MA every summer for researchers new to fish (http://courses.mbl.edu/zebrafish/).

FUTURE PROSPECTS AND OTHER UTILITIES

To date zebrafish have principally been used as a model for developmental genetics, but they will likely find an even broader role in biomedical research in the future. This review has largely focused on embryonic analysis, but adult phenotypes can also be studied in zebrafish as well as adult-onset models of disease. This will be even truer as our ability to create inducible and conditional genetic alterations improves. Zebrafish are also an excellent model for neuroscience. Zebrafish neural activity can be monitored through imaging in whole, living larvae as they perform natural behaviors.[41] Zebrafish are also an excellent system for performing small-molecule/drug analysis. Small molecules can be screened in high-throughput with a chemical genetics strategy by simply soaking zebrafish embryos in an array of drugs using a 96-well plate-based format and screening for specific phenotypes.[18] Drugs can also be profiled rapidly for toxicological effects by embryo/larvae soaking.[68] Finally, zebrafish can be useful for identifying the target and mode of action of pharmaceuticals. Biochemical methods can be used to identify proteins that bind a drug as is normally done to identify targets, but the powerful genetic and genomic tools of zebrafish can also be applied. For example, it is possible to screen for interactions between genetic and small molecule-induced phenotypes.[18] Finally, since zebrafish can be analyzed very powerfully from a number of different angles (genetics, genomics, imaging, drug screening), they may also serve as an ideal model for integrative approaches such as systems biology.

14 Zebrafish as a Model for Studying Adult Effects of Challenges to the Embryonic Nervous System

Nicole Marie Roy and Elwood A. Linney

ABSTRACT

Zebrafish is introduced as a model system to study environmental, chemical, and pharmaceutical challenges to the embryonic nervous system that can affect adult behavior/learning. The characteristics of the zebrafish system that make it possible to examine the developing nervous system in live embryos and larvae are presented. Gene discovery techniques, methodologies to generate fluorescent transgenic indicator embryos, as well as larval and adult zebrafish behavioral assays are described.

Key Words: Zebrafish, Transgenics, Neurodevelopment, Behavior, Microarrays, Neurotransmitter.

INTRODUCTION

In this chapter we will introduce the zebrafish model system and discuss how it can be used to investigate early challenges to the embryonic nervous system and the resulting impact of challenge on adult behavior. We hope to present (1) the importance of studying neurotoxins, embryonic nervous system challenge, adolescent and adult developmental disabilities, and societal impact; (2) the power of the zebrafish model system to study the nervous system, challenges to the developing nervous system, and associated learning, memory, and behavioral deficits; (3) the embryonic challenge hypothesis; and lastly (4) the methodologies and techniques used in zebrafish with which to study early embryonic challenge and adult learning/memory and behavior.

TOXINS AND DEVELOPMENTAL DISABILITIES Developmental, learning, and behavioral disabilities are of increasing concern among the population and pose a serious public health problem. It has recently been estimated that 12 million U.S. children under the age of 18 years are affected by developmental disabilities affecting cognitive function, language and learning ability, sensory and motor function, behavior, and emotion.[1] For example, attention deficit hyperactivity disorder (ADHD) affects conservatively 3–6% of all school aged children and treatment with Ritalin has doubled every 4–7 years since 1971.[2] Similarly, the incidence of autism has increased from a previously reported 0.5 case per thousand to 2.0 cases per thousand,[3] suggesting an increasing trend for these disorders over time. Children with developmental disabilities often require costly special educational and therapeutic treatments at significant financial cost to the family or state. Each year in the United States, between $81.5 and $167 billion is spent on neurodevelopmental deficits.[4] In addition, developmental disabilities are thought to affect only children and adolescents, but in reality, they pose lifelong challenges. Adults who suffered from childhood developmental disabilities have difficulties maintaining employment and learning new skills and techniques, are often socially alienated, and suffer from mood and anxiety disorders.[1] Thus, it is of significant importance to understand the etiology of these developmental disabilities and prevent their occurrence in future generations.

Normal neurological development is based on a choreographed sequence of cellular events. During development, brain cells are born, divide, migrate, differentiate, and establish synaptic connections in a highly organized series of events controlled by neurotransmitters and neurotrophic factors.[5] Disruption of this cascade, even subtle, can lead to serious long-term consequences. With the exception of single-gene disorders, heredity accounts for approximately half of the variances in cognitive, behavioral and personality traits.[5,6] The increase in the incidence of developmental disabilities has led to a considerable focus on environmental, pharmaceutical, or chemical factors that can influence the developing neural environment.

Studies with human fetal meconium have shown that in certain parts of the world human fetuses are being exposed to high levels of metals and pesticides[7] and several studies have demonstrated the neurotoxic effects of these heavy metals, pesticides and solvents. Lead is the most extensively studied developmental neurotoxicant and has been shown to cause deficits in language, learning, memory, attention, and motor coordination as well as hyperactivity, aggression, and even mental retardation in high doses.[1,8–11] These studies prompted the government to remove lead from gasoline and paint in the 1970s. Other heavy metals linked to developmental disabilities include cadmium, mercury, and manganese, which have also been linked to decreased IQs, attention deficit, hyperactivity, and motor dysfunction.[1,5] Pesticides are an important player in commercial food production and in lawn and garden weed and pest control and are used in quantities over one billion pounds per year. However, pesticides are toxic chemicals often designed to work specifically on the nervous system. For example, organophosphate pesticides have been linked to devel-

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.),

opmental delays, hyperactivity, behavioral disorders, and motor dysfunction.[1,12,13] Other toxicants that pose a risk to the developing nervous system include the industrial solvents styrene, toluene, and xylene as well as the industrial lubricant and electrical insulator polychlorinated biphenyl (PCBs). These solvents are of particular concern as they contaminate soil and ground water affecting grazing animals used as beef cattle or as dairy animals.[14] Maternal ingestion of alcohol and nicotine also pose a risk to the developing brain.[11] Embryonic exposure to alcohol results in fetal alcohol syndrome (FAS), a condition hallmarked by craniofacial abnormalities, developmental delays, low brain weight, learning disabilities, memory impairment, and attention deficit.[15,16] Woman who smoke during pregnancy and expose the fetus to nicotine often have children who suffer from hyperactivity, learning disabilities, and developmental delays in cognitive function.[17–19] Lastly, as chemistry advances and pharmaceutical research progresses, more pharmacotherapeutics are routinely prescribed by medical practitioners. We are only in the infancy of understanding minute alterations these drugs may have on the developing brain or their long-term potential neurotoxicity.

Environmental, chemical, or pharmacological challenges to the nervous system often do not cause overt phenotypic changes to the developing brain, but rather cause minute, subtle changes that are not detectable with modern technologies. The complex nature of the human nervous system makes detecting these changes quite difficult to study. However, the zebrafish model system is an ideal organism with which to investigate early challenges to the developing nervous system and the subsequent impact on adult behavior and memory.

THE ZEBRAFISH MODEL ORGANISM Zebrafish are inexpensive, easy to maintain, have a short generation time, and individual females produce a large number of progeny. Unlike many other vertebrate models, zebrafish eggs develop *ex utero* and are transparent, meaning development is easily viewed under a simple dissection microscope. Zebrafish develop rapidly, are juveniles in a few weeks time, and are sexually mature adults by 3 months. More importantly, zebrafish are vertebrates, like humans, and follow the vertebrate path of embryonic development. In fact, there are several zebrafish models of human diseases including Alzheimer's disease, congenital heart disease, polycystic kidney disease, and cancer.[20] Accordingly, pharmaceutical companies are utilizing zebrafish in pharmacological trials to test drug candidates prior to investing in costly higher vertebrate models.

The zebrafish nervous system is highly amenable to investigation, particularly due to its transparency and the ability to clearly visualize fluorescent or stained neurons. The ability to identify small changes in neuronal architecture or molecular properties of neurons during development in response to environmental, chemical, or pharmaceutical challenge is of high importance in identifying potential neurotoxicants that cause early neural defects that can lead to adolescent and adult neurodevelopmental disorders. If minute changes can be detected, we can then link these early neuronal alterations with later staged behavioral changes and learning impairments. Luckily, work from several laboratories using calcium imaging, backfilling techniques, confocal imaging, *in situ* hybridization, immunohistochemistry, neuronal lesioning, and laser ablations has identified individual neurons and elucidated neuronal function and functional relationships between neuronal subtypes.[21–26] Furthermore, understanding the distribution patterns of subtypes of neurons is of importance to understanding neuronal circuitry. This is especially important in the spinal cord where neuronal circuits are essential for rhythmic movements and locomotor behavior. The development of the locomotor network in zebrafish has also been well characterized.[27,28] Full reviews of zebrafish movement and neuronal circuitry responsible for movement are available.[27–32]

Because of the relative long human life-span (and the shorter career span of scientists who might study such things), early exposure to any chemicals or pharmaceuticals that might produce an effect years later would be difficult to notice, let alone study. Therefore, developing an alternative model system that makes it possible to watch neuronal development and evaluate behavior within a reasonable amount of time could be a valuable means to examine early neural challenge and impact on adult behavior. The knowledge of the early developing nervous system and the imaging techniques available to study subsets of neurons and neuronal circuits coupled with rapid embryonic development into adulthood makes the zebrafish a particularly good candidate for studying early challenges to the nervous system and their impact on larval and adult learning, memory, and behavior.

CHALLENGING THE EMBRYONIC NERVOUS SYSTEM

THE EMBRYONIC CHALLENGE HYPOTHESIS This laboratory's work on challenging the zebrafish nervous system developed out of studies initiated through the Duke NIEHS funded Superfund Center. Following the lead of the Slotkin laboratory,[12] which utilized the rat model system to look at the effects of the organophosphate pesticide chlorpyrifos (Dursban) on embryonic signaling, we exposed zebrafish embryos to different concentrations of chlorpyrifos and examined its effects. High levels of chlorpyrifos exposure (500 ng/ml) resulted in muscle, notochord, and embryo morphology[33–35] defects, resembling the zebrafish acetylcholine esterase mutant phenotype. As we lowered the dose to one that allowed the fish to survive but still inhibited acetylcholine esterase activity, we found that adults that had been exposed to a low dose of chlorpyrifos demonstrated learning deficiencies.[36] From these studies we developed the following hypothesis: perturbing the neuronal signaling of the developing nervous system before it matures affects adult learning and/or behavior. Implicit in this hypothesis is the clear distinction that embryos are not just smaller adults in terms of their sensitivity to environmental insult and that any compound that has been used or tested on an adult may have a distinctly different effect and dose–response curve.

SENSING THE ENVIRONMENT AND REGULATORY CONSEQUENCES Looking back to the very early origins of molecular biology and the elegant experiments and interpretations of Jacob and Monod[37] we recall how their work generated basic concepts involving gene activation and repression. These were derived from experiments on how a simple bacterium senses the sugars in its environment and adjusts to this change with a regulation in gene expression. Obviously the cues that allow the nervous system to develop are somewhat pre-ordained in the developmental roadmap—proteins that allow some neuronal processes to move through the body to make connections that allow one part of the body to "speak" to another part. With industrialization and the development of the pesticide and pharmaceutical industries,

we are being accidentally and purposely exposed to biological mimetics or cues to which a developing organism might respond. In a series of experiments that involved perturbing the developing *Xenopus* nervous system the Spitzer laboratory showed that perturbation could actually change the neurotransmitter produced by the perturbed neuron; this neurotransmitter "switching" was placed within the context of a homeostatic explanation or how the plasticity of the early nervous system might accommodate challenge by responding to an inhibitory influence with an excitatory influence.[38] While their study was focused upon the early embryonic nervous system and not the possible consequences to the adult, it does raise questions concerning how accommodating the nervous system can be to such challenges. As such, this laboratory has been approaching the developing nervous system in a more classical manner—with a focus on the decisions made by neurons to produce specific neurotransmitters rather than the more developmental focus of how regulators produce broader neuronal transitions. When the nervous system is viewed in this developmental context it provides an opportunity to address questions of neuronal decisions regarding the neurotransmitters that individual neurons produce. Similarly, since a presynaptic neuron's signal has to reach a postsynaptic receptor it raises the question of what neurotransmitter receptor subunits the postsynaptic neuron has available and how they become available. This level of questioning naturally leads to the use of a live fluorescent transgenic indicator approach to identify neurons producing, for example, acetylcholine rather than serotonin. This is one of our major technical approaches for addressing the question of early challenge of the nervous system.

TESTING THE HYPOTHESIS

CONCERNS FOR STUDYING THE MECHANISM: DIFFERENTIATION VERSUS DIRECT GENE REGULATION

One major concern in attempting to identify early events in developing embryos that might affect later behavior and learning, particularly from the standpoint of trying to dissect the mechanism, is that a compound that challenges embryos might influence differentiation in an inappropriate manner. Such an event might trigger an inappropriate repertoire of differentiation affecting many genes rather than a direct effect on a single gene regulator. This would make dissecting the mechanism by following gene expression extremely difficult. Therefore to investigate effects of early embryonic challenge on later events in life, it is necessary to consider several different approaches to try to distinguish the possible differences in mechanism. Below are described techniques others have used and techniques we employ.

TECHNIQUES USED BY OTHERS TO CREATE A KNOWLEDGE BASE ABOUT THE NERVOUS SYSTEM

Mutants The large scale genetic screens originally described in the December 1996 issue of *Development*[39] characterized many mutants by outward phenotype. Subsequent studies with these mutants and others have identified mutations affecting various forms of motility. There is now a battery of mutants affecting genes in neurotransmitter pathways (acetylcholine esterase,[33,34] glycine,[40,41] and other pathways), some of which have proven valuable in investigating early challenges to the nervous system. Furthermore, in those cases where genes have been linked with mutant phenotypes, the "morphant" phenotype can be generated utilizing antisense morpholino[42] technology. We have benefited from this since zebrafish exposed to a high concentration of organophosphate display phenotypic characteristics that overlap with the acetylcholine esterase mutant phenotype.

***In Situ* Techniques** Several laboratories have outlined the developing zebrafish nervous system by morphology using *in situ* hybridization and/or *in situ* immunolocalization or backfilling neurons with fluorescent probes. In a series of articles the Fetcho laboratory studied the development of the neural tube with reagents specific to GABA, glycine, glutamate,[26] serotonin, dopamine, and noradrenaline[43] producing neurons. While the specific anatomical localization and developmental time points were limited, they provide a very detailed and valuable picture of the developing zebrafish nervous system from embryogenesis through early larval development.

Recording Neuronal Activity The Drapeau laboratory[44] has pioneered techniques for recording electrical activity from the zebrafish nervous system including whole cell *in vivo* recording techniques via patch clamping. Others have used fluorophores for calcium imaging to evaluate neuronal activity.[25,45] Transgenic reporters for measuring ion movement can at least partially be used for the evaluation of changes in conductivity that reflect neuronal activity. This is currently being used in zebrafish,[46] but on a somewhat limited basis due to the weakness of fluorescent signal strength, a problem inherent with the physical characteristics of fluorescent molecules and/or the sensitivity of recording devices. Given the current limitations in recording neuronal activity as reported by fluorescent molecules, this technique is not a commonly used practice. Hopefully improvements in fluorescent reporter molecules will be made for recording neuronal activity via fluorescence directly.

Agonist/Antagonist Work The effects of compounds can be very complex and very dose specific. Therefore, in determining how some of their effects may impact the developing nervous system in more specific ways, it is sometimes useful to ask experimental questions using neurotransmitter-specific reagents such as receptor agonists, antagonists, and neurotransmitter specific reuptake inhibitors to investigate how disrupting a specific neurotransmitter pathway might lead to later effects. In this regard, reagents that affect various neurotransmitter pathways are available to us from various sources—toxins with specific receptor specificity (e.g., bungarotoxin with specific binding affinity to the acetylcholine receptor subunits, strychnine for glycine receptors), pharmaceuticals that impact upon neurotransmitter reuptake (e.g., the selective serotonin reuptake inhibitor Prozac), and a host of other selective reagents. Some of these display exquisite specificity and thus can be used in a selective manner, a benefit if antisense morpholino approaches are unsuccessful. In addition, antagonist/agonist strategies provide an option if the targeted gene product is something that is expressed later in development and hence not possible to effectively and selectively inhibit utilizing morpholinos.

TECHNIQUES WE HAVE BEEN USING

Transgenic Indicators This laboratory has a long history in the construction of transgenes and transgenic animals both in mice and in zebrafish. For example, we have made parallel transgenics in mice and zebrafish whose reporter activity is detected in at least a subset of embryonic tissue for which there is retinoic acid receptor activity.[47,48] These transgenics and their signal localization strongly support the homology in gene regulation via retinoic acid between mice and zebrafish. The transgenic lines also serve as inducible transgenes since exogenous retinoic acid exposure

induces expression of the transgene ectopically in regions in which it is not necessarily expressed. In zebrafish, we have been working with several transgenic lines using fluorescent reporters [mainly green fluorescent protein (GFP) derived] that express selectively in the nervous system—lines we made and lines that we acquired from other laboratories.[35] However, as the organism develops it becomes increasingly complex to sort out the vast array of neurons in these lines. The early work that defined neurons present in the neural tube was based upon identifying neurons by morphology. However, since specific probes for neurons usually localize to one specific region of the neuron, an incomplete view of the neuron may be detected skewing interpretations. In our more recent work, we have used modified fluorescent reporter genes engineered with sequences that code for a farnesylation site. In doing so, the fluorescent reporter will be embedded into the neuronal membrane, yielding a more comprehensive visualization of the neuronal body and network. Currently, we have constructed transgenic lines containing a farnesylated GFP as well as a farnesylated mCherry, a monomeric red fluorescent protein (mCherry and several other different colored reporters were developed by the Tsien laboratory[49]).

As the organism develops, the neuronal network becomes quite vast and difficult to decipher. As such, the goal of our laboratory is to generate a series of transgenic lines that run from regulatory sequences of genes that identify neurons producing a specific neurotransmitter. Using this plan we hope to transgenically "dissect" the nervous system in fluorescent colors enabling us to visually examine different neurotransmitter pathways. It should be emphasized that while this program highlights the identification of presynaptic neurons that produce specific neurotransmitters, the production of transgenics that identify postsynaptic neurons that receive the neurotransmitter input is equally valuable. However, due to the complex diversity of subunit genes for neurotransmitter receptors, this is a task that we are not prepared to undertake at this time. However, once there is a better understanding of the expression specificity of various receptor subunits, transgenics can then be constructed. Overall, these transgenic lines will be used to identify the appearance of neurons producing specific neurotransmitters and for examining coexpression of different neurotransmitters produced by the same neuron. By utilizing these transgenic lines, we can visualize "neurotransmitter switching" in response to the challenge of a specific neurotransmitter pathway and possibly for following the development of the nervous system in a selective manner.

Transgenic Construction Our general procedures for making and characterizing transgenics have been detailed previously.[50] However, techniques evolve and these studies emphasize using much larger genomic regions for driving transgenes. There are two procedures for manipulating larger genomic regions into transgenic constructs. One, called recombineering, takes advantage of microbial recombination systems to homologously target a reporter gene in a genomic Bac or Pac clone so that the reporter gene is surrounded by the signals (known and unknown) that drive developmental expression of the endogenous gene.[51,52] This has been used in a limited way in zebrafish[53,54] and more commonly in mouse. While this is an elegant procedure, it does take considerable time since for most constructions two recombination events are necessary and the large clones have to be screened for the proper construction. An alternate, but less elegant procedure is to move large fragments into position to drive expression of the reporter gene. The larger genomic fragments, in most circumstances, will not have convenient restriction enzyme sites to allow one to recombine the proper construct. Thus, in order to recombine the construct, it is necessary to employ techniques for modifying "joints" of DNA so that they can ligate together: two common procedures are (1) to PCR change the sequence at the ends to create workable restriction sites for cloning and (2) to modify an existing restriction enzyme site with oligonucleotide adaptors to change an end of a DNA from one restriction site specificity to a more convenient one. We are currently using these nonrecombineering procedures for the design and construction of our transgenes.

Efficiency of Making Transgenics We find that if we prescreen transgenic injected embryos for expression, that approximately 10% of the adults with be germline for the transgene. However, we have found that in most cases, using our procedure, 2–50% of the resulting progeny are transgene positive, indicating that our procedures are producing founder transgenics that are chimeric for the transgene in their gonads. If we breed the transgene-positive progeny we obtain a normal Mendelian recovery of approximately 50% transgenic embryos. Occasionally we have transgenic founders with two separate integrations of the transgene resulting in transgene progeny percentages that are complicated until we can segregate the two transgenic integrants. Recently reports have come out indicating that the efficiency for producing germline transgenics can be enhanced by using the tol2 system.[55,56] By flanking their transgene with tol2 sequences and coinjecting the transgene with mRNA for the tol2 transposase, the efficiency of producing germline integrants is enhanced.

Microarray Analysis of Neurotransmitter Pathways For someone not familiar with using microarrays to investigate widespread gene expression changes a number of factors have to be considered: (1) the interpretation and analysis of the data are statistically based—many developmental biologists are not familiar with working with tab-delineated tables having thousands of rows. At best the information provides leads as to where to look and, thus, it is a technology that requires complementary or confirming techniques to develop an understanding of events; (2) in general the technology is expensive, and in going from "homemade arrays" that are arrayed at one's institutional microarray core to commercial arrays, the price increases; what adds to this cost is the need to have a number of biological repeats of the arrays to reach statistical significance; (3) the purpose of the array work: is it for gene discovery where one would want to work with an array having thousands of genes or is it to probe a defined pathway where making a smaller array would be more efficient and less costly; (4) for zebrafish in particular, the genome is still being assembled and many genes have yet to be defined and localized; some of the large commercial arrays are based not just on the whole gene sequence but on expressed sequence tags (ESTs) that can result in having several oligonucleotides on the array representing the same gene as the genome gets assembled; in our experience the Agilent 22k zebrafish array has more than several "genes" represented by two and sometimes three oligonucleotides; (5) because the assembly of the genome is still a work in progress, some of the arrays have little or no annotation for some of the oligonucleotides placed upon the array; this is improving with finer definition of the zebrafish genome.

Given all of the above, there are a variety of reagents available for zebrafish microarray work. One option is a Compugen library

of ~16K oligonucleotides that can be purchased and arrayed. We have used this to study gene expression changes during the development of the neural tube[57] and to study transcript changes during early embryonic development.[58] However, in both cases the number of oligonucleotides that gave statistically significant data was proportionally small. This has caused us to use commercial microarrays whose oligonucleotides were based upon a newer assembly of the zebrafish genome. Both Affymetrix and Agilent produce larger zebrafish arrays (14.5k and 22k, respectively). While arrays of this kind provide a level of consistency that is usually not matched by "homemade" arrays, the flexibility of having oligonucleotides designed and synthesized for the genes of choice is a valuable factor when considering what to use. While we are developing a large (several hundred) Agilent 22k zebrafish array database, we find that the array is missing many neurotransmitter pathway genes, in part because many of these are at best algorithm predicted rather than defined by isolated cDNAs. That is why we are developing our own, much smaller array that will focus upon genes selectively expressed in neurons and genes associated with known neurotransmitter pathways.

Therefore, our purpose in this array will not be gene discovery but pathway exploration. In addition to microarrays for studying the steady-state level of transcripts, there are other microarrays for studying aspects of gene regulation beyond direct transcriptional control. There are now commercial designs of microarrays for using chromatin immunoprecipitation on microarrays (chIP-chip arrays) for zebrafish. These are oligonucleotide arrays that cover sequences near and 5 to mRNA start sites so that it is possible to examine which transcription factors are binding to which genes. The Agilent arrays cover over 11,000 zebrafish genes. Alternatively, it has become clear that microRNAs can play significant posttranscriptional roles in governing gene expression—either through hybridizing to mRNAs for their destruction or by inhibiting the translation of the mRNAs. In the second category, the homology between the microRNA and the mRNA does not have to be absolute, so some microRNAs can control the translation of many different mRNAs. Microarrays for examining the presence of microRNA have been constructed by researchers[59,60] and commercially.

In our use of the Agilent 22k zebrafish array, we have identified distinct changes in gene expression associated with a brief embryonic challenge to the glycine neurotransmitter pathway; this same brief embryonic challenge has been shown to have lasting behavioral effects on adults. The analysis of the data is complex, but we do see transcript level changes in genes associated with the glycine neurotransmitter pathway and the glutamate neurotransmitter pathway. However, as mentioned above, the coverage of genes in these pathways is not complete and is the major reason for our developing a new, smaller microarray.

For challenging the embryonic nervous system, these arrays can be used in combination with the challenges, i.e., comparing the transcript patterns of embryos and larvae with and without challenge. A chemical challenge via a pesticide exposure or a receptor agonist or antagonist makes it possible to limit the time of exposure; alternatively, but more specifically, injecting antisense morpholinos into one-cell embryos affords the possibility of knocking down expression of specific genes. The drawback to the morpholino approach is the lack of careful control over the time period by which the morpholino inhibits the synthesis of the target protein. We have and are using both of these approaches in our work.

Fluorescent Cell Sorting One of the benefits of the development by many laboratories of live, fluorescent reporter, zebrafish embryos is that it allows for a variety of different forms of visualization: fluorescent microscopy, confocal microscopy, multiphoton microscopy, and also the use of flow cytometers and fluorescent cell sorters to analyze populations. Some of the first fluorescent transgenic lines labeled blood cells and this made it possible to isolate fluorescent blood cells for transplantation into mutants defective in the hematopoietic system for subsequent real-time visualization of the reconstitution of a functional system.[61] As the number of reporter, fluorescent lines of zebrafish increases, each marking distinct subpopulations of cells in the embryo, it becomes possible to use embryo dissociation techniques in combination with fluorescent cell sorting to recover distinct subpopulations of cells. Dr. Ava Udvadia of the University of Wisconsin, Milwaukee has succeeding in doing this with a transgenic line driven by the gap43 promoter. This line marks embryonic neurons and she has successfully sorted fluorescent neurons and used them as a source of RNA to isolate cDNA clones of genes expressed in the neurons. We have recently collaborated with her to examine the expression of genes in these neurons using the Agilent 22k zebrafish microarray. We expect this procedure to be of value in the future in identifying transcript differences in different populations of neurons as well as a convenient alternative to laser microdissection techniques for examining gene expression in specific tissues of the embryo.

STRATEGIES FOR EXPLORING MECHANISMS We are suggesting that early challenge of the nervous system creates structural or regulatory effects that last beyond the exposure period and result in behavioral/learning effects in the adult. Obviously, explaining this mechanistically for something as complex as the brain is an immense goal. There are some possible clues regarding events, if not mechanisms, that might be affecting these changes. The work of the Spitzer laboratory[38] and some preliminary microarray work by this laboratory support the possibility of neurotransmitter switching. This could be tested in the organism with the transgenic lines we are generating to mark neurons producing specific neurotransmitters. Complementing this is the use of microarray analysis during the challenges to determine whether there are distinct changes in neurotransmitter pathway component expression. Introducing regions into the fluorescent reporters that allow them to be embedded into the membrane allows the outward morphology of the neurons to be delineated and we hope these lines will allow us to follow the development of the nervous system as the organism grows. Obviously, any challenge requires evidence that it does induce a behavioral change, and the definition of the vulnerable window of challenge should make it possible to narrow down the candidate changes. Both of these require analysis procedures for behavior and learning. Our progress with this is described below.

ADDRESSING BEHAVIORAL CHANGES

Swimming behavior of the larval zebrafish can be monitored with high-speed video and digital imaging software to study changes in burst and slow swims, tail bending amplitude, and fast, large-angle turns indicative of the escape response.[62] For example, video recording was used to differentiate wild-type and *accordion* mutant embryos as well as embryos chemically challenged with

strychnine, to assess defects in touch response.[30,45,63] Zebrafish prey capture swimming behavior has also been analyzed by this method.[64] As the embryo matures, the swimming behavior can be monitored with more complex computerized video-tracking systems, e.g., Noldus-EthoVision, to track swimming and movement. Using the Noldus system, single zebrafish can be placed in multiwell plates and monitored simultaneously, greatly increasing the throughput of experiments. Once the fish are tracked, the software allows the investigator to dissect out various parameters of swimming movement including angular velocity (degrees/sec), meander (degrees/mm), time spent in defined zones, total distance moved, and time spent immobile, mobile, and strongly mobile. Analyzing these various parameters makes it possible to detect small changes in motor behavior in response to challenge. Assessment of learning and memory in adult zebrafish is still being developed, but researchers have devised ways to characterize simple learning, memory, and cognition by testing reflexes,[65–67] fear conditioning,[68] and spatial orientation.[69,70] For example, zebrafish can learn to swim to one side of the tank in response to a tap on the side that signals delivery of food.[71] In addition, a three-chambered shuttle maze can be used to test choice behavior and response latency. In this tank there is a central compartment and left and right choice compartments separated by sliding dividers. Zebrafish are trained to preferentially go to one side by placing the fish in the central compartment and allowing it to acclimate. After a period of acclimation, both side chambers are simultaneously opened. If the fish chooses the correct side chamber, the door closes and the fish is left alone. If the fish chooses the incorrect side chamber, the door is closed and a sliding partition is moved close to the wall placing the fish in a restrictive position. Within a few trials, the fish learn to avoid the chamber that will push them toward the wall.[70] Once trained, it is possible to measure the chamber choice accuracy and the time it takes for the fish to make a decision. Using this technique, it was demonstrated that early embryonic exposure to chlorpyrifos led to significant spatial discrimination impairments and response latency as adults.[36] Furthermore, utilizing this task, it was demonstrated that acute nicotine administration to adults causes a significant improvement in delayed spatial alternation at low nicotine doses, but impairs performance at high doses,[72] mimicking results seen in higher vertebrates.[70]

Recently, a novel study utilizing adult zebrafish to test diving and escape predation was performed.[73] When zebrafish are placed in a novel environment, they tend to dive to the bottom of the tank as a method to escape predation. Wild-type fish show a gradual decrease in the time spent in the bottom third of the tank and habituate to their new environment. Utilizing this test, Levin *et al.*[73] have demonstrated that acute nicotine treatment caused a significant decrease in diving throughout the test. The antianxiolitic effects of nicotine treatment were reversed by cotreatment with mecamylamine, a nicotinic receptor antagonist. These data suggest that the effect of nicotine on diving was due to net stimulation at nicotinic receptors, an effect that is blocked by mecamylamine.

Utilizing a variety of testing apparatuses and methodologies, researchers have demonstrated the use of adult zebrafish as a behavioral model for testing reflexes, habituation, Pavlovian conditioning, and operant conditioning. A review of the experiments and a full description of testing apparatuses can be found in Cerutti and Levin.[70] As behavioral biologists and psychologists continue to refine and create new testing parameters, we hope to elucidate more behavioral abnormalities and learning and memory deficits as a result of early challenge to the nervous system.

CONCLUSIONS

We have tried to outline how developing technologies and useful characteristics of the zebrafish model system can now allow us to investigate how embryonic exposures to the developing nervous system and concomitant adult effects can be studied. This combination of approaches and technologies will ultimately be used at various levels to study molecular, developmental, and behavioral effects relevant to the functions of the nervous system.

15 Modeling Cognitive and Neurodegenerative Disorders in *Drosophila melanogaster*

JUNJIRO HORIUCHI AND MINORU SAITOE

ABSTRACT

Significant conservation in cognitive and neurodevelopmental mechanisms exist between *Drosophila* and mammals. In addition, while mechanisms of aging are relatively well conserved, *Drosophila* age much faster than mammals. Thus *Drosophila* are an ideal organism in which to study cognitive and neurodegenerative diseases. Powerful genetic techniques exist that allow genes to be disrupted and overexpressed easily. Phenotypes observed from these mutants can then be used to screen for genetic modifiers to elucidate pathways involved in disease pathology. Here we describe recent advances obtained from *Drosophila* models for five diseases, neurofibromatosis 1, fragile X syndrome, Alzheimer's disease, tauopathies, and Parkinson's disease.

Key Words: Neurofibromatosis 1, Fragile X, Alzheimer's disease, Tauopathy, Parkinson's disease, *Drosophila melanogaster*.

INTRODUCTION

In choosing an organism for the study of a biological process, it is necessary to compare the relative advantages of using that particular organism versus the amount of conservation in the process between the organism in question and humans. *Drosophila melanogaster* has been used extensively as a model system in the study of development. *Drosophila* offers numerous advantages including powerful genetic techniques and a short life span. In this chapter, we will describe how *Drosophila* has been used in the study of several human cognitive and neurodegenerative diseases.

CONSERVATION OF PROCESSES BETWEEN HUMANS AND *DROSOPHILA*

How conserved are cognitive, behavioral, and neuronal processes between flies and mammals? *Drosophila* has been an essential organism in the study of behavior and memory. Two widely used, highly quantitative and reproducible behavioral assays, a Pavlovian olfactory association assay[1] and a courtship conditioning assay,[2] have been used to identify mechanisms of memory formation, storage, and recall. These mechanisms are conserved with those of mammals. Using the Pavlovian conditioning assay, a single cycle of training generates a short form of memory in flies that decays relatively quickly.[3] Similar to mammalian systems, multiple training trials generate longer lasting forms of memory and multiple training trials with rest intervals interspersed between trainings generate a protein-synthesis-dependent long-term memory.[4] In addition, the cyclic AMP/protein kinase A (cAMP/PKA) pathway is critical for memory formation in *Drosophila* and this is also the case in mammalian systems. Furthermore, activity of the CREB transcription factor has been shown to be essential for long-term memory formation in many organisms including *Drosophila* and mammals.[5]

For the study of synaptic morphology and neurotransmission, the *Drosophila* neuromuscular junction (NMJ) has been extensively used. NMJ preparations allow rapid screening for mutants that affect synaptic morphology.[6] Combined with temperature-sensitive paralytic mutants, they provide a critical tool for the identification of genes important in synaptic transmission.[7,8] Genes required for synapse formation and transmission are highly conserved between flies and mammals and genes involved in human diseases that affect synaptic structure or function often have similar functions at the *Drosophila* NMJ.[9–12]

An advantage that *Drosophila* has over mammals in the study of neurodegenerative diseases is a short life span of approximately 30–60 days after eclosion. This allows age-dependent changes that occur in *Drosophila* to be easily measured. Furthermore, *Drosophila* and mammals show much conservation in terms of mechanisms affecting aging.[13] Calorie restriction (CR) extends the life span of organisms ranging from yeast to mice.[14,15] CR seems to function by inactivating pathways that promote growth while activating pathways that increase protection from oxidative and other forms of stress. Thus, in many organisms including flies and mice, inhibition of the insulin/insulin-like-growth factor signaling (IIS) pathway extends the life span.[16] Fly homologs exist for the majority of genes involved in insulin signaling.

ADVANTAGES OF STUDYING *DROSOPHILA*

A short generation time of approximately 10 days and the ease of maintaining large numbers of fly stocks in a laboratory setting have been invaluable in establishing *Drosophila* as a model genetic organism. *Drosophila* has a relatively small genome that has been completely sequenced and approximately 75% of the genes involved in human diseases have a counterpart in *Drosophila*.[17] Genetic techniques in *Drosophila* are highly developed with several being particularly advantageous in the study of disease. The commonly used GAL4/UAS system allows expression of a gene of interest in specific anatomical regions.[18] Briefly, a transgenic fly is generated expressing a gene of interest under control of the GAL4-UAS. Thus, the gene is expressed only in the presence of the heterologous yeast GAL4 activator. These flies can be crossed with various GAL4-enhancer trap lines, which express GAL4 in particular locations or cell types, to express the transgene at those specific regions. Newer versions of the GAL4/UAS system have been generated in which GAL4 has been mutated to be active only in the presence or absence of a drug, RU486. This allows gene expression to be regulated in both a spatial and a temporal manner.[19,20]

In forward genetic screens, enhancer-promoter (EP) lines are available where P-element transposons, carrying GAL4-regulated promoters, designed to express flanking genomic sequences, have been inserted throughout the genome.[21] If an EP element is inserted proximal to a gene in the appropriate orientation, that gene can often be expressed under GAL4 control. If the element is inserted in the opposite orientation, gene expression can often be inactivated. EP lines are particularly useful in genetic modifier screens when searching for genes whose altered expression will modify the phenotype of a particular mutant.

A particularly useful organ for genetic screening in flies is the compound eye.[22] GAL4 enhancer trap lines are available that specifically drive expression in the eye and expression of disease genes in this structure often causes a rough eye phenotype. Forward genetic screens using EP lines or random mutagenesis can be used to isolate genetic modifiers, either suppressors or enhancers, of this phenotype. In addition, reverse genetic techniques can be used to modify expression of specific candidate interacting genes to determine whether they have an effect on the rough eye phenotype. These techniques are used extensively to identify genetic interactions between genes of interest.

Finally, for pharmacological studies, similar to other organisms, flies can be injected with drugs. However, more usefully, flies are much more sensitive to ingested compounds compared to mammals. Thus, in contrast to mammals, in which active compounds may have to be injected directly into the brain, in flies, the compound can often be simply mixed with the food and fed to flies to produce effects.[23]

Taken together, we can conclude that *Drosophila* offers numerous advantages in the study of cognitive and age-related human diseases.

NEUROFIBROMATOSIS I

Neurofibromatosis type I (NF1) is a dominant genetic disorder caused by mutations in the NF1 gene, which encodes a Ras-specific GTPase-activating protein (Ras-GAP).[24] Symptoms include tumors of the nervous system, learning disabilities, defects in development, and a predisposition toward short stature.[25,26] Tumors result from the removal of NF1, which normally represses the growth-promoting functions of the Ras proteins. Until recently, it was also thought that the learning defects associated with the disease resulted from aberrant brain development due to abnormal Ras activity. However, results from fly models suggest an alternate function for NF1 in regulating intracellular cAMP levels which affect learning (Figure 15–1A).

The *Drosophila* homolog of NF1 is 60% identical to the human protein and viable NF1 null mutants have been generated.[25] Similar to phenotypes seen in human NF1 patients, NF1 null flies have learning defects and are physically smaller than their wild-type counterparts. While an increase in tumor incidence has not been reported in the fly, fly NF1 has ras-GAP activity similar to the human protein.[25]

Indications that *Drosophila* NF1 may be involved in regulating the cAMP pathway came from studies of the *Drosophila* NMJ in which the addition of the neuropeptide, pituitary adenylyl cyclase-activating polypeptide (PACAP), induces a strong enhancement in K^+ currents.[27] This enhancement is dependent on activation of both an adenylyl cyclase/cAMP/PKA pathway and a Ras-Raf kinase pathway. Interestingly, null mutants in NF1 are defective for this K^+ current enhancement.[28] However, neither mutations in GAP1, another Ras-specific GAP, nor overexpression of constitutively active Ras, blocked enhancement. Rather, a *rutabaga* (*rut*) mutant defective for an adenylyl cyclase had phenotypes similar to the NF1 null and cAMP analogs and adenylyl cyclase activators restored K^+ currents in NF1 mutants.[28] These results indicate that NF1 may function in a common pathway with *rut* to increase cAMP levels.

cAMP is known to be critical for learning and the *rut* mutant, which is defective for cAMP production, was initially identified as a learning mutant. This raises the possibility that the memory defect in NF1 mutants could be a result of defective cAMP rather than Ras signaling. In support of this idea, the learning defects of NF1 mutants are extremely similar to those of *rut* mutants and double *NF1*;*rut* mutants do not have phenotypes more severe than single mutants, demonstrating that both mutations affect the same pathway.[29] Furthermore, heat shock induction of a constitutively active PKA catalytic subunit complements the learning defects of NF1 mutants.

Interestingly, while acute expression of PKA seems to complement the learning defects of NF1 flies, developmental expression is required to complement the size defects. These results suggest three roles for NF1: an acute role in maintaining cAMP levels for memory formation, a developmental role in generating proper body size, and a Ras-GAP function in preventing tumor formation.

The role of NF1 in modulating K^+ currents[30] and in regulating cAMP levels[11,31] has been shown to be conserved in mammalian systems. If this conservation extends further, the learning defects of NF1 patients are likely to result from signaling rather than developmental defects, suggesting the hopeful idea that acute pharmacological interventions that increase cAMP signaling might be used to treat patients.

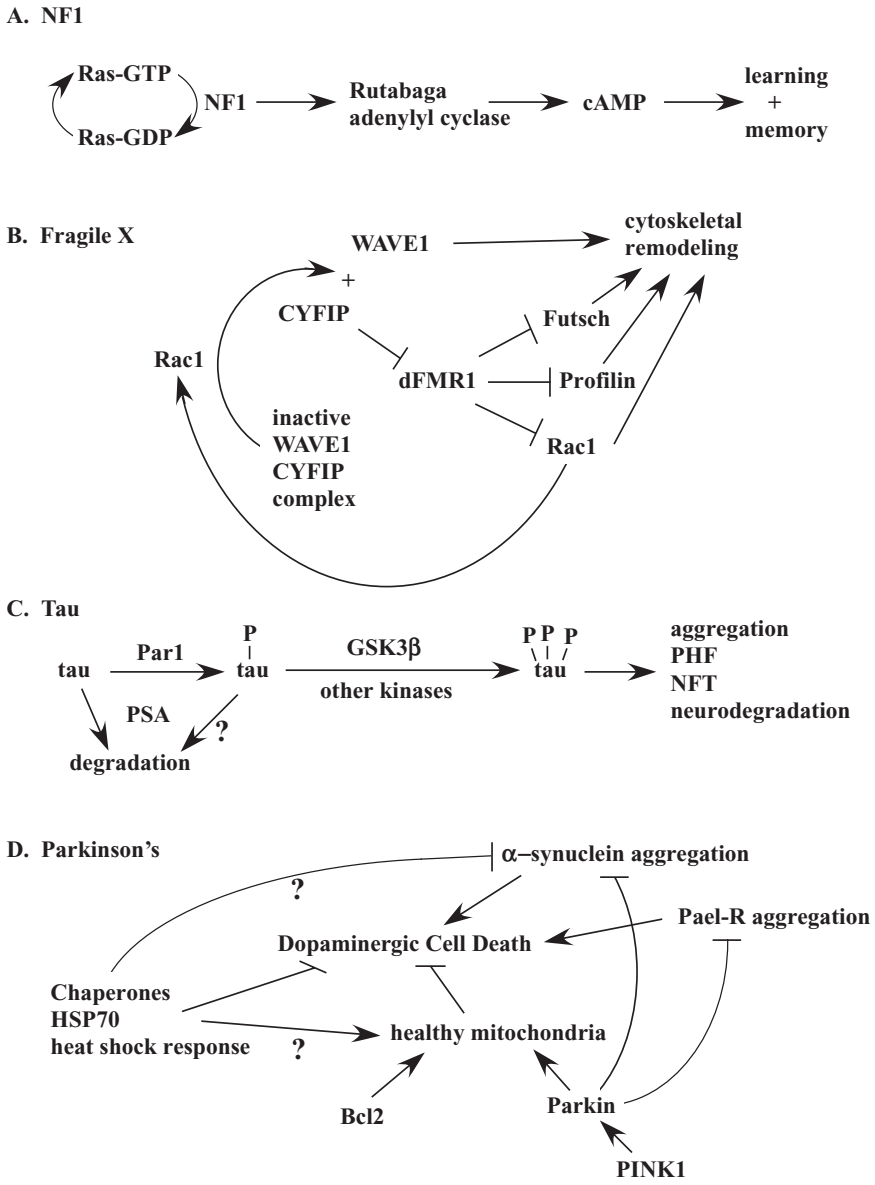

Figure 15–1. Selected disease pathways in which *Drosophila* models have contributed significantly (see text for references). (A) Although NF1 is well characterized as a Ras-GAP, *Drosophila* work has demonstrated that the learning defects associated with neurofibromatosis 1 may be due to a second role of NF1 in regulating cAMP levels through the rutabaga adenylyl cyclase. (B) Rac-GTPases control cytoskeletal components to regulate cell shape. Activation of Rac1 causes dissociation of an inactive complex containing WAVE1 and CYFIP as well as other proteins. Free WAVE1 stimulates cytoskeletal remodeling through actin nucleation while CYFIP may function by inhibiting FMR1. Inhibition of FMR1 allows excess futsch and profilin to be synthesized, stimulating microtubule and actin dynamics. In addition, Rac1 production is increased by inhibition of FMR1, suggesting a positive feedback mechanism. Fragile X syndrome, caused by loss of FMR1, may exert its effects through the increased activity of cytoskeletal remodeling components. (C) In tauopathies, increased accumulation and phosphorylation of tau lead to its misfolding and aggregation. Aggregated tau forms PHFs and NFTs leading to neurodegeneration. Phosphorylation follows an ordered sequence in which initial phosphorylation by the Par1 kinase primes tau for phosphorylation by GSK3β and other kinases. Increased expression of the peptidase PSA may be a way to treat tauopathies since it leads to degradation of tau. (D) Parkinson's disease results from progressive loss of dopaminergic neurons. Pathological phenotypes indicate that aggregation of proteins such as α-synuclein and Pael-R may be involved in cell death. Parkin, a ubiquitin E3 ligase, identified from familial forms of the disease, may be involved in preventing protein aggregation. In addition, parkin and PINK1 are required for normal mitochondrial function, suggesting that Parkinson's disease may result from mitochondrial damage. Increased activity of chaperones, heat shock response, and Bcl2 ameliorate toxicity in several *Drosophila* models of Parkinson's disease.

FRAGILE X SYNDROME

Fragile X syndrome, the most common inherited form of mental retardation, results from loss-of-function mutations in the FRM1 gene.[32] In addition to cognitive defects, symptoms include attention deficit disorders and hyperactivity, obsessive compulsive and autistic behaviors, and mild facial dysmorphologies. At the cellular level, loss of FMR1 leads to cytoskeletal defects, including increases in the density of synaptic spines, which tend to be longer, thinner and immature in appearance.[33,34] FMR1

encodes FMRP, a protein that is thought to function by binding mRNAs and repressing translation.[35,36] A fly homolog of FMR1, dFMR1, exists and mutations have been used to generate fly models of this disease.[37]

Although many potential RNA-binding targets have been identified in mammalian systems,[38,39] studies in *Drosophila* have yielded the most convincing data regarding the *in vivo* relevance of identified targets (Figure 15–1B). Similar to mammals, null mutations in dFMR1 cause altered cytoskeletal morphology at both NMJs and at central nervous system synapses. Reducing dFMR1 levels results in increased synaptic branching, increased numbers of boutons, and enlarged synaptic areas, while overexpression of dFMR1 reduces branching and growth and increases synaptic bouton size.[10,12] DFMR1 binds to the mRNAs of three proteins implicated in cytoskeletal structure, futsch, the *Drosophila* homolog of the mammalian microtubule-associated protein MAP1B,[10] profilin, a protein that stimulates both polymerization and depolymerization of filamentous actin,[40] and Rac1, a small rho-GTPase involved in cytoskeletal remodeling.[41] Both futsch and profilin protein levels are upregulated upon deletion of dFMR1 and futsch expression decreases when dFMR1 is overexpressed.[10,40] Furthermore, overexpression of futsch, profilin, or Rac1 causes increased growth and branching of neurites, similar to phenotypes of dFMR1 null mutants.[10,40,41] Reduction of futsch or Rac1 causes reduced branching and growth, similar to phenotypes observed when dFMR1 is overexpressed. Importantly, futsch, profilin, and Rac1 all show genetic interactions with dFMR1. *dFMR1;futsch* double mutants have morphologically normal synapses,[10] overexpressing dFMR1 suppresses the phenotypes caused by overexpressing profiling,[40] and overexpression of Rac1 suppresses the reduced branching phenotype caused by overexpressed dFMR1.[41] These data all support a model in which dFMR1 affects the synaptic structure by binding to the mRNAs and repressing expression of genes involved in cytoskeletal dynamics.

Interestingly, Rac1 may also function upstream of dFMR1. The cytoplasmic FMRP interacting proteins (CYFIP) 1 and 2 were initially identified in a two-hybrid screen for proteins that bind to human FMRP.[42] CYFIP1 also binds to Rac1 protein, indicating that FMRP is found in complexes with both Rac1 protein and Rac1 mRNA.[43] The genetic consequences of these interactions have been studied in *Drosophila*.[44] CYFIP null mutants are pupal lethal and display contracted or shortened synapses at NMJs. This phenotype is the opposite of the elongated synaptic phenotype seen in dFMR1 mutants. Furthermore, overexpression of dFMR1 in the *Drosophila* eye causes a rough eye phenotype that can be partially rescued by overexpression of CYFIP and exacerbated by reduction of CYFIP.[44] Thus CYFIP seems to work antagonistically to dFMR1. The Rho-GTPase pathways are thought to regulate cytoskeletal remodeling by causing dissociation of an inactive protein complex containing both WAVE1 and CYFIP.[45] Dissociated activated WAVE1 stimulates actin nucleation. The above results indicate that free CYFIP also has a function consisting of binding and inhibiting dFMR1. Inhibition of dFMR1 results in increased translation of proteins including futch, profilin, and Rac1, leading to changes in cytoskeletal structure.

Futsch, profiling, and Rac1 were identified as dFMR1 interactors by biochemical means (i.e., interaction of mRNAs with dFMR1 protein). Another gene, *Drosophila* lethal giant larvae (dlgl), was isolated in a genetic modifier screen as a dominant suppressor of the rough eye phenotype of flies overexpressing dFMR1.[46] Dlgl is a cytoskeleton-associated protein associated with the partitioning/atypical PKC (PAR) complex involved in cellular polarity.[47] Subsequent experiments have demonstrated genetic interactions between dFMR1 and members of the PAR complex,[46] indicating that dFMR1 functions in a variety of different complexes and demonstrating that the genetic approaches in *Drosophila* can be used to identify novel functional partners of dFMRP.

What are the electrophysiological phenotypes disrupting the FMR1 gene? Synaptic activity can cause alterations in connectivity between neurons resulting in long-lasting changes in synaptic strength. The best known of these changes are long-term potentiation (LTP), an activity-dependent strengthening of the synaptic connections, and LTD, an activity-dependent depression of synaptic connectivity.[48] LTP and LTD are not single phenomena, but rather consist of various types that utilize different mechanisms. LTD can be separated into a form that requires activation of postsynaptic *N*-methyl-D-aspartate (NMDA) receptors and one that requires activation of postsynaptic metabolic glutamate receptors (mGluRs).[49] mGluR-dependent LTD requires rapid translation of postsynaptic proteins. In addition, activation of mGluRs also induces translation of FMRP. Thus it seemed likely that mGluR-dependent LTD would be reduced in FMR1 mutants. Surprisingly though, LTD was enhanced in FMR1 knockout mice, suggesting that induction of FMRP functions to modulate LTD by inhibiting excess protein synthesis caused by mGluR activation.[50,51] If this is the case, inhibition of mGluR activity might be expected to suppress the phenotypes of FMR1 mutants.

Evidence supporting the mGluR theory of fragile X has recently been obtained from behavioral studies in *Drosophila*. Male dFMR1 null mutants court virgin females less actively than wild-type males.[52] This decreased courtship can be rescued by feeding flies mGluR inhibitors. Furthermore, when male flies are exposed to and attempt to court previously mated females, they are continually rejected and over time, decrease their attempts at courtship.[2] This is a learned behavior and both learning and memory can be quantified by measuring the number of courtship attempts that a male makes at various time points after courtship conditioning. Learning occurs normally in dFMR1 null flies such that nulls learn to reduce their attempts at courtship upon conditioning, similar to wild-type flies.[53] However, short forms of memory, within 1 h after conditioning, are defective in dFMR1 null flies and they resume courtship attempts much earlier than wild-type flies. Feeding flies mGluR inhibitors during adulthood rescues this memory defect, supporting the idea that increased mGluR activity may be responsible for the cognitive defects associated with fragile X syndrome.[53] It will be interesting to determine whether feeding flies mGluR inhibitors also decreases expression of futch, profilin, and Rac1 in dFMR1 mutants, possibly linking mGluR activity, cytoskeletal remodeling, and behavior. It is particularly hopeful to note that feeding flies mGluR inhibitors during adult stages improves their cognitive activity, suggesting that acute drug treatment may function in human patients as well.

ALZHEIMER'S DISEASE

Alzheimer's disease (AD), the most common cause of senile dementia in the human population, is characterized by two pathological phenotypes: accumulation of extracellular plaques con-

sisting of aggregated amyloid β peptides, and accumulation of aggregated tau protein into intracellular neurofibrillary tangles.[54] The relationship between plaques and tangles is still unclear, but both are associated with progressive neurodegeneration.

β-AMYLOID MODELS Amyloid β (Aβ) peptides are generated by sequential cleavage of the amyloid precursor protein (APP), first by the β-site APP-cleaving enzyme (BACE) and subsequently by the γ-secretase enzyme.[55] In familial forms of Alzheimer's disease (FAD), mutations have been identified in the APP gene, and in the presenilin 1 and presenilin 2 genes, which encode components of the γ-secretase enzyme. Due to heterogeneity of γ-secretase cleavage, at least two peptides, Aβ40 and Aβ42, are generated, of which Aβ42 is considered more toxic.[56] FAD mutations are associated with increased levels of Aβ40 and Aβ42 or with an increased ratio of Aβ42 to total Aβ.

Several *Drosophila* transgenic lines useful for the study of Aβ-induced neurotoxicity have been developed. Lines overexpressing human APP, *Drosophila* presenilin with FAD-associated mutations, and human BACE are available. Using these lines, Greeve *et al.*[57] have shown that expression of APP in the *Drosophila* eye causes an age-dependent neurodegeneration in photoreceptor cells that is enhanced upon coexpression of presenilin and suppressed by reduction of endogenous presenilin. APP overexpression causes an age-dependent appearance of large globular deposits of Aβ, which can be accelerated by coexpression of presenilin. Also, expressing APP, BACE, and presenilin under actin promoter control results in semilethality that can be suppressed by raising flies on food supplemented with either BACE or γ-secretase inhibitors.[57]

Iijima *et al.*[58] used transgenic flies directly expressing secreted forms of Aβ40 and Aβ42. While expression of both peptides caused age-dependent learning defects, expression of Aβ42 but not Aβ40 caused age-dependent neurodegeneration, shortened life span, progressive locomoter defects, and diffuse amyloid deposits. Crowther *et al.*[59] extended these results by demonstrating that feeding Aβ42 flies MK-801 or Congo Red extends their life span and ameliorates neurodegeneration. Congo Red is an azo-dye that binds to Aβ42 *in vitro* and has been shown to inhibit aggregation. MK801 is an inhibitor of the NMDA glutamate receptor. It is unclear how MK801 extends the life span of Aβ42 flies, but it may function similarly to mamantine, a glutamate antagonist that has been shown to slow progression of Alzheimer's disease. Furthermore, Crowther *et al.*[59] demonstrate rough eye phenotypes in Aβ42 flies suggesting a quick screening method for isolating mutations and compounds that affect Aβ-mediated neurodegeneration.

TAUOPATHIES Alterations in the microtubule-associated protein tau have been implicated in a number of neurodegenerative diseases, collectively known as tauopathies, including AD, progressive supranuclear palsy, and frontotemporal dementia.[60] Tauopathies are characterized by the accumulation of abnormally phosphorylated forms of tau that aggregate into paired helical filaments (PHF) and cytoplasmic inclusions known as neurofibrillary tangles (NFTs). Formation of NFTs parallels the progression and anatomical distribution of neuronal degradation in tauopathies, suggesting that tau aggregation plays a role in neurodegeneration in these disorders.[61] A *Drosophila* model for tauopathy was developed by overexpressing wild-type human tau or tau mutated at sites associated with early onset dementia.[62] Overexpression of both wild-type and disease associated forms of tau cause an expression level-dependent shortening of the fly life span. Shortened life span is associated with neurodegeneration and increased tau phosphorylation, although NFTs are not observed in the fly models.[62]

Using this model system, modifiers of tauopathies were identified using both forward and reverse genetic techniques. Expression of tau specifically in *Drosophila* eyes results in a dose-dependent rough eye phenotype.[63,64] In a forward genetic screen for suppressors and enhancers of this phenotype, the major class of modifiers identified involved kinases and phosphatases, consistent with the idea that abnormal phosphorylation of tau leads to decreased association with microtubules and increased aggregation.[64] In a reverse genetic approach, a major kinase known to be involved in tau phosphorylation, GSK3β, encoded by the *Drosophila* gene *shaggy* (*sgg*), enhances the tau rough eye phenotype when overexpressed, and suppresses the phenotype when mutated.[63] Moreover, antibodies that specifically recognize a phosphorylated form of tau unique to PHFs show a dramatic increase in phosphorylated tau upon cooverexpression of *sgg*. While PHFs are not observed upon overexpression of tau alone, PHFs are observed when *sgg* is cooverexpressed with tau.[63] Inhibitors of apoptosis suppress tau-induced neurodegeneration.

Most substrates must be prephosphorylated by other kinases at nearby sites before they can become efficiently phosphorylated by GSK3β. Is there a priming phosphorylation required before tau is phosphorylated by GSK3β? Reverse genetic experiments by Nishimura *et al.*[65] indicate that Par-1, a homolog of the mammalian MARK kinase that regulates microtubule dynamics and neuronal differentiation, phosphorylates tau. Prior phosphorylation by Par-1 is required before downstream phosphorylation can occur by kinases including GSK3β (Figure 15–1C).

Although presenilins are generally thought to function in Alzheimer's disease by cleaving APP to produce cytotoxic Aβ peptide, a novel model proposes that presenilin may also function to regulate phosphorylation of tau. In support of this model, it has recently been shown that loss of presenilin drastically enhances the rough eye phenotype of flies overexpressing tau.[66]

In another approach, *Drosophila* has been used to identify the *in vivo* effects of genes identified in other organisms as possible tau interactors. Puromycin-sensitive aminopeptidase (PSA) was identified as a gene upregulated in the cerebellum following overexpression of a dominant mutated form of tau associated with frontal temporal dementia.[67] Since the cerebellum is particularly resistant to tau-dependent neurodegeneration, increased PSA expression was proposed to function in a protective manner. This was verified using *Drosophila* where it was shown that loss of function of PSA enhances the rough eye phenotype caused by overexpressed mutant tau.[67] Overexpression of PSA suppresses the phenotype. It was further determined that PSA functions to degrade tau *in vivo* and *in vitro*. This approach illustrates the efficacy of using *Drosophila* to test the *in vivo* phenotypes of biochemical connections identified in other species.

PARKINSON'S DISEASE

Parkinson's disease (PD), the second most prevalent human neurodegenerative disease, results in movement disorders, tremors, and muscle rigidity due to the selective loss of dopaminergic neurons. Pathological phenotypes associated with PD include the formation of Lewy bodies and Lewy neurites, protein inclusions containing α-synuclein, and ubiquitin.[68–70]

While PD is generally sporadic, mutations associated with familial forms have been characterized, leading to the identification of the *α-synuclein* gene.[71] Although an obvious *Drosophila* α-synuclein homolog has not been identified, a *Drosophila* model of PD was developed using transgenic flies expressing wild-type and mutant human α-synuclein.[72] Development and eclosion of transgenic flies occur normally. However, an age-dependent and specific loss of dopaminergic neurons was observed in transgenic flies, indicating that high expression of α-synuclein can cause PD. In addition, α-synuclein aggregates that strongly resemble human Lewy bodies are observed in aged transgenic flies.[72] Furthermore, an age-dependent loss of locomotor activity is greatly enhanced in transgenic flies. These phenotypes demonstrate significant similarities between the human disease and the fly model.

In addition to α-synuclein, at least five other genes have been linked to familial forms of PD and analysis of these genes suggests that two pathways may be involved in disease pathogenesis.[73] *Parkin*, which encodes an E3 ubiquitin ligase that directs proteins to be degraded by tagging them with ubiquitin, and ubiquitin carboxy-terminal hydrolase L1 are components of the ubiquitin proteosome system (UPS). DJ1 and PINK1, Pten-induced putative kinase 1, are involved in mitochondrial function. Although *parkin* loss-of-function mutants have been reported to have mitochondrial defects, direct interaction between the genes involved in the UPS and mitochondrial function have been lacking until recent results in flies.

Recently, several groups have generated *PINK1* mutant flies, either null mutants[74,75] or reduced activity mutants using RNAi.[76,77] *PINK1* mutants are, in general, viable, but have reduced longevity. They also suffer energy depletion, male sterility, and an age-dependent muscle degeneration associated with impaired mitochondrial function. In addition, an age-dependent loss of dopaminergic neurons is generally observed.[74,76,77] These phenotypes are similar to those observed in *parkin* mutants[78] and indeed reducing PINK1 expression results in reduced parkin levels.[76] Furthermore, overexpression of parkin dramatically restores *PINK1* loss-of-function phenotypes, *parkin;PINK1* double mutants do not have more severe phenotypes than single mutants, and overexpression of *PINK1* does not restore the defects of a *parkin* mutant.[74–76] These results indicate that parkin and PINK1 function in a common pathway with PINK1 functioning upstream to control parkin expression (Figure 15–1D). It will be of significant interest in the future to include the other four genes associated with familial PD in epistasis experiments in order to further elucidate the pathway or pathways involved in Parkinson's pathology.

Studies in *Drosophila* have facilitated the identification of possible therapeutic targets to combat PD. Auluck and collegues[79] have shown that overexpression of HSP70, a stress-response chaperone that functions in refolding misfolded proteins, suppresses the neurodegeneration seen in α-synuclein flies (Figure 15–1D). Furthermore, the drug geldanamycin, which blocks the activity of HSP90, a negative regulator of stress response genes, also prevents neurodegeneration.[80] Overexpressing Pael-R, a putative G-protein- coupled transmembrane protein, causes it to form insoluble aggregates and leads to endoplasmic reticulum stress and loss of dopaminergic neurons. Pael-R is degraded through ubiquitination by parkin.[81] Thus upregulation of stress response/chaperone pathways may be a useful therapeutic strategy for treatment of PD. Reducing PINK1 activity in the *Drosophila* compound eye results in ommatidial degeneration, which can be suppressed by expressing the human *SOD1* antioxidant gene or by feeding flies either vitamin E or SOD1 protein, both of which have antioxidant activity.[77] Also, overexpression of the fly *Bcl2* gene, which functions to inhibit apoptosis and is involved in protecting mitochondrial integrity, suppresses many of the phenotypes of *PINK1* mutants.[74] These results suggest that *Drosophila* models of PD have great potential in identifying factors or compounds that may be used in the treatment of the disease.

SUMMARY AND FUTURE DIRECTIONS

Drosophila have proven to be particularly well suited as a model organism for human cognitive and age-dependent neurodegenerative diseases as shown by the five disease models discussed in this chapter. This is likely due to several factors including the high degree of conservation between *Drosophila* and mammals with respect to memory formation, aging, neuronal development, and neurite guidance. In addition, these diseases all affect fundamental cellular processes such as cAMP/PKA signaling, translation, and protein misfolding and aggregation. As long as processes are this conserved, flies will continue to be extremely useful in elucidating pathways involved in disease progression and identifying therapeutic targets for drug screening.

Constructing *Drosophila* models of diseases is relatively straightforward. The *Drosophila* genome has been fully sequenced and, importantly, many P-element transposon lines and many genomic deletion lines exist. When a human disease is caused by mutations that result in reduced expression or loss of function of a gene, the *Drosophila* homolog can be readily identified and mutations in this homologous gene can be rapidly made by imprecise excision of nearby P-elements or by other mutagenic techniques. Reducing expression using RNAi is also commonly used. When disease pathology is caused by a dominant mutation or by increased accumulation of a gene product, transgenic *Drosophila* can be easily made that can be used to overexpress the gene of interest in a variety of tissues. This approach can even work when the gene of interest has no obvious homolog as seen in the case of overexpressing α-synuclein in a *Drosophila* Parkinson's disease model.

Once a disease model has been made, a major advantage of using *Drosophila* is that it is amenable to genetic screening for genes that can enhance or suppress the disease phenotype when either mutated or overexpressed. Large-scale unbiased screens of this nature are not practical in mammals. Even when genes encoding candidate interacting proteins are known, the large number of available mutants in *Drosophila* and the short generation time that facilitates the rapid construction of transgenic lines makes *Drosophila* an ideal choice in which to study genetic interactions. Furthermore, the ability to introduce many compounds into *Drosophila* through feeding allows for the rapid screening of large libraries of compounds for those that alter a disease phenotype. Of course, genes, genetic interactions, and compounds identified through *Drosophila* models will have to be confirmed using mammalian systems, but the use of *Drosophila* as an initial screen has the great advantage of rapidly identifying strong candidates.

Similarities between *Drosophila* and mammals suggest that in addition to the successes in studying specific diseases, *Drosophila*

may be useful in the study of less well characterized aging effects. Recent advances in medicine and healthcare have led to increases in human life expectancy. A consequence of this has been an increase in the incidence of neurodegenerative diseases. However, normal age-related memory impairment (AMI), not associated with neurodegenerative diseases, is also becoming a major concern. What are the causes of AMI? Are the mechanisms involved in AMI the same as those involved in neurodegenerative diseases? How can AMI be treated? Recent results indicate that *Drosophila* also suffer a quantifiable and reproducible AMI.[82] Although large-scale screening of memory in aged-fly populations is challenging, identification of mutants or compounds that accelerate or suppress AMI should be feasible. In addition, compounds and mutations that suppress neurodegenerative diseases or extend the life span can be tested for their effects on AMI. Thus, *Drosophila* will continue to be a vital model system for the study and treatment of human diseases.

16 Biomedical Research with Honey Bees

MICHELLE M. ELEKONICH

ABSTRACT

In addition to the economic benefits honey bees provide through pollination and honey production, this species is an important model system that provides insight into many areas of biomedical science. With a long history as a subject of studies of social behavior, learning and memory, and immunology (due to the allergens in their venom), the honey bee is emerging as a major model for phenotypic plasticity, development and aging, circadian rhythms, muscle metabolism and behavioral genomics. Sequencing of the honey bee genome revealed that honey bees share many genes and biochemical pathways with humans, thus opening new avenues of research. Biomedical research with honey bees benefits from this species' well known physiology, the tractability of its natural behaviors both in and out of the laboratory, a fully sequenced genome with accompanying suite of cellular and molecular tools, and a large interactive community of basic and applied researchers. Only *Drosophila* rivals the honey bee as an insect model system for biomedical research.

Key Words: *Apis mellifera*, Social behavior, Learning, Development, Aging, Muscle physiology, Circadian rhythms, Venom, Neurobiology, Olfaction, Genetics, Genomics, Beekeeping.

INTRODUCTION

Depicted in Spanish cave paintings dating from 6000 BC, the honey bee has long provided pollination of crops and numerous beneficial products including honey, wax, and propolis for human usage. Today the honey bee is also a well-established medical model for memory and learning, odor perception, behavioral plasticity, behavioral development, sociality, exercise metabolism, and aging. In addition, honey bee venom proteins have been the focus of many studies in immunology and protein biochemistry.

With a rich research literature containing more than 5000 references on honey bee evolution, behavior, physiology, and genetics dating back to the early 1800s, the honey bee model system is (1) the focus of a large interactive research community with basic and applied perspectives, (2) has well-described ecologies, natural behaviors, and phylogenies, (3) is well characterized with respect to natural genetic variation, associated phenotypic variation, and the evolutionary forces maintaining such variation, and (4) and has a sequenced experimentally tractable genome.[1] In fact, honey bees like *Drosophila* share many genes and biochemical pathways with humans,[2] suggesting many additional uses for this model system will soon emerge.

HONEY BEE NATURAL HISTORY

Honey bees are members of the insect order Hymenoptera, which includes approximately 100,000 species of sawflies, wasps, ants, and bees. The order Hymenoptera is one of 11 orders of holometabolous insects, those that undergo a metamorphic molt to reach their adult phenotype. Honey bees (*Apis mellifera*) live in large colonies usually containing one egg-laying queen and her progeny, some 20,000–40,000 nonreproductive female "workers," and 200–300 male "drones." Females, queens and workers, arise from fertilized (diploid) eggs laid by the queen. Diploid eggs become queens or workers depending on the cell in which they are laid and whether the resulting larvae are fed royal jelly or worker jelly by the bees performing brood care. In contrast, males, known as drones, arise from haploid unfertilized eggs. This system is known as haplodiploidy.[3] Male and female larvae undergo a series of larval stages followed by pupation and a full metamorphosis within a cell in the honeycomb. Emerging from the cell as fully formed adult bees, female workers undergo a form of behavioral development termed "temporal polyethism," moving through a series of behaviorally defined life history stages in an age-related fashion.[4]

BEEKEEPING STOCKS AND TOOLS

As of the year 2000, it was estimated that honey bee pollination adds as much as 14.6 billion dollars per year to crop productivity in the United States alone.[5] The important role of the honey bee in pollination means that beekeeping courses, equipment, and stocks of honey bees are easily obtained. To work with the bees a beekeeper will want a bee veil, bee gloves, and sturdy shoes at the minimum. Full bee suits with integrated veils and elastic at the ankles are a popular choice. A smoker to create cool smoke to control the bees, a hive tool, and a bee brush are also necessary. Each hive consists of a stand to keep the hive off the ground, two standard movable frame hive boxes (Langstroth hives), a bottom board, a queen excluder, smaller hive boxes (called supers) for the honey, and an inner cover, and a top cover. Individual beekeepers may vary in their use of the queen excluder and inner cover but they are standard parts of the hive. All pieces of equipment and hive parts are available premade from standard beekeeping suppliers (see the Appendix). Each colony will forage in an area a few hundred meters to 6 km around the hive. Thus, a beekeeper must ensure there is sufficient forage for a colony as well as a local water supply. Protection from wind and morning sun is

also desirable. Finally, there are the bees themselves, which can be bought as a small hive (called a "split" or "nuc") or as a package (essentially a swarm in a container) to be placed in your equipment. Both of these can be bought with or without a queen, but will need to be picked up as neither the postal service nor any private carriers will deliver them. However, queens can currently be purchased and sent through the mail (see the Appendix).

There are numerous additional beekeeping tools that researchers sometimes find useful, although often for unintended uses. For example, the queen excluder can be used to modify the hive entrance. Then regular workers can exit but workers with attached raised tags that increase their size, known as "big-backed" workers, are confined to the hive. This manipulation can keep some members of a group of bees that are motivated and flight capable from flying to test the role of flight activity in physiology, neurobiology, or subsequent behavior.[6] Likewise, pollen traps that are meant to allow a beekeeper to collect bee gathered pollen, in the hands of the researcher, become tools to limit the amount of pollen coming into a colony. Because pollen is the only source of protein, this manipulation can be used to set up nutritional differences between colonies.[7] Similarly, cages typically used to introduce a new queen into a colony can be used to introduce groups of treated individuals.

Bees suffer from a number of parasites and diseases (bacterial, viral, and fungal). Beekeepers typically treat prophylactically for some of these and after the fact for others.[8] Many of the treatments are controlled as insecticides, so individual researchers will have to check to see which are legal for the state where they are located. The destructive force and spread of the varroa mite (*Varroa destructor*) has led to a renewed interest in integrated pest management and bee breeding. Various nonchemical solutions for varroa treatment such as rotating drone pupae and using screened bottom boards have been shown to decrease mite loads.[9,10] Although additional chemical treatments are available, beeswax retains many chemicals and the long-term hopes of the honey bee community to combat varroa, other parasites such as the small hive beetle, and diseases rest on the development of new strains of bees.

There are currently no isogenic lines of bees available. The behavioral and physiological qualities of a colony of bees are determined by the identity of the queen and the drones with which she mated. Virgin queens and male drones mate in the air at "drone congregation areas" that tend to be highly stable over time.[11–13] The price of a breeding queen depends on whether she was naturally mated, allowed to mate freely in nature with local drones, or artificially inseminated. Most beekeepers buy naturally mated queens, but if you require specific genotypes many queen breeders can produce custom inseminated queens for experiments. Instrumentally inseminated queens can cost up to 20 times as much as naturally mated queens, but give the researcher control over genotype. Courses in instrumental insemination are also available at Ohio State University (see the Appendix).

All commercially available honey bees in the United States are of the same species, *Apis mellifera,* mostly developed from the Italian *ligustica* strain, but scientists at the U.S. Department of Agricultrue (USDA), Universities, and commercial breeders have bred strains with various qualities in addition to the original *ligustica* qualities of fecundity, gentleness, and honey production. The Buckfast strain, one of the oldest and still available strains, was originally selected in part for resistance to tracheal mites. Other stocks available include the lighter colored Cordovan bees (also called Golden Italians). They are more golden and have brown rather than black bands. The gold color serves as a natural genetic marker. In contrast, Carniolan bees are darker colored and are bred for being winter hardy and producing lots of bees quickly with the onset of spring. Russian bees imported and tested at the USDA appear to have resistance to varroa mites, tracheal mites, and chalkbrood, a fungal disease.[14] Another strain developed at the USDA known as SMR (suppressed mite reproduction) and/or VSH (varroa sensitive hygiene)[15] and the strain developed at the University of Minnesota by Dr. Marla Spivak known as Minnesota Hygenic bees also exhibit increased resistance to the varroa mites. The Minnesota Hygenic bees are also well known for their resistance to foulbrood.[16,17] Other breeders have developed popular mite-resistant strains, but not all have scientifically tested the performance of those strains. In addition, some breeders offer queens resulting from combinations of these strains.

RESEARCH TOOLS AND MANIPULATIONS

A critical and widely used manipulation to discriminate age vs. behavioral effects during honey bee behavioral development is the use of single-cohort colonies (SCCs) to induce precocious foraging.[18–20] SCCs made entirely of newly emerged bees use skewed colony age demography to dissociate worker age and behavior. The lack of older workers in the hive causes about 10% of the bees in a single cohort colony to forage precociously, usually at 7–10 days of age.[19,21,22] In a typical colony older bees work outside the hive as foragers while younger bees would work inside the hive, while foragers and hive workers are the same age in an SCC. Critically, SCCs allow the observation and collection of same-aged bees performing different tasks. SCCs initially yield young (precocious) foragers and young (typical age) hive bees, and after a few weeks, old (typical age) foragers and old (over-aged) hive bees. If all of the bees caring for brood in the hive are removed, a percentage of the members of the foraging force will revert to hive tasks including brood care (now a "reversion colony"). These individuals have been foragers and are the same age as the colony's foragers but now are behaviorally and physiologically at an earlier developmental stage.[23]

In addition to SCCs, honey bee researchers have invented a number of other manipulations that increase the usefulness of the honey bee as a model system. Of course the best known of these is the ability to train bees to specific feeding stations, individual markings, and observation hives as used by von Frisch[24] and his students in his Nobel Prize winning work on the honey bee waggle dance. Using cohorts of known age bees, as for an SCC described above, researchers can set up colonies with specific multiple-aged cohorts[25] to look at the role of age in socially mediated effects on behavior and physiology. As is the case for many other animals, honey bees can be cross-fostered[26] to separate the role of genotype from that of developmental environment. Colonies containing adult workers of mixed genotypes can also be made to investigate the genotypic influences on any number of individual and colony traits.[27,28]

Physical characters of bee colonies can be manipulated in many ways to facilitate data collection such as adding modified entrances to remove pollen,[29] collect dead bees,[30] lengthen the entrance to increase flight distance, or mark and/or capture bees individually as they leave or return.[31] The role of the queen and her pheromone secretions have been investigated using colonies

where the queen's genotype differs from that of the workers or where the queen is removed and her presence simulated with pheromone.[32] Additionally, bee behavior and physiology have been manipulated with numerous pharmacological treatments[33] and exposure to pheromones[34] and other odors.[35]

The honey bee model system also has a number of neurobiological, physiological, and cellular tools. Honey bee brain neuroanatomy has been studied since the mid-1800s[36,37] and a bee brain atlas was recently completed.[38] Changes in the neuropil volume, dendritic arborization, and neurochemicals in both the mushroom bodies and antennal lobes of the honey bee brain occur in concert with behavioral development and its associated changes in physiology.[39–42]

In addition to anatomical studies of the honey bee brain, the functional role of individual types of cells, brain areas, receptors, and channels is increasingly being studied.[43,44] For example, the biogenic amine receptors, the cholinergic, GABAergic, and glutamatergic pathways in the central brain, and the subesophageal ganglion of the honeybee have all been well described.[34,45,46] Electrophysiological recordings and voltage clamp, *in situ* hybridization and immunocytochemistry are all well-established techniques for use in honey bees.[47–53]

Although there are many well-established insect cell lines derived from the fruit fly, house fly, and flesh fly,[54–57] honey bee cell lines are not yet available. Honey bee neurons have proven to be especially amenable to short-term culture[43,45,58–61] supporting studies of ion channels, receptors and neurotransmitters, and neurophysiology. Hemocytes (circulating immune system cells), antennal cells, and embryonic cells have also been cultured for short time periods.[62–64] Recently, embryonic cells taken from 36- to 40-h-old honey bee eggs have been cultured for as long as 3 months,[65] suggesting that the production of honey bee cell lines is not far off.

Transgenic bees have been created by incorporating DNA constructs into sperm used for instrumental insemination of queens. Transgenic lines produced in this way have been maintained for up to three generations. One drawback to this technique is that the construct did not appear to be integrated into the genomic DNA.[66] Chimeric bees have been created by transplanting embryonic cells into other embryos.[67,68] Although larval honey bees are typically reared in individual cells by the adults in the colony, *in vitro* rearing of embryonic and larval bees to adulthood is well established for toxicity studies on larvae and studies of caste determination.[69–76] Thus, with the ability to create chimeras in addition to the sequencing and annotation of the honey bee genome, the honey bee system is poised to pursue detailed studies of gene expression and biochemical pathways involved in phenotypic canalization and plasticity, development of genetic knockouts/knockins, and additional advances in honey bee breeding.

Several recent studies have effectively used RNA interference to disrupt gene expression. Injection of double-stranded RNA (dsRNA) into the neuropil of the antennal lobe disrupted expression of octopamine receptors at a level that decreased with distance from the injection site and length of time postinjection. Disruption of octopamine signaling decreased olfactory acquisition and recall in an operant conditioning task but did not disrupt olfactory discrimination.[77,78] Injection of dsRNA into the hemocoel via the intraabdominal segments decreased levels of vitellogenin, a storage protein, in the bees' hemolymph (blood). dsRNA injected into eggs also disrupted vitellogenin gene function across development.[79] Similarly, injection of the dsRNA encoding the E30 homeobox motif into preblastoderm stage embryos disrupted homeobox gene function producing embryonic phenotypes similar to those observed in the *Drosophila engrailed* mutants.[80] In another developmental study, Beye and colleagues disrupted sexual differentiation by suppressing *csd* expression in larvae that had developed from eggs injected with dsRNA for the part of the csd gene that is thought to be an SR-type protein.[81]

SOCIAL BEHAVIOR

Honey bees live in complex and cohesive societies characterized by "eusociality." Much like our own societies, generations overlap, there is cooperative care of young and importantly division of labor including reproduction.[3,82] Honey bee social behavior is studied both at the level of the individual and the level of the colony, often described as a "superorganism."[3,82,83] Studies of social behavior have focused on social control of behavior, individual response thresholds, physiology and group behavior, network dynamic models, communication, group decision making, the molecular basis of sociality, physiological control, colony need, and timing of response.[67,21,84–91] The following sections discuss some specific types of social behavior in more detail.

AGING AND BEHAVIORAL DEVELOPMENT

Worker bees perform several different tasks in the hive during the first 2–3 weeks of adult life, including brood care ("nursing") and hive maintenance, and then shift to foraging for nectar and pollen outside the hive for the remainder of their 5- to 7-week life.[4] Social interactions signaled by a pheromone pace the rate of adult worker bee behavioral development via the actions of juvenile hormone.[21,92–94] But juvenile hormone (JH) is not required for foraging behavior. Workers lacking JH following removal of the corpora allata (the sole source of JH) on the first day of adult life still become foragers but at older ages; this delay is eliminated with hormone replacement.[95] Adult behavioral development also varies with a colony's genetic background and is sensitive to factors such as weather, season, parasite infestation, and colony nutritional status.[18,22,27,96–99]

In times of colony need individual workers can develop more rapidly, in essence aging faster, to become precocious foragers. Similarly, if the colony loses many of its middle-aged workers, foragers can revert to earlier behaviors and their physiology also returns to more youthful states.[23,100] This socially mediated behavioral plasticity makes the honey bee a unique model for the physiology of aging.

As honey bees switch from in-hive tasks to foraging, they transition from constant exposure to the controlled homogeneous physical and sensory environment of the hive to prolonged periods in a far more heterogeneous environment outside the hive. Within the hive there is little light and the workers actively keep the temperature at 33–35℃ by contracting their fl ight muscles and keep the humidity near 70%.[4] Foraging outside the hive occurs at air temperatures between 10 and 50℃ [101] and exposes workers to wind, rain, and increased predation. The physiology of honey bees also changes as they age and move from nonflying tasks in the hive to flight-intensive foraging behaviors. For example, hypopharyngeal glands regress and produce enzymes for processing nectar instead of brood food, body mass decreases, body water content increases,and, as we describe in detail below, juvenile hormone levels and metabolic and flight capacity increase.[4,16,102–107]

In addition, more complex spatial and sensory information than that encountered in the hive must be integrated to successfully forage.[31,108]

Microarrays developed from a honey bee expressed sequence tag (EST) database[2] have revealed different patterns of gene expression in forager vs. nurse brains independent of age.[109] Among the genes differentially regulated between behavioral groups are those with strong sequence matches to annotated *Drosophila* genes important in axiogenesis, cell adhesion, and intracellular signaling. In the latter class is *foraging (for)*, a previously identified cGMP-dependent protein kinase whose pharmacological activation causes precocious positive phototaxis and precocious foraging.[33,110] Similarly, a recent macroarray study demonstrates higher expression levels for genes involved in signal transduction, ion channels, neurotransmitter transport, transcription factors, plasma membrane proteins, and most cell adhesion proteins in foragers as compared to newly emerged bees, suggesting plasticity and remodeling of neurocellular properties during aging and/or behavioral development in honey bees.[111]

Most adult honey bee workers live 3–6 weeks during spring and summer and up to 8 months if they emerge from metamorphosis in late fall and overwinter in the hive.[4,112,113] Bees that overwinter have higher levels of vitellogenin in the hemolymph, lower JH, and overall higher protein reserves.[112] Honey bee life span is determined by the onset of foraging; the earlier in life a worker becomes a forager, the sooner she dies.[114–117] As foragers age, the time required to collect food from a feeder at a known distance increases[118] and bees often return to the hive with only a partial load of nectar due perhaps to decreased flight ability.[119] Mechanistically, life span appears to be limited by foraging-induced damage to the flight apparatus. This damage includes physiological/biochemical impairment of the flight muscle and mechanical damage including the loss of wing surface area due to wing wear.[114,120,121] The amount of physiological and mechanical damage is directly related to the amount of flight, independent of age. As foragers age, they lose the ability to synthesize glycogen. Bees that make more flights per day exhaust their glycogen reserves and reach the point where glycogen synthesis breaks down sooner.[114,120,121]

In contrast, queen honey bees are quite long lived, typically living 1–3 years, but may live as long as 8 years.[4,113] Queen bees make one to several mating flights a few days after they emerge from the cell where they completed metamorphosis. The only other time a queen will fly during her entire lifetime is during colony reproduction or swarming.[4,113] Queens appear to age more gracefully than workers at the molecular level as well. Expression of most antioxidant genes decreases with age in queens but not workers.[122] The relatively short life span of worker bees in contrast to the longer life span of queens suggests that bees may be particularly well suited to investigations of the cellular mechanisms underlying individual differences in the rate of aging.[123]

CIRCADIAN RHYTHMS

The onset of foraging also marks a transition from relatively constant arrhythmic activity to diurnal activity patterns. As worker bees age, they develop a circadian rhythm,[124,125] but their behavioral rhythms are task dependent. Workers who are caring for brood, nurses, work around the clock while workers who forage work only during the day.[126] These behavioral rhythms are socially mediated—foragers that have reverted to brood care lose their behavioral rhythmicity.[100] Honey bee circadian rhythms are entrained by cycles of both light and temperature and act to coordinate foraging behavior with appropriate flight temperatures, sun compass navigation, and the timing of visits to specific floral sources with nectar availability.[127] Foraging age bees are positively phototactic. Phototaxis is modulated by the honey bee *foraging* gene (*Amfor*), which encodes a cGMP-dependent protein kinase (PKG). Increases in PKG activity cause precocious foraging and are correlated with increases in positive phototactic behavior.[9] As in other animals, honey bee circadian rhythms are influenced by *Period* gene expression in the brain.[125,128] However, the mechanism underlying the plasticity in behavioral rhythms and its relationship to the circadian rhythm are unknown.[100]

Circadian rhythms may also be important for the physiological support of foraging behavior. JH titers in foraging bees are consistently higher than those of bees working in the hive, even on their first foraging flight.[129,130] Increased JH titer causes degeneration of the hypopharyngeal glands and a shift from producing brood food to production of α-glucosidase, amylase, and glucose oxidase, the enzymes needed to process nectar into honey.[4,105,131] High JH titers also promote degradation of the fat body and consequent decreases in hemolymph vitellogenin, the most common storage protein in the hemolymph.[132] As brood food is high in protein, decreases in fat body and hemolymph vitellogenin levels further mark the switch from a bee well suited to caring for young to a bee well suited for flying, carrying heavy loads (in relation to body size), and processing nectar. In addition, there is a diurnal rhythm in JH titer in foragers that is not present in preadult bees.[129] Interestingly, the timing of the diurnal peaks in JH titer matches the timing of the peaks in *period* mRNA expression with the highest titers during the mid-subjective night.[125,129] However, it appears that JH titer does not influence diurnal locomotor activity as allactectomy has no effect on circadian locomotor rhythm, nor does treatment of young bees with methoprene, a JH analog, accelerate the onset of circadian behavior.[133]

It may be that the high titers and diurnal rhythms of JH support foraging physiology directly. In other insects, JH affects muscle properties directly influencing muscle maturation[134] and initiating muscle degeneration and ovarian development in postdispersing insects in preparation for reproduction.[135–137] JH also affects both cellular and whole animal metabolism. Allatectomized honey bee foragers have lower metabolic rates and are flight deficient compared to controls. However, this difference is abolished with treatment with the synthetic JH analog methoprene.[138]

LEARNING AND MEMORY

Experience-dependent changes in neural architecture and function may reflect changes in information processing and sensory thresholds in response to the greater complexity of foraging tasks relative to hive work. Honey bee foragers make use of visual, auditory, and olfactory information while locating flowers, assessing the sugar content of the nectar, communicating the quality and location of the food to other foragers, and repeatedly navigating between the hive and food sources.[4]

To support the complex task of foraging, olfactory sensitivity, learning ability, and volume of the neuropil of the mushroom bodies, associative brain areas involved in memory consolidation, increase as bees switch from in-hive to out-of-hive tasks.[40,108] Increased cholinergic signaling in the mushroom bodies is coin-

cident with the foraging bees increased interaction with the world and increased mushroom body neuropil.[41] Field tests of honey bee learning make use of our ability to train honey bees to a food source, which the bees then communicate to new recruits via the waggle dance, thus in effect "teaching" other bees where to find food by reporting what has been learned.[24] A large body of literature suggests that foraging, recruitment via the waggle dance, and subsequent navigation to the food source require complex cognitive abilities including a compass sense, learning the local area and landmarks during orientation flights providing a detailed map, path learning, path integration, and higher order integration of these processes and redundancy of cues to enable foraging even in poor conditions.[108,139,140] These experiments continue to suggest that even with a small brain bees can be "smart."

In the laboratory, honey bee learning is investigated using the Proboscis Extension Reflex (PER) assay, a classical conditioning associative learning paradigm. Honey bees naturally extend their proboscis when receptors on the antennae are stimulated by sucrose, naturally found in nectar, to taste the food. In the PER assay restrained bees are taught to associate an odor with the food and learn to extend the proboscis in the presence of the odor.[141,142] These studies have shown that bees can learn simple associations, context, categorization, and discrimination, even performing successfully in reversal learning and negative patterning tasks.[58]

Because the bee is immobilized with the head, antennae, and mouthparts easily accessible, researchers can gain direct access to the brain to measure physiological correlates of learning during conditioning.[58,143] The octopaminergic VUM_{mx1} neuron of the subesophageal ganglion carries the information along the olfactory pathway from the antennal lobes to the mushroom bodies.[143] Likewise, downregulating VUM_{mx1} octopamine receptors using RNAi impairs learning.[77] In addition to the role of cholinergic signaling described above, olfactory memory processing in the mushroom bodies and antennal lobes relies on cAMP-dependent phosphorylation via protein kinase A (PKA) and the Ca^{2+}/phospholipid-dependent phosphorylation by protein kinase C (PKC), similar to other model systems.[33,144,145] Similar to vertebrate systems, glutamate signaling in the mushroom bodies facilitates memory stabilization.[146] Exposure to toxins such as pesticides can interrupt PER-based learning and may become an important tool for investigating sublethal effects of pesticides or environmental toxins.[72] The relative simplicity of the honey bee brain combined with powerful tools to study learning and physiology and the natural behavioral richness of the species probably owing to its high degree of sociality suggest that honey bees will continue to serve as a valuable model for studies of learning and memory.

MUSCLE METABOLISM

Honey bee flight muscles are very similar in structure and function to vertebrate skeletal muscle except that metabolism is completely aerobic, using only carbohydrates for fuel, and each muscle is composed of a sign fiber type.[147–151] In the honey bee, flight muscle metabolism accounts for over 90% of O_2 consumption during flight.[148] Honey bees possess an asynchronous flight muscle (AFM). Unlike synchronous muscles (which like typical striated muscles have a 1 : 1 ratio of neural stimuli to contractions with contraction initiated by intracellular calcium release and terminated by calcium uptake by the sarcoplasmic reticulum), AFMs show an approximately 1 : 10 ratio of neural stimuli to contractions. Neural stimulation in AFM releases intracellular calcium, which removes thin filament inhibition, but the cross-bridges themselves are activated by stretch and deactivated by sarcomere shortening. AFMs are stretched by thoracic deformation caused by contraction of antagonistic muscles, and this mechanical feedback keeps AFMs contracting over many cycles.[152] The large power-producing AFMs are controlled by a set of small synchronous muscles that produce little or no power but are capable of rapid and finely graded responses to neural stimuli.[153,154] Troponin-T is the tropomyosin-binding protein of the calcium-regulated troponin complex of striated muscle. As bees move from hive work to foraging, the troponin-T expression increases along with aldolase and the antioxidant protein superoxide dismutase.[115]

Adult honey bees are unable to fly during the first day following adult emergence, yet within 2 weeks generate spectacular rates of metabolism and aerodynamic power (up to $0.8\,W\,g^{-1}$ and $0.2\,W\,g^{-1}$, respectively)[155] that enable later work outside the hive, traveling up to 8 km from the hive and carrying loads equivalent to their body mass during foraging and undertaking. The development of flight ability generally occurs in two distinct periods, the first being the 3–4 days following adult emergence and the second typically at 14–21 days postemergence during the transition from hive work to foraging. Day-old bees that are physically agitated (a manipulation generally assumed to induce maximal metabolic capacity) can generate metabolic rates of only $0.1\,W\,g^{-1}$ and are isothermic with the surrounding air. Hovering 2-day-old bees have metabolic rates approaching $0.3\,W\,g^{-1}$ and are more endothermic; coincident with the increase in metabolic capacity of young bees are dramatic increases in thoracic pyruvate kinase and citrate synthase activities as well as thoracic glycogen levels.[103,114,156–158]

Such biochemical changes should in theory greatly increase flux capacity through the citric acid cycle and the rate of NADH and $FADH_2$ recycling. Flight metabolic rates, thoracic enzyme levels, and thoracic glycogen levels remain relatively constant over the 1- to 3-week period when the bees work within the hive. Then, at the onset of foraging (14–21 days postecolosion) there is an approximate 15% increase in agitated flight metabolic rate, coincident with an approximate doubling of thoracic glycogen levels.[156,157,159,160] In fact, flying honey bees have the highest aerobic metabolic rates ever measured in any animal, between 100 and $120\,ml\,O_2\,g^{-1}\,h^{-1}$. These values are 3-fold higher than hovering hummingbirds and 30-fold greater than human athletes undergoing maximal aerobic exercise.[161–164] Thus, in the honey bee mechanisms for resisting oxidative damage may be highly specialized and critically important. When combined with the ability to manipulate age, behavior, aerobic expenditure, oxidative stress, functional senescence, and life span independently, the exceedingly high rates of aerobic capacity suggest that the honey bee may be a superior exercise model.[151,165]

HONEY BEE VENOM

In the United States, 40–50 people die each year from systemic reactions to stings from Hymenopteran insects, most often due to anaphylactic reactions to stings from vespid wasps commonly known as yellow jackets.[166] Severe anaphylactic reactions can result in permanent hypoxic brain damage, myocardial infarction, and death.[167] After a systemic reaction, a patient diagnosed with an insect sting allergy is given immunotherapy over a period of months starting at low doses and building up to a maintenance

dose, which is continued at 4–6 week intervals for as much as 5 years. Semirush protocols (giving multiple doses each week for several weeks) and rush protocols (where all doses are given on a single day) have been developed. These faster protocols carry some additional risk of adverse reaction relative to the conventional protocol.[102,168,169]

Cross-reactivity to different Hymenopteran venoms is observed in half of the patients with allergic reactions to wasp or bee stings.[101,170] In addition to species-specific proteins, Hymenopteran venoms contain a number of conserved cytolytic and cytotoxic compounds including phopholipases (A_1 in bees and A_2 in wasps), hyaluronidases, and acid phosphatases.[171,172] Cross-reactivity has been ascribed to immune responses to shared hyaluronidase epitopes and production of IgE specific to the carbohydrate side chains of the glycoproteins.[67,68,71,100] Melittin (Api m 4), Api m 6, and the recently identified icarpin are honey bee-specific allergenic proteins.[167,173,174]

Many of the components of honey bee venom have specific cellular targets and concomitantly stimulate the immune system. The bee-specific protein melittin acts by disrupting the cell membrane and activating phopholipases, calmodulin, and arachadonic acid release[175] and may also prove to be a useful molecule to target tumor cells, similar to phospholipase A_2.[176] Effects of bee venom may be somewhat cell specific. Bee venom appears to be more destructive to renal cells, inducing vasoconstriction, nephrotoxicity, and rhabdomyolysis, possibly resulting in renal failure.[177] Possible uses of venom components, individual differences in reactivity, reactivity of special groups such as beekeepers, test accuracy, and therapy safety and efficacy are ongoing foci of research in this area.[168,178]

Finally, there has been a renewed interest in apitherapy with therapeutic stinging touted to help everything from arthritis to multiple sclerosis. Most of the research in this area has occurred in the area of traditional Chinese medicine. In many of these studies bee stings or diluted bee venom are applied to traditional acupuncture points. Several studies suggest that bee venom therapy effectively reduces inflammation and induces analgesia in rodent models, but many of these studies were methodologically flawed.[179] However, two randomized controlled studies suggest that bee venom therapy can be useful for rheumatoid arthritis and osteoarthritis in the knee joint.[180–182] The outcomes for patients with multiple sclerosis are not so hopeful. To date, in the only randomized controlled study of the use of bee venom therapy to ameliorate symptoms of the disease, bee stings were not any more effective than no therapy at all.[183] There has also been a renewed interest in the wound-healing properties of honey and the antiinflammatory properties of propolis.[184] As the public's interest in complementary and alternative medicine continues to increase, this will likely continue to be an active area of research.

CONCLUSIONS

Research with insect models continues to suggest that many neural, hormonal, and molecular mechanisms are evolutionarily conserved across a broad range of taxa. A truly integrative approach to biomedical problems requires understanding the genetic, physiological, and social/ecological mechanisms and their interactions. With a combination of a sequenced genome, well-described natural history including ecology, social behavior that rivals our own in complexity and development, as well as a large, interactive community of researchers with a variety of tools to manipulate all aspects of honey bee biology, the honey bee will continue to be a highly tractable and interesting medical model system for a long time to come.

APPENDIX

BEEKEEPING EQUIPMENT

Beesource: includes lists of suppliers, plans for building equipment, and other useful information.
http://www.beesource.com/

A.I. Root, one of the oldest beekeeping families and supply companies in America, established in the 1800s and publisher of *Bee Culture.*
http://bee.airoot.com/beeculture/index.htm

Dadant & Sons, another beekeeping supply company established in the 1800s and publisher of *The Am Bee J.*
http://www.dadant.com/

Mann Lake Ltd: another large beekeeping supplier with a very informational website.
http://www.mannlakeltd.com/

Walter T. Kelly: beekeeping supplies, U.S. maker of honey extraction equipment.
http://www.kelleybees.com/

QUEEN BREEDERS For local breeders in your area, your best sources of information in the United States are the two major beekeeping magazines: *The Am Bee J* and *Bee Culture.*

Glenn Apiaries: sells instrumentally inseminated breeder queens.
http://members.aol.com/queenb95/catalog.html#anchor2391365

Ohio Queen Breeders: another source for instrumentally inseminated queens.

17 Establishing and Maintaining a *Xenopus laevis* Colony for Research Laboratories

PUNITA KOUSTUBHAN, DEBRA SOROCCO, AND MICHAEL S. LEVIN

ABSTRACT

This Chapter describes in detail the construction and maintenance of a *Xenopus laevis* colony. It covers *Xenopus* husbandry, facility design and construction, necessary maintenance protocols, and monitoring/disaster recovery procedures. Facility components and management protocols described within this chapter are based on our experience with the frog colony at The Forsyth Center for Regeneration and Developmental Biology as well as the information obtained from many other investigators. The system described in this chapter is AAALAC accredited and provides a steady supply of embryology-quality eggs and ensures excellent water quality and adult frog care. This information is a complete guide, allowing a new investigator to begin work with this powerful model species that has resulted in profound advances in developmental, cell, and cancer biology.

Key Words: *Xenopus laevis*, Frog, Developmental biology, Colony, Husbandry, Protocols.

INTRODUCTION

There are numerous advantages that steer investigators toward this South African clawed frog as a vertebrate model.[1] *Xenopus laevis* embryos develop externally allowing observation throughout all stages of development. Frog eggs are large and the developing embryo is visible making them an excellent research model. A tremendous number of cell, molecular, genetic, and developmental biology techniques have been developed for *Xenopus* and this model has been used in more than 33,000 papers in Medline as of 2006. *Xenopus* has been in practical use since at least the 1940s, once being a popular diagnostic tool for human pregnancy.[2–5] An excellent practical resource for embryonic work with *Xenopus* is Sive *et al.*,[6] and standard atlases provide extremely detailed information on embryonic development in this species.[7,8] The zoology of *Xenopus* tadpoles is covered in McDiarmid and Altig.[9] As a result, the *Xenopus* model system has contributed to both classical and modern breakthroughs in developmental and evolutionary biology, ethology, neurobiology, regeneration, endocrinology, toxicology, and cancer biology.

Xenopus is a convenient and powerful model for vertebrate biology. However, a wide variety of husbandry methods is used, with little standardization.[10–14] Current frog laboratories utilize techniques inherited from a previous mentor (and anecdotal suggestions abound in the community), but the task of designing, building, and maintaining a thriving frog colony is very daunting and time-consuming to the beginning investigator who needs to set up this model system from scratch. In the absence of such specific protocols and construction details, it is estimated that it took us over a year of hard work, from the opening of the new laboratory to the ability to routinely do embryo experiments. This chapter is presented in the hopes that we can radically shorten this time period for new investigators, and lower the barrier for others to become involved in the use of this model system.

This chapter provides most of the necessary information, protocols, considerations, and materials lists to run a facility. We give general advice where possible, but the specific details are taken directly from our running habitat at the Forsyth Center for Regenerative and Developmental Biology, where we have been using *Xenopus* to understand the biophysical control mechanisms of laterality, spinal cord regeneration, and eye development.[15–23] This chapter is intended to provide all of the information necessary to build and operate such a system. The lessons learned through the years of practical experience and discussions with the *Xenopus* community resulted in what we believe to be a very successful system. Our laboratory obtains large number of excellent embryos every week, with no seasonal variability.

Because our goal is to provide specific and detailed information on a working system, we do not give details on the construction of other types of habitats. A wide range exists in the community, and many people run successful colonies with standing tanks (in contrast to our flow-through system). We have found our system to be a good choice for a medium-sized laboratory, but there are many other ways to keep *Xenopus*.[24–26] The key principle is to build an environment conducive to very happy and healthy frogs, which is the best way to ensure high-quality eggs for any research program. In this chapter, we describe the optimal setup, but some aspects of it can be simplified if necessary to minimize cost.

FACILITY DESIGN AND COMPONENTS

PLANNING AND CONSIDERATIONS FOR DESIGN The first step is to make decisions on how the embryos will be used in the program. If *Xenopus* usage is low, the investment in a complex flow-through system may not be justified. In such cases, simple standing tanks or even purchasing females on an as-needed basis may be good alternatives. However, given the cost of good-quality *Xenopus* females (~$40), and the fact that a single female

Table 17–1
Estimate of facility design and installation costs

Item description	*Vendor*	*Part number*	*Price estimate*
Frog facility design and install	Marine Biotech, Inc.	X-MOD System	$40,000 (2001)
Water chillers	Marine Biotech, Inc.	N/A	$2,600 (2001)
Water polishing system	Hydro Service & Supplies	Picopure 2 UV Plus	$3,400 (2001)
Supply cart, nets, buckets, ladder, digital thermometer, etc.	Aquatic Ecosystems	Varies	$500 (2001)
Monitoring system	Electromechanica, Inc.	N/A	$7,500 (2002)
Web camera	Veo Observer	V700000	$160 (2002)
Total		~$54,000	

should rest for 3–4 months between uses, a medium to large-sized laboratory will find it cost-effective to maintain the kind of facility described here. The expense should also be considered in terms of materials for the initial construction, supplies, and labor costs for maintenance. As a rough guideline, maintenance of this facility requires a minimum of 20 h per week. A dedicated technician who is available at least 30 h a week (including extended holidays and unpredictable emergency efforts) is ideal. The facility needs human attention daily, but when everything is working well, weekend attendance is not required. In general, the most crucial factor is the human element: it is essential to have a smart technician, preferably with experience in animal care and a dedication to their well-being, and to restrict access to the colony to as few individuals as possible. Establishing continuity of expert attention to the facility is the only way to ensure efficient and trouble-free operation. A commitment of at least 1 year is a minimum when choosing a technician. A skilled technician can learn to perform the day-to-day maintenance and monitoring in about 2 months. Becoming an expert in some of the rarer procedures and especially in handling crises (mechanical and biological) takes significantly longer.

The availability of the following nearby (especially making sure they are willing to make house calls on a time scale of 1–2 days) will prove very useful: an aquatic animal veterinarian, a company to do aquatic habitat plumbing, and a company providing water purification technology). The system we describe below services a laboratory in which five postdoctoral fellows utilize the frog embryo almost exclusively. It is sufficient to provide 16 frogs per week on a 365 days/year continuous cycle, which is enough for *Xenopus* experiments 4–5 days out of the week. Some of the costs associated with establishing this facility from scratch are shown in Tables 17–1–17–6. Also to be taken into account are space considerations; a room at least 600 ft^2 in area is needed, and if possible, all of the plumbing and pumps should be located in a separate, adjacent room to allow plumbers and other personnel to work without impacting the facility itself (also reducing the significant ambient noise for the technician maintaining the colony). Costs may be conserved by relying on ambient air temperature and water quality provided by the building instead of the water purifier and chillers we describe below. However, it has been our experience that in the long run, this is not cost effective because building air conditioning and water quality controls are rarely sufficient for a healthy colony, regardless of their official specifications.

OVERVIEW OF A FLOW-THROUGH X-MOD SYSTEM Good water quality is central to managing a frog colony. Any toxins or major fluctuations in water chemistry will cause physiological changes eventually leading to disease and reducing embryo quality even if adults do not seem obviously affected. This facility is designed to eliminate these sources of stress, and provide exceptional care for the frogs. As a rule, one frog per gallon (3.79 liters) is the optimum population density, however, there are other factors to consider when housing *X. laevis*. It is important that there is enough surface area available for the frogs to be able to rest on the bottom without touching any other frogs. Another important task is to calculate whether the biological filter and other components in the recirculating system, such as the carbon and particulate filters, are large enough to handle the amount of waste material generated by the frogs.

Table 17–2
Spare parts[a]

Item description	*Vendor*	*Part number*	*Price estimate*
Small UV (25 W)	Aqua Ultraviolet	A20025	$58
Large UV (40 W)	Aqua Ultraviolet	A20040	$68
UV sleeves	Aqua Ultraviolet	A10025, A10040	$70, 80
Air pump	Hailea	LT24	$170
Large water pump	March	TE-6T-MD	$250
Reservoir pump	March	BC-3C-MD	$190
Ultrameter pH/ORP probe	Myron-L	RPR	$137
Total		$1023

Table 17–5
Operational costs and consumables

Description	*Cost*
Utilities (electricity/water/HVAC)	Varies with overhead
Water polishing system service contract	$3000/year
Water chemistry additives	$120/month
Cleaning agents (pipe cleaners, scrub mitts, solvents)	Varies
Filtration (prefilter, 1 µm, particulate, carbon)	$70/month
Frog brittle (for 200 frogs)	$16/month
Male frogs (36/year, $21/each)	$756/year
Medications (oxytetracycline, levamisole, stresscoat)	$144/year
Technician salary	$30,000/year
Total annual cost	$38,094

Table 17–6
Time commitment

Task	*Hours*
Daily water chemistry	2.5 h/week
Feeding/cleaning	5 h/week
System maintenance	4 h/week
Troubleshooting	1 h/week
Technical training period	~1 month
Annual technician hours	650 h/year

Described below is a recirculating housing system (Figure 17–1) known as an X-MOD (Marine Biotech), designed to hold many aquatic animals in a clean environment. One major feature of this facility is that if any of the electrical/mechanical components stop functioning, the frog tanks automatically stabilize as static containers with a constant water level. Thus, this system can handle emergencies lasting for about 2 days (after which wastes build up and algae growth becomes a problem). The design incorporates three racks. Each rack has two rows of clear, polycarbonate tanks. There are six 75.8-liter tanks on each rack. Every tank has a securable lid with holes drilled in it allowing airflow at the surface of the tank. At the center of a tank, there are inner and outer tubes that are designed to drain water and particles out of the tank while preventing the frogs from being pulled into the drain tubes. The water leaves the tank along a pipe that connects to the return pipe in the sump draining over a polyester filter pad into the sump. There are two sumps labeled "sump 1" and "sump 2." Both sumps are connected by an "equalization" pipe, which allows water flow from sump 1 to sump 2. There are three racks in the 10 × 16-foot room. The room has tiled walls and a tiled floor with two floor drains. Our design accommodates 275 frogs comfortably.

Fluorescent lights connected to an automatic timer regulate photoperiod. The lights are mounted on the ceiling in between the racks. The timer is set on a 12 : 12 day : night cycle and the frogs receive a consistent light cycle year round (the room contains no windows). Full spectrum lights may be used and are often suggested, but we have achieved excellent results with fluorescent lighting. It is questionable whether the additional wavelengths provided by full-spectrum bulbs can penetrate the water to any depth.

In their native habitat, South African clawed frogs rest on the bottom of dark ponds, under leaves or in logs, so naturally they do not like bright lights. Keeping the lights dim and providing the frogs' tank with large PVC pipes enable the frogs to have a welcome hiding place. Indirectly, it also discourages the growth of nuisance algae. Many frog facility managers are incorporating behavioral enhancement into animal protocols due to mounting evidence that environmental enrichment promotes well-being and health.[27,28] The tank walls are covered with black plastic sheets that are taped to the back and sides of each tank to provide a "cave-like" environment.

The logic of water flow in the system is shown in Figures 17–2 and 17–3A. Our tanks are maintained at a flow rate of 6 gallons per minute (GPM). This works out to a system turnover rate of about once every 22 min or approximately three full circulations per hour. These racks have flow meters measuring flow rate in GPM, and use simple ball valves to adjust the flow to the racks. Each tank has its own spigot to regulate water flow, which is used to turn off the water supply to an individual tank or control the water flow during feeding, cleaning, or quarantining frogs. Excessively strong water flow contributes to frog stress by irritating their sensitive lateral line system; water flow should be monitored daily.

A 0.5-horsepower pump drives water through the circulation loop. It is placed before the filtration series to maximize water pressure across the filters. All of the filters have an automated pressure gauge. The pressure gauge from each piece of equipment is also connected to an automated monitoring system (see below). Routine inspection and maintenance of filters and following a weekly cleaning protocol keep the water pressure constant throughout the system.

As water flows into each tank (Figure 17–3B), debris is swept toward the drain tubes; the outer tube allows water and debris to enter at the base, but creates a barrier between the frogs and the actual drain. Heavy debris accumulates at the bottom, while smaller particles are carried into the inner drain tube and down the drain. Two valves beneath each tank control the direction of tank water; one controls flow to the floor drain while the other recirculates the water. By default, we keep the system drain valve closed and the recirculation drain valve open. The only time to switch would be to temporarily switch the orientation of both valves simultaneously to clear debris, especially after feeding, or to close both drains and shut off the water flow when quarantining frogs. All of the tank wastewater is collected into two central wastewater pipes that empty onto prefilter assemblies over the sumps.

FILTRATION COMPONENTS OF AN X-MOD SYSTEM Filtration occurs at several levels in the frog facility. We will begin by looking at what happens in each frog tank, and then follow the flow of water through the recirculating system. As water flows into each tank, debris is swept toward the drain. The outer grated tube allows water and debris to enter at the base while creating a barrier between the frogs and the actual drain. Heavy debris accumulates at the bottom, while smaller particles are carried into the inner drain tube and down the drain. Two valves beneath each tank control whether the wastewater goes back into circulation (to the sump) or out the floor drain to a sewer. The system drain valve is kept closed and the recirculation drain valve is open unless the tank is being drained during quarantine or cleaning.

The prefilter assembly is composed of a polycarbonate housing that holds prefilter pads supported by a PVC grid underneath. Polyester prefilter pads provide the first level of mechanical filtration by capturing solid debris and allowing wastewater to drain through the grid to the biofilter in the sump below. Beneath the prefilter assembly is a sump with a separator for biofilter media (we use Kaldness™ bioballs). The biofilter (Figure 17–4) removes toxins released from decaying organic matter and metabolic byproducts using a two-step biochemical reaction. The Kaldness™ media greatly increases the surface area available for nitrifying bacteria colonization. Nitrifying bacteria and seeding the sumps are discussed in the section on Water Quality. An air pump attached to a perforated PVC manifold provides bubbles to continuously move and thus aerate each biofilter.

The wastewater from each sump is diverted into the bead filter (Figure 17–5A), The X-MOD has a Hayward Pro™ series bead filter containing 1 ft^3 (55 lb) of Perm-Beads™. Not only does the

Figure 17–1. (A) A schematic of the FCRDB *Xenopus laevis* facility. Probes reporting to the online monitoring system are shown on Rack 1, Other components such as the RO-DI polishing system, housing racks, filters, pumps, and chillers are shown. The arrows indicate water flow through the system. (B) *Xenopus laevis* facility. A photograph of a three-rack system. Filters and chiller barrels are located below the middle rack against the back wall. Not shown are the holding tank and water purification equipment.

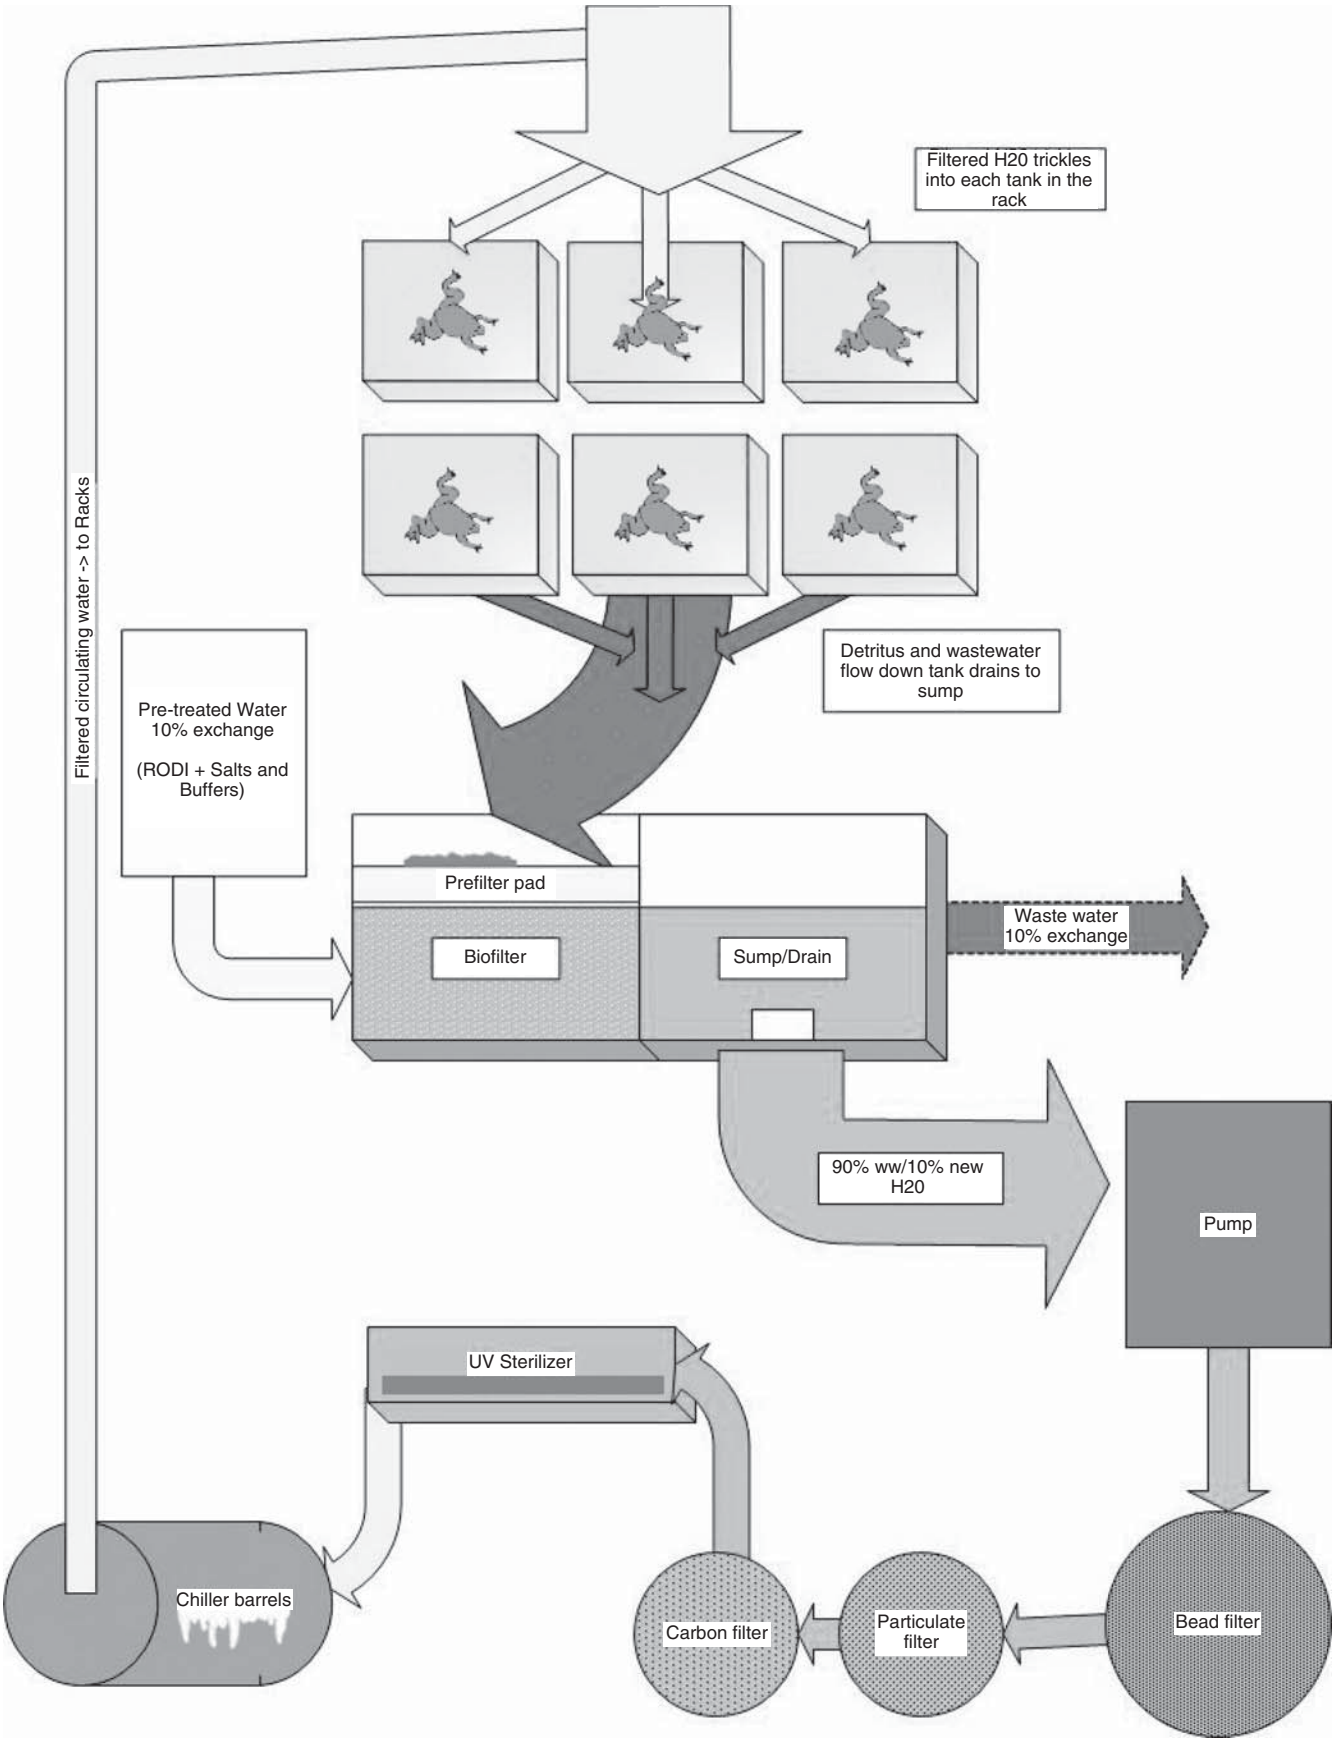

Figure 17–2. Schematic of water flow through the X-MOD system The water flow through the X-MOD system starts with the system pump, which drives water through the bead filter, the particulate filter, and the carbon filter, to thoroughly remove large particles and contaminants. The water passes through the UV sterilizer and the chiller barrels. The tanks are designed so that water is gently drawn toward the center of the tank pulling in debris and flushing out of the tanks down the pipe. The pipes are all connected and wastewater from the tanks ends up in the sump. A prefilter pad catches large particles.

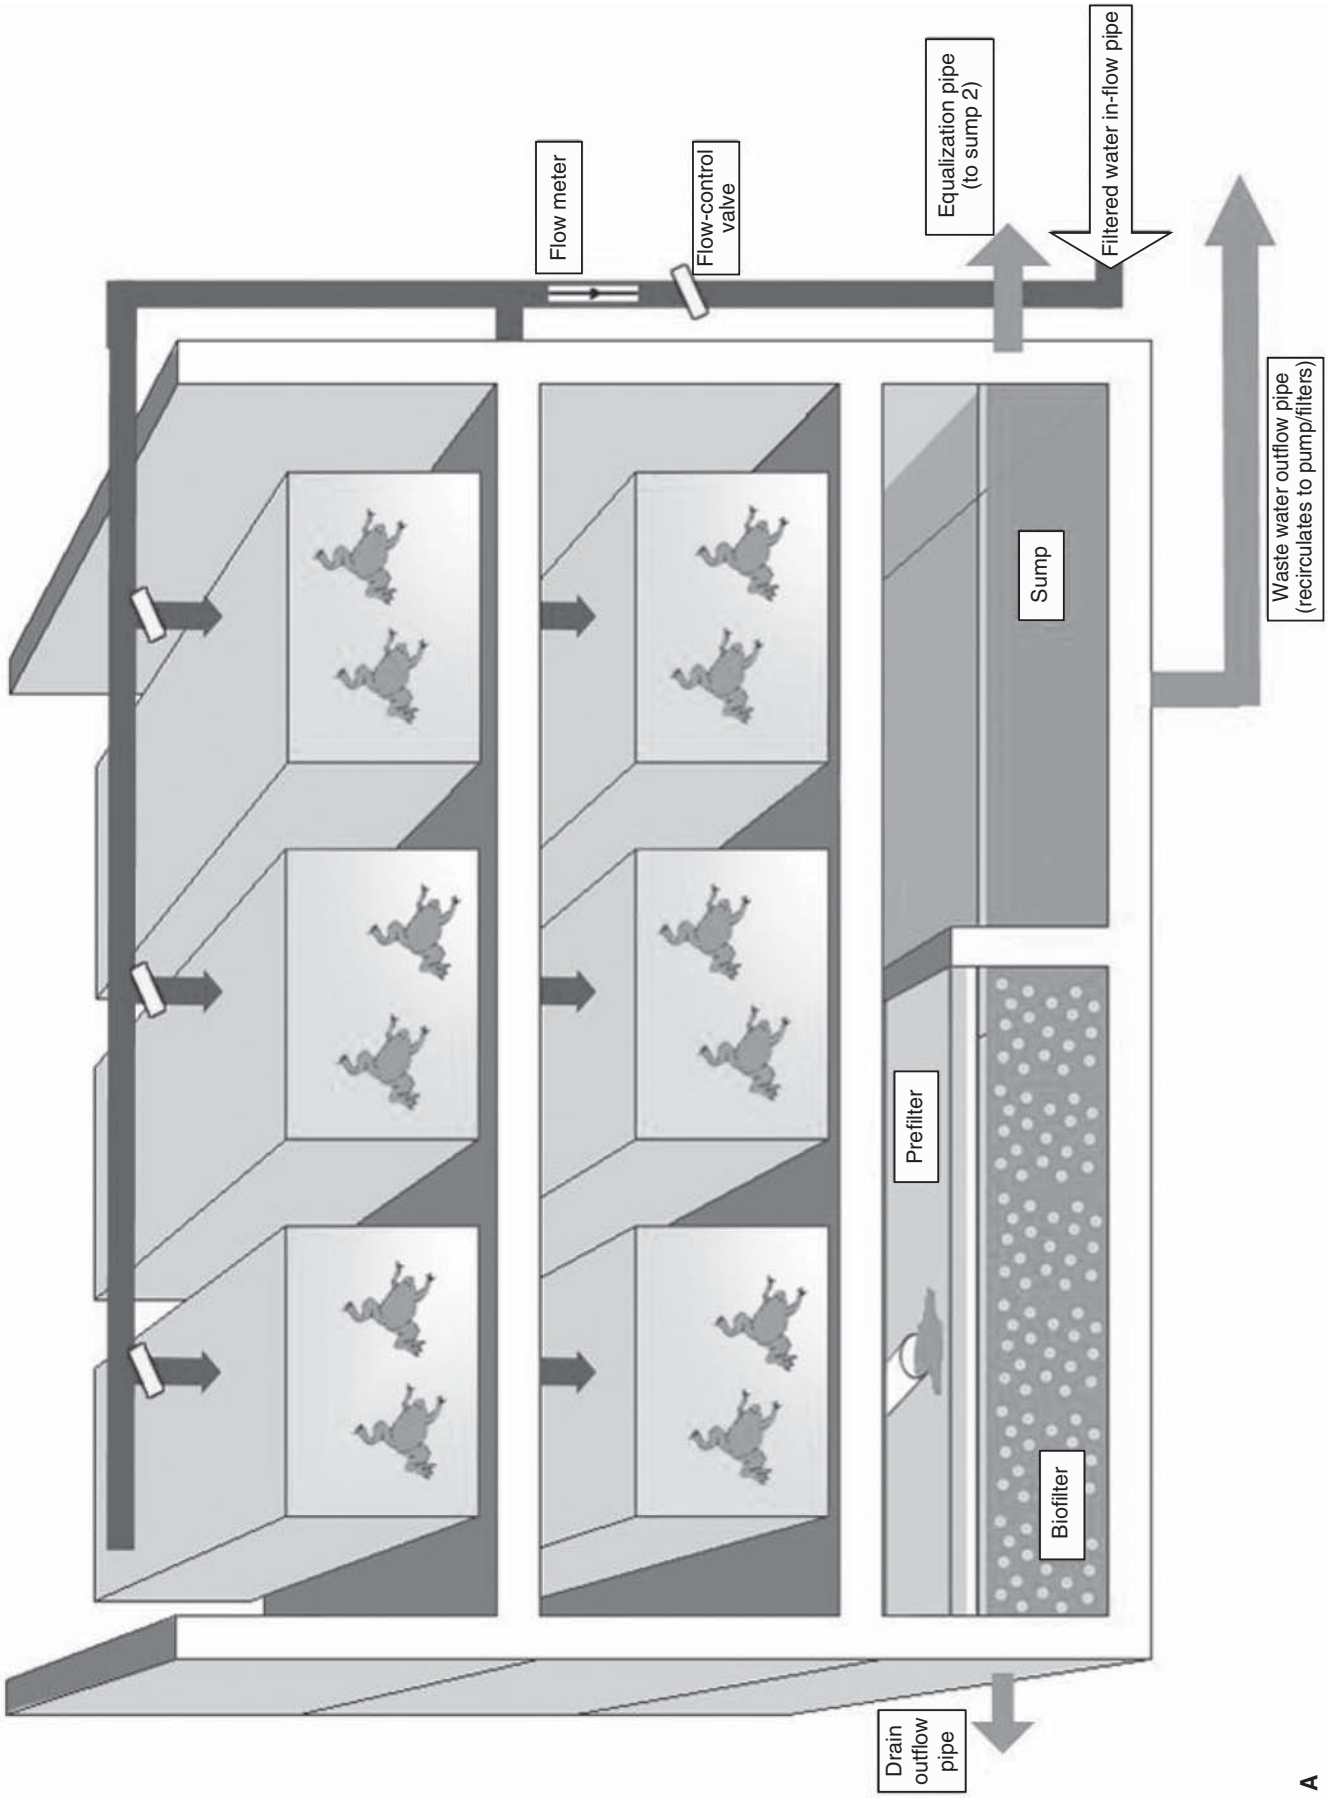

Figure 17–3. (A) Diagram of a single rack This schematic depicts how the racks are designed to hold frog tanks and circulate water. Water is pumped up the vertical pipe, into each tank, and then flows down into the sump, passing over the prefilter and biofilter. Wastewater flows back through filtration, out the drain overflow pipe, or to the other rack's sump to equalize the water level.

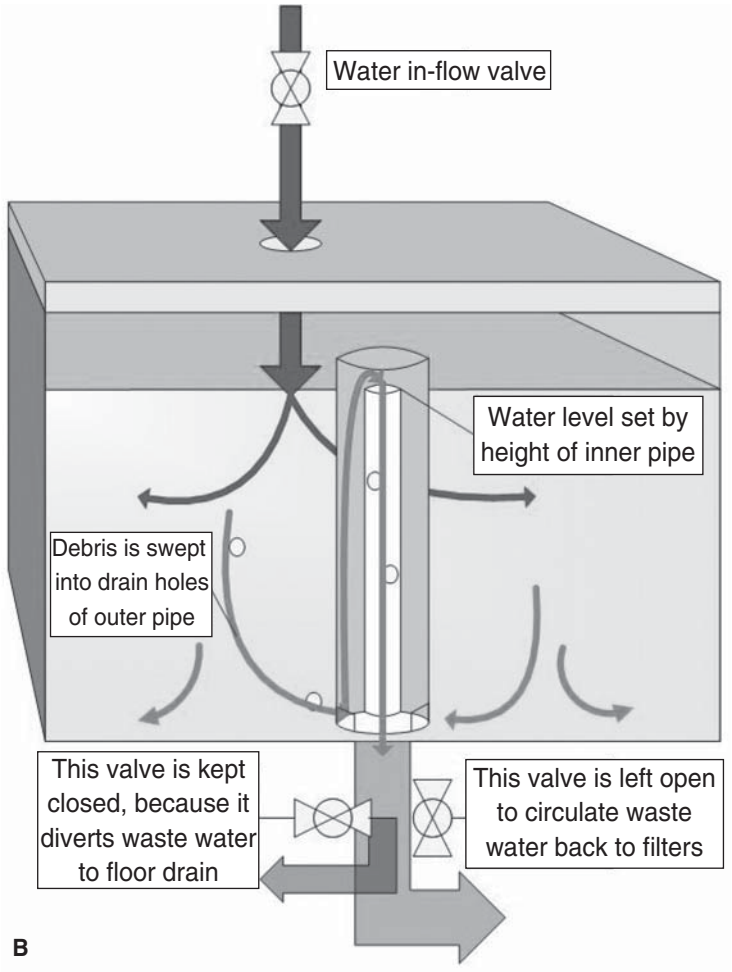

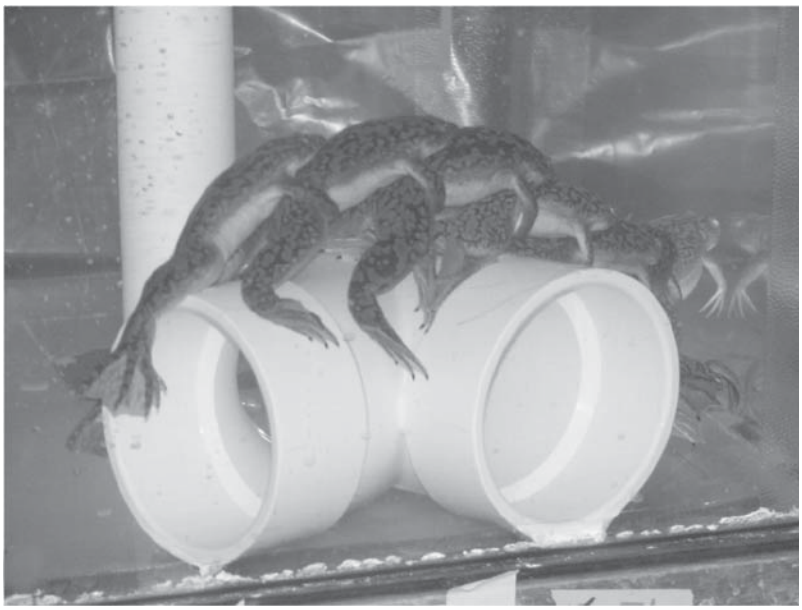

Figure 17–3. (continued) (B) Diagram of an individual tank (A). This diagram illustrates the design of each frog tank. Water pressure from the pump forces water into each tank, as controlled by the water in-flow valve. Excess water flows into the holes at the base of the outer pipe, and drips down the drain inside the inner pipe. The current created from the water flow draws wastewater and debris. (C) A chain of male frogs sitting on top of a PVC tube provided for enrichment.

Figure 17–4. Photo of a biofilter with Kaldness media The tank on the left contains Kaldness media or "bioballs" made of PVC. The bioballs provide adequate surface area for the growth of beneficial bacteria. The particles in this biofilter are continuously aerated by a powerful air pump. The tank on the right is one of the sumps, and the wires are connected to the WebDaq probes that continuously monitor water quality.

bead filter break up debris, assisting with the mechanical filtration component of the system, but it is also a major part of the biological filter. The Perma-Beads™ in the bead filter provide surface area for the bacteria to colonize and are almost indestructible. They have a unique oval shape that keeps water flowing and reduces clumping while breaking up debris and breaking down toxins. Most of the nitrification takes place in the bead filter. Often this bead filter will become loaded with frog waste material, so it is important to constantly monitor the pressure and backwash if it exceeds the proper pressure rating. In the absence of a pressure gauge, backwash after feeding or at least three times a week to keep the beads fluid and keep water flowing throughout all filter components. Follow the individual manufacturer's instructions if purchasing a bead filter from anyone other than Hayward Pro.

The particulate and carbon filters are the final step in mechanical filtration (Figure 17–5B). Together these filters remove smaller particles (particulate filter) and any colors or odors (activated carbon) as they exit the bead filter. These filters require changing at least once a month, or whenever there is a significant rise in pressure. A decreased flow rate through the frog tanks could indicate the need to change the particulate filter. When changing the particulate and carbon filters, turn off the pump and close the pump intake valve. Open the waste drain valve to drain the particulate and carbon filters. If using a CFR50 model, unscrew the valve on top releasing the pressure inside the chamber. Holding the yellow lever down, unscrew the large plastic band, firmly grip the lid, and pull it off. Once the chamber is open, slide the filter out to remove and replace it. When finished, reassemble the chamber, open the water valves, start the pump, and be sure to check for leaks. To service filters other than the Jacuzzi CFR50 free-standing carbon filter follow the manufacturer's instructions to properly remove and replace the filter.

The final filtration step is a 40-W sterilizing ultraviolet (UV) bulb, with an intensity of 100,000 $\mu W \cdot sec/cm^2$. The UV light targets any microorganisms circulating in the system water. When servicing the unit, inspect the O-rings and seals for degradation and promptly replace worn parts. Follow the manufacturer's instructions concerning changing the bulb. In this facility, the bulbs are changed annually. Be sure to use gloves when handling

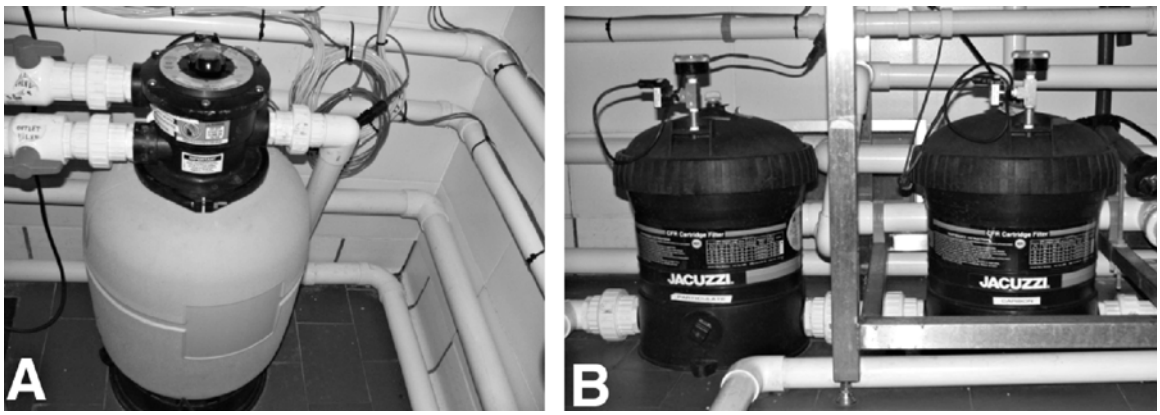

Figure 17–5. The filters. (A) Bead filter; (B) particulate filter and carbon filter with pressure gauges.

the UV bulb and quarts sleeve. Any residue or dirt left on the bulb will reduce the effectiveness of the UV sterilizer. Always have an extra supply of quarts sleeves and a UV bulb in stock in case of an emergency.

The water leaves the UV sterilizer and passes through the chiller barrels, cooling the water before entering the tanks. Temperature in our facility is maintained between 17.0˚C and 18.5˚C. Although these frogs can tolerate a wide range of temperatures, keeping the water at 18.0˚C will ensure excellent egg quality[29] and healthy frogs. The X-MOD system is equipped with a chiller to maintain water temperature, which results in good egg quality throughout the year (avoiding the "Summer downtime" seen in many *Xenopus* laboratories). Our chiller system uses a combination of outdoor air supplementation as well as conventional refrigeration. An outdoor air-cooled chiller regulates water temperature in the winter and a mechanical water-cooled chiller controls it in the summer. This "hybrid" system saves energy and reduces wear on the chiller barrels. We set a 1˚C temperature differential between the activation settings on each chiller. The primary chiller remains active at 1˚C above desired temperature, and the backup chiller activates only if the temperature rises an additional degree or the primary chiller malfunctions.

WATER QUALITY

Water is the main determinant of health in the system. When building a facility, the main concern is to avoid distress and disease; investing in a polishing system exclusively for purifying incoming water for the frog facility is imperative.[30] Our institution provides the building with reverse osmosis deionized (RO-DI) water by passing municipal water through a series of sand, carbon, reverse-osmosis, and deionization membranes. The RO-DI water is held in a large storage tank on the roof of our building. Although this water is RO-DI and appears pure, there are many sources of contamination in the old pipes that can change the quality of the water needed for the facility. Public water systems in the United States use chlorine and/or chloramine as a disinfectant. Chlorine can be removed by aerating the water, but chloramines are persistent, requiring either chemical agents or carbon filtration for neutralization. Chloramine is a combination of ammonia and chlorine, and can directly enter the bloodstream of aquatic animals, slowly poisoning them. If you choose to use chemical neutralizing agents, you must monitor both ammonia and chlorine levels as each are released into the water after chloramine breakdown. There are many other dissolved substances with unknown effects on water chemistry that can impair the health of the colony. These substances include metals, minerals, dissolved gases, and organics, to name a few. Only a well-maintained water purification system will be able to effectively remove these harmful substances.

A resistivity meter displays the purity level of the water as it is drawn into the facility from the building's supply. The reading varies anywhere between 5 and 20 megohms (MΩ) and changes throughout the day. These readings are not consistent and indicate the variable presence of unknown dissolved ions and chemicals in the water flowing through the pipes to the facility. One major concern is that buildings' RO-DI systems are periodically flushed with harsh sterilization chemicals, which could contaminate the frog water and cause problems that are impossible to trace. The institutional RO-DI water is sterilized by the dedicated polishing system. This ensures that there are no contaminants introduced to the holding reservoir.

The frog facility's polishing system (Figure 17–6) consists of an activated carbon tank, a resin tank, two ultraviolet sterilizing lamps, and an ultrafilter cartridge. When the frog facility is not actively drawing water, the purifying system continuously recirculates in a loop so that there are no stagnant water pockets in the

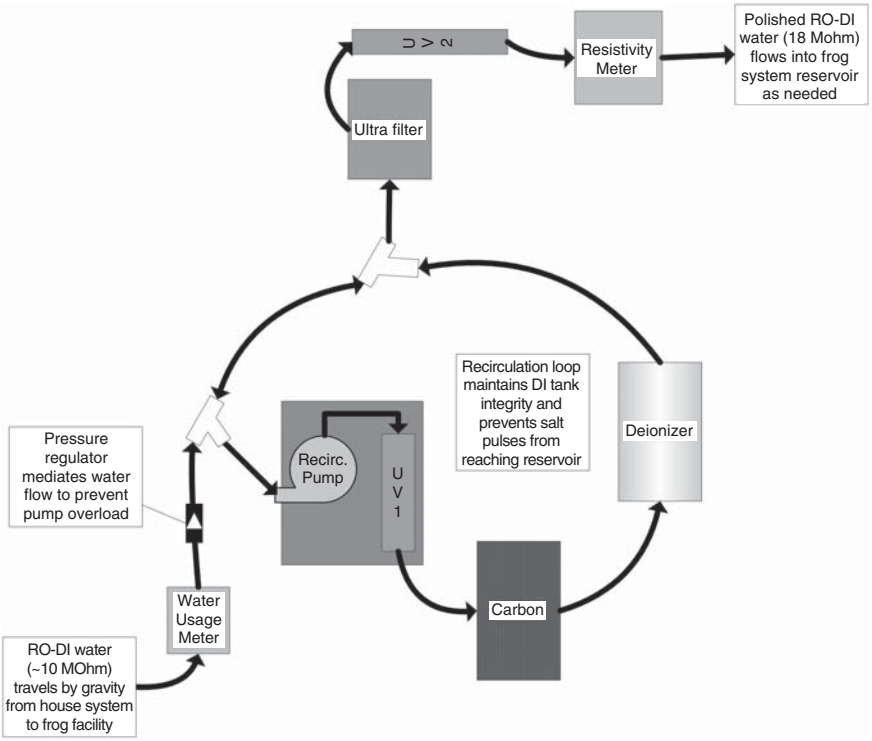

Figure 17–6. Schematic of a water polishing system The polishing system is necessary to purify water before it enters the holding reservoir. It is imperative to maintain the highest quality and standard of water. The water that is gravity fed to our facility from the building's water system on the roof passes through the water-usage meter, which records the amount of water entering the frog system in gallons. The water is driven by a small pump, through a UV sterilizer and a carbon tank, and then finally deionized as it passes through a resin tank. The water keeps recirculating through this loop until it is drawn into the frogwater reservoir as needed. As soon as the level in the holding tank drops (when it is drawn by the system for a daily 10% exchange), water is drawn through a UV sterilizer and "ultrafilter" trapping bacteria/particulates before filling. A resistivity meter was installed to monitor this system and to ensure the water is ~18.0 MΩ before entering the reservoir.

two tanks. When the water is ready to be drawn, it passes through the ultraviolet (UV) sterilizer and ultrafilter as a final step in purification. Measuring the resistivity is necessary to ensure consistent water quality. A meter measures the resistivity (a measure of purity, ideally 17.75 MΩ or above) at the last point before water enters our holding tank, ensuring ultrapure water for the system. The holding tank or reservoir has a KENT® float valve at the top that regulates the water level of the polishing system. When the reservoir is full, the float valve is horizontal and automatically stops filling until the level drops. The polishing system is always on, running to fill the reservoir on an as-needed basis.

After the incoming water passes through the polishing system, ultrapure water is drawn into the 90-gallon frog water holding reservoir that is manually dosed twice daily with salts and pH buffers. Since this reservoir is dosed by hand and not a sealed system, it is exposed to airborne materials and pathogens. To avoid contamination, the reservoir has its own circulating pump with a 1-μm particulate filter and UV sterilizer. We advise obtaining as large a tank as your space will allow: the more system water that can be replaced when necessary (e.g., when the building water supply is shut off), the easier it is to weather emergencies.

Individual components of the polishing system and their functions are as follows. (1) Activated carbon tank: with a porous surface for trapping organics and attracting charged articles, the activated carbon also removes chloramines. It is essential to protect the integrity of the RO membranes, which are susceptible to chlorine oxidation and clogging from organics. (2) Reverse osmosis deionization (RO-DI): RO-DI is the standard practice for producing reagent-grade water. Reverse osmosis is a process of forcing water against a tightly coiled semipermeable membrane at high pressure. The membrane allows only water to permeate its tiny pores, causing particles to be rejected when they cannot pass through the mesh. Deionization removes dissolved inorganics and gasses using a mixed-bed ion-exchange process. (3) Ultrafilter: the ultrafilter, the final filter on the polishing system, removes bacteria and pyrogens by trapping particles including microorganisms, their by-products, and organics from 10,000 MW to 100,000 MW. (4) Ultraviolet bulbs: a UV sterilizer at a wavelength of approximately 254 nm is sufficient to penetrate cells, damaging genetic material and proteins. Any bacteria or other pathogens present in the water will be destroyed or damaged by the UV filter. (5) Recirculation pump: the recirculation pump on the polishing system should always be running and maintaining a consistent pressure (PSI). Sometimes the PSI will drop when the polishing system is actively drawing water. Keeping the water circulating at specific pressure and rate maintains the integrity of the mixed bed DI tank and prevents contamination.

Service contracts are provided by the RO-DI system supplier. Service contracts must include routine maintenance of the pretreatment system (Table 17–7). A good service contract provides annual scheduled maintenance, including details on emergency repair costs. A list of equipment and replacement parts and maintenance information for the facility manager and technicians (monitoring and reporting system performance) should be reviewed before signing any contract. Since there are many unpredictable events that can happen in aquaculture, necessary steps need to be put in place to ensure that the polishing system is performing optimally. In our experience it is imperative to keep an eye on water system personnel working in the facility because many of them are not sufficiently experienced and/or sensitive to the needs of an animal habitat and can make mistakes that endanger the colony.

Table 17–7
Maintenance schedule

Daily checklist
Survey tanks for sick frogs
Flow meters at 6 gallons per minute
UVs on
Water meter pH/ORP compartment full and plugged
Air is being pumped through biofilter media
Water flowing into each tank
Polishing system resistivity is ≥16 MΩ/cm
Fill out system maintenance and daily water quality records
Adjust water quality as needed
Change prefilter pads if necessary
Tuesdays and Fridays
Feed frogs
Clean up after feeding
Check filter pressure gauges
Once a month
Clean particulate filter
Every other month
Change carbon
Every 3–4 months
Scrub out drainage tubes in each tank
Scrub tank interiors if dirty
Clean open areas in biofilter mixing tanks
Every 6 months
Clean quartz sleeve on UVs
Open bead filter and clear compacted beads/flush
Schedule semiannual maintenance on polishing system
Once a year
Change UV
Clean enclosed biofilter mixing tanks

Typically, UV lights, UV sleeves, the ultrafilter, RO-DI, and carbon tanks all require semiannual replacement. To keep the pump from running the UV filter dry, prevent any air from entering the RO-DI piping and make sure water levels do not fall below the intake of the pump. Another important way to safeguard against water contamination is by monitoring and recording the resistivity reading of the RO-DI water filling the reservoir on a daily basis. Any significant drop in resistivity indicates loss of purity and should be reported to the supplier immediately.

X. laevis has a life span of up to 20 years. Daily monitoring of water quality and proper conditioning will prolong the life and health of the frogs, keeping the facility thriving for many years. The main water testing parameters are temperature (air and water), pH, GH (general hardness), ammonia (NH_3), nitrate/nitrite, oxidation–reduction potential (ORP), and conductivity (μS). Although *X. laevis* can tolerate a wide range of salinity and pH, drastic changes in water chemistry are detrimental to its health, causing stress as well as bacterial and fungal attacks. Proactive measures should be taken to prevent fluctuations in water chemistry and provide frogs with excellent water quality standards that do not deviate from the designated parameters.

Table 17–8
Daily salt and buffer use and costs[a]

Add	*Concentration*	*10% exchange*	*Unit size*	*Cost*	*Ex/U*	*$/U*
Ocean	0.6 g/liter	90.6 g	11.3 kg	$34.99	124	0.28
CLS	0.4 g/liter	60.4 g	3.2 kg	$42.99	52	0.83
ES	0.067 g/liter	10.1 g	600 g	$7.19	59	0.12
Alk	0.325 g/liter	49.1 g	1 kg	$14.99	20	0.75
Ac	0.325 g/liter	48.9 g	1 kg	$14.49	20	0.72

[a]Cost per exchange = $2.70. Cost per month = (Ex × 30) + (afternoon salts × 30) = $81 + $36.90 = $117.90/month.

In the beginning, the additives that were used for the frog water in this facility were a combination of Marine Biotech's Sea Salt, along with $NaHCO_3$, to maintain the pH levels in the system water. This did not work well because it was difficult to strictly monitor parameters since we did not know what was in the Marine Biotech sea salt blend. It was also difficult to keep the pH in range because the sea salt that was used had additives that often increased the pH in the system and made it difficult to control since the sodium bicarbonate increases the pH. Instant Ocean salt components include calcium, magnesium, carbonate, and other trace elements needed by *X. laevis*, such as sodium chloride, iodide, bromide, and strontium. To increase GH and provide minerals, we supplement with Seachem Cichlid Lake Salt (CLS) and Seachem® Equilibrim salts to maintain hardness within 200–400 ppm. The protocol was changed to include SeaChem® buffers after reviewing the data in Godfrey and Sanders.[31] Their data showed that water hardness increases egg quality and is necessary for normal development of embryos to tailbud stages. Using Cichlid Lake Salts® in combination with the Instant Ocean® gives the proper salinity and trace minerals needed for *X. laevis* without affecting the pH. After changing our water chemistry protocol there was a noticeable improvement in water quality; the eggs were firm, and fewer incidents of illness were noted in the colony. Temperature, salinity, and water hardness (GH) all work together to maintain excellent water quality, health, and normal development of embryos. Guidelines for adjusting water chemistry are given in Table 17–8.

DAILY WATER CHANGES A 10% water change automatically occurs in the facility every day, at a designated time. An automatic timer controls a solenoid valve that is attached to the holding reservoir circulation loop. The solenoid valve is a two-way valve with an electromagnet that is triggered when the timer turns on, opening the valve. The valve stays open for 35 min draining water from the reservoir into sump 1, the approximate time needed for 30 gallons to exchange. The timer automatically shuts off, closing the valve. At 12:00 PM each day, the valve, which is operated by the timer, opens and clean frog water flows into sump 1. At the end of sump 2, there is a PVC pipe overflow drain that pushes the water out of the system when the water level rises. By adjusting the parameters of the water content in the holding tank, it is possible to ensure the gentle regulation of water quality and maintain strict water quality in the main facility, so that the frogs are always in good health. This helps discourage outbreaks that easily erupt if there is stress in the system. It has been observed and stated that wild *X. laevis* can withstand a wide range of salinity and pH; however, this is not necessarily true for laboratory frogs as they live in a clean environment where a certain range of salinity and pH should be maintained in the absence of unknown ecological components that may provide beneficial environmental buffering in the wild. Changes in pH, salinity, and even mineral deficiencies induce stress, making the animals susceptible to infections and parasites. Like all aquatic species, *X. laevis* is sensitive to changes in water quality and has an optimal range of conditions conducive to its survival and the survival of its offspring.

FROG FACILITY MONITORING

MANUAL MONITORING Trained technicians manually monitor the frog facility twice per day, checking frog health, water quality, and mechanical functionality of system components. System checks of pumps, UVs, filter pressures, temperatures, and water chemistry are necessary as a preventive measure (Table 17–9; Table 17–10 gives some sample readings in our facility over several days). The technicians dose the reservoir with appropriate salt and buffer ratios for the daily water exchange based on water readings in the holding tank and main system. Water chemistry is recorded for chlorine/chloramines in the reservoir periodically to make sure that the polishing system is performing properly. A consistent and disciplined monitoring schedule is essential to prevent disasters. The data should be kept and plotted in Microsoft Excel to show variations and provide records that can monitor long-term trends and other sources of potential problems.

TESTING EQUIPMENT AND PARAMETERS TO BE MONITORED We keep track of the following parameters, in both the

Table 17–9
Checklist for the facility monitoring

Temperature check
Air temperature
Water temperature
Pressure check: check for problems and leaks
Bead filter pressure (do backwash if pressure is greater than 20 psi)
Carbon pressure
Polishing system pump pressure
Water usage
How many gallons/liter per day? Record water usage
Tank water flow
Maintain 5 GPM?
Equilize individual tank flow: gentle water flow?
Check Air Pump
Bioballs being aerated?
Check UV sterilizers
Are they all ON?

holding tank (to make decisions about how much salt and buffer to add) and the system itself. It is important to keep separate beakers for taking water samples for manual measurements from the holding tank and the main system, to avoid contaminating the holding reservoir with system biota. Resistivity (MΩ/cm) is a measure of opposition to electric current flow and is directly related to the purity of the water. Optimal RO-DI water should range between 16 and 18.2 MΩ/cm. The resistivity of the water entering the frog facility and polishing system product water should be monitored using in-line digital meters. Conductivity (µS) is the inverse of resistivity, measuring the water's ability to carry an electric current, and is used to measure the salinity of system water. System water in this facility is maintained within a pH range of 6.5 to 6.7. At a lower pH ammonia is less toxic and egg production and quality are improved. Godfrey and Sanders[31] observed that the *X. laevis* populations that live in acidic lakes of South Africa were thriving compared to the higher pH lakes.

Dissolved oxygen (DO, measured in mg/liter H_2O or percent saturation) is a critical parameter in the recirculation system.[32] Low DO (usually caused by decaying material) can stress out the animals as well as deplete aerobic bacteria from the biofilter causing nitrite and ammonia spikes, eventually killing the frogs. High DO can cause irreversible stress to the frogs, especially if they are exposed to supersaturated water. Safe ranges to maintain are between 30% and 70%. Levels over 90% will cause serious injury and death, as O_2 supersaturation causes gas bubble disease in the animals.[29] Supersaturation can be caused by an air leak before the intake of a pressurized pump. Even a hairline fracture can draw in enough air at an alarming rate by a Venturi effect. Air is drawn into the pump and at that pressure it dissolves into water and in minutes the system becomes supersaturated. Animals will appear listless, disoriented, and start to float. Many will start to die unless they are immediately transferred to new water. Air bubbles will enter their blood and their organs, potentially killing them before the problem is apparent. A DO meter or dissolved gas probe is an important investment to make for a facility.

ORP is a measure of the potential of a solution to either gain (oxidation) or lose (reduction) electrons. This is also a very important parameter to measure because it is an indicator of how well the water remains buffered (activity of ions) and of how well balanced the proportion of ions and minerals is in the system. Keeping the ORP in range keeps contaminants from fouling the system. Usually a rapid change in ORP is an indication of poor water chemistry. Normal ORP for a frog facility ranges between 100 and 300 units.

Temperature is maintained between 16.5 and 18ºC for optimal egg production. We monitor the temperatures of the following components: the two chillers (with digital thermocouples), sump 1, recirculating water (with a digital thermometer), and air temperature in the room (with a digital thermometer). Variations

in temperature related to seasonal changes in water and air temperature can drastically affect embryo quality and give rise to the well-known "Summer slowdown" experienced in some facilities.

Water level is topped off by KENT® float valves in sump 1 and the frog water reservoir. This water top off system is automatically controlled by changing the water level in the system. When the sump water level drops, the float valve position changes and starts to refill with water from the reservoir tank. The reservoir has the same float valve that is connected by a 0.5-inch pipe that draws water from the polishing system. As water evaporates or is lost from the system (during cleaning, etc.) it is automatically replaced. As an additional safety measure, float sensors placed in sump 2 indicate high or low water levels and are attached to the remote monitoring system (see below). In addition to this we have other float sensors that actually have audible and visual alarms that go off if the water gets low enough to allow air into the pump intake. Water pressure is monitored by pressure gauges on the bead, particulate, and carbon filters. These gauges are useful for diagnosing filter blockages and for alerting us of pump failure over the Internet through the automated monitoring system.

A Myron L ULTRAMETER® is used to measure all conductivity, pH, and ORP. Meter calibration should be done weekly to ensure accuracy. Follow the instructions for the pH calibration solutions from Myron L. In addition, we regularly use chemical Aquarium test kits to compare with the Myron L readings.

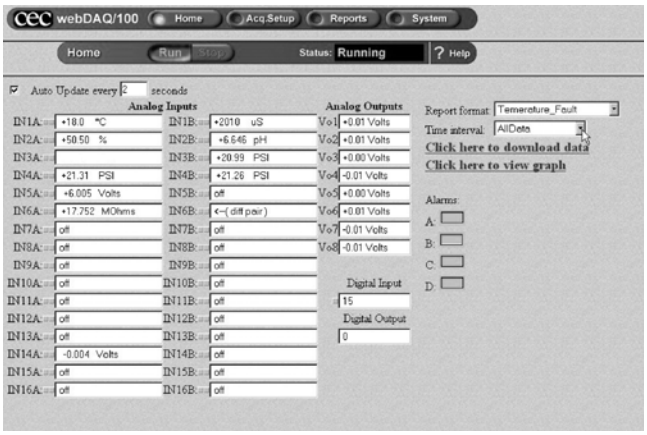

Figure 17–7. Screenshot of WebDaq monitoring system output This is a screenshot of real-time WebDaq information seen through a web browser. Various probes and gauges are connected to an embedded server that measures and records water quality parameters in the frog facility. The analog inputs correlate with probes in the frog facility. For example, "IN1A" is the analog input that is connected to the temperature probe in the sump and always shows the current water temperature. IN1B is connected to the conductivity probe, which is currently reporting the salinity in µS. Analog input "IN2B" is the pH probe. To visually keep track of what probes are linked to the inputs on the WebDAQ, we have included the units in the display. Notice the "click here to download data" and "click here to download graph" links. The download data link allows for instant downloading of text data of the desired report in a set number of time intervals. The download graph link displays the data, through Java Machine, in a customizable graph. These tools, and others of the WebDAQ program, ease and enhance remote monitoring of the facility.

REMOTE MONITORING SYSTEM While a *Xenopus* facility requires attention and close monitoring throughout the day, it is usually not possible for most laboratories to maintain staffing in the overnight hours and weekends or holidays. To ensure that a situation does not get out of control and cause a major disaster, the FCRDB utilizes a *WebDAQ*© device to automate remote monitoring of the water quality (conductivity, pH, ORP, resistivity, temperature, and pressure). The *WebDAQ* is a self-contained wall-mounted system that contains inputs to which many different probes and sensors can be connected, and an embedded web server that provides these data in real time to any internet browser (Figure 17–7). *WebDAQ*'s monitoring capabilities include a variety of customizable reporting and alarm formats. The facility staff can be emailed any time a water quality parameter exceeds or falls below an acceptable range or when there is a change in pressure or water level. *WebDAQ* also stores these data so that trends and readings prior to a critical event can be examined later. Thus, *WebDAQ* provides two services: remote monitoring and recordkeeping. An uninterruptible power supply (UPS) is useful to ensure that the WebDAQ can send a message in the event of a power outage.

In addition to the *WebDAQ*, the FCRDB uses a webcam that allows visual monitoring of the facility at any time (the *WebDAQ* allows us to remotely turn on a light if it is necessary to see the facility when the overhead lights are off at night). If there is an emergency email, such as a low water alarm, it is important to be able to assess the situation remotely by checking the webcam to see if, for example, a blocked pipe is causing a tank to overflow or if the system lost a large volume of water. This has been a "lifesaver" for our facility and the investment and time taken to install these components have averted many calamities.

RECORDKEEPING Recordkeeping is crucial to tracking the performance of your frog facility as well as diagnosing problems and long-term trends. Below is a brief description of the parameters to document frog colony conditions (sample forms are given in Table 17–11 and 17–12, frog tank labels in Table 17–13, and frog identification systems in Table 17–14).

Water chemistry and facility maintenance: Water chemistry and support system conditions should be recorded daily: twice daily for water chemistry and once for other system parameters. These records are crucial for correlating environmental conditions with egg quality and frog health.

Quarantine/incoming frogs: New frogs are quarantined according to procedures described in the section on Disease. Quarantined animals are placed together in an isolated tank that is clearly labeled "Quarantine through mm/dd/yy." A treatment schedule is

posted on the tank, and facility managers are required to initial the dates as they are completed.

Sick/euthanized frog log: Any frog that is isolated for treatment of illness or euthanization should be noted in the sick frog logbook. Documentation includes date of isolation, date of last use, frog size (body length), a description of the symptoms and condition, original tank number, and treatment type, dose, and dates. See the section on Disease for further details.

SYSTEM MAINTENANCE

Frog facility maintenance requires proper communication with facility staff and well-written service contracts with outside vendors. The following are periodic maintenance tasks that must be performed.

RESERVOIR STERILIZATION Despite the purity of the polished water supplied to your reservoir, you should periodically examine the reservoir for buildup or biofilm. A product called Minncare® Cold Sterilant, a peracetic acid solution that removes biofilms, is a widely used product to sterilize RO membranes. Follow the instructions for sterilizing RO units and be sure to rinse the reservoir several times. Keep the room well ventilated and follow the safety guidelines. This is a nontoxic and biodegradable product, but it emits fumes. Minncare® decomposes into oxygen, water, and acetic acid, and test strips are available to check for residue after rinsing.

Table 17–14
Frog identification systems

The following identification system resources were gathered from literature and suggested on the *X. tropicalis* listserv.[a]

We do not use any tagging procedure, so caution is strongly advised and no one system is advocated by the authors.

1. *Tattooing* involves the marking of frog skin with different colors and patterns of tattoo ink to identify individuals. Tattoos often fade within a few months.
2. Branding utilizes heat, cold, or chemicals to mark frog skin. A few respondents reported that cold-branding can last several years.
3. *Chip embedding systems* require skin incision or injection of a radio-signal microchip transponder that can be accessed by placing the tag reader over the animal.
   a. AVID labtrac system:
   http://www.avidid.com/special/index.html
   b. Biomark PIT system:
   http://www.biomark.com
4. *Tag embedding systems* utilize magnetized coded wire tags (CWT) or visual implant alphanumeric tags (VI-alpha) that are embedded in the tissue of the animal. One source is Northwest Marine Technologies CWT and VI-alpha systems: http://www.nmt.us/.
5. *Bead identification* involves the sewing of a small plastic thread behind the armpit, with different colors and combinations of beads.
6. *Skin grafting* uses transplantation of different shaped, colored, and sized skin grafts from the ventral to dorsal surface of the frog to uniquely identify it.
7. *Toe clipping* involves cutting off the tips of toes in codified combinations. This technique may not work effectively since *Xenopus* can regenerate the clipped toes.

[a]*X. tropicalis* listserv, post thread "frog identification system" from May 2004: http://faculty.virginia.edu/xtropicalis/newsgroup.html.

MAINTAINING PUMPS Electrical pumps generate heat during their operation, so it is important to keep airflow unobstructed. Inspect pump air intakes monthly for dust buildup to prevent overheating. The water-driving pumps (for the reservoir, recirculating system, and polishing system) can function only with an uninterrupted supply of water. If air enters the flow, or if a flow valve is closed before or after the pump, you may damage the motor. To reduce noise pollution, cushion the pumps on a bed of heat-resistant neoprene to dampen vibration.

MAINTAINING CLEAN FILTERS AND SUMPS Filters require regular monitoring and replacement to maintain clean water. Prefilter pads should be changed three times a week: Mondays and after feeding on Tuesdays and Fridays. If you neglect to change them debris will flow off the pad and into the biofilter. The biofilter should be cleaned only if a noticeable amount of debris has collected on the bottom of the sump. Once a year shut off the air pumps, remove the prefilter assembly, and carefully siphon out the debris making sure you do not remove any Kaldnes® beads in the process. The open portion of the sump can be cleaned every 3 to 4 months using a siphon. The bead filter requires regular backwashing to prevent the beads from being compacted with debris. In a healthy system the bead filter should be backwashed once a week. Every 3–6 months, open the bead filter to manually stir up the compacted beads with a thin PVC pipe to prevent buildup. The particulate filter must be changed at least once a month, or whenever there is a noticeable drop in pressure from the bead to the particulate. The carbon filter should be replaced with fresh carbon every time you change the particulate. Thoroughly rinse the new carbon to remove excess dust before placing the cartridge back in its housing.

To clean the biofilter tank, gently wipe down the sides with Python® mitts or any other kind of algae scraper. We use a gravel vacuum to suction all of the large debris from the bottom of the system sump. This process requires a 25% water change from the system. Carefully monitor and alter water chemistry as needed while the replacement water flows in.

ULTRAVIOLET STERILIZATION BULBS All of the UVs in the facility should be examined, with gloves, every 6 months for buildup on the quartz sleeves. If the sleeve is dirty, clean it with KimWipes® dipped in isopropyl alcohol. If there is residue on the bulb, or the bulb is discolored, it should be replaced. Generally, most manufacturers advise that UV bulbs should be replaced once a year. UV bulbs contain mercury and therefore legally must be disposed of as hazardous waste. When returning a bulb to its housing, check that the bulb and sleeve are completely dry and that the gasket is properly positioned to prevent leaks.

ROUTINE CLEANING OF EACH FROG TANK Once a month, remove both drain tubes and scrub them out, without using detergent. Never use any soaps or cleaners of any kind when cleaning the tanks or the pipes of the recirculation system. Invest in a few dozen bottle brushes of various sizes and use one brush per tank to avoid cross-contaminating with other tanks. Clean the outer tube first, then replace it and clean the inner tube, leaving one of the two tubes as a cover on the drain to prevent frogs from being sucked into the pipe drain. Frogs will instinctually swim with a current, so they will try to head down the tube and could get stuck. The vinyl inflow tubing that supplies water to each tank, and flow meters, can be scrubbed out whenever a visible biofilm accumulates. Once a year, if you are comfortable with manipulating the pipes, you can scrub out other elements of the system, including water intake pipes and sump drains. Be cautious when unscrewing the pipe fittings as PVC tends to become brittle over time. Never clean pipes or components of the system with detergents. Contaminating the system with chemical solvents and cleaning agents will poison the frogs and the beneficial bacteria.

After cleaning, soak all of the used items in a bucket with Sanaqua® overnight. Sanaqua® is a concentrated sanitizer and fungicide and should be used sparingly (add 5 drops per gallon until the water is slightly pink with suds). Let them soak overnight. Fill a new bucket with RO-DI water and transfer all of the items to the clean fresh water bucket. Wash each item individually making sure that there are no particles left on the nets or brushes. Wash in RO-DI water, making sure there are no suds or residue left on the equipment. Hang brushes, mitts, and other cleaning tools on hooks to dry.

RECOMMENDED CLEANING AGENTS We recommend avoiding harsh chemical cleaning agents to avoid frog stress and maintain proper water quality. The only chemicals used on a regular basis are Sanaqua® sanitizer and Anti-Chlor chlorine/chloramines removal solution. These solutions are used only for cleaning aquarium equipment such as nets and brushes in 5-gallon buckets. Never use any chemicals to clean any part of the recirculating system. Common cleaning applications include Sanaqua® for nets, sponges, mitts, or anything in contact with quarantined animals; Anti-Chlor for anything in contact with untreated tap water; and finally three rinses in RO-DI water to thoroughly clean off any residues.

FROG HUSBANDRY

Our facility currently houses 200–250 frogs. We have enough frogs to rotate through the months of the year while providing a rest period for each batch of frogs that are used per week. Our laboratory primes about 8–10 frogs every week allowing a "rest period" of 4 months between priming and hugging. The frogs are rotated to different tanks when they are returned to the colony after priming and hugging. The tanks are labeled according to the date at which the frogs are returned to the colony to "rest" for 4 months before they are primed again, so it is important to keep track of the frogs and label the tank appropriately to ensure an adequate rest period of at least 3 months.

Male frogs are kept separated from females in their own tank. When they arrive at the facility, they undergo a 3-week quarantine period in which they are treated for parasites and observed before putting them on the recirculation system to ensure that new parasites do not enter the system.

CYCLING THE BIOFILTER AND ADDING NEW FROGS Beneficial bacteria are responsible for breaking down and nitrifying animal wastes: *Nitrosomonas* oxidizes ammonia into nitrite, while *Nitrobacter* and *Nitrospira* oxidize the nitrite into a less harmful form.[33]

Our facility orders frogs from Nasco®, which is highly recommended over other suppliers. In the beginning, order 15–20 frogs and quarantine them for 6 weeks. During the quarantine, the frogs are treated with levamisole HCl (see the section on disease below). After treating the frogs with salt baths and deworming them with levamisole, check skin scrapings and examine them for scrapes or infection. When they are healthy, put them on the recirculation system. Simultaneously, seed the biofilter media with *Nitrosomonas* and *Nitrobacter* or *Nitrospira* when you add these

frogs, and then carefully monitor the water quality twice a day. We add KoiZyme® at this time to allow a good combination of bacteria colonizing the system. Ammonia and nitrate testing should be conducted daily after adding bacteria to monitor the system biofilter growth. Ammonia, nitrates, and nitrites should be low (<0.1 ppm) in the beginning and then undetectable after a few days. It is a good indication that the nitrifying bacteria are doing their job if ammonia and nitrite test results are undetectable after a week. If the water quality parameters are in range, and there are no mysterious pH spikes, more frogs can be added gradually. Note that the bacteria levels cannot rise without frogs being present in the system (since they need the waste products to thrive); thus, animals and the bacterial colony should be ramped up in parallel.

FEEDING ADULT FROGS Frogs should be fed at least twice a week; some facilities feed frogs more often, however, these frogs have adjusted well to a 2 day per week feeding schedule. A number of diets have been used,[34,35] and in our experience commercial Nasco frog pellets work well. It is better to feed less than overfeed the frogs. *Xenopus* should not be handled after feeding because they will regurgitate their food. The frogs become nervous and stressed, so it is advisable to wait a few hours before cleaning the tank of debris and uneaten food particles. Females should be taken from the colony for priming only on days on which they have not been fed.

When feeding, turn the water supply off. Overfeeding creates excess debris and clogs up filters, so feed less food until it is known how much the frogs will consume in a 15-min time period. Most frogs eat approximately six or seven frog pellets each. Males eat about half the quantity of females and new arrivals usually take a few days to acclimate before they eat. Observe frog behavior during feeding to make sure every animal is eating and behaving normally. As soon as food is dropped into the tank the frogs lunge toward the food making a "shoveling" motion with their forelimbs. Sometimes when feeding, the whole group becomes competitive and can bite each other's limbs in a feeding frenzy. Usually there is no injury and the frog releases its victim after realizing they are missing out on food. In case of wounding, the frog should be removed and treated to avoid bacterial septicemia. After 15 min of feeding or whenever the food has been cleared in the tanks, return the water flow to the tanks.

CLEANING TUBES AND TANKS AFTER FEEDING After 3–4 h, uneaten food and fecal matter will accumulate in the drain tubes of every tank. The outer tube is used to avoid pulling large objects into the drain. The inner tube controls the water level and drain flow. Turn off the incoming water valve and clean the drain by carefully removing each tube (these tubes pop out of their slots) one at a time, blocking the drain hole to prevent curious frogs from escaping. Water drains rapidly when the tubes are removed, so the technician must act quickly. Remove the tubes and return the wider tube back to the drain. While the water drains, gently swirl the smaller tube above the drain to vortex the particles toward the center so that they get flushed down the pipe. Replace the inner tube and securely snap the lid on the tank. Finally, wipe down the PVC grid in the prefilter assembly and replace the prefilter pads. Check and balance the flow to the tanks. Check the pressure gauges and backwash filters if necessary.

QUARANTINE Disease prevention in the colony begins with effective quarantine procedures (Tables 17–15 and 17–16). New frogs entering the facility are generally the major sources of contamination. New frogs should be quarantined for a minimum of 3 weeks in a tank that is closed off from the recirculating system. This tank stays isolated from the rest of the system until the frogs have completed antihelmintic treatments.

REARING TADPOLES The day after fertilization, *X. laevis* tadpoles should be transferred to a clean Petri dish and cleaned with 0.1× MMR (Marc's Modified Ringer's[6]). Embryos should be incubated at 18°C in 0.1× MMR with a pH of 7.8. Like the tadpoles, the eggs need plenty of room for proper growth and development. Clean and observe the embryos every day, removing any dead or dying eggs. Transfer the eggs to new Petri dishes to avoid pathogenic attack.

The embryo will sustain itself off of the yolk for about 5 days, or until about stage 44, which is when they become free swimming (not clinging to the sides of the dish or laying on the bottom). Tadpoles will begin foraging for food with their head facing the bottom. *X. laevis* tadpoles are filter feeders at this stage of their development and will feed on 100- to 150-µm-sized algae and copepods. Split up the tadpoles so that there are 20 tadpoles per dish and start feeding *Spirulina*. Sera® Micron is a good choice because it contains a variety of microorganisms and *Spirulina,* which is an extremely nutritious type of algae. Feed twice or three times a day, making sure that the water is changed at the end of the day. Do not overfeed the tadpoles! Give them enough so that they clear the water in a few hours and then add more if they seem to be panning the bottom. The tadpoles hover at a 45° angle in the water column and feed off the bottom, so it is important to add the Sera® Micron and disperse it throughout the water, allowing it to settle on the bottom. Alternatively, mixing 1 mg/ml of water and then adding this mixture to the dish is an effective method for dispersing food.

Tadpoles can live in the dish for 2 days, at which point they need to be moved to a 4-quart Tupperware® for adequate spacing. Remember not to overcrowd the tadpoles. Cut holes in the lid and keep them covered. They should have at least 500 ml per tadpole and water should be twice as deep as the length of their body. At this point, an air-stone may be used to create circulation and oxygenate the water, but it is not essential since they use their lungs to gulp air at the surface. Slowly start adding NASCO® tadpole powder with the Sera® food at about stage 60[7]. NASCO® tadpole powder provides balanced nutrition, such as vitamin C, calcium, and magnesium, and it is a high protein diet providing the energy required during metamorphosis. During metamorphosis adding crushed pelleted food (NASCO® Frog Brittle) enhances their diet and growth rate. Soak the pellets in 0.1× MMR until they absorb and expand before adding them to the tank. The tadpoles cannot eat the dry powder/food if it floats on top of the water.

Metamorphosing tadpoles and froglets should be fed every other day for optimal growth. Nasco recommends feeding every day if time allows; otherwise it is sufficient to feed three times a week.

WATER QUALITY TESTING FOR TADPOLES It is important to maintain high general hardness (200 dH–400 dH) for the tadpoles because calcium and magnesium deficiencies will cause stunted growth and adversely affect metamorphosis. Again, water quality is the central theme because tadpoles generate large amounts of waste material that can alter the pH rapidly. Ammonia (NH_3, NH_4) is a silent killer that can wipe out all of the tadpoles in a few hours. Since there is no biological filter or biofilm established yet, it is necessary to change their water every day after the last feed. Although many husbandry manuals and

Table 17–15
Frog quarantine protocol

All new frogs must be quarantined for 6 weeks. Do not cross-contaminate with the rest of the colony. Wash your hands after handling quarantined frogs. Disinfect (Sanaqua) anything that comes in contact with quarantined frogs (net, sponge, etc.).

1. Label an empty tank "Quarantine Through __/__" with the date 6 weeks from arrival. Because of the life cycle of the nematode and to ensure that they are eradicated, we quarantine for 6 weeks in our facility.
2. Close off the water inlet and drain the tank to the upper notch (so drain tubes are above water level, about 4 inches). Close both drain valves.
3. Remove frogs from Nasco boxes and place in a "quarantine" labeled 5-gallon bucket filled with fresh frog water.
4. Use a net to remove excess peat moss floating in the bucket.
5. Place each frog, one by one, into the quarantine tank. Be sure to examine the frog for signs of infection or injury (if injured, keep isolated in a plastic container and see Table 17–18: Sick Frog Protocol).
6. Once all frogs have been placed in the tank, replace the tank cover and **do not turn on the water** because the tank will be closed off.
7. Treat the tank with 1.5 g levamisole hydrochloride (dosage 75 mg per frog or 20 mg/liter) overnight in standing water.
8. The next morning, drain the tank using the floor drain valve (the right-hand valve attached to the smaller drain pipe under the tank, **not the system valve on the left**), and refill with fresh frog water. It is beneficial to wipe away any biofilms that have accumulated in the tank(s).
9. Repeat this treatment for 4 days, allow a 1-week rest period, then resume 4-day levamisole hydrochloride soaks.
10. Additionally, frogs should be treated with a salt bath two or three times a week during quarantine. In the morning, weigh out extra "instant ocean." Increase the salinity to 3000 µS.
11. Keep the frogs in the salt bath for 30 min (unless you see signs of stress) and then drain and refill the tank as usual. Stress indicators include reddened skin and excessive movement (trying to escape).
12. Once the quarantine period is over, place frogs in a new tank and label it appropriately. Drain and scrub the quarantine tank (and drain tubes) with diluted Sanaqua and rinse thoroughly. Drain all wastewater into the floor drain (using the floor drain valve).
13. Reopen the system recirculating drain valve, close the floor drain valve, and refill the emptied tank.

Sample schedule

Sunday	*Monday*	*Tuesday*	*Wednesday*	*Thursday*	*Friday*
Week 1		Frogs arrive	Salt bath AM	Levam PM	Salt bath AM

Week 3	Salt bath AM	Levam PM	Salt bath AM	Levam PM	Salt bath AM
			Levam PM		Levam PM

specialists advise against changing all the water, tadpoles in containers without any biofiltration are prone to stress caused by toxic levels of ammonia and nitrite. The same care and vigilance should be taken when raising tadpoles as with caring for adult frogs. Daily water testing, providing essential minerals, and quality nutrition should be standard practices when rearing tadpoles in the laboratory.

Metamorphosis rates differ within the tadpole population. Typically, after around 40 days[7] hind limbs grow and the tail begins to disappear into the body. Tadpoles become carnivorous at this stage and will devour their tank mates, especially the ones that have not morphed yet. Place the froglets into a separate container and continue to feed and check water quality on a daily basis.

TROUBLESHOOTING AND PREVENTING DISASTERS

A number of unexpected events can adversely impact the colony, leading to immediate or long-term delays in egg availability. Disasters are of two general types: specific and immediate electrical/mechanical/plumbing events, and steady-state problems in system parameters that affect frog health gradually.

Table 17–16
Quarantine schedule[a]

	Treat	*Date*	*Initial*	*Treat*	*Initials*	*Treat*	*Initials*	*Treat*	*Initials*

[a]Levamisole (Levam) HCl 20 mg/liter (1.5 g/20 gallons). Sea salt 200 g/20 gallons.

INTERRUPTED OR CONTAMINATED WATER SUPPLY Many problems can affect incoming water quality: bacterial outbreak, gas supersaturation, ammonia spike, etc. If there is a contaminant, the tanks can be closed off and water should be drained out of the system into the floor drain and replaced with fresh water from the reservoir. To save water, the tanks can be filled halfway or just enough so that the frogs have plenty of room to stretch without touching any other frogs. Ideally, the frog facility has a frog water reservoir large enough to be able to replace at least 50% of the water in the system at any given time. Our holding reservoir has enough water to do a 10% water change for 3 days.

PIPE LEAK/BROKEN SPIGOT/DAMAGED BALL VALVE Always have a backup of supplies. If pipes leak the system will need to be shut down until the leak is fixed. Usually, if it is more involved than resealing a joint, it will be necessary to have plumbing parts and tools, nontoxic aquarium cement, and hopefully someone with plumbing expertise to replace the pipe if it is broken. The spigots are easy to change and replacement parts should always be ordered and kept in the facility. If the main pump or any other pumps break or run dry, a disaster can occur if another pump is not on hand. Sometimes it can take weeks to order a replacement part. Always have a backup pump, as well as the tools and parts to replace the pump.

PH OUT OF RANGE Many factors can cause the pH to spike up or rapidly drop. In most cases, this might be caused by a break-down of the biofilter or wrong proportions of salts added to the system. Buffers are often made up of sodium bicarbonate that eventually disassociates after 12 h, causing the pH to crash. This can be adjusted by adding specific ratios of buffers (depending on whether you want to slowly raise or lower the pH) to the reservoir and manually exchanging the water until the pH is raised 0.1–0.2 units. **Caution: Never raise the pH more than 0.2 units a day** in an attempt to solve a pH problem. This could result in major stress that throws off the frogs' osmotic balance. The frogs can withstand a wide range of pH, but it is a rapid change in pH that degrades their slime coat, making them susceptible to infection.

LOSS OF ELECTRICAL POWER *X. laevis* can be left in standing water as long as there is enough reserve frog water to be able to do a partial water change daily. We strongly recommend having all of the key pumps, purifier systems, and monitoring probes on emergency backup power.

FROG HEALTH PROBLEMS The diagnosis and treatment of medical conditions discussed in Tables 17–17 and 17–18[36,37] were carried out under the supervision of James G. Fox, D.V.M. One of the key features of a flow-through system is that diseases and infections can spread rapidly. Thus, it is imperative to keep a close watch on the animals and remove any that seem problematic (see Tables 17–19 and 17–20). If a treatment looks to be successful after a significant infection, frogs should not be returned to the facility since the infection can recur and spread to others. The purpose of treatment is mainly as a diagnostic for the problem (the success of the various treatments is informative as to what the illness was) and it is not worth the risk to return frogs that had a serious infection.

Frog skin is a crucial barrier to infection and skin quality is a major diagnostic for disease. *Xenopus* skin contains a number of

Table 17–18
Sick frog protocol and suggested treatments

1. *Nematode infestation*: Symptoms include grayish, sloughing skin that may feel tacky rather than slimy. Examine shed skin using a dissecting microscope for the presence of zigzagging tunnels in the skin, which indicate presence of nematodes. These parasites undergo a life cycle while embedded in the skin of the frog. Treatment involves a 3-week protocol of antihelmintic baths using levamisole HCl, 75 mg/frog (see Table 17–16 for the schedule).
2. *Protozoa*: We had one case of a frog infested with an Epistylis-like ciliate (Table 17–21: Tinsley, p. 237). Its symptoms included whitish, thread-like tufts growing off hind limb claws. We treated it with a series of 10 min 12–15 g/liter salt baths, but the infestation did not respond to treatment and led to secondary infections after 2 weeks, so the animal was euthanized.
3. *Red leg infection*: Symptoms include reddening of skin on the hind limbs, lower back, and ventral region. Reddening intensifies to dark open sores that quickly spread all over the body, and can lead to secondary infections. Frogs may begin to tremble at later stages. Red leg is caused by a few types of opportunistic bacteria (*Aeromonas*, *Pseudomonas*, etc.) that are normally associated with frog colonies but can overcome animals weakened by stress or injury. A few occasions of red leg have resulted from elevated pH (which may cause degradation of the protective slime coat), stress from excessive handling, and/or secondary to other infections (i.e., nematodes). These frogs are treated with oxytetracycline (0.2 mg/liter) until symptoms subside, but it is not 100% effective. In advanced cases the animal usually must be euthanized.
4. *Fungal infection*: Symptoms include long whitish threads growing off of skin and/or toes. We treat fungal infections with a commercially available product called fungus cure, at a dose of 1 ml per 4 liters, until symptoms subside. Again, this is not 100% effective, as in some cases secondary infections develop that are hard to treat.

Table 17–18
(continued)

5. *Bloating/edema*: Symptoms include gradual swelling just beneath the skin of hind limbs, back, etc. Frogs appear "full of water" under the skin. This may be caused by damage to the lymph system during injection of Chorulon, or general trauma from egg harvest procedures. I have not found a protocol that successfully treats this condition, despite recommendations for high salt solution baths.
6. *General ill health*: Symptoms can include undiagnosed skin discoloration (brownish or greenish), bruises (often "bite marks" from conspecifics during feeding), scratches, etc. We treat unknown but seemingly minor conditions with soaks in Melafix (1 ml/4 liters), a commercially available product consisting of tea tree oil, which is healing to the skin. If the frog appears infected, we may use a series of high salinity salt baths (see Table 17–15 for the quarantine protocol) and/or oxytetracycline (0.2 g/liter) to prevent bacterial infections.
7. *Dead frogs*: Dead frogs should be removed from the tank immediately. If discarding, follow your institution's animal disposal policy. You may wish to have the animal examined by a pathologist to determine the cause of death. If the frog is to be brought to a veterinarian or pathology laboratory for necropsy, cut a slit in the skin and connective tissues vertically along the underside of the frog (as if you were going to dissect it). Place the frog in either formalin or 10% formaldehyde. If none is available, DO NOT cut the frog open, but place it in a 4˚C refrigerator until it can be brought to the veterinarian. It usually takes just over a week to receive the pathology results.

Table 17–19
Change in the appearance of frogs is indicative of health problems

Edema
Excess skin shedding
Skin discoloration–red, brown, gray, black
Growths on the skin–filamentous, tumors
Hemorrhages on skin
Loss of slime coat–sticky or rough skin
Anorexia
Eggs or shed skin sticking to the frog

antimicrobial and antifungal compounds,[38–42] and in the absence of handling and excessive contact, the regenerating slime will keep frogs resistant to the omnipresent background population of nematodes and bacteria.

Rough patchy skin and excessive shedding may indicate a *Pseudocapillaria xenopodi* infection, usually a secondary infection caused by stress from parasite load (usually involving nematodes). Examine shed skin under a microscope for holes and tunnels caused by exit wounds from the worms; sections of skin can reveal nematode cysts (Figure 17–8). There are usually many wavy lines throughout the skin samples. These parasites begin their life cycle in the subcutaneous skin layer. Treatment involves a 5-week protocol of antihelmintic treatment[43] using levamisole HCl (MP Biomedical), 100 mg/frog; one frog/gallon of system water has worked well in preventing the infection from returning.

Our facility has had a few cases of *Capillaria xenopodis* infections in the past 6 years. This nematode burrows in the skin and leaves cysts (embryos) that are not affected by the levamisole treatment when it is in this stage of the life cycle. These parasites cause severe skin irritation and make *Xenopus* prone to secondary bacterial infections, weakness, rapid weight loss, and finally death. Treating the colony is labor intensive for the facility staff but patience and careful observation will save the colony.

Oxytetracycline treatment in conjunction with Stress Coat (aquarium pharmaceuticals) should be used for 1 day before and 1 day after hugging for egg harvesting.

Trembling

CONCLUSION

Xenopus laevis and its genetically tractable cousin *Xenopus tropicalis*[44–48] are profoundly powerful vertebrate model systems in which physiological, developmental, and cell-biological mechanisms may be studied. They will be increasingly used by both basic biology and pharmaceutical efforts (as drug screening platforms), requiring stable, effective protocols for maintenance of adult frogs. The information presented in this chapter should be sufficient for any laboratory to design a useful system and maintain happy frogs that give high-quality eggs suitable for biochemical or molecular investigation of embryonic development (Table 17–21). The protocols for frog husbandry will surely continue to evolve, and we urge workers in *Xenopus* to make use of and contribute their experiences to the frog community.

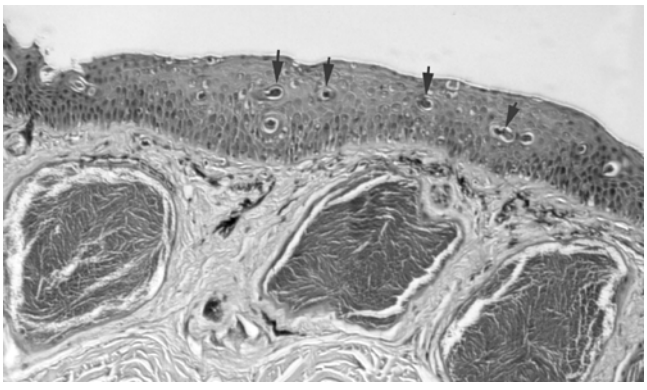

Figure 17–8. Photograph of skin parasites. *Capillaria* cysts just under the epidermis are shown at the sites of the arrows. These nematodes are at the larval stage and will be protected from levamisole treatment at this stage in their life cycle. This is a paraffin section of skin from a *Xenopus laevis* female from our facility that was infected by the nematode *Pseudocapillaria xenopodi.*

18 The Chicken as a Model Organism

JANICE M. BAHR

ABSTRACT

Selection of appropriate animal models is essential to the advancement of basic and clinical research. This chapter provides an overview of the reproductive biology of the chicken (*Gallus domesticus*), also known as the domestic hen, and then introduces the chicken as a model for investigations of mechanisms controlling ovarian follicular growth and maturation, ovulation, and changes in ovarian function with aging. The chicken is currently the only animal model available to probe the etiology and progression of human ovarian cancer as well as to test chemotherapy agents. Finally the chicken is an ideal model for toxicology studies because of its sensitivity and rapid response to environmental toxicants and expression of external indicators, e.g., number of eggs laid, thickness of shell, as a mark of toxic exposure.

Key Words: Chicken, Ovary, Reproduction, Follicle, Ovulation, Ovarian cancer, Toxicology.

INTRODUCTION

Advances in basic and clinical sciences depend heavily on the successful use of appropriate animal models. Today there is widespread use of the mouse with its various genetic modifications, but there are also limitations to this model, particularly when an essential gene is deleted in all tissues. This systemic genetic modification of the entire animal's physiology may make it difficult if not impossible to draw valid conclusions regarding the function of a specific gene in a specific tissue. However, the choice of appropriate animal models is dependent on familiarity of scientists with different animal models, the availability of animal models, and the cost of the animal and housing requirements.

The chicken, also referred to as the domestic hen, has served science well. The chick embryo has been the basis for understanding the stages of early development and its control and is widely used in embryology classes. The young chick was the popular animal of choice for the discovery of steroid receptors, namely progesterone and estradiol receptors. The chick's oviduct, a rich source of these receptors following treatment with steroids, yielded large amounts of tissue for isolation, characterization, and cloning of the steroid receptors. A great deal of vitamin D research was done using the shell gland of the chicken. Awareness of the toxicity of some chemicals used in the environment, such as dichlorodyphenyltrichloroethane (DDT), came from observing that birds exposed to this chemical laid soft-shelled eggs.

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

The purpose of this chapter is to introduce the scientist to the chicken and indicate how the chicken is a valuable animal model for studies in basic reproductive biology, reproductive disease, and toxicology. First a brief overview of the basic reproductive physiology of the chicken will be given.

BRIEF OVERVIEW OF THE REPRODUCTIVE PHYSIOLOGY OF THE CHICKEN

HATCHING CHICKEN EGGS The chick egg has an incubation period of 21 days. Fertilized eggs are placed in an incubator that is maintained at a temperature of 100°F and has a humidified environment. To hatch a large number of eggs, it is advisable to have a commercial incubator. However, if only a small number of chicks is needed, e.g., 10–12, it is possible to incubate eggs in a laboratory incubator provided the eggs are rotated several times each day and humidity is high. Upon hatching, the chicks are placed in a warm environment maintained at 90°F for 3 weeks, after which the temperature can gradually be reduced to 70°F. At all times chicks are provided with commercial chick feed and water *ad libitum*. Chicks move to larger housing quarters as they increase in size. If chicks will not come in contact with other chickens or birds, it is not necessary to immunize the chicks against the common diseases of chickens. Whereas it is possible to raise adult chickens starting with the fertilized egg, it is easier and in some cases less expensive to purchase adult chickens from a producer.

BREEDS OF CHICKENS There are two commercial breeds of chickens, one which has been selected for egg laying and the other breed which has been selected for meat. Depending upon the research interest, either can be used. The laying breed grows slowly, reaching a weight of about 2.3 kg at maturity. In contrast, the meat breed grows rapidly, weighing 2.3 kg at 6 weeks of age, and if not feed restricted it will be obese at maturity. Generally the laying breed is selected for research because it does not have a weight problem, making it easier to manage. The most common strain is the white Leghorn, which is the strain used in most reproductive studies.

ONSET OF PUBERTY The egg laying Leghorn hen reaches sexual maturity at ~5 months of age and starts to lay eggs. Egg production is high during the first year of lay at a rate of 90–95%. As the hen ages, egg production will decrease slightly. In the commercial poultry production, hens are molted at the end of the first year of lay, which will result in increased egg production and also better egg quality. However, in a research environment, it is not necessary to molt hens after the first year of lay, albeit egg production will be less.

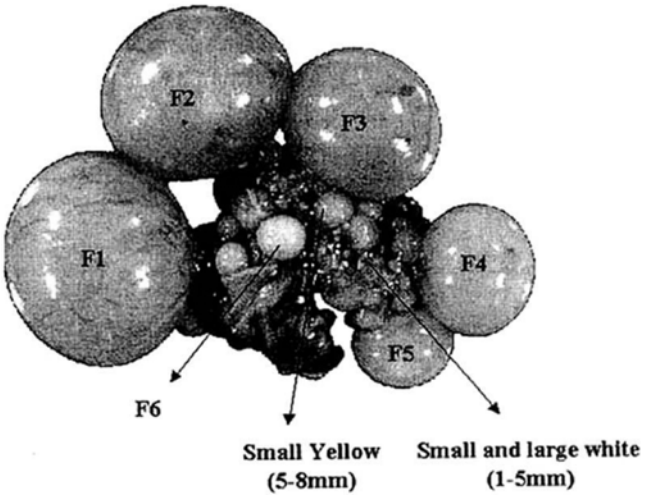

Figure 18–1. A chicken ovary. The preovulatory follicles of the hierarchy are identified according to size with the F1 follicle being the largest follicle and the next one to ovulate, followed by the F2 follicle, the second largest follicle, etc. Small follicles are classified according to size and color of yolk. The postovulatory follicle (not visible) is a saclike structure containing all the cell layers present in the preovulatory follicle.

LEFT OVARY DEVELOPS In the chicken only the left ovary and oviduct develop. The ovary contains five or six large yolk-filled follicles that are arranged in a hierarchy based on their size, F1–F6, with F1 being the largest follicle and the next follicle to ovulate (Figure 18–1). These preovulatory follicles are attached to the ovary by a stalk through which nerves and blood vessels pass. When the F1 follicle ovulates, the other preovulatory follicles move up one position in the hierarchy. At the same time, another follicle is selected from the small yellow follicles to enter the hierarchy. This follicular growth and maturation pattern works with almost clockwork precision in Leghorn chickens.

STRUCTURE OF THE FOLLICLE The follicle consists of an outer superficial epithelium single cell layer, a theca layer, a granulosa layer, a perivitelline membrane, a germinal disc, and a yolk (Figure 18–2). The theca layer, externa and interna, is a heterogeneous layer consisting of fibroblasts, steroidogenic cells, nerve cells, extracellular matrix, and blood vessels. In contrast, the granulosa layer is a single cell layer and is not innervated and has no blood vessels. The theca and granulosa layers are separated by a basement membrane, which allows an easy and clean separation of the two cell layers. The theca layer is the major site of testosterone and estrogen (estradiol-17β and estrone) synthesis, whereas the granulosa layer is the primary site of progesterone production.[1] Inhibin, a hormone that regulates follicle-stimulating hormone in a negative feedback manner, is produced mainly by the granulosa layer of the hierarchical follicles.[2]

OVULATORY CYCLE The ovulatory cycle, described as the interval from one ovulation to the next ovulation, is approximately 24–26 h in length depending upon the age of the chicken. Young hens, in their first year of lay, will ovulate at about 24 h intervals, whereas as the chicken ages this interval between ovulations can increase to ~26 h or even greater. Ovulation is preceded by a significant increase in progesterone, which induces the luteinizing hormone (LH) surge. Ovulation of the egg occurs as the stigma, a visible avascular strip on the follicles, ruptures (Figure 18–3). The egg, picked up by the oviduct, passes down the oviduct where albumen and shell membranes are secreted and then into the shell gland where the shell is deposited. It takes ~24 h for the egg to move down the reproductive tract. At the time of oviposition, the passage of the egg from the shell gland through the vagina is dependent upon prostaglandins $F_{2\alpha}$ and E_2 and arginine vasotocin. Upon the laying of the egg, ovulation of the next egg occurs 15–30 min after oviposition. The close temporal relationship between oviposition and ovulation makes it easy to determine the time of ovulation. For this reason, events during the ovulatory cycle are identified as hours before ovulation of the next (F1) egg. If the egg is to be fertilized, sperm stored in vagina-shell gland junction sperm storage glands are released and fertilize the egg as it enters the oviduct. For further information regarding the reproductive physiology of the chicken, see reviews by Bahr and Johnson[3] and Sharp.[4]

ENVIRONMENTAL CONDITIONS FOR MAXIMAL REPRODUCTIVE PERFORMANCE Chickens are easy to maintain and require only a few specific conditions. Commercial cages and watering systems are available and are relatively inexpensive. If possible, chicken cages should be suspended over a pit that has a stream of running water; however, this housing condition is not necessary. The water reduces the odor of the chickens and makes it easy to clean the pit by pulling the drain plug. Chickens should be housed in a room with adequate air exchange at an ambient temperature of 65℉ with 14–17 h of light. Chickens are sensitive to wavelength, therefore warm fluorescent lights should be used and not the cool fluorescent lights. Chicken feed is available from commercial sources. Feed and water should be provided at all times.

MALE CHICKENS The rooster or cockerel reaches puberty at 4–5 months of age. The rooster has two testis that are located internally and attached to the dorsal wall of the body cavity. Spermatogenesis occurs at 41℃, the internal temperature of the rooster. There are no accessory reproductive glands, such as the

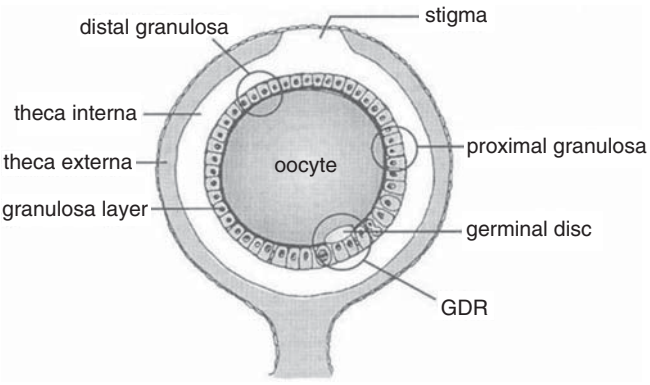

Figure 18–2. A cross section of a chicken preovulatory follicle. Note structural differences in the granulosa layer. The granulosa layer in contact with the germinal disc is called the germinal disc region (GDR). The columnar-shaped granulosa cells located proximal to the GDR (proximal granulosa) are proliferative and synthesize less progesterone. The cuboidal-shaped granulosa cells located distal to the GDR (distal granulosa) are differentiated and synthesize greater amounts of progesterone. (From Tischkau and Bahr,[5] reprinted with permission from the Society for the Study of Reproduction.)

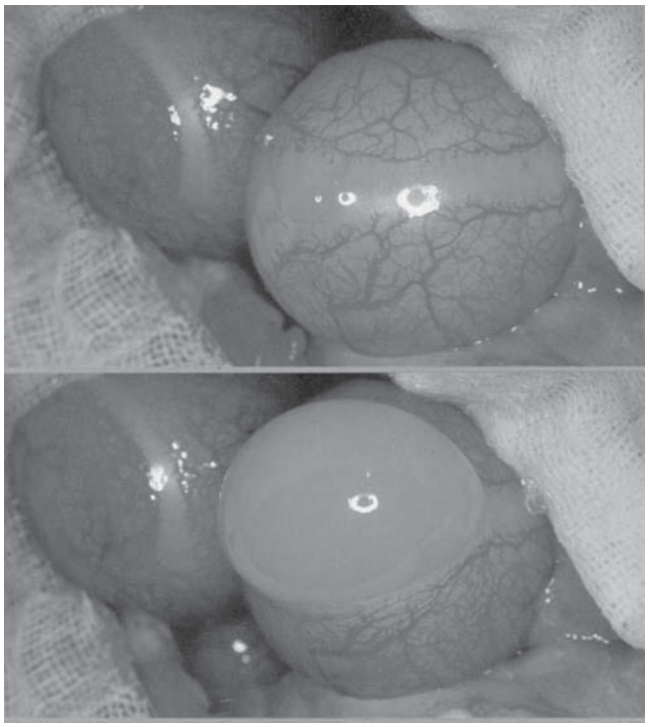

Figure 18–3. Ovulation of a chicken follicle. (A) A picture of the F1 follicle (largest) and the F2 follicle (smaller) several minutes before ovulation. The nonvascular stigma, the site of follicular rupture, is very obvious. (B) Ovulation of the F1 follicle as the stigma is ruptured. Note the size of the clear stigma in both the F1 follicle and the F2 follicle, which allows for easy isolation of the stigma and nonstigma parts of a follicle.

prostate and seminal vesicles. As a result, seminal plasma has the same constituents as the epididymal fluid. Roosters also lack an intromittent organ. Sperm, stored in the lower end of the ductus deferens, are transferred directly from the rooster's cloaca to that of the hen's cloaca at mating. For further information see the review by Sharp.[4]

VALUE OF THE CHICKEN AS A RESEARCH ANIMAL The benefits of using the chicken are many. Chickens are inexpensive to purchase, are healthy, and are easy to maintain. Specific pathogen-free eggs and chickens are available. Transgenic hens are produced commercially, though the supply is limited at this time. In the next section, examples of how the chicken is ideal for reproductive studies will be described.

THE CHICKEN AS A MODEL FOR BASIC REPRODUCTIVE STUDIES

FOLLICULAR DEVELOPMENT Its hierarchical arrangement of follicles, large preovulatory follicles, visible germinal disc, clean separation of the granulosa and theca layers, accurate prediction of ovulation, and change in follicular maturation and ovulation with aging are a few of the chicken's valuable qualifications as a model for ovarian studies. Hence the cellular changes and those associated with changes in gene expression that occur in the granulosa and theca layer as follicles mature and approach ovulation can be easily studied. In particular, the large number of granulosa cells (~5 million) easily and quickly obtained from the F1 follicle makes the chicken follicle an ideal model for investigating signaling, transcription factors, clock genes, etc. in the control of follicular development.

ROLE OF GERMINAL DISC For many years, it was thought that the oocyte was a passive inhabitant of the follicle. With the discovery of factors made by the oocyte that regulate the differentiation of the follicle, investigations into the role of the oocyte in follicular development has intensified. The chicken follicle is an excellent model to study the role of the germinal disc in follicle function. The germinal disc contains the genetic material and cellular organelles of the egg; thus the germinal disc is equivalent to the oocyte of the mammal. The germinal disc, attached to the overlying granulosa cells through cytoplasmic interdigitations, is called the germinal disc region (Figure 18–2). These granulosa cells have a higher rate of proliferation and are less differentiated than the granulosa cells distal to the germinal disc.[5] The visibility of the germinal disc *in vivo* is enhanced by injection of chickens the day before they are used with 0.8 ml Sudan black [10 mg/ml of 1 : 1 phosphate-buffered saline (PBS):100% ethanol, filtered through a 0.45-μm filter], which is taken up by the yolk.[6] To understand the role of the germinal disc, it can easily be destroyed *in vivo* by freezing it with dry ice for 20 sec.[7] The germinal disc along with its overlying granulosa cells can be obtained by isolating the granulosa layer.

OVULATION Identification of the biological changes, particularly expression of genes, associated with ovulation, has been a challenging and intriguing subject for many years. Whereas progress has been made in understanding the process of ovulation using the mammal, this animal model is limiting because of the inability to obtain adequate tissue to measure cellular changes in the stigma, the site of rupture, and in nonstigma tissue. The chicken's large preovulatory follicles overcome these difficulties. The hierarchical follicles have a distinct stigma area that can be easily isolated from the nonstigma area (see Figure 18–3). Furthermore comparison of the F1 follicle, the next one to ovulate, with the F2 follicle, the follicle to ovulate the next day, provides an excellent comparable tissue to measure the cellular changes associated with ovulation (Figure 18–4).[8] The short ovulatory cycle (24–25 h) and the accurate prediction of ovulation based on oviposition further bring superior precision to measuring the changes associated with ovulation. In the chicken follicle, unlike the mammalian follicle, there is no dilution of the measured endpoints due to the use of a large amount of ovarian tissue not associated with ovulation.

OVARIAN FUNCTION WITH AGING A longer interval between ovulations, hence a lengthening of the ovulatory cycle, occurs as the chicken ages. The follicle requires a longer time to gain competency to ovulate.[9] This delay in ovulation represents changes at the level of the follicle as well as at the level of the hypothalamus, which becomes less responsive to the positive feedback of progesterone to induce the luteinizing hormone surge. The accuracy with which the time of ovulation based on oviposition can be determined and the large amount of tissue available from individual follicles facilitate the investigation of changes in gene expression with age. The chicken is a particularly good model to study the role of clock genes at the level of the hypothalamus and the ovary in the aging process.

THE CHICKEN AS A MODEL FOR OVARIAN CANCER

Progress in eliminating a disease depends heavily upon the availability of an appropriate model. For many years scientists

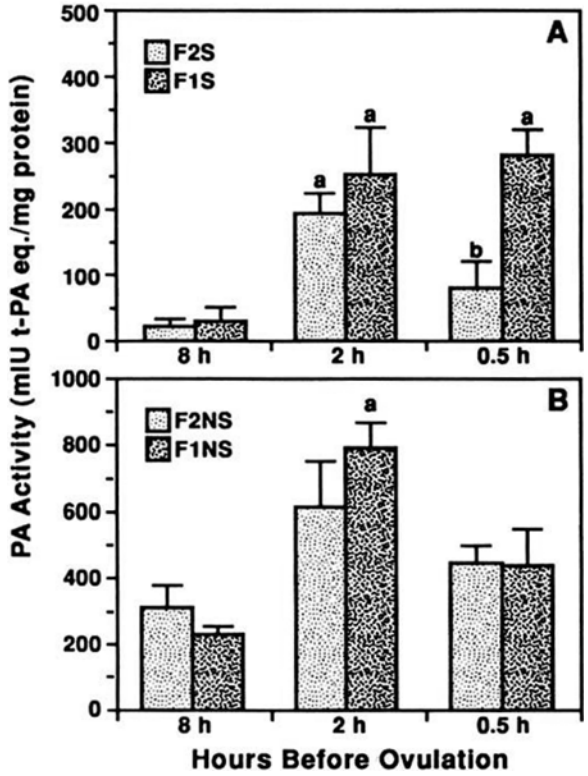

Figure 18–4. Plasminogen activity (PA) in (A) the stigma region (S) of the theca layer and (B) the nonstigma region (NS) of the theca layer of F1 and F2 preovulatory follicles, which will ovulate next and 26 h later, respectively. Follicles were obtained at 8 h (before the LH surge), 2 h (immediately after the LH surge), and 0.5 h immediately before ovulation. Each bar represents the mean ± SE of three to five experiments. a, significant differences in PA activity compared to 8 h before ovulation ($p < 0.05$); b, significant difference in PA activity in F1 versus F2 ($p < 0.05$). (From Jackson *et al.*,[8] reprinted with permission from the Society for the Study of Reproduction.)

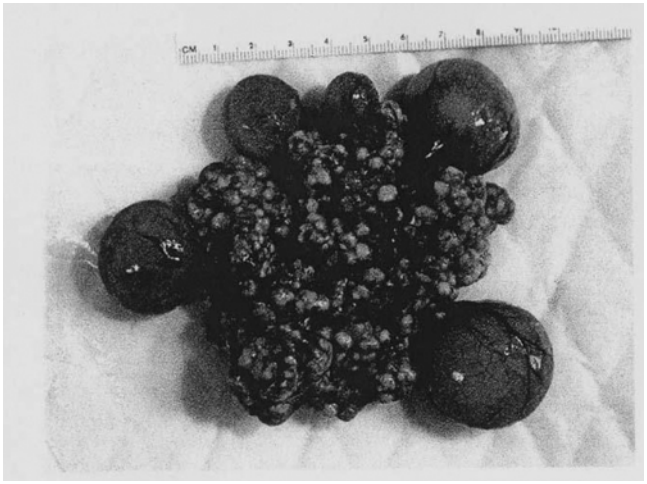

Figure 18–5. Ovarian cancer of the hen. Gross appearance is characterized by firm, white nodules. Cystic or hemorrhagic follicles are also often present. (From Johnson and Giles,[10] reprinted with permission from the Poultry Science Association.)

have attempted to develop a mammalian model to investigate ovarian cancer in humans. Human ovarian cancer is the most common fatal gynecologic malignancy with a 5-year survival rate of 25–30%. One of the reasons for this low survival rate is the inability to detect ovarian cancer early. For example, the availability of a blood marker such as the prostate-specific antigen in males would be a significant advancement in early detection of ovarian cancer. Therefore a model that would make it possible to determine if there are markers in the blood for ovarian cancer and also the use of the presence of these markers to follow the effectiveness of chemotherapy would be ideal. To date, despite the use of specific hormone treatments of rat to induce ovarian cancer and the recent availability of a transgenic mouse model, a mammalian animal model that spontaneously develops ovarian cancer has not been developed.

In contrast, the chicken does develop ovarian cancer spontaneously and the types of cancers are similar to those that occur in the human.[10] The chicken seldom develops ovarian cancer before 2 years of age, but does develop it with increasing age. It has been hypothesized that women and chickens develop ovarian cancer because they are persistent ovulators.[11] The number of ovulations that occur in a woman's lifetime, which in most cases may be interrupted by one or two pregnancies, is similar to the number of ovulations a chicken will have during a 2-year period, with the chicken ovulating 80% of the time. In contrast, most mammals are either pregnant or nursing and therefore are not persistent ovulators.

Fredrickson[12] provides an early report of cancer in chickens. He biopsied 466 hens, ages 2–7 years, and found that 24% had malignant ovarian adenocarcinomas and that the incidence increased with age. He observed that the ovarian adenocarcinomas at their early stages are firm white cauliflower-like nodules that resemble atrectic follicles (Figure 18–5). Histological studies done by Fredrickson[12] indicated a similarity between the germinal epithelium and the ovarian adenocarcinoma cells. This observation supports the current hypothesis that the ovarian superficial epithelial (OSE) cells are the cellular source of the ovarian adenocarcinomas. Recent studies by Johnson and Giles[10] show that ovarian cancer in the chicken has a glandular growth pattern and simple columnar epithelium lines the glands (Figure 18–6). It is hypothesized that at the time of ovulation, cells located at the rupture site may have DNA damage; along with defective DNA repair mechanisms, this mutagenesis results in malignant transformation followed by clonal expansion and metastasis.[13] Another hypothesis that has a great deal of support is the epitheliomesenchymal conversion of OSE cells that occurs following ovulation when the OSE cells are displaced from the surface to the stroma.[11] This displacement can also occur in the aging ovary due to an invagination of the OSE. The epithelial cells that are converted to mesenchymal cells can be incorporated into the stroma. However, if the OSE remain epithelial, they can aggregate and form inclusion cysts that are the preferred sites of metaplastic and dysplastic changes that can lead to tumorigenesis. With malignant progression and depending upon the genetic predisposition of the woman, fewer of the OSE will become mesenchymal cells and be incorporated into the stroma.

The use of two chicken strains, C and K, that have a different incidence of ovarian cancer, different concentrations of estrogen

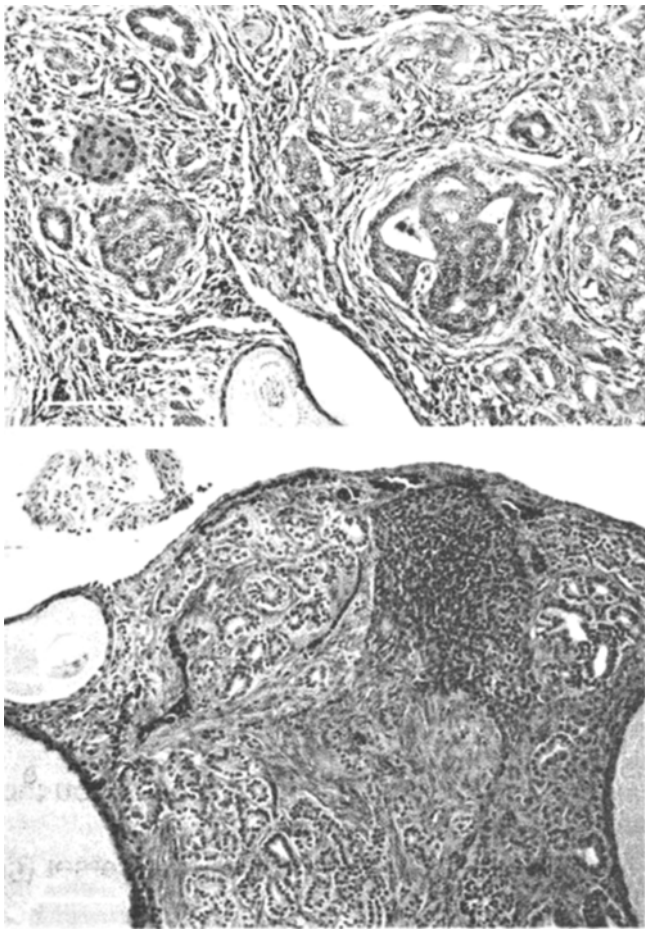

Figure 18–6. Hematoxylin and eosin photomicrographs of ovarian cancer in the hen. The cancer is characterized by a glandular growth pattern. The glands are generally lined by a simple columnar epithelium. Scale bar = 50 μm. (From Johnson and Giles,[10] reprinted with permission from the Poultry Science Association.)

in the blood, and a different amount of mRNA expression for the α-subunit of inhibin in the granulosa layer suggests that there may be a genetic basis for ovarian cancer.[10] The use of these two strains of chickens should be helpful in exploring the etiology of ovarian cancer.

Immunohistochemical expression of molecular markers associated with ovarian cancer in humans was performed on chicken ovarian cancer tissue.[14] A number of different antigens (cytokeratin AE1/AE3, pan cytokeratin, EGFR, Lewis Y, CEA, Tag 72, PCNA, p27, and TGF-α) were identified, which indicated the immunohistochemical similarity between human and chicken ovarian cancer tissue. Also this study demonstrated the potential utility of the avian model for the testing of chemoprevention agents.

THE CHICKEN AS A MODEL FOR TOXICOLOGY

Silent Spring, the book written by Rachel Carson in the late 1960s, indicates the value of birds to make us aware of dangerous toxicants in our environment. Rachel Carson called attention to the dangers of the pesticide, DDT. Birds were laying soft shelled eggs, which made it impossible for these eggs to hatch and produce the next generation of birds. Without these birds, spring would be silent. Just as the canary in the coal mine can detect dangerous gases before humans can smell them, wild birds can act as sentinels to alert us to dangerous chemicals in our environments. Whereas wild birds are not a good research animal for toxicology, the chicken is an excellent model. In fact, in many cases, the chicken is a more sensitive model with easily observable outcomes when compared to rodent models.

The list of xenobiotics and toxicants is long; however, a select few will be cited: DDT, polychlorinated biphenyl (PCB), and phenobarbital (PB). These lipophilic chemicals are metabolized by the mixed-function oxidases (MFO) present in the liver. The MFO metabolize substrates including drugs, lipophilic substances, and steroids. Hepatic cytochrome P450 (P450) is an indicator for the activity of this enzyme system. Exposure to these lipophilic substances results in an increase in the activity of the P450 in an effort to remove the toxic substances from the body. However, because these enzymes are not highly specific, an increase in their activity will increase steroid metabolism, thus lowering systemic concentrations of these steroids. Therefore physiological activities in the body that depend upon a certain blood concentration of steroids will be modified, which in the chicken would be the laying of soft shelled eggs or even complete cessation of egg laying.

The chicken, as an egg-producing species, is dependent upon a properly functioning ovary, liver, and shell gland to produce eggs. The ovary is the site of steroidogenesis and formation of yolky follicles. Ovarian estrogens act on the liver via an estrogen receptor to cause the synthesis of yolk proteins, which are then secreted into the blood and taken up by the ovarian follicles. Once the follicle has attained its proper size and is competent to respond to luteinizing hormone to ovulate, the egg is released and enters the oviduct where it obtains albumen and shell membranes. The egg then enters the shell gland where the shell, rich in calcium, is laid down. The mobilization of calcium from the medullary bone to the shell gland and its secretion into the shell gland are dependent primarily on estrogen. Therefore any chemical that changes the synthesis of estrogen by the ovary, its metabolism and ability to stimulate yolk synthesis in the liver, and the availability of estrogen to make available adequate calcium and its accretion for shell formation will affect the laying of eggs. Simply stated, the chicken has three specific tissues whose function can be altered by exposure to xenobiotics and toxicants. Furthermore, the response of chickens to these chemicals is rapid, occurring in 5–7 days, and can be easily determined by observing the number of eggs laid, measuring the thickness of the shell, and determining the absence of a hard shell.

Two toxicology studies done in the chicken[15,16] demonstrate the usefulness of the chicken for these types of studies. The objectives of these studies were to investigate the effect of xenobiotics on the induction or depression of the MFO, changes in hepatic cytochrome P450, blood concentration of estradiol-17β (E_2), plasma calcium (Ca), rate of egg lay, and thickness of egg shell in laying Leghorn hens.[15] They used PB and carbon tetrachloride (CCl_4) as the xenobiotics of choice. There was a dose–response decrease in E_2 concentrations in the blood (Figure 18–7) and an increase in the liver P450 concentration in response to feeding increasing amounts of PH (0–100 mg for 3 or 7 days; Figure 18–8). The response to CCl_4 for the concentration of P450 was

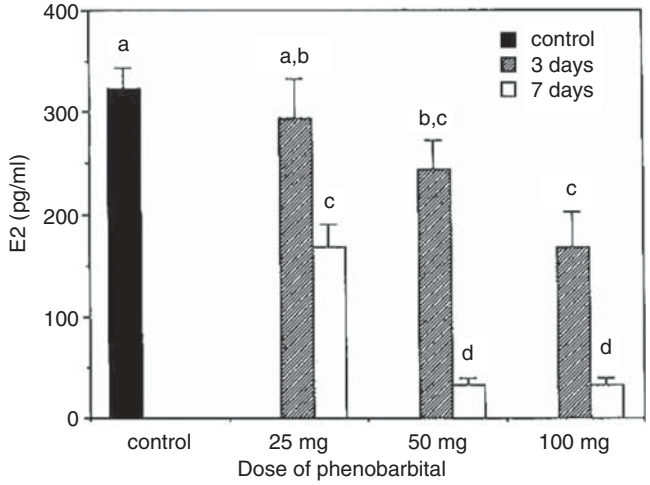

Figure 18–7. Concentrations (mean ± SE) of estradiol (E_2) in the plasma after the administration of phenobarbital for 3 or 7 days to laying hens. Means with the same letter are not different from each other ($p > 0.05$). Circulating E_2 was decreased by doses of phenobarbital in a linear manner. Three days: $R^2 = 0.413$ ($p < 0.001$). Seven days: $R^2 = 0.693$ ($p < 0.001$). (From Chen *et al.*,[15] reprinted with permission from the American Association of Animal Science.)

similar to the data obtained following phenobarbital. In the second study, Chen *et al.*[16] tested the effectiveness of four environmental toxicants that affect liver P450 concentrations. Three of the toxicants (aroclor 1254, a PCB, DDT, and benzo[α]pyrene) were hypothesized to induce different isoenymes of P450 and one toxicant, lead acetate, inhibited the induction of the P450. The PCB and DDT significantly increased P450 with a consequent depression of circulating E_2. Data from this study indicated that the environmental effects of these toxicants are an elevation of P450, which increases steroid metabolism by the liver and decreases circulating concentrations of E_2 with negative effects on reproduction.

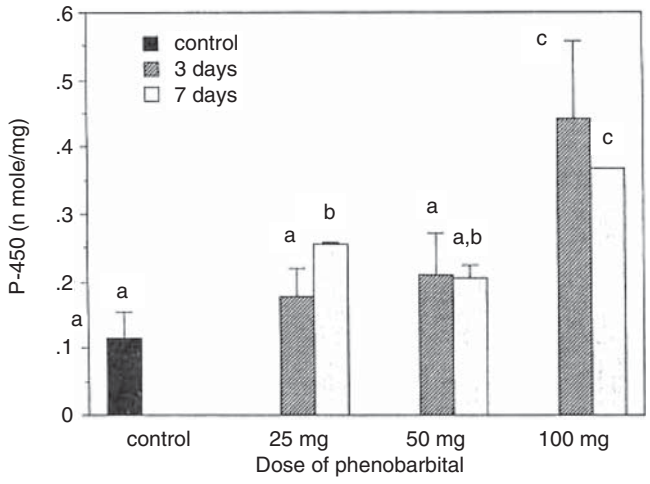

Figure 18–8. Concentrations (mean ± SE) of cytochrome P450 in the hepatic microsomal fraction in laying hens after the administration of phenobarbital for 3 or 7 days. Means with the same letter are not different from each other. The P450 was induced by doses of phenobarbital in a linear manner. Three days: $R^2 = 0.304$ ($p < 0.005$). Seven days: $R^2 = 0.389$ ($p < 0.001$). (From Chen *et al.*,[15] reprinted with permission from the American Society of Animal Science.)

CONCLUSIONS

This chapter has provided a brief overview of the chicken's reproductive physiology to introduce scientists in biomedical research to a valuable model. Examples of three specific areas of research were presented, namely, basic reproductive biology of ovarian function and ovulation, ovarian cancer, and toxicology. The size of the follicles, availability of ample tissue, and accurate prediction of ovulation make the chicken an ideal model to probe basic questions about ovarian function. The fact that it is the only animal model that spontaneously develops ovarian cancer with histological changes and expression of genes similar to that observed in human ovarian cancer makes the chicken an extremely important model to investigate this serious gynecological disease in humans. Finally, with the increasing need to determine the toxicity of substances in our environment, the chicken has a number of attributes that makes it an invaluable model. Only a few select references regarding these studies in chickens were cited in this chapter; however, the interested scientist will find many more informative references in the published literature. The author of this chapter who has used chickens in research for 30 years is also a resource person to anyone needing help or having unanswered questions. She can be reached at jbahr@uiuc.edu.

19 Rat Knockout and Mutant Models

Bart M.G. Smits, Jill D. Haag, Michael N. Gould, and Edwin Cuppen

ABSTRACT

The development of rat genetic models has rapidly progressed over the past decades and has become an important strategy to connect gene function to various aspects of health and disease. Reverse genetics or gene-driven genetics is a broadly accepted approach to study gene function. An indispensable reverse genetic tool is the generation and characterization of knockout and mutant animals for the genes of interest. Recently, the laboratories of Dr. Michael Gould (Madison, WI) and Dr. Edwin Cuppen (Utrecht, The Netherlands) have independently developed methods using *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis to make rat knockouts and mutants in any gene of interest. This chapter describes experienced-based considerations from both laboratories that could serve as a guideline for initiating ENU mutagenesis-based screens in the rat.

Key Words: ENU mutagenesis, Point mutation, Reverse genetics, Inbred and outbred strain, Target gene, TILLING, CEL I, High-throughput resequencing, Yeast-based truncation assay.

INTRODUCTION

THE RAT AS A GENETIC MODEL ORGANISM Not long after rats were first captured for experimental purposes in the first half of the nineteenth century, rat genetic research (genetics of coat color) made its introduction.[1] Despite the early foundation, rat genetic research lost popularity, mainly since the early mammalian geneticists preferred the mouse for genetic experiments because of its smaller size and excellent reproductive characteristics. The rat with its larger size became the first choice for physiologists and nutritionists. Many inbred strains have been created to resemble specific aspects of human health and disease. The Rat Genome Database (http://rgd.mcw.edu/strains) currently contains over 500 rat strains. It is now the geneticist's turn to identify the genetic factors underlying the clinically relevant traits for which these strains have been bred. Comparative genomics by means of genetic mapping and positional cloning of quantitative trait loci (QTLs) in animal models has become a general strategy to genetically dissect these traits.[2,3] The possibility of rapidly creating congenic, consomic, and recombinant inbred strains has undoubtedly facilitated the annotation of genomic loci of importance to a phenotype. In addition to that, the availability of the rat genome,[4] a high-density radiation hybrid map,[5] and the ongoing generation of dense genetic marker sets[6–9] are completing the set of rat genomic resources.

Although these important advances in rat genetic research over the past decades have accelerated the identification and annotation of hundreds of QTLs, the next critical step in the process of coupling the clinically relevant trait to the genome is the identification of the causative genetic element(s).[10] Frequently, traditional positional cloning efforts result in the identification of a large locus containing many putative functional genetic elements, such as genes, enhancers, and noncoding RNAs. At the stage where continuing positional cloning becomes inefficient due to the lack of recombination events, the accessibility of genetic tools, such as knockout technology, is needed to evaluate the contribution of these functional genetic elements to the QTL.[10]

FUNCTIONAL GENOMICS Mammalian genomics in the years around the millennium change was characterized by the collecting of tremendous amounts of sequencing data culminating in the publication of the human,[11,12] mouse,[13] and rat[4] genomes. The "functional genomics" era aims for the identification and characterization of the functional genetic elements in these genome sequences, which will always require genetic approaches. Genetic approaches can roughly be divided into two categories: forward genetics and reverse genetics. Forward or classical genetics starts with a phenotype. To reveal the genetic variant that is causing the phenotype, genetic mapping and positional cloning are performed. Many model organisms have been subjected to large-scale phenotypic screening, including *Drosophila*,[14] zebrafish,[15,16] and mice.[17,18] These immense efforts have resulted in many interesting phenotypic mutants for which the underlying gene mutations have been identified.

On the other hand, reverse genetics is a gene-driven approach. For many genes the sequence is currently annotated or predicted. Hence, the gene of interest can be knocked out or mutated in the model organism of choice and the phenotype can be studied. For a long time, mammalian knockouts were composed solely of mice. The technology relied on homologous recombination in embryonic stem cells (ES cells) to replace an exon of interest with a selectable marker, thereby creating a nonfunctional allele of the target gene.[19] Rat embryonic stem cells capable of producing viable embryos have not been found thus far. This has hampered the production of rat knockouts for many decades, until recently. The first rat knockouts reported were generated by ENU mutagenesis-driven reverse genetics.[20–22]

N-ETHYL-N-NITROSOUREA MUTAGENESIS Mammalian *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis was first developed in the mouse. Large-scale forward genetic screens could not rely on spontaneous mutation rates, since these are far too low to make this approach viable. Early work by Russell and colleagues[23] at Oak Ridge demonstrated that the mutation rate could be dramatically increased by germ-line mutagenesis. Several mutagenic agents, including chemical mutagens and X-irradiation, were examined using the specific locus test in mice. ENU was found to be the most favorable germ-line mutagen for three reasons.[24] First, ENU was the most potent mutagen in producing loss-of-function mutations. It is a directly acting alkylating agent not requiring metabolic activation to elicit its effect. Second, in contrast to X-irradiation, which produces larger deletions, ENU induces point mutations that merely affect single loci. Nonetheless, researchers should take into account that multiple background mutations could potentially distort phenotypic analysis. Third, ENU is considered a stem cell mutagen. When injected in males, DNA adduct formation occurs primarily in the spermatogonial stem cells,[25] which triggers misincorporation of bases during spermatogenesis, and ultimately results in fixed mutations.[26]

Additionally, repetitive application of lower doses of ENU gave a higher hit rate in the single locus test compared to a single high dose.[27,28] Above a certain threshold, the relationship between dose of ENU and hit rate in the specific locus test is linear, suggesting that at lower doses the DNA repair system in the spermatogonia is apparently capable of fixing the majority of ENU-induced DNA damage.[29] Finally, ENU-induced mutagenicity and toxicity are strongly strain dependent in the mouse.[24]

Recently, ENU mutagenesis has been utilized for gene-driven knockout/mutant production in several vertebrate species, such as zebrafish,[30] mice,[31] frogs,[32] and rats.[20–22] The universal methodology known as target-selected mutagenesis, gene-driven mutagenesis, or targeting local lesions in genomes (TILLING) is outlined in Figure 19–1. Male founder animals are mutagenized and mated with wild-type females to produce a large library of F_1 animals, carrying many random heterozygous point mutations across their genome. From each F_1 animal a tissue sample is taken and DNA or RNA is isolated and screened for induced point mutations in the genes of interest using a high-throughput mutation discovery platform. Mutations are randomly distributed across the genome, but only coding regions are screened. Missense mutations could potentially be very interesting, as amino acid changes could result in hypermorphic or hypomorphic proteins. Nonsense mutation that introduce a premature stop codon lead to an early truncated protein that is likely nonfunctional, thereby creating a knockout animal. This methodology allows for the generation of an allelic series, i.e., a nonsense allele, hypermorphic/hypomorphic alleles, and the wild-type allele, which is highly informative to study the function of the gene. Finally, the animals harboring interesting mutations are selected from the library and the mutation is outcrossed to reduce the amount of background mutations and incrossed to homozygosity.

PRODUCTION OF RAT KNOCKOUTS AND MUTANTS

Recently, Dr. Michael Gould's laboratory (Madison, WI) and Dr. Edwin Cuppen's laboratory (Utrecht, The Netherlands) have independently developed ENU mutagenesis protocols for several rat strains, resulting in the identification of the first rat knockouts and mutants worldwide. The Gould laboratory focused on genes related to breast cancer, whereas the Cuppen laboratory screened mainly genes involved in neurological processes and diseases. Although the technology seems rather uncomplicated, implementing it in the rat model system requires careful preparations. Which strain will be most suitable? Which doses of ENU and what mutation detection strategy could be used? After an interesting mutant has been identified, what follow-up will be performed? This section describes results and experiences from these two laboratories and can serve as a stepwise guideline for initiating an ENU mutagenesis-based screen in the rat.

STRAIN SELECTION Currently, over 500 rat strains have been developed to resemble a wide variety of aspects of human health and disease. It is often highly desirable to target candidate genes in the genetic background of interest, since numerous

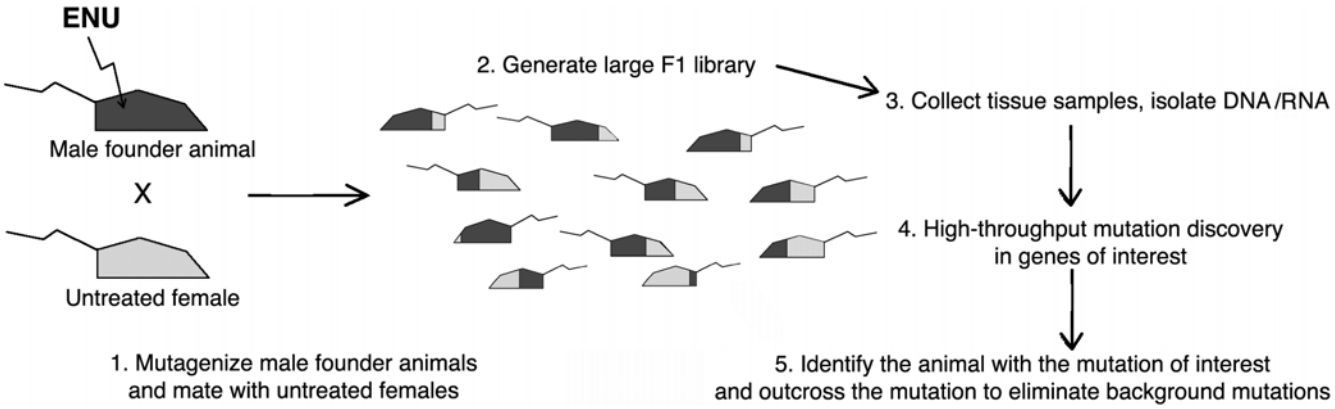

Figure 19–1. Schematic representation of a universal rat reverse genetic ENU mutagenesis screen. Mutagenized male founder animals are mated with untreated females to produce a large library of F_1 animals that contain random heterozygous point mutations in their genome. From each F_1 animal a tissue sample is collected from which DNA or RNA is extracted and screened using high-throughput mutation discovery technology for induced mutations in the genes of interest. Animals harboring interesting mutations are identified. The mutation is first outcrossed to the wild-type background and subsequently incrossed to homozygosity. Outcrossing for at least six generations will eliminate most (>98.5%) of the background mutations on other chromosomes and will on average leave <35% of the donor chromosome surrounding the mutation.

Table 19–1
Guidelines for choice of strain in *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis experiments

Strain[a]	*Optimal dose*[b]	*Sterility dose*[b]	*Mutation rate*[c]	*Suitability(0–6)*[d]				*Reference*

[a]The first six strains are inbred; the last two strains are outbred.

[b]Dose of ENU in mg per kg bodyweight. 2× or 3× are weekly spaced injections. Optimal dose is determined as the dose at which at least half of the founder males are fertile at 10 weeks after the ENU treatment. Sterility dose is the dose at which none of the founder males is fertile at 10 weeks after the ENU treatment.

[c]Mutation rates BN, F344/Crl, and Wistar are molecular mutation rates determined by resequencing. The rates for F344/NHsd and SD are visible mutant phenotype rates, as determined by physical examination of the offspring. Nonmutagenized SD results in a visible mutant phenotype rate of 1 in 283.

[d]0 = not suitable, 6 = very suitable. Suitability is determined using three criteria: reproductive capabilities (RC), tolerability to ENU (ET), and induced mutation/mutant phenotype rate (MR). Each criterion is awarded 0, 1, or 2.

modifiers could influence phenotypic analysis dramatically. However, not every strain is equally suitable for ENU mutagenesis. Data from mouse ENU mutagenesis experiments have unambiguously shown a strong strain-dependent susceptibility toward the effects of ENU.[24] The Gould and Cuppen laboratories have independently established ENU mutagenesis protocols for a total of five inbred strains, Brown Norway (BN), Fischer (F344/Crl and F344/NHsd), Lewis (LEW), Wistar–Furth (WF), and Wistar–Kyoto (WKy), as well as for two outbred strains, Sprague–Dawley (Hsd:SD; SD), and Wistar (Wistar/Crl). Table 19–1 shows the results of several titration experiments using split doses of ENU. The strains were awarded a "suitability score" based on three criteria: reproductive capabilities (RC), tolerability toward ENU (ET), and mutation/mutant phenotype rate (MR).

First, the reproductive capabilities of outbred strains are generally better than those of inbred strains. Among the inbred strains, F344 showed the best reproductive performance (http://rgd.mcw.edu/strains; on average 7–10 pups/litter in our hands, compared to 11–14 pups/litter for Wistar and SD). BN, WF, and WKy are known to be the moderate breeders (http://rgd.mcw.edu/strains), which make those strains less efficient for production of large libraries of mutant offspring.

The second criterion is the tolerability toward ENU (Table 19–1). The optimal split dose of ENU for the above-mentioned strains was determined. We define the optimal dose as the highest dose for which at least half of the males are fertile 10 weeks after the ENU treatment. A dose group in which less than half of the males are fertile will not be able to extensively contribute to the library. In general, the outbred strains Wistar and SD appear to tolerate higher doses of ENU compared to the inbred strains; however, inbred F344 animals appear equally tolerable toward ENU. The recommended doses for these strains are 2 × 60 (mg of ENU per kg body weight) or 3 × 40. The recommended doses for BN is 3 × 20. WF never reached a fertility percentage of over 50. The inbred strains LEW and WKy became completely sterile at the lowest split doses injected. The latter three strains are therefore considered less efficient for ENU mutagenesis screens. If a knockout or mutant in those genetic backgrounds is absolutely essential, two possibilities can be explored. First, the optimal dose for these strains could be determined by titrating a series of even lower split doses or single doses of ENU. The Gould laboratory obtained viable offspring from WF males injected with single doses of 25, 35, and 50 mg/kg, but only 33% or less of the males in all dose groups regained fertility (Table 19–2). However, it remains questionable if these low doses are capable of inducing mutations in these strains, knowing that ENU mutagenesis is efficient only above a certain threshold in mice.[29] Alternatively, the mutation of interest could be induced in a different genetic background and subsequently introgressed into the desired genetic background. Pitfalls of this procedure are discussed later on.

Finally, the suitability of using a certain strain in an ENU mutagenesis-based screen is dependent on the induced mutation rate. A higher mutation rate means that on average fewer animals need to be screened to find the desired mutant. The data from the Cuppen laboratory gives an accurate reflection of the molecular mutation frequencies in genes of interest in the F344/Crl and Wistar strains (Table 19–1). Given the optimal doses of ENU, the mutation frequencies were one mutation per 1.76 and 1.24 Mb, respectively.[21] The mutation frequency for the BN strain treated with its optimal dose of ENU was not reliable (only eight mutations with most of them derived from a single founder).

The Gould laboratory has estimated the mutagenicity of ENU to a strain from the rate of visible mutants produced.[22] A large-scale phenotypic screen in offspring of mutagenized SD (2 × 60) and F344/NHsd (2 × 60) animals revealed a visible mutant phenotype rate of 1 in 64 pups, respectively, compared to 1 in 283 abnormal phenotypes in untreated animals. To test the heritability of the induced mutant phenotypes, approximately half of the mutant phenotypes could be bred to the next generation.[22]

To summarize, based on these three criteria the two outbred strains were awarded the highest scores (Table 19–1). Among the

Table 19–2
Effects of *N*-ethyl-*N*-nitrosourea (ENU) treatment on male rat fertility[a]

Inbred strain	*Dose (mg/kg)*	*Fertile males*	*Fertile males (%)*	*Outbred strain*	*Dose (mg/kg)*	*Fertile males*	*Fertile males (%)*

[a]A founder is considered fertile if it produces more than one litter between 10 and 26 weeks after the ENU treatment.

inbred strains tested, F344 gave the highest scores. Hence, we recommend using Wistar, SD, or F344 for ENU mutagenesis-based genetic screens in the rat.

N-ETHYL-N-NITROSOUREA MUTAGENESIS Proper application of an exactly measured amount of ENU to the rats is critical for reproducibility in consecutive mutagenesis experiments. Hence, it is important to establish a standardized procedure for dissolving, measuring, and administering ENU. The Gould and Cuppen laboratories have used the same protocol with some minor differences.

ENU was always freshly dissolved less than 1 h prior to injections. ENU comes as a powder in a sealed vial (SIGMA; 1 g). It is predissolved by vigorous shaking in 95% (v/v) ethanol (Gould laboratory 10 ml; Cuppen laboratory 5 ml) and diluted with phosphate/citrate buffer (Gould laboratory: 90 ml of 0.2 M Na_2HPO_4, 0.1 M citric acid, pH 5.0; Cuppen laboratory: 95 ml of 0.1 M NaH_2PO_4, 0.05 M citric acid, pH 5.0). The concentration is determined by measuring the optical density (OD) of a 10 times dilution at 395 nm wavelength. Preferentially, vials with the same lot number are used for all injections. One OD unit equals a concentration of ~1 mg/ml. Final concentrations typically varied between 6 and 8.5 mg/ml, but were relatively constant for vials with the same lot number. The desired dose is injected intraperitonially in weekly intervals. The male germ-line should be fully developed (~8 weeks of age) at the first ENU treatment. The Gould laboratory started the first ENU treatment at 9 weeks of age, whereas the Cuppen laboratory started at 10 and 11 weeks of age, which in all cases resulted in successful mutagenesis.

The number of males to be mutagenized depends on the reproductive capabilities of the selected strain, as outlined above, on the fertility rate of the selected strain treated with the optimal dose of ENU, and on the mutation/mutant phenotype rate. Fertility rates of the rat strains tested by the Gould and Cuppen laboratories are listed in Table 19–2. For example, if researchers decide to mutagenize BN males with a dose of ENU of 3 × 20, they should envision that nearly 20% of the mutagenized males will become sterile and that BN has less than one-third of the reproductive capabilities of either the Wistar or SD strains. Additional males have to be mutagenized to compensate for the resulting moderate litter size.

LIBRARY PRODUCTION Using a mutation rate of roughly 1 in ~1.2 Mb, the Cuppen laboratory estimated that a knockout probability of 96% for an average-sized rat gene (~1300 bp of coding region) requires an F_1 library of ~50,000 mutant animals.[21] This estimation is based on a total coding region size of ~28.4 Mb, of which ~1.7 Mb could be mutated into a stop codon by the three most frequently occurring ENU-induced mutations (AT-TA, AT-GC, GC-AT).[21] Nonetheless, the Gould laboratory experimentally showed that the library sizes to find a truncation in breast cancer genes 1 and 2 (*Brca1* and *Brca2)* were 1965 and 788, respectively.[22] F_1 libraries of thousands of animals take considerable time to generate and require an adequate logistical plan. Most laboratories do not have sufficient housing capacity. Since successful rat sperm cryopreservation is still limited to a single laboratory worldwide[33] and is certainly not a routine procedure, we suggest a rolling-circle model for the library production, which means that preweanling pups are produced to be consistent with the screening capacity. Only the pups harboring interesting mutations are kept and all other pups are discarded shortly after screening to prevent accumulation in the animal facility.

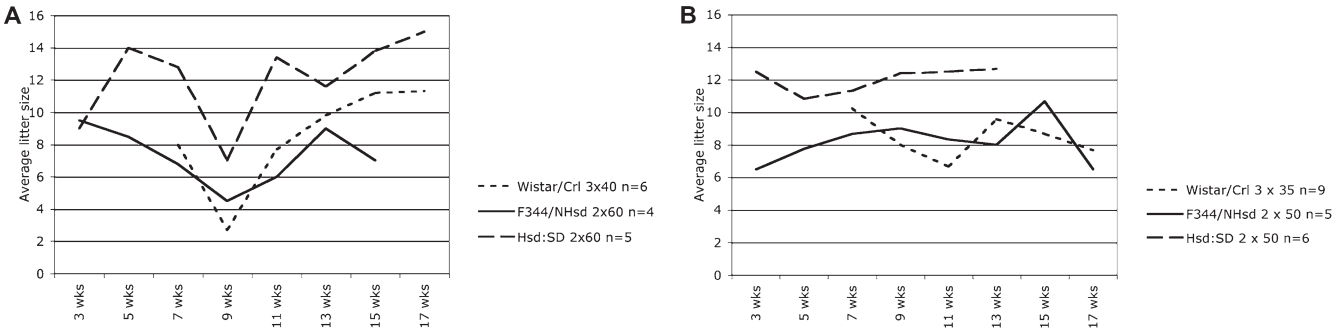

Figure 19–2. Average litter size for three different strains, Wistar/Crl, Sprague–Dawley (Hsd:SD), and Fischer (F344/NHsd), measured from 3 to 17 weeks (wks) after the ENU treatment (Hsd:SD, F344/Nhsd: wks after the first injection; Wistar/Crl: wks after the last injection). The dip in pup production manifests between 8 and 9 weeks after the last ENU injection. (A) Strains mutagenized with an optimal dose of ENU (in mg per kg body weight). (B) Strains mutagenized with a suboptimal dose of ENU (in mg per kg body weight).

The Gould and Cuppen laboratories set up matings with the mutagenized founder males every 2 or 3 weeks and each male was paired with one or two females. Using combinations of these two variable conditions, the pup production speed could be customized depending on the screening capacity. Mutagenized fertile males gave viable offspring up to 15 months of age, although some males experience a reduced life span due to tumor formation resulting from the mutagenesis.

To fix the mutations that are induced in the spermatogonial stem cells, it is important to let the mutagenized males undergo a full round of spermatogenesis (~60 days). However, to monitor fertility and to stimulate sperm production of the mutagenized founders, both laboratories have started matings as soon as 3 and 5 weeks after the ENU treatment. Pups born earlier than 10 weeks after the ENU treatment could be chimeric resulting from ENU-induced DNA adducts in spermatozoa and were subsequently discarded. These pups could be used to optimize the high-throughput mutation detection assay. Typically, the optimal dose of ENU for a certain strain is characterized by a dip in the pup production around 9 weeks after mutagenesis (Figure 19–2A), which is less pronounced or absent at suboptimal doses of ENU (Figure 19–2B). Unlike many mouse strains that might regain fertility up to 26 weeks after the ENU treatment,[24] ENU-treated male rats rarely regain fertility after a long period of sterility.

MUTATION DISCOVERY Due to the recent intensification of interest in genome-wide genetic variation, many high-throughput mutation discovery technologies became available. To date, three mutation discovery strategies have been applied to mutagenized rat libraries, namely CEL I-mediated heteroduplex cleavage,[20] high-throughput resequencing,[21] and a yeast-based screening assay.[22] This section will describe the most important pros and cons of each methodology (Table 19–3).

The Cuppen laboratory adopted the CEL I-mediated enzymatic heteroduplex cleavage method (CEL I) from the *Arabidopsis* field[34] and initially applied it to screening zebrafish in a high-throughput fashion.[35] The method relies on an exon-specific polymerase chain reaction (PCR) (~500–800 bp) with fluorescent primers that label both sides of the product with a different fluorophor. If a mutation was induced in the exon of interest, two alleles are present in that sample. Denaturing and reannealing of the samples will result in heteroduplexes in the mutant sample, which are specifically cut by the endonuclease CEL I. Denaturing polyacrylamide gel electrophoresis using an LI-COR DNA analyzer will detect the fluorescently labeled full-length and digested products. The mutations will appear as extra dots on a gel image, which are easily recognized by the eye. The corresponding sample is then resequenced to reveal the nature of the mutation.

An advantage of the method is that all reactions can be performed in an automated fashion, which makes the procedure easily scaleable (Table 19–3). In addition, after PCR amplification samples can be pooled up to four times to increase throughput. Investment costs are reasonably low. The assay requires a PCR machine, an LI-COR DNA analyzer, and depending upon the anticipated throughput, a liquid handling station for automation. The running costs are also low, especially if samples are pooled and PCRs are standardized using primers with universal adapters and universal fluorescent primers that fit these adapters. The disadvantages are that in our hands LI-COR gel images of variable quality (resolution, signal intensity) were produced. This was

Table 19–3
Overview of mutation discovery strategies applied to mutagenized rat libraries

	CEL I	*Resequencing*	*Yeast-based assay*
Automation[a]	+	++	−−
High-throughput[b]	++	++	−
Scalability[c]	+	++	−
Flexibility[d]	−	+	−
Robustness[e]	−	++	+/−
Accuracy[f]	−	++	+/−
Investment costs	+	−−	++
Running costs	+	+	++

[a]Automation: Can the method be run in a fully automated fashion, i.e., without manual operations?

[b]High-throughput: Does the method allow for the screening of large amounts of bases per day?

[c]Scalability: Can the amount of genomic DNA/RNA samples easily be scaled up or down?

[d]Flexibility: Does the method easily allow for the screening of additional amplicons/exons?

[e]Robustness: Is the quality of the data constant between amplicons, samples, or runs?

[f]Accuracy: Does the method produce false positives/negatives?

partially amplicon dependent and partially unknown, which makes the assay score lower in robustness. Additionally, researchers planning to use this technology should take into account that it is not 100% accurate. The CEL I method does miss some mutations and produces a considerable amount of false-positive dots that have to be followed up by an independent PCR and sequencing reaction.[35]

Dideoxy sequencing is considered the gold standard for the discovery of genetic variation.[36] The Cuppen laboratory has developed a cost-effective high-throughput automated resequencing platform that allows for the screening of literally millions of bases per day.[21] All reactions are performed in an automated fashion and data are analyzed using Polyphred software.[37] Polyphred awards a score to putative heterozygous positions, for which the original sequence trace was individually scanned by the eye. All potential mutations that pass this manual selection are repeated by an independent PCR and sequencing reaction for verification.

Resequencing is the most direct way of finding induced mutations and the method is extremely robust and scaleable (Table 19–3). Very few if any mutations are missed and the false-positive rate is low, making this method highly accurate. On the other hand, the investment costs are high, since the method requires a capillary sequencing machine, PCR machine, and liquid handling robot. As all reaction are standardized by the use of universal adapters and diluted to limited conditions, the running costs are surprisingly low.

The yeast-based screening assay employed by the Gould laboratory to generate knockouts in *Brca1* and *Brca2* allows for the identification of only truncations, caused by premature stop codons or frame shifts, induced by splice site mutations or insertions/deletions (INDELs). The advantage is that only those mutations that have the highest chance to alter gene function are found. However, potentially interesting functional missense mutations are neglected by this method. There are two versions of the method, namely the cDNA (copy DNA) version and the gDNA (genomic DNA) version. PCR-amplified fragments of the cDNA target or the large gDNA exon are transformed into competent yeast cells together with a linearized customized gap-repair vector containing sequences of the fragment of interest. Upon transformation, the amplified fragment is "cloned" *in vivo* into the gap-repair vector by homologous recombination, which places it behind the yeast *ADH1* promoter and in frame with the reporter gene *ADE2*. Yeast cells that produce the functional chimeric protein grow efficiently and form large white colonies on plates with selective medium. If the fusion protein is truncated due to a premature stop codon or frame shift mutation in the cloned fragment, the yeast cells will grow inefficiently and produce small red colonies. Since the original mutation is heterozygous, such a plate should theoretically contain half white and half red colonies. The corresponding sample is resequenced to reveal the nature of the mutation.

The yeast-based assay does involve substantial manual operation, especially the cDNA version, which includes isolation of total RNA and a reverse transcriptase reaction, and is not easily automated. In the final step, the transformed yeast cells have to be plated out manually and read by the eye. This also negatively affects the throughput and scalability of the method (Table 19–3). The method is not flexible, since it requires a different customized gap-repair vector containing a gDNA/cDNA product for every gene of interest. The method produces a background rate of red colonies, which is generally higher for the cDNA version (12.5–15%) compared to the gDNA version (0.5%).[22] Both versions do produce false positives, which are initially repeated in the same assay and subsequently followed up by resequencing. The main advantage of the yeast-based screening method is that the verified mutations will in almost all cases result in loss of gene function. Additionally, the cDNA version allows for the screening of larger fragments (up to the full-length cDNA). Finally, the investment costs are low, since only a PCR machine is needed. The running costs are also low; however, if the method is scaled up, personnel costs become a considerable issue due to many manual steps in the procedure.

These are three examples of mutation discovery platforms used in the rat, but many other methods not discussed here are available. Every mutation discovery platform has its own advantages and disadvantages. Depending on the purpose of the screening, the desired throughput, and the available personnel/funds, a method can be selected.

OUTCROSSING OF AN INTERESTING MUTATION All mutations identified in the F_1 library will be heterozygous. To obtain a homozygous mutant, the corresponding rat must first be outcrossed to an untreated rat. Progeny of the outcross are genotyped to ensure germ-line passage of the mutation in a Mendelian fashion. Although generating a homozygous mutant seems straightforward, a repeatedly posed question about the ENU mutagenesis-mediated knockout/mutant procedure is whether background mutations that are inevitably induced by ENU are a major concern. Given a mutation rate of 1 in ~1.2 Mb, a genome size of ~2.5 Gb, and a coding region size of ~28.4 Mb, of which ~1.7 Mb could be mutated into a stop codon by the three most common ENU-induced mutations, every mutagenized genome will on average contain ~2000 mutations, of which ~24 are located in coding regions, of which one or two will change an amino acid into premature stop codon. Theoretically, for every backcross the number of background mutations is reduced by on average 50%. Thus, after five backcrosses mutant animals will consist of ~97% of the wild-type genome and will contain approximately 1 mutation in coding regions and 63 mutations elsewhere in the genome. Although this may hold true for all unlinked background mutations, potentially confounding mutations that are linked to the mutation of interest will remain, as they are located nearby on the same chromosome. For the mouse, Keays *et al.*[38] modeled the decay of linked mutant DNA to a randomly selected position on a chromosome (e.g., a mutation) over the number of backcrosses and found that after 10 backcrosses there is still on average ~20% of mutant DNA linked to the selected site, which depending on the size of the chromosome corresponds to ~53.6 (chr *1*)–9.4 (chr *12*) Mb in the rat. These segments could still contain ~45–8 background mutations, which, depending on the proportion of coding or other functional regions surrounding the mutation of interest, could have a small chance of influencing phenotypic analysis.

In the case of introgressing an induced mutation into a different genetic background, the animal harboring the smallest portion of the mutant genome could be traced in each cross by marker-assisted selection,[38] thereby speeding up the backcrossing process. This procedure could more efficiently abandon confounding mutations and give insight in the amount of mutant DNA accompanying the mutation of interest; however, it could never eliminate all possibly linked mutations. Thus, while backcrossing

to a wild type background is an effective strategy to eradicate unlinked mutations and to a certain extent linked mutations, the small chance of a closely linked confounding mutation contributing to the phenotype can be excluded only by functional experiments.

First, the phenotype–genotype relationship must always be 1 : 1, meaning that all homozygous mutant animals in every cross of the entire experiment must display the phenotype under study. If one homozygous animal does not display the phenotype, a closely linked mutation is most likely involved. This test becomes less penetrant if modifiers attenuate the phenotype. The gold standard to demonstrate the phenotype–genotype relationship is the generation of a second functional allele of the same gene that should give rise to a comparable phenotype. This is a rather common strategy in organisms with high induced mutation rates, like worms and zebrafish. However, for the rat, which allows for a fairly moderate mutation rate, it might not be feasible to find an additional functional allele, especially for below average-sized genes. Alternatively, a transgenic animal harboring a wild-type copy of the gene in the mutant background could be generated, which should rescue the phenotype. Technologies to produce transgenic rats are broadly established.[39,40] Finally, a phenocopy could be made by stable transgenic RNA interference-mediated gene silencing.[41]

RAT KNOCKOUT/MUTANT STATUS AND FUTURE PERSPECTIVES

Since the first publication of rat knockout technology in 2003, a total of 18 ENU-induced knockout rats have been reported by the Gould laboratory, the Cuppen laboratory, and the PhysGen program (http://pga.mcw.edu; Milwaukee, WI). In addition, 121 amino acid-replacing mutants have been reported. Several knockouts currently undergo detailed phenotypic characterization.[42] Recent publications on the rat knockouts for the adenomatous polyposis coli (*APC*) gene generated in a collaborative effort by the Gould and Dove laboratories (Madison, WI)[43] and the serotonin transporter (*SERT*) gene generated by the Cuppen laboratory[44] indicate that these models reflect human biology better than the corresponding mouse knockouts. The *Brca2* knockout, recently characterized by the Gould laboratory, does not provide an improved model for human *BRCA2*-related predisposition to breast cancer. However, it has a novel ocular phenotype (cataracts) never seen before in existing mouse *Brca2* knockouts.[45] In addition, homozygous knockout rats live longer compared to knockout mice with a truncation at a similar position in the *Brca2* gene. Finally, a rat knockout for *Myosin7a*, the gene affected in patients suffering from Usher syndrome Type 1B, was identified by an ENU mutagenesis-driven forward genetic approach.[46] In this case, the rat knockout model is phenotypically similar to existing mouse knockout models. However, due to the rat's greater size it provides better access to the affected organs, such as the inner ear, vestibular organ, and retina, and is also more suited for (micro)surgical manipulation.

This initial evidence suggests that rat knockouts could certainly complement other existing knockout models to study the genetics of specific aspects of human health and disease. Currently, the PhysGen program and the Cuppen laboratory are still pursuing ENU mutagenesis-based reverse genetics for genes involved in human cardiovascular processes, possibly resulting in novel interesting knockouts and mutants.

In addition to the reverse genetic approaches that have been discussed in this chapter, rat forward genetics could also lead to novel insights in gene function. Many rat strains have been thoroughly characterized in the past and are currently being systematically phenotyped (e.g., PhysGen program; The National Bio Resource Project in Kyoto, Japan; http://www.anim.med.kyoto-u.ac.jp/nbr). If these validated assays are converted into a streamlined high-throughput screening pipeline, they could be well suited for a large-scale systematic ENU mutagenesis-based screen. Previous ENU mutagenesis experiments have already produced a number of dominant and recessive mutant phenotypes, such as polydactyly, tail and eye aberrations, hip dysplasia, diphally, and circling behavior.[20,22,46] Only for the circling mutant (Tornado) has the underlying gene defect been found. This appeared to be a premature stop codon in *Myosin7a*, as mentioned above.

Despite the lack of embryonic stem cell-related technologies for the rat, the genetic toolbox has recently been filled rapidly. Historically, the rat has always been the model of choice for physiology rather than for genetics. However, because of these recent advances in ENU mutagenesis-based forward and reverse genetics, as well as the development of other genetic technologies for the rat, such as transgenesis,[40] and transient and permanent RNAi-mediated gene-silencing,[41] rat genetic and genomic approaches have recently gained momentum.[2,10]

ACKNOWLEDGMENTS

The work of the Gould laboratory has been supported by grants from the U.S. National Institutes of Health (CA28954, CA77494, and CA106216). The work of the Cuppen laboratory has been supported by the Dutch Ministry of Economic Affairs through the Innovative Oriented Research Program on Genomics and NV Organon.

20 Rodent Genetics, Models, and Genotyping Methods

Sheryl J. Wildt, Andrew I. Brooks, and Robert J. Russell

ABSTRACT

Laboratory mice (*Mus musculus*) and rats (*Rattus norvegicus*) are the most commonly used animals in biomedical and behavioral research. Today, there are many inbred, outbred, hybrid, congenic, and genetically modified mouse and rat models that have made essential contributions to advances in the diagnosis, prevention, and control of human disease. Routine genetic monitoring of these animals is essential to their successful use. Herein, we discuss the basic structure of the mouse and rat genome; common breeding protocols to preserve innate and exogenous genetic backgrounds; and the methods used for creating specific types of mutant model, research applications, and current genotyping methods.

Key Words: Genetics, Genotyping, Genetically modified, Microsatellite marker, Single nucleotide polymorphism, Polymerase chain reaction, Allelic discrimination.

MODEL USE AND HISTORY

Laboratory mice (*Mus musculus*) and rats (*Rattus norvegicus*) are the most commonly used animals in biomedical and behavioral research.[1] Mice and rats have made essential contributions to advances in the diagnosis, prevention, and control of human disease.[2–5] Mice and rats originated in Asia and then spread throughout the world as they became commensal with humans. *M. musculus* is most likely the result of a hybrid of several species of the species, *Mus*. The laboratory mouse is a subspecies of *M. musculus*; *M. musculus musculus*. In 1664, Robert Hooke was the first to use the mouse in the laboratory while studying the properties of air and oxygen. Albino mutant rats (*R. norvegicus)* were first brought into the laboratory in Germany in the 1870s, and thus, are the first mammal domesticated for experimental purposes.[4]

Many of the strains and stocks of mice and rats used today in research were initially started by coat color breeding fanciers (or pet breeders) in Asia (Chinese mouse fanciers are recorded as early as 307 AD), Europe, and the United States (Abby Lathrop). The first inbred mouse strain (DBA/1) was developed by C.C. Little in 1909. The Wistar Institute in Philadelphia is the original source of many of the currently used rat stocks and strains. Commercial and government supported breeding colonies of mice and rats were established throughout the world to supply a broad range of characterized genotypes for support of broad-based scientific studies. Standard nomenclature rules for mice and rats stocks and strains have been published.[6] Specific sources for mice and rats models are also available,[6] and genome databases have been established.[7–9]

Mice and rats have been widely used in the study of immunology, cancer, cardiovascular disorders, metabolic disorders, neurological disorders, organ transplantation, renal disease, genetics, toxicology, and behavior, just to name a few. The ever growing use of genetically modified mice and rats (transgenic, knockout, knockin, conditional mutants), in addition to the use of the standard stocks and strains of outbred, inbred, hybrid, congenic, consomic, and recombinant strains, has made major contributions to the advancement of genomic medical knowledge in the past 20 years.[10–14] The first transgenic mammal created by pronuclear injection was a mouse.[15] Recently, to ensure that unique strains will be available to future generations of scientists, a number of government sponsored repositories have been established in the United States, Europe, and Japan.[16–19] Improvements in genetic engineering technology and methodology are continuing for the development of inducible transgenics, conditional mutations, speed congenic production, transgenic and knockout rats, and chemical-induced and radiation-induced mutants. The need for evolving genetic testing services and technologies continues to be of utmost importance.[20,21]

BASIC RODENT GENETICS

THE MOUSE GENOME

Scientific interest in the study of the mouse genome dates back to at least 1866 when Gregor Mendel began investigating coat color alleles in mice. Upon hearing of the monk's activities, a local bishop forbade Mendel to share his living quarters with any creature that engaged in sexual intercourse, and thus Mendel was forced to use pea plants for his now famous genetics research.[22] In 1902, Lucien Cuénot became inspired by reading Mendel's Laws of Independent Assortment and Segregation, and he began his own experiments, using the mouse to study segregation of the albino and yellow coat color alleles.[23] This work was continued by Cook and Little, who described nine color coat loci in mice.[24,25]

The mouse genome consists of 19 pairs of autosomes and the X and Y sex chromosomes. Each chromosome is acrocentric, meaning that the centromere, or "waist" of the chromosome, is positioned at one end. The short arm of acrocentric chromosomes have structures called "satellites," which are round, circular

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.),

figures on the end of a stem that code for ribosomal DNA. The organization of the mouse genome consists of approximately 8% highly repetitive DNA, 76% repetitive DNA, 15% semirepetitive DNA, and 1% fold back DNA.[26,27]

THE RAT GENOME The scientific study of the rat dates back to as early as 1828. The first genetic experiments were performed on the rat by Crampe from 1877 to 1895 and focused on the inheritance of coat color alleles. In 1908 the first inbred rat (PA strain) was developed by King.[28]

In the early 1990s, many scientists argued that sequencing the rat genome would be redundant because the mouse and human genome had already been sequenced. It was assumed that the rat genome would be quite similar to the genome of the mouse. Despite scientific protest, investigators led by the Baylor College of Medicine Human Genome Sequencing Center sequenced the DNA from the Brown Norway rat (BN/RijHsd) obtained by the Medical College of Wisconsin from Harlan. The entire genome of the rat has not yet been sequenced; however, a high quality draft representing 90% of the DNA sequence is currently available. Despite the gaps in the DNA sequence, it is still quite evident that the organization and size of the rat genome were much different than first expected.[29]

The rat genome consists of 21 pairs of autosomes and the X and Y sex chromosomes. The size of the rat genome is approximately 2.75 gigabases (Gb), as compared to the mouse genome of 2.6 Gb and the human genome of 2.9 Gb.[30]

BREEDING METHODS

INBREEDING Each individual animal in an inbred strain is genetically uniform, thus eliminating experimental variability due to genetic effects. An inbred strain is defined as having at least 20 generations of brother × sister matings. An inbreeding program begins with breeding siblings produced from a first filial mating (F_1). Inbreeding is continued by performing full sibling matings at each successive generation. As the filial number increases, the level of heterogeneity in the colony decreases, and after 20 successive generations of brother × sister matings (F_{20}), a colony is considered to be fully inbred,[31] although many currently available strains are over 100 generations.

OUTBREEDING A rodent outbreeding program is the opposite of an inbreeding program with the goal being to retain maximum heterogeneity by avoiding matings between closely related individuals. Although outbred rodents (referred to as stocks) are not genetically defined, advantages for some investigators include increased body weight, larger size and frequency of litters, increased life expectancy, increased resistance to disease in some cases, and lower cost due to higher reproduction. Outbred stocks are useful in experiments in which the genetic background of the experimental model is not the major factor in the outcome of the study and they are used extensively in toxicology and safety assessment.[32]

F_1 HYBRIDS Fully inbred strains often display undesirable characteristics, including low fecundity, small litter sizes, reduced life span, and increased susceptibility to disease due to homozygosity. It is possible, however, to create a colony of rodents that is genetically identical without suffering the consequences of homozygosity. This is accomplished by crossing two inbred strains to produce an F_1 hybrid animal that is heterozygous at almost all loci. These animals display hybrid vigor for the characteristics mentioned above. F_1 hybrid strains also exceed the life span of either of the inbred parent strains.[33]

CONGENICS Congenics are created by backcrossing a "donor" strain that contains the gene of interest to an inbred "recipient" strain for 10 or more generations. With each generation, the allele of interest from the donor strain is maintained in a heterozygous state, while the rest of the genome is bred to homozygosity during the 10 generations. The resulting offspring are genetically identical to the recipient strain, except for a small chromosomal region that carries the gene of interest from the donor strain. Congenics are useful in studying multiple gene effects and also for studying a particular mutation of interest on various inbred strain or outbred stock genetic backgrounds.[32]

Marker-assisted breeding, or speed congenics, can reduce the time necessary to produce a transgenic by 50%. Speed congenics is performed by utilizing a genome wide screen at each generation to select breeders (typically males) for the next generation of backcrossing. Selected breeders not only carry the gene of interest, but are also the most genetically similar to the recipient strain.[34,35] Backcrossing using standard breeding methods and speed congenic techniques are commonly used today in most research institutions.

CONSOMICS Consomic strains are a variant on the congenic; they differ from the recipient strain by an entire chromosome instead of just a single gene of interest. They are created by performing complex long-term breeding schemes. These strains are useful in associating specific phenotypic traits with a particular chromosome, and also for studying and mapping complex genetic traits, such as quantitative trait loci (QTLs).[36]

SELECTED MUTANT MODELS

SPONTANEOUS MUTANTS A spontaneous mutation in the genome of an organism typically occurs due to errors made by the DNA replication and repair mechanisms in the cell, thus altering the gene nucleotide sequence. Chromosomal mutations arise due to a structural change or a change in the number of chromosomes in an organism. Scientists usually recognize mutations when they have some effect on the phenotype of the organism. Rodents that carry spontaneous mutations are very important in the study of basic biological processes, in studying gene relationships, and as human disease models.

A strain with a spontaneous mutation that has been extremely useful in the study of immunology, tumor cell growth, and transplantation studies is the C.B-17/Icr-*Prkdc*^{scid} inbred mouse. These mice accept grafts and tumors from other species of animals as well as mice. The *Prkdc*^{scid} mutation was first discovered when it was noted that several C.B-17 pups from a litter were deficient in IgM, IgG_1, and $IgG_{2\alpha}$.[37] The mutation, termed scid or severe combined immunodeficiency disease (SCID), was shown to be a recessive, single nucleotide polymorphism (SNP) located on mouse chromosome 16.[38,39] The *scid* mutation affects normal T and B cell development, and these mice are highly susceptible to opportunistic infections, similar to the severe combined immunodeficiency disease in humans.[37,40] The *scid* mouse is available on a variety of genetic backgrounds from several commercial breeders.

TRANSGENIC (MICROINJECTION) MODELS Transgenic models are created by modifying the genetic material by insertion of genetic material from another organism by

nonbreeding methods. The most common technique used for creating a transgenic model is microinjection. This technique involves injection of foreign DNA directly into the male pronucleus of a fertilized oocyte.[41]

There are many examples of important rodent disease models that have been created by using microinjection techniques. One such model is the HLA-B27 transgenic rat. This model expresses human HLA-B27 and β_2M, and is useful in studying HLA-B27-related diseases in humans, including psoriasis, reactive arthritis, and inflammatory bowel disease.[42]

TARGETED MUTANTS Although microinjection is a powerful method, a major limitation is that it does not permit creation of targeted mutants. Several techniques, such as targeted mutagenesis and gene trapping, have now been developed to overcome this limitation. Through these techniques, investigators can create mutations at any locus of interest, and thus study the function of cloned genes.[43]

KNOCKOUT MUTANTS Knockout mice are generated by inactivating or "knocking out" the function of a single gene of choice without affecting any other gene in the genome. These techniques include homologous recombination and gene trapping.

Homologous recombination is performed by introducing a segment of DNA that has an identical sequence to the gene of interest, but also includes a mutation that renders it inactive, into an embryonic stem (ES) cell. ES cells from the 129 mouse strain are typically used. The cell's DNA replication and repair machinery recognizes the artificial DNA sequence and exchanges it with the target gene, thus "knocking out" the function of the gene of interest.[44]

The gene-targeted mouse ES cells are then microinjected into mouse blastocysts that are transferred to pseudopregnant female mice and permitted to develop to term. After the pups are born, some pups may be chimeric and they are usually identified by their coat color. The chimeric mice are bred to appropriate wild-type mice and the resulting pups are screened for germ-line transmission by identifying the heterozygous targeted allele. Homologous recombination is the most commonly used method for generating knockout mice.[45]

Gene trapping is a similar method, except that the artificial DNA sequence is designed to be inserted into any gene and disrupt the cell's RNA splicing mechanism. This technique prevents the gene that harbors the foreign DNA from producing a functional protein, and thus knocks out its function.

An example of an important knockout model is the *p53* knockout mouse. The *p53* gene codes for a protein that arrests cell division and thus halts tumor growth. Humans who have a mutated form of the *p53* gene have a much higher risk of developing many types of cancer at an early age, including breast cancer and leukemia. The *p53* knockout mouse has been an important tool for studying tumor growth and regulation of cell division.[46,47]

Rat ES cells are not available and homologous recombination and gene trapping are feasible only in mice. Until recently, the rat lagged behind the mouse in the development of genetic baseline information; however, the rat is now catching up.[7] Knockout rats have been developed. The recent advances in rat genetics will permit broader use of the rat in genomic studies with links to phenotypes and comparative mapping to both the mouse and the human.

A concerted effort to create a knockout for every gene in the mouse genome is currently being undertaken by major research institutions around the world, including Canada, Europe, the United States, and China. In the United States, the National Institutes of Health (NIH) has announced the Knockout Mouse Project (KOMP), which aims to create and identify approximately 10,000 knockout mouse lines for scientific research.[48]

KNOCKIN MUTATIONS Knockin mice are also created by microinjecting gene-targeted mouse ES cells into mouse blastocysts. The injected blastocysts are transferred to pseudopregnant female mice and allowed to develop to term. The chimeric mice are bred to appropriate wild-type mice and the resulting pups are screened for germ-line transmission.

One well-studied knockin mouse model is the *APOE2* mouse. The apolipoprotein E2 (*APOE2*) allele is recessive and is the cause of human Type III hyperlipidemia in humans. In the *APOE2* knockin mouse, the endogenous mouse *Apoe* gene has been replaced by the human *APOE2* gene. This mouse develops a severe diet-induced hyperlipidemia and shows marked cholesterol and triglyceride lowering upon treatment with fibrate, an agonist of peroxisome proliferator activator receptor α (PPAR-α).[49]

CONDITIONAL MUTANTS A variety of techniques are used to create conditional gain and loss of function mutations, but the most popular current method is the Cre-*loxP* recombinase system. The Cre recombinase enzyme functions like molecular scissors, cutting out the gene of interest that has been flanked by two *loxP* sites. Cre recombinase can be expressed in a spatial and temporal manner conveying cell type specificity, and allowing the targeted gene to be eliminated (or added) in specific cell types.[50,51]

The *BRCA1* conditional knockout mouse is an important model for the study of breast cancer tumorigenesis in women. Loss of function of the *BRCA1* tumor suppressor gene predisposes women to both breast and ovarian cancer. Knocking out the function of this gene in mouse tissue types results in embryonic lethality. To overcome this obstacle, a model was created by use of the Cre-*loxP* recombinase system, which knocked out the function of the gene in a tissue-specific manner.[52]

ETHYLNITROSOUREA MUTANTS Mutations in the DNA sequence of an organism can be induced by chemical mutagenesis. Ethylnitrosourea (ENU) is the most commonly used chemical mutagen, and it causes multiple untargeted point mutations. ENU mutants are created by exposing males to ENU and then breeding those males to normal females. Using high-throughput phenotyping methods, the offspring are screened for phenotypic traits of interest that originate from the point mutations inherited from their ENU-treated male parent.[53–55]

IRRADIATION MUTANTS By exposing an animal to ionizing radiation in the form of X-rays, gamma rays, or neutrons, multiple untargeted mutations in the DNA sequence can be induced.[56] Ionizing irradiation most often induces rearrangements, translocations, or deletions in the genome as much as 100 times higher than the rate of spontaneous mutation.[57] Although higher than the rate of spontaneous mutation, the frequency of mutation induced by ionizing radiation is still considered relatively low, and is practical only for laboratories with the means to screen large numbers of exposed animals using high-throughput phenotype screening programs.[28]

GENETIC MONITORING/GENOTYPING

HISTORICAL BACKGROUND The need for routine genetic monitoring of the thousands of rat and mouse strains used today in biomedical research is well established.[13,58–61]

Genetic quality control and monitoring of these animals are essential to their successful use. Continual change in the gene pool of inbred strains is unavoidable due to residual heterozygosity and spontaneous mutations that continually occur. In addition, genetic contamination due to mismating is a continuing threat in breeding colonies and must be prevented by appropriate husbandry techniques. The experimental use of nonauthentic or genetically contaminated rats and mice has been identified as the cause of erroneous research results.[62–69]

It is generally expected that genetically authentic or genetically modified animals will arrive as expected from the collaborating investigator, institutional source, or commercial supplier; however authenticity should be ascertained by the receiving laboratory. Information regarding the genetic background, genetic modification(s), and relationship to the background strain should be understood prior to research use. Genetic authenticity of strains should be ensured by appropriate testing and the results compared to those published for the reference strain. Increased transfer of animals between research institutions has resulted in an increased potential for genetic and microbiological contamination.

Institutional policies for the importation of mice and rats from outside sources should be developed and carefully followed to prevent potential genetic or health problems. Many strains and stocks (embryos, ovarian tissue, sperm) of mice and rats are now cryopreserved at repositories or individual institutions to protect their long-term genetic and microbiological quality.

Previously, biochemical markers;[13,59] strain-specific typing sera;[70,71] immunological methods using monoclonal and polyclonal antibodies to major histocompatibility haplotypes and lymphocyte antigens;[72–74] skin grafting;[63,75] phenotypic, morphological markers and characteristics (mandible shape);[62] coat color; behavior; and reproductive characteristics were used to monitor genetic quality. More recently, as our understanding of the mouse and rat genome has evolved, DNA from individual mice and rats is now used for genetic evaluation, and once the DNA has been extracted, it can be preserved indefinitely to perform a variety of analyses.

DNA fingerprinting,[76–79] using multilocus probes [also known as minisatellites or restriction length polymorphisms (RFLP)], microsatellite markers, and SNP markers [80,81] are now routinely used to replace the older methods that were primarily based on phenotypic expression.

DNA fingerprinting is useful for comparing different colonies of the same inbred strain. It is reassuring that the multiple bands observed using DNA fingerprints of inbred rat and mouse strains bred in different countries by the same supplier are similar, and that strains, known to differ at many biochemical loci as a result of past genetic contamination, have different DNA fingerprints. DNA fingerprinting is technically quite demanding even when nonisotopic fingerprinting protocols are used. The approach requires some time to become technically proficient in routinely producing high-quality Southern blot gels, preparing high-quality large-molecular-weight DNA, sample well loading, and membrane handling, not to mention data analysis and interpretation. A high mutation rate of visible bands implies that segregation of such bands within an inbred strain can be confused with genetic contamination. DNA fingerprinting also requires a longer period of time to obtain results than other techniques that are currently available.[82]

When microsatellite markers were introduced in the early 1990s, they greatly improved the efficiency of genetic evaluation. These tests are readily performed using polymerase chain reaction (PCR), and batteries of microsatellite markers, amplified using PCR, have been developed for both mice and rats. This method provides single locus DNA-based methods without the time limitation of fingerprinting and without having to amass large numbers of cloned probes. Microsatellites involve tandem repeat units, typically of one to five bases, and are detected using unique sequence DNA that flanks the tandem repeats. Only one or two bands are produced in each sample because DNA is amplified by unique sequence primers instead of the multiple primer sets used in DNA fingerprinting.

The availability of even greater numbers of SNPs provides the opportunity for greater resolution between DNA-based information. Over three million SNPs have been characterized in humans and one million SNPs in the mouse and rat. The resolution of SNPs in rodents is approximately 3 kb, allowing this information to be used in more detailed genetic mapping scenarios. SNP detection is currently becoming the method of choice for genetic evaluation of rats and mice.

MICROSATELLITE MARKERS The utilization of microsatellite markers has been a valuable tool and subsequently has been applied to many applications in genetics research laboratories. In the context of this review, the primary application being exploited is the use of microsatellite markers for monitoring genetic backgrounds in laboratory strains of mice and rats. Identifying well-defined polymorphic regions provides the information needed to distinguish the genetic background in most inbred strains. Although many public repositories exist to mine sequence information, the Center for Inherited Disease Research (CIDR) database (see Additional Web Links) is among the richest resource for selecting markers to characterize rodents. Once genetic regions of interest are identified, which include those that show the largest polymorphic differences between the strains being evaluated, a standard set of PCR conditions is often employed to "screen" animals. The sizing of the PCR products is aligned with reference controls in order to determine the genetic background of the animals of interest.[83]

The sizing of PCR products from microsatellite markers can be conducted in many ways. A variety of technologies can be employed depending on the resolution, throughput, and cost restraints of the experimentalist. Below is a review and description of the most commonly used techniques for sizing PCR products produced by microsatellite marker amplification.

Polymerase Chain Reaction The PCR is based on a molecular principal defined by Kary Mullis in the 1980s. The synthesis of DNA is used to make qualitative and, in some instances, quantitative measurements of nucleic acid. PCR, as defined by the 1989 editor of *Science*, Daniel Koshland Jr., is as follows:

> The starting material for PCR, the "target sequence," is a gene or segment of DNA. In a matter of hours, this target sequence can be amplified a million fold. The complementary strands of a double-stranded molecule of DNA are separated by heating. Two small pieces of synthetic DNA, each complementing a specific sequence at one end of the target sequence, serve as primers. Each primer binds to its complementary sequence.

Polymerases start at each primer and copy the sequence of that strand. Within a short time, exact replicas of the target sequence have been produced. In subsequent cycles, double-stranded molecules of both the original DNA and the copies are separated; primers bind again to complementary sequences and the polymerase replicates them. At the end of many cycles, the pool is greatly enriched in the small pieces of DNA that have the target sequences, and this amplified genetic information is then available for further analysis.

For most microsatellite marker PCR protocols, a standard set of reaction conditions is used to amplify products that range from 80 to 300 bp.

The main reason primers are designed with similar melting temperatures is to allow for many sequences to be amplified simultaneously. Following PCR, the analysis of PCR product sizes allows for the assessment of genetic contributions to segregate specific strains.

Visualization of DNA products: Capillary Electrophoresis, Traditional Gel Electrophoresis, and Lab-on-a-Chip Technologies A number of technologies exist to determine the size of DNA fragments produced during PCR. Although the importance of specificity and sensitivity of PCR is a given, the mechanism by which the results are measured is equally important. Until recently, gel electrophoresis in an agarose matrix was the technology of choice for measuring the size of DNA in a low-throughput manner. The resolution of detection is achieved by varying the percentage of agarose in the gel matrix. Lower concentrations of agarose lead to better resolution of larger DNA fragments (1 kb and higher), whereas higher concentrations of agarose lead to better resolution of smaller fragments (500 bp and lower) while resolution of even smaller fragments (100 bp and lower) requires a different matrix (i.e., polyacrylamide or PAGE gels).

Given that most microsatellite markers yield products that range from 80 to 250 bp, the resolution of PCR product sizes is of paramount importance when using absolute fragment sizes to compare PCR band sizes for the same marker between different inbred rodent strains because the strains typically differ by only a few base pairs. Traditional gel electrophoresis can be somewhat variable, leading to absolute differences between different markers, gels, and screens. Lastly, electrophoresis anomalies such as bowing, skidding, and smearing lead to variable interpretations that can confound important observations regarding the genetic integrity of a rodent colony. To this end, there are two new approaches that convey the sensitivity, specificity, and throughput to perform the sizing needed for this application.

The first is a capillary electrophoresis approach that is commonly employed by forensic laboratories for fragment analysis. Fragment analysis requires the use of a modified forward primer that results in a fluorescent PCR product that is resolved on a capillary electrophoresis DNA sequencer. In an optimal environment, markers can be multiplexed by using different fluorescently labeled oligonucleotides (primers) to distinguish marker-specific PCR products. Another slightly more cost effective option is Caliper's Lab-on-a-Chip technology.[84] Hundreds of samples can be run in 1 day, achieving resolution of less than 5 bp. This method allows for the most sensitive and efficient sizing of a wide variety of markers. Data are represented via an electropherogram, which depicts a sensitive array of all DNA products in a mixture. Either capillary electrophoresis or Lab-on-a-Chip technologies greatly increase the throughput and resolution to make accurate measurements that ensures reliable data interpretation.

SINGLE NUCLEOTIDE POLYMORPHISMS DETECTION TECHNOLOGIES SNPs are becoming a preferred method for monitoring the genetic basis of disease. In human studies, SNP profiling has become the primary source of genetic inquiry, surpassing the use of microsatellite markers for many clinical and forensic applications. As additional sequence information becomes available for different strains of rodents, the trend toward adaptation of SNP measurement to determine genetic purity is rapidly increasing. Currently, a large number of technologies can be employed to measure individual SNPs, thus enabling investigators to analyze over 500,000 SNPs at one time in a single sample.[85,86]

Low-, moderate-, and high-throughput techniques are available when using SNP analyses. Low-throughput analysis approaches are primarily PCR based and used for allelic discrimination applications as described later.

Moderate-throughput applications are capable of measuring up to several thousand SNPs in as many samples. Detection technologies range from high-order multiplex PCR (Applied Biosystems SNP-plex), single base extension technologies (Beckman Coulter SNPstream), and more recently, detection using mass spectrometry (Sequenom). All of these technologies provide robust data sets and use different detection technologies, which relate heavily to the cost associated with data generation.

High-throughput applications are currently microarray based. The Affymetrix GeneChip and Illumina bead-based arrays are the densest arrays available and allow for the simultaneous detection of over 500,000 genotypes in a single assay. Regardless of the mechanism for generating data, it is imperative to emphasize that the analytical tools used for analyzing genotyping data transcends the technology used for data acquisition. Since most panels for distinguishing inbred strains of rodents require at least several hundred SNPs for a concrete segregation, moderate-throughput technologies are typically employed for genetic monitoring and speed congenic applications.[87,88]

Allelic Discrimination Determination Allelic discrimination is an approach used to determine the zygosity of a spontaneous or genetically targeted single base pair mutation. One of the most commonly used technologies for this application is the Taqman fluorogenic 5′ nuclease assay. A single nucleotide polymorphism is identified through differential binding of two dual labeled probes designed to distinguish a single base pair mutation in the DNA sequence. The level of fluorescence generated by the cleaving of each probe (once bound to the template) allows for a sensitive and accurate detection of heterozygotes and homozygotes for the genetic mutation of interest. There are a number of real-time thermal cyclers capable of making measurements that range in capacity from 24 to 384 samples at a time.

Inbred Strain Verification and Speed Congenic Programs Animal models of disease are a critical component of most biomedical research programs. A major advantage of utilizing rodents in these paradigms is the ability to control most genetic contributions across generations. In addition, genetic diversity across inbred strains provides critical information regarding the genetic component of disease onset and progression. To this end, studying specific biological perturbations in the context of an a priori selected strain of rodent is of paramount importance.

Traditional backcrossing can require 3 years of breeding to transfer a gene of interest onto a genetic background different

from the donor strain. Speed congenic or marker-assisted backcrossing methodologies reduce this time by 50% (or more), resulting in a new congenic strain in as few as five generations. Once a mutation has been characterized in a new genetic background, it is necessary to perform routine genetic monitoring to ensure the genetic integrity of the congenic strain. Both inbred strain verification and speed congenic programs employ microsatellite and SNP-based technologies.

The utilization of these approaches requires a fine balance between identifying the optimal resolution generating genetic information and the cost associated with data generation. Typically, chromosomal regions that require a finer resolution will benefit from the informatics and technology utilized in an SNP profiling panel. When using a panel that consists of several hundred SNPs, an investigator can cover all autosomes at approximately 15-cM intervals, to convey a level of specificity needed for most inbred strain and speed congenic applications. In addition to selecting a technology suitable for genetic monitoring, it is essential that a comprehensive husbandry strategy is employed to ensure the genetic integrity of any rodent colony.

GENE EXPRESSION ANALYSIS: DNA MICROARRAYS AND QUANTITATIVE POLYMERASE CHAIN REACTION Gene expression analysis has become a widely used approach for making predictions, characterizing biological perturbations, and defining the molecular mechanisms of complex diseases. Similar to SNP profiling, there are now a plethora of technologies that measure gene expression in a variety of tissue types.

Irrespective of the technology being used to measure gene expression, it is important to underscore the importance of RNA quality. Additionally, RNA is a labile and depletable resource, so many laboratories archive cDNA that is the stable template used for measuring gene expression. NuGEN Inc. has developed a technology (Ovation) that amplifies cDNA from limiting amounts of RNA in a regionally unbiased manner. This technology allows an investigator to use any downstream gene expression technologies and still archive a precious resource for future investigation. Assuming that the quality of RNA is acceptable, the use of DNA microarrays is widely accepted for high-throughput gene expression measurements. A number of array manufactures, including Affymetrix, Applied Biosystems, and Agilent Technologies, offer full genome expression arrays. These arrays simultaneously measure the entire transcriptome in a single assay. Many caveats associated with performing microarray studies are outside the scope of this review; nevertheless, the technology has now been accepted globally for a variety of profiling and mechanistic discovery programs.

The most commonly used validation technique is that of real-time quantitative (Q) PCR. There are a number of chemistries that can be used for QPCR that range from SYBR dyes that intercalate double-stranded DNA to probe-based technologies such as Taqman and Roche's Universal Probe Library. Quantitative real-time PCR has become a standard for measuring the most sensitive changes in gene expression when interrogating a handful of genes in large numbers of samples. It is necessary to proceed cautiously with gene expression experiments and be certain to create and execute a solid experimental design while confirming the quality of RNA before making any measurements. Lastly, the analysis of gene expression experiments requires significant bioinformatics tools and resources to maximize the use of these large data sets.[89,90]

CONCLUSIONS

Mice and rats are the animal models of choice in biomedical research due to the ability to understand, manipulate, and study their genome with relative ease not to mention the strong genetic relationship with humans allowing for the development of direct, translational models of human disease. Newer techniques for genotyping and genetic manipulation continue to evolve, ensuring that the mouse and rat will remain important in furthering our understanding of human disease, leading to earlier and more accurate diagnosis, the development of cutting edge therapeutics, and disease prevention through a better understanding of genetic predisposition and gene–environment interactions.[91]

21 The House Mouse in Biomedical Research

JOHN G. VANDENBERGH

ABSTRACT

The house mice has become the primary rodent model in much of biomedical research because of its ability to adapt to a variety of environments. They are omnivorous, adapt to the environment with varied social structures, show considerable genetic variability, and share many similar physiological functions with humans. Recently the mouse has become the species of choice in transgenic studies because of the relative ease to transfer genes from other species, including humans. This chapter reviews the origins of the laboratory mouse, the use and care of the mouse, and its social structure and adaptability to different environments. Furthermore, it discusses the influence of pheromones on puberty onset, ovarian synchrony, and social communication. By making appropriate genetic selections and genetic manipulations, and providing an appropriate environment for the laboratory mouse, it will continue to serve the biomedical research community.

Key Words: Laboratory mouse, Origins, Adaptability, Social structure, Reproduction, Pheromones, Puberty, Ovarian synchrony, Husbandry.

INTRODUCTION

The laboratory mouse is to biomedical research as Mickey Mouse is to Disneyland. Just as Mickey has captured the attention of children and adults around the world, the laboratory mouse has captured the attention of biomedical scientists. In fact, it is the most commonly used nonhuman mammal in biomedical research with over 32 million mice in use per year (estimate by J. Zurlo, ILAR). Rats, which are often associated with biomedical research by the public, are used less often, about 8 million per year. The ability to alter the genome in the mouse resulted in a sharp increase in their use and the numbers are likely to continue into the future. A detailed description of the use of genetically altered mice is given elsewhere in this volume. Here the focus will be on the natural biology of the mouse and how this relates to its life in the laboratory.

In the hands of cartoonists the mouse is cute and frisky. For researchers it is small, easily bred, often tame, and has proven to be a useful model of human physiology and pathology (see Table 21–1 for a list of attributes). In this chapter I will discuss the origins of the laboratory mouse, the natural history of the species that relates to its use as a laboratory animal, and how the adaptability of the mouse makes it useful as a mammalian model for biomedical research.

ORIGINS OF THE LABORATORY MOUSE

The Order Rodentia has a world-wide distribution and has been classified into over 2000 species grouped into 28 families.[1] The Family Muridae consists of approximately 1300 species. Three subspecies of this family in the complex of *Mus musculus* are pertinent to readers interested in the "laboratory mouse."

The *M. musculus* complex originated in the Indian subcontinent and moved throughout Eurasia and into northern Africa before humans began serving as a vector for species distribution. The *M. musculus* complex consists of *M. m. domesticus* originally found in Europe, parts of Africa, and the near East, *M. m. castaneus* from Asia, and *M. m. molossinus* originally from the Japanese archipelago.[2] Mice of the *M. musculus* complex rarely hybridize, but where they are sympatric some genetic exchange occurs.[3,4] Thus, the taxonomy is complex with many authors using *M. musculus* and others using *M. m. domesticus* to identify the species being used. The latter is apparently utilized because much of the early research with the mouse occurred in Europe, the distribution of the *domesticus* subspecies. The majority of papers reporting on research involving the mouse simply use "mouse" or "house mouse" to identify the animal. The laboratory mouse is now available in many strains and with a number of genetic backgrounds,[5] so stain identity may be the most pertinent taxonomic designation for many studies. For more information on specific strains that have been developed see Chapter 22, 23, and 24.

The mouse has been associated with humans since the beginning of agriculture and the rise of cities. The earliest association between man and mouse is apparently in neolithic communities at around 6500 BC in what is now Turkey.[6] The mouse's association with agriculture may be reflected in the name for its genus, *Mus*. "Mus" came to Latin via Greek and before that from the ancient Sanscrit word "Mush," a word that means "to steal." [7] The mouse has been "stealing" food from humans for thousands of years. Its adaptability allowed it to disperse along with human hosts and, as the humans penetrated new environments, the mouse accompanied them. The house mouse, often seen as a pest species, is found throughout most of the world commensally with humans and as feral animals in a variety of natural habitats.[8]

The laboratory strains of mice used today derive from the activities of mouse breeders producing "fancy" mice, primarily

Table 21–1
Laboratory-friendly attributes of the house mouse

Life history traits	*Reproduction*	*Genetic*
Small size	Breed year-round	Tolerates inbreeding well
Omnivorous	Large litters	Inbred strains available
Short generation time	Ease of cross-fostering	Genetic sequence described
Adapt to social grouping		Totipotent embryonic stem
Short life span		Cells can be grown *in vitro*

in Japan, England, and the United States.[9] Mice were bred for unusual pelage and for striking behaviors such as "waltzing." An important source of the laboratory mouse strains in the United States resulted from the activities of Abbie Lathrop. Miss Lathrop was a retired school teacher who bred fancy mice on her farm in Massachusetts at the turn of the twentieth century.[10] She obtained mice from dealers, other mouse fanciers, and from the wild. A few animals in her colony developed tumors and, in collaboration with Leo Loeb, she attempted to learn more about this condition. The work resulted in two early scientific reports on cancer in mice.[10,11] She further collaborated with William Castle and his student Clarence C. Little at Harvard. C.C. Little went on to found the Jackson Laboratory in Bar Harbor, Maine. The result of their collaboration is the founding of inbred strains, usually credited to C.C. Little.[11] The first named mouse strain emerged from Little's research: the *dba*,[12] with *dba* standing for dilute brown nonagouti. The strain is ancestral to the currently used DBA1 and DBA2 among others.[5] Little's line "C" was the origin of the C57/58 strains, which gave rise to the commonly used C57BL/6 and other strains (see Chapter 22 for more information on strains). The work of C.C. Little and his co-workers and successors resulted in the Jackson Laboratory growing into a primary source of mouse strains as well as a major research center.[11,13] Phylogenetic analyses of 144 separate loci confirm this historical record on the origin of strains and provide an accurate picture of the genealogical relationships among the mouse strains.[14]

Mice have been used as mammalian models to help explain biological phenomena from the earliest days of modern scientific research. Robert Hooke, for example, used mice in 1664 to determine the biological consequences of high air pressures.[8] With the mouse emerging over the past few decades as the primary mammalian genetic model, it is interesting to note that Gregor Mendel may have begun his selection studies to examine the inheritance of coat colors in the mouse.[13,15] His superiors apparently objected to the monk's use of mice. Their obvious interest in sex plus their odor probably made them unwelcome cooccupants of Mendel's cell. Under pressure to give up the mouse, Mendel switched to the pea as a model organism and, as they say, the rest is history.

ADAPTABILITY AND SOCIAL STRUCTURE

The adaptability of the house mouse allows it to live in the wild as a pest consuming or damaging agricultural products, or commensally in human habitations, or as a laboratory animal. The house mouse is considered to be the most adaptable of all mammals, especially for its reproductive traits.[16,17] It can adjust to the major factors that influence reproductive ability: diet, physical environment, and social environment, as well as the interactions among these factors.

The importance of diet was tested by creating bioenergetic stress on mice of both sexes through restricting caloric intake under different thermal conditions.[18] The surprising results showed that bioenergetic restriction affected reproduction only in the female. Both sexes showed a high tolerance to restriction, but the females showed delayed puberty and impaired reproduction in adulthood.[17] The males continued reproductive development even to the point of ceasing growth.[17] The genetic or hormonal mechanism for this remains unknown. Such a striking sex difference in the mouse should be considered in the design of biomedical studies on diet, environmental stress, and other bioenergetic issues.

Maintenance of laboratory mice in a relatively stable thermal neutral zone is important for their health and well being and may have an important effect in studies such as those of feeding behavior or with drugs having a thermoregulatory influence. The recommended dry bulb ambient temperature for housing mice is 18–26℃. [19] A review of studies on the laboratory mouse indicated that animals have a thermoneutral zone of about 26–34℃, [20] so it seems that the upper end of the recommended range is more appropriate for thermoneutrality. However, the use of covered cages, air flow-regulated racks, cage material, type and quantity of bedding used, and the number of mice housed in a cage can all influence the ambient temperature to which the mouse is exposed. The effects of different types of bedding and the depth of the bedding on core temperature, metabolic rate, and motor activity have been investigated.[21] Mice housed on deep wood shavings compared to shallow wood shavings or beta chips were able to maintain a significantly higher core temperature during the day, when they are relatively less active, than at night. The CD-1, an outbred strain, was used in this study.[21] Other strains or genetically modified mice may have specific thermal and metabolic requirements.

Another anomalous finding emerging from studies of mouse reproduction[21] is that reproduction in the house mouse does not seem to respond to seasonal changes in photoperiod. Seasonal breeding is strongly influenced by photoperiod in many mammals,[22] but not no in the mouse. Several stocks of mice have been maintained under constant day length for extended periods of time without apparent effect on reproduction. In addition, a study of wild-caught mice held under constant darkness for 75 days showed the same reproductive productivity as mice held under a 14:10 L:D schedule.[18] Though some seasonal variability occurs in feral populations with a peak in late spring/early summer, many breed throughout the year. In a meta-analysis of the breeding seasonality in feral and commensal (human structures) populations of mice in the temperate zone, Bronson[17] reported that four of five feral populations examined were seasonal breeders, whereas none of the four commensal populations were seasonal. The important variable regulating reproduction seems to be the continuous availability of food to females, rather than photoperiod. Despite the apparent absence of an effect of photoperiod on reproduction in the mouse, other physiological functions with a circadian cycle may be affected, so the usual laboratory

light : dark cycle of 12:12 or 14:10 in laboratory colonies is probably warranted.

Mice are nocturnal rodents showing most activity in the dark; however, they will also show sporadic bursts of activity during daylight hours. Mice can control exposure to light and temperature by burrowing or building a nest if given an opportunity, which is seldom available to laboratory caged mice.

Under natural circumstances mice commonly live in a deme, a small group usually consisting of kin. As with reproduction, variability in social grouping is the rule. Individual feral male mice have been found to have home ranges of up to 400 m^2.[23] At the other extreme, mice can be found in extremely dense populations as in a mouse plague of 100 mice per hectare.[24] Under conditions of high food availability such as in corn ricks in England, Southwick[25] found populations of over 2000 mice per corn rick or 15 adult mice per cubic meter. From these field studies of the mouse, it is apparent that the high degree of social flexibility available to the mouse allows it to adapt to and breed in a wide variety of captive conditions.

Although the importance of pheromonal communication is much greater in the mouse than in humans, attention to or manipulation of chemical signals can be useful in the laboratory setting. Mice use pheromones both to signal information to conspecifics and to prime several developmental and reproductive traits. For example, mice signal by marking continuously with urine as they move on a new substrate. Males show more intense marking behavior than females.[17] Such marking results in the deposition of pheromones that are important for territorial boundary marking among house mice. Signaling pheromones also provide information concerning an individual's sex, gonadal state, and social status.[26,27] The primary source of signaling pheromones seems to be urine, and that may help explain the commonly observed anogenital sniffing of strangers. However, mice also attend to the face area of a stranger, due perhaps to a sex identification pheromone that has recently been identified in lacrimal glands of the mouse.[28] It seems that tears can also convey olfactory information.

Pheromones can also induce developmental or physiological changes and are thus called "priming pheromones." Temporal regulation of ovulation in the female seems to be strongly influenced by such pheromones. The onset of puberty in the female is particularly sensitive to a chemical stimulus contained in male urine.[29,30] Female mice denied the presence of a male or his urine show a prolonged prepubertal period followed by a disorganized ovulatory cycle. The production of the puberty-accelerating pheromone is androgen dependent and as little as 10 µl of urine per day induces onset of puberty as early as 28 days of age. The active ingredient in urine that is responsible for puberty acceleration seems to be a protein-bound heptone.[31]

Puberty onset in the mouse is a consequence of both stimulatory and inhibitory pheromonal influences. Juvenile females housed in a group of four or more or those exposed to urine of grouped females show delayed onset of first ovulation.[32,33] The puberty-inhibiting pheromone has not been identified, but is known to result from grouping of the females and possibly from adrenal activation.[33]

One priming pheromonal effect that may have little relevance in wild populations[17] but may be useful in laboratory populations is the ovarian synchronicity effect. Inhibition of adult ovarian cycles occurs in all-female groups. In addition, if grouped females are exposed to an adult male or male urine, ovulation usually occurs 3 days later.[34] Thus, conception can be at least partly synchronized to a specific date by grouping females four or more per cage for 2 weeks prior to mating with a male.

CARE AND USE OF MICE IN THE LABORATORY

The *Guide for the Care and Use of Laboratory Animals*[19] contains the information needed and often required for maintaining mice used in biomedical research. Mice, rats, and poultry are not included in the Federal Animal Welfare Act of 1987 as amended, but many institutions have placed mice and rats under the same restrictions and oversight as other mammals covered in the Animal Welfare Act.[35] Details on housing conditions, diet, and use of mice can be found in the *Guide*.[19] To be useful as a laboratory model, mice should be maintained to allow as much normal behavior as possible in a cage. "Normal" is difficult to define in the case of the house mouse since it is such an adaptable animal as noted above. Certain behaviors, such as stereotypic actions expressed in confinement, may interfere with the usefulness of the animals as a model for biomedical research.[36] However, as a recent review suggests,[37] stereotypic behavior may also serve as a model for abnormal brain function and be useful in elucidating underlying causes of certain mental illnesses.

Avoidance or reduction of abnormal behaviors in experimental subjects is important in the majority of studies. Even though the house mouse is a highly adaptable species, it can show environmentally induced abnormal behaviors[38] that may interfere with the outcome of studies. An array of environmental enrichment procedures, both social and physical, includes housing animals in groups and providing nesting materials; providing some complexity to the cage environment may reduce or eliminate such behaviors.[39]

CONCLUSIONS

Both rats and mice are highly adaptable animals. As is true for humans, they are omnivorous, adapt to the environment with varied social structures, show considerable genetic variability, share many similar physiological functions, and show many of the same diseases. Perhaps for these reasons and others listed in Table 21–1 mice and rats, but especially mice, have become the model of choice for an array of biomedical studies.

By making appropriate genetic selections, genetic manipulations, and providing an appropriate environment for the laboratory mouse, it will continue to serve the research community just as the cartoon character, Mickey, continues to provide entertainment for the public. Humans must deal with the house mouse as a pest, but also should appreciate the role of the mouse in helping to understand the origins and cures of human and animal diseases. It seems that such an appreciation was attempted when C.C. Little tried to arrange a joint 25th birthday celebration at Walt Disney for both Mickey Mouse and the JAX mouse.[13] Unfortunately, Disney showed little interest in Little's proposal and Mickey got all the attention.

22 Mouse Model for Alzheimer's Disease

M. Azhar Chishti and Shaheen M. Nakeeb

ABSTRACT

Transgenic mouse models for Alzheimer's disease (AD) are now extensively used to understand the physiological and biochemical mechanisms of the disease as well as to discover new potential therapeutics. The identification of disease-causing mutations in proteins such as amyloid precursor protein (APP) and presenilins (PS1 and PS2) as well as pathogenic mutations in the tau protein has led to the creation of several transgenic mice including those expressing bigenic and trigenic constructs. Each model has unique pathologies that provide insight into disease mechanisms and features of neuropathologies and cognitive functions. Therapeutic hypotheses are now testable in these transgenic mice and the effectiveness of these therapeutics is testable in preclinical and clinical trials in AD patients. A number of therapeutic approaches including active and passive immunization, small molecule monoclonal antibodies, and nonviral DNA vaccines are available. It is hoped that in the near future a treatment for AD will be available as a result of these advancements.

Key Words: Transgenic mice, Amyloid plaques, Tau protein, Amyloid β peptide, β-APP, Pathology, Cognitive deficits, Immunization, Therapeutics.

INTRODUCTION

Alzheimer disease (AD), a progressive neurodegenerative disorder that is the most common cause of dementia, is characterized by a deterioration in mental functions leading to dementia and pathologically by two hallmark lesions: diffuse and neuritic amyloid plaques and neurofibrillary tangles composed of filamentous aggregates of hyperphosphorylated tau protein in the cerebral cortex and hippocampal region of the brain. The clinical manifestations of AD are mild cognitive impairments at the early stage leading to severe cognitive deficits, generalized behavioral impairments, and, ultimately, death. The typical course of the disease is 6–10 years.[1] AD may be characterized as early onset (30–60 years) or late onset (60 years and above). At least 10% of AD cases are of the early-onset type, which shows a strong genetic linkage and is transmitted as autosomal dominant traits with almost 100% penetrance. Since there is no naturally occurring rodent form of AD, there has been great interest in creating accurate transgenic facsimiles of AD. Such models have the potential to mirror the key pathological events and practical utility for testing interventions directed against the synthesis or deposition of the Aβ peptide or tau protein.

BIOCHEMICAL PATHWAY

AD amyloid β peptide is derived from two endoproteolytic "secretase" cleavages of the Alzheimer amyloid precursor protein (APP) encoded by the APP gene on chromosome 21. Familial Alzheimer's disease (FAD) mutations enhance proamyloidogenic cleavages at the β- and γ-secretase sites that release Aβ from APP,[2] while FAD mutations in presenilin 1 and 2 enhance γ-secretase cleavages (Figure 22–1).[3–6] The phenotypic ablation of presenilin 1 results in skeletal defects and accumulation of APP C-terminal fragments (CTFs) due to processing of notch signaling via a deficit in cleavage at the juxtamembrane "site3," further underscoring the connections between presenilins and endoproteolysis.[7–9] An anonymous FAD locus on chromosome 10 has been identified on the basis of presymptomatic elevations in plasma levels of Aβ peptide.[10] ApoE, a genetic modifier associated with the incidence of late onset AD,[11] also affects the biochemistry of Aβ peptide *in vitro*[12] and in transgenic mice.[13–14]

Thus FAD provides overwhelming evidence that an accumulation of Aβ peptide stands at the head of the pathogenic cascade that accounts for the hallmarks of the disease. This perspective adds two further pieces of information that help to clarify the roles of Aβ and tau in the cognitive deficits seen in AD.[15–17] First, this indicates that cognitive dysfunction is well correlated with the levels of soluble Aβ present within the parenchyma, and other studies have documented increased burdens of Aβ at earlier time points in the development of AD[18–22] and in Down syndrome patients (with trisomy 21 and hence three copies of the APP gene) prior to dementia.[23] The second concerns the pathogenic effect of mutant tau in frontotemporal dementia with Parkinsonism (FTPD17). A plethora of mutations in the tau gene indicate the pathogenic effects of an excess of "four repeat" tau, and in some cases missense mutations in the C-terminal region of tau.[24] These findings, as well as the generation of neurofibrillary tangle-like pathology and cell loss in transgenic mice expressing the P301L mutant form of human tau,[25] demonstrate a potential pathogenic role of tau. It is important to bear in mind that tau mutations do not exist within FAD kindred and that tau pathologies occur in many different diseases. In sum, penetrating FAD mutations causing AD indicate that Aβ must lie upstream of tau in a pathogenic pathway, with tau pathologies arising as a consequence of Aβ overaccumulation, perhaps contributing to the cognitive dysfunctions observed in the later stage of AD.

DIAGNOSIS OF ALZHEIMER'S DISEASE

The definitive diagnosis of AD is made on postmortem examination. The pathological hallmarks of this disease are extracellular amyloid plaques composed of amyloid β protein (Aβ), a metabolic product of amyloid precursor protein (APP), and intracellular neurofibrillary tangles composed of hyperphosphorylated tau protein.[26] This pathology shows a distinct spatial–temporal pattern, initially affecting areas of the temporal cortex, notably the transentorhinal region, before extending to the hippocampus and certain other cortical zones. At the latter stages, a more widespread pathology may be seen in certain brain areas, particularly cortical (frontal, temporal) and limbic regions, although other areas, such as the cerebellum, show no such signs.[27] Biochemical processes not completely understood, the accumulation of Aβ, and neurofibrillary tangles produce local neurodegeneration, which ultimately accounts for the clinical signs of this disease.

GENERATION OF TRANSGENIC MICE

Transgenic mice are produced by the introduction of a human gene sequence or mutated sequence into the mouse genome, resulting in the expression of a human protein. This is most commonly achieved by the microinjection of complementary DNA constructs of genomic fragments (with or without known altered mutations) complete with promoters, introns and exons, which have been used for the better expression of a single whole gene. Other methods are also used to manipulate endogenous genes to "knockin or knockout" a human sequence. Regardless, the challenge of creating a mouse model of AD involves recapitulating a chronic, progressive disease that takes decades to develop in humans, but develops in a short period of time, from 3 to 9 months, in a mouse that has a short life span of less than 2 years. Mice expressing pathogenic mutations of human genes have become a critical tool for biomedical research in testing hypotheses of AD pathogenesis and testing novel therapeutic strategies. The pathological and behavioral characteristics of AD transgenic mice are summarized in Table 22–1.

Table 22–1
Key features of transgenic mouse models for Alzheimer's disease[a]

Transgenic line	*Mutation*	*Promoter*	*Pathology*	*Behavior*	*Immunotherapy*	*Reference*
PDAPP	APPV717F	PDGF-β	Astrocytosis, microgliosis, Aβ deposits, and synaptic loss	Age-independent and age-related deficits in spatial learning	M266, more than 50% plaque reduction and cognitive improvement	28
Tg2576	APPSwedish	Hamster PrP	Aβ elevation and plaque deposition	Age-related deficits in spatial learning	Amyloid β 1–42, 50% plaque reduction, and cognitive improvement	29
TgAPP23	APPSwedish	Murine Thy-1	Amyloid plaques immunoreactive with tau hyperphosphorylation, angiopathy	Age-related deficits in spatial learning	Nonviral amyloid β DNA vaccine, 30–50% reduction	30
TgCRND-8	APPSwedish and V717F	Hamster PrP	Early onset amyloid plaques, neurotic pathology	Early impairment in learning acquisition	Amyloid β 1-42, 50% plaque reduction and cognitive improvement	33
PS/APP	APPSwedish and $PS1^{M146L}$	Hamster PrP/PDGF-β	Elevated levels of amyloid β 42 or 43	No information is available	Amyloid β 1-42, 50% plaque reduction, and cognitive improvement	35
JNPL3	Tau^{P301L} (4R,2-,3-)	Murine PrP	Development of neurofibrillary tangles	Age-related motor and behavioral deficits	N/A	41

TgTau^{P301L}	Tau^{P301L}	Hamster PrP	Development of neurofibrillary tangles with gliosis, neuronal loss, and atrophy	Cognitive impairments	N/A	45
Triple transgenic	APPSwedish, PS1^{M146L}, and Tau^{P301L}	Thy-1.2	Development of amyloid plaques, neurofibrillary tangles, and synaptic dysfunction	Age-related cognitive deficits; LPT severely impaired at 6 months	Clearance of early hyperphosphorylated tau	46

[a]Behavioral and pathological features of different transgenic models of Alzheimer's disease (AD) and effects of immunotherapy in these AD transgenic mice.[52]

TRANSGENIC LINES ON THE BASE OF THE AMYLOID CASCADE

Most current animal models of AD are built upon early-onset genetic forms of the disease. However, familial AD cases number only about 10% of all cases of AD, with the sporadic form constituting the remaining 90%. The assumption that current models are reasonable facsimiles of nonfamilial forms of AD is based upon a variation in the theme that Aβ is the key pathogenic moiety in all forms of AD. Genetically engineered mice can be created by the addition of microinjected transgenes into unselected sites in the mouse genome that drive expression beyond the endogenous levels and accelerate the onset of neurodegenerative diseases. The main objective in creating an APP transgenic line is to obtain enough expression of human β APP in the central nervous system (CNS) to produce amyloid deposits without toxicity and mortality.

PDAPP MOUSE Games and co-workers[28] created PDAPP transgenic mice with a V717F mutation that showed many of the pathological features of AD including extensive deposition of extracellular amyloid plaques, astrocytosis, and neuritic dystrophy. A histological analysis of PDAPP mice revealed that plaques are first formed in the cingulate cortex and hippocampus followed by spreading to other subcortical areas except for the cerebellum, and that amyloid plaque loads increased as a function of age. At a later time point the amyloid plaque burden may reach 50% of the cortical areas, but clear neurodegeneration has not been demonstrated, except for some synaptic loss in the molecular layer of the dentate gyrus, and neurofibrillary tangles have not been identified. Behavioral studies with PDAPP mice describe early cognitive deficits before the amyloid plaques could really be detected. Modified Morris water maze testing showed memory impairments that were age dependent and correlated with amyloid plaque load. At a young age (6–9 months) PDAPP mice showed a level of acquisition similar to control mice, but middle-aged (13–15 months) and old (18–21 months) mice showed slow acquisition compared with age-matched controls. The common finding of PDAPP mice are both age-related (plaques) and age-unrelated cognitive changes. Test selection seems critical for their detection.

TG2576 MOUSE In 1996, Hsaio and colleagues[29] developed an APP695 transgenic line with a K670N/M671L (Swedish) mutation under the control of the prion protein promoter to ensure high CNS expression. Initially the development of this mouse was emphasized due to background strain effects in FVB/N or C57B/6 mice on pathology and early death, but changing the genetic background to C57B6XSJL resulted in better survival and deposits of thioflavin S-positive amyloid burden at age of onset of 9–12 months. The earliest deposition of amyloid plaques appears in the entorhinal and pyriform cortices and then the hippocampus, thus showing subtle differences from the PDAPP mouse possibly related to a different promoter. The Tg2576 mouse has since become the most widely used transgenic mouse in the AD field. With aging, Tg2576 mice exhibit a phenotype that includes learning and memory deficits, an abnormal pattern of glucose metabolism in the brain, and pathological changes including amyloid plaque deposits, elevated Aβ40 and Aβ42 levels, neuritic changes, phosphorylated tau epitopes, A-synuclein-positive dystrophic neuritis, gliosis, and inflammatory changes; however, these mice did not show any neurofibrial tangles and neuronal loss. A variety of inflammatory and oxidative markers have also been studied in these mice to examine the involvement of these processes in AD-like pathology.

APP23 MOUSE These transgenic mice were developed at Novartis[30] with an hAPP751 construct containing the Swedish mutation, under the control of the Thy-1 promoter for high neuronal expression. These mice were characterized extensively in terms of pathology and have features similar to PDAPP and Tg2576 mice such as neuritic plaques with local astrocytosis and microgliosis mainly in the neocortical and hippocampal regions. Interestingly, neurodegeneration has been reported in the CA1 region of the hippocampus and neocortex in 14- to 18-month-old mice that was not seen in the above lines. The other feature of the APP23 mouse is the development of cerebral amyloid angiopathy (CAA), which is significantly correlated clinically with hemorrhagic stroke in up to 90% of AD patients. Modest cholinergic deficits have also been reported in aged App23 mice.[31] Behavioral characterization of these mice showed no sensorimotor changes at 3, 18, and 25 months. However, visible and hidden platform acquisition performance was impaired at 3 and 25 months, suggesting transgene-induced neophobia and sensory changes.[32] Although soluble Aß levels did not change across the age range, subtle qualitative changes in the Aß form, such as conversion into small oligomers/protofibrils, may contribute to behavioral

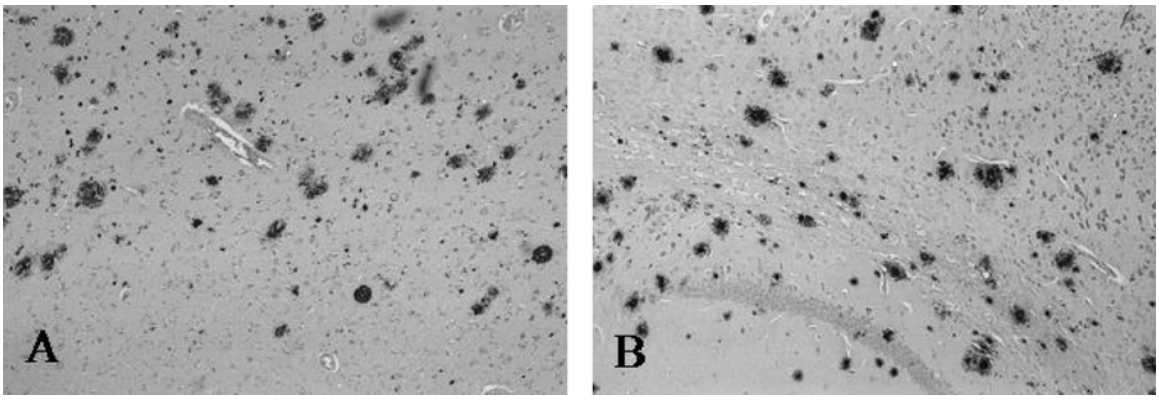

Figure 22–2. Amyloid plaque deposition is a pathological hallmark for Alzheimer's disease. (A) Human AD brain (70 years old): the deposition of amyloid-β plaques is visualized on cortical brain sections after immunolabeling with antiamyloid-β antibodies (4G8 monoclonal diluted 1 : 400). (B) Animal model (6 month old): transgenic CRND8 mice express human mutated amyloid precursor protein recapitulated pathological features of amyloidogenesis present in AD.

changes. The APP23 model has similarities to plaque-related changes in the PDAPP and Tg2576 models, but these are unrelated to cognitive changes.

CRND8 MOUSE The CRND8 mouse was created from a double mutated form of hAPP695 under the control of the hamster prion protein promoter. The combination of the Swedish K690N/M671L and V717F Indiana APP mutation results in extremely high levels Aß42, and a very early onset of thioflavin S-positive amyloid deposits becomes evident in all mice at 3 months of age.[33] These plaques are associated with dystrophic neurites and gliosis. A number of genetic backgrounds was used to overcome the early lethality evident in other lines. The most satisfactory is C57B6XC3H and 129 SvEv-Tac, with approximately 50% of CRND8 mice surviving by 12 months of age. The lethality may be associated with the increase in seizure liability, which is possibly related to the very high Aß levels attained in these mice. The amyloid burden in 6-month-old transgenic CRND8 mice is similar to that found in a human AD brain from a 70-year-old AD patient (Figure 22–2). In terms of cognitive status, at 11 weeks of age the CRND8 mice showed impaired acquisition of spatial learning in a Morris water maze test. Most recently, separate cohorts of 6- to 8-week old (preplaque) and 9- to 22-week old and 40-week old (postplaque) CRND8 mice showed spatial learning impairments increasing with age and a considerable burden of corticohippocampal plaques.[34]

PS/APP MOUSE Following the identification of pathogenic mutations in the presenilin (PS) genes in AD, transgenic animal models have been generated to address the role of PS1 and PS2 in APP processing *in vivo*. FAD mutant forms either alone (PS1) or in combination with APP and knockout of endogenous presenilin genes were tested. PS1 knockout mice are not viable and develop skeletal defects and CNS phenotype due to defects in the notch pathway. This lethal phenotype was rescued by expression of the FAD mutant $PS1^{M146L}$. Transgenic mouse lines overexpressing the *PS1* gene containing the M146L mutation were established in the $hPS1^{M146L}$ mouse;[35] although these mice do not appear to develop plaques, they show an increase in extracellular Aβ1-42 levels. Subsequently, the crossing of the Tg2576 with the $hPS1^{M146L}$ transgenic mouse resulted in a novel mouse line (PS/APP) that showed greatly accelerated plaque pathology and concomitant gliosis.[36] For example, in contrast to the 9- to 12-month onset of plaque deposition seen in the Tg2576 line, by 3 months of age thioflavin-S-positive plaques are invariably detected in the cingulate cortex of PS/APP mice. By 6–8 months of age, amyloid deposition and plaque size increased and extended to most cortical regions as well as the hippocampus. Beyond this time point, Aβ deposition appeared in the thalamus, striatum, and occasionally the cerebellum. Despite the extensive amyloid pathology by 12 months of age (an approximately 30% amyloid burden in the frontal cortex), no clear evidence for neurodegeneration in either frontal cortex or CA1 hippocampus was evident.[37] In common with all the aforementioned APP transgenic mouse models, neurofibrillary tangles have not been identified in the PS/APP mouse at any time. The behavioral phenotype of the PS/APP mouse has been described: a reduced Y-maze alternation in age-matched (12–14 week) PS/APP and Tg2576 mice compared to wild-type controls, a finding that clearly suggests no relationship to Aβ pathology. A subsequent study comparing $hPS1^{M146L}$, Tg2576, and PS/APP mice in cognitive and sensorimotor tests at 3, 6, and 9 months of age[38] showed Y-maze alternation was at chance levels in the PS/APP mice at each time point, and there was evidence of hyperactivity, since total arm entries were increased. Both of these behaviors were suggestive of impaired hippocampal function, although curiously, water maze performance (acquisition and 24 h probe test) was similar in all groups at the 6- and 9-month time points. In later studies, the clearest cognitive deficits emerged at 15–17 months of age, a time point at which there was intense amyloid deposition and signs of local oxidative stress and neuroinflammation.[39] This age of onset seems later than that described for the PDAPP and Tg2576 lines, which display less amyloid pathology, although an inverse correlation between cognitive performance and Aβ plaque load (frontal cortex and hippocampus) has been described.[40]

TRANSGENIC LINES ON THE BASES OF THE TAU CASCADE

In FAD, no mutations have been identified in the tau gene. However, exonic and intronic mutations were identified in the tau gene that were linked to frontotemporal dementia and

Parkinsonism (FTDP-17), a familial dementia related to AD. In comparison to the various lines of APP transgenic mice, relatively few tau-based transgenic mice have been reported to date. The transgene contains the most common tau mutation associated with the FTDP-17 P301L mutation under the control of the mouse or hamster prion protein promoter.

JNPL3 (TAU) MOUSE Hemizygous JNPL3 mice express the transgenic tau at levels equivalent to endogenous tau, while homozygous mice express double this amount. From 6 to 7 months, a neurological phenotype becomes manifest in hemizygous JNPL3 mice, consisting of a delayed righting reflex, hypolocomotion, and muscular weakness;[41] within 4 weeks of symptom onset, the mice become moribund. In terms of pathology, in contrast to APP transgenic mice, the JNPL3 mice develop neurofibrillary tangle (NFT) pathology, confirmed by tau immunostaining, silver staining, and electron microscopy (EM). No amyloid plaques have been identified. Astrogliosis also becomes evident in regions containing NFTs, which include the spinal cord and pons, and to a lesser extent the amygdala, cortex, and hippocampus.[41,42] Indeed, spinal cord pathology seemed to correlate with neurological phenotype. Not surprisingly, given the severity of this phenotype, no cognitive data have yet been described for the JNPL3 mouse. The TAPP mouse, a combination of mutant tau and APP, also supports the view of APP mismetabolism as the central event in the disease cascade. The JNPL3 mice develop relatively little NFT pathology in limbic areas; however, in age-matched TAPP mice, limbic NFTs are increased 7-fold.[42] Furthermore, Götz *et al.*[43] reported that discrete CNS microinjections of Aβ peptide into a mutant tau line[44] resulted in a 5-fold increase in NFTs in areas innervated by neurons originating from the injection site. Consequently, these studies support the view that APP/Aβ overexpression promotes NFT formation.

TGTAU^{P301L} MOUSE This transgenic line (TgTau^{P301L}) expresses a frontotemporal dementia with Parkinsonism linked to chromosome 17 (FTPD-17) mutations within the longest form of tau (2N, 4R) under the hamster prion protein promoter. TgTau^{P301L} mice developed florid pathology including neuronal pretangles, numerous Gallyas-Braak-positive neurofibrillary tangles, and glial fibrillary tangles in the frontotemporal areas of the cerebrum, in the brainstem, and to a lesser extent in the spinal cord.[45] These features were accompanied by gliosis, neuronal loss, and cerebral atrophy. Accumulated tau was hyperphosphorylated, conformationally changed, ubiquitinated, and Fn1 sarkosyl-insoluble, with EM demonstrating wavy filaments. Aged TgTau^{P301L} mice exhibited impairment in hippocampally dependent and independent behavioral paradigms, with impairments closely related to the presence of tau pathologies and levels of insoluble tau protein. These TgTau^{P301L} mice recreate the substantial phenotypic variation and spectrum of pathologies seen in FTDP-17 patients. Identification of genetic and/or environmental factors modifying the tau phenotype in these mice may shed light on factors modulating human tauopathies. These transgenic mice may aid therapeutic development for FTDP-17 and other diseases featuring accumulations of four-repeat tau, such as Alzheimer's disease, corticobasal degeneration, and progressive supranuclear palsy. These mice showed neurofibrillary tangles at 1 year of age that were similar to those seen in a 76-year-old human AD brain (Figure 22–3).

TRIPLE TRANSGENIC MOUSE To study the interaction between Aβ and tau and their effect on synaptic function, a triple transgenic model harboring the PS1^{M146V}, APP^{swe}, and Tau^{P301L} transgene was developed. Rather than crossing independent lines, two transgenes DNA was microinjected into single cell embryos from homozygous PS1^{M146V} knockin mice, resulting in a triple transgenic mouse with the same genetic background.[46] These triple transgenic mice progressively developed plaques and tangles. Intraneuronal Aβ immunoreactivity is first detected in neocortical regions and subsequently in CA1 pyramidal neurons. Extracellular amyloid plaques first become apparent at 6 months in the frontal cortex but there was no tau immunoreactivity, and were readily available by 12 months in the hippocampus and other regions. Synaptic dysfunction and phosphorylated and hyperphosphorylated tau were revealed in age-related progression between 12 to 15 months of age, but PHF1 did not become evident until the mice were 18 months of age. Tau-reactive dystrophic neurites were also evident surrounding globular structures in 18-month older brains. The triple transgenic mice develop a progressive and age-dependent Aβ and tau pathology, although Aβ deposits manifest prior to tangle formation. It is likely that Aβ pathology affects the development of tau pathology including LTP deficits in an age-related manner but before plaque and tangle pathology.

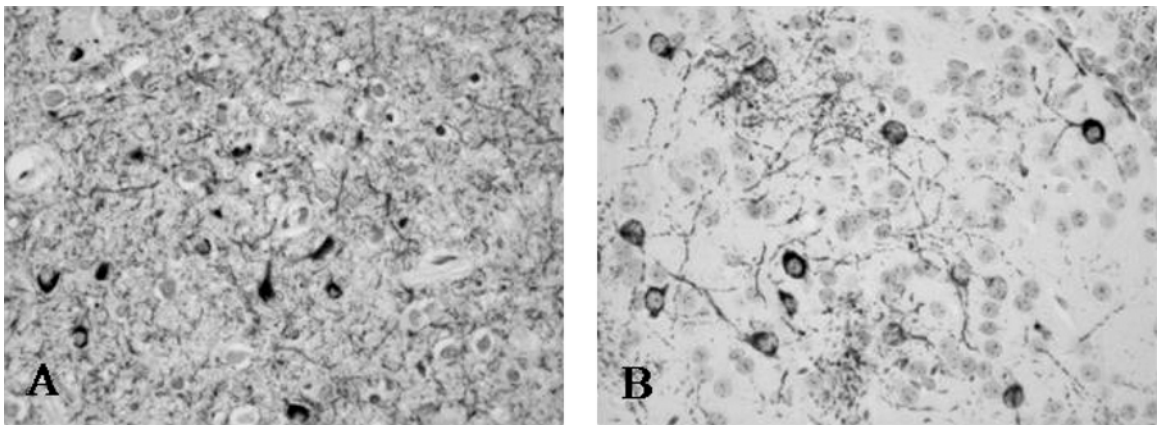

Figure 22–3. Alzheimer's disease brain reveals an intracellular accumulation of hyperphosphorylated tau. (A) Human AD brain (76 years old) cortical neurons showing neurofibrillary tangles. (B) A tau^{P301L} transgenic mouse (1 year old) showed similar neurofibrillary tangles in a cortical section immunolabeled with AT8 monoclonal antibodies.

TRANSGENIC MICE WEB SITES

The Alzheimer Research Forum website (http://www.alzaform.org) contains important up-to-date information on the numerous strains of mice used in biomedical research related to Alzheimer's disease. Information is presented in chart format including the name or symbol, strain name, transgene or promoter and regulatory elements, genetic background, behavioral phenotype, neurological characteristics, availability, and primary citations for each of the mice strains related to APP, APOE, α-synuclein, Cox-2, PS1, PS2, tau, Double-Cross, and Triple-Cross. Furthermore, Jackson Laboratory (http://www.jax.org) data sheets on available strains contain essential information on the genetics, phenotypes, husbandry, and production; the same applies to Taconic (http://www.taconic.com), which provides data sheets on numerous available strains on AD. Transgenic animals require conventional care and do not need any special care.

THERAPEUTIC APPROACHES

The most widely replicated and thoroughly investigated approaches in these preclinical studies have involved the use of anti-Aβ immunotherapies[47] using AD transgenic mice. In 1999, the Schenk group described the preventive effects of AD neuropathology associated with immunizing the PDAPP transgenic mouse with Aβ peptide; this reduced amyloid plaques and preserved synaptophysin levels, important correlations to human AD.[48] Further studies in our laboratory and by other groups demonstrated a reduction of amyloid plaques and improvement of cognitive functions in a water maze test in hβAPP and PS1 transgenic mice. Passive immunization studies in which Aβ antibodies were given for short-term treatment resulted in positive cognitive changes in transgenic mice. The possible mechanism of action of these immunotherapies is still not clear, but antibodies may be capable of clearing plaques through both a monocyte-mediated and a direct effect on the clearance of soluble Aβ species that are neuroactive/toxic.[49] Immunization with Aβ1-42 peptide (AN-1792) was tested in human AD patients with noteworthy effects. These clinical trials were suspended due to the development of meningioencephalitis in a few cases.[50] These side effects highlight a limitation of animal models, which may not perfectly predict clinical outcomes due to limitations in the models' pathology as well as the more genetically varied human population. Interestingly, several cases from these studies have gone to autopsy and showed a strikingly similar reduction in AD neuropathologies as predicted in animal models. Recently, the cerebrospinal fluid biomarker tau showed an encouraging improvement of cognitive function and a robust reduction in pathology and passive immunization of Aβ monoclonal antibodies used in the original trials to avoid inflammatory responses. In a recent study, nonviral Aβ DNA vaccines against Alzheimer's disease were administered to model (APP23) mice and the reduction in Aβ burden was

Table 22–2
Therapeutic approaches to reduce the pathology of Alzheimer's disease (AD) in transgenic mouse models[a]

Test compound	*Mechanism of action*	*Dose and route*	*Duration*	*AD model*	*Age/amyloid burden at start of therapy*	*Reduction in plaque burden*	*Reference*
Curcumin	Amyloid binding antioxidant in curry powder	160 and 5000 ppm in chow	6 months	Tg2576	10 months with few plaques	At low dose more than 50%	53
iAβ5p	β-Sheet disrupting peptide	1.0 mg intravenously 3 times/week	8 weeks	APPV717I × PS1A246E	9 months (3 months after plaques start to appear)	45% in cortex and 29% in hippocampus	54
Lithium	GSK3ß kinase inhibition	2.4 g/kg in chow	7 months	PDAPP	1 month old before plaques	More than 75%	55
CP-113,818	ACAT inhibitor	7.2 mg/kg/day 2 month subcutaneous implant	2 months	APPSwedish + London	Plaques are just beginning	More than 90%	56
Clioquinol	Copper-zinc chelator	30 mg/kg/day orally	9 weeks	Tg2576	21 months of age; well after plaques start	49%	57
NCX-2216	NO-releasing NSAID; microglial activator	375 ppm in chow	5 months	APPSwedish + $PS1^{M146L}$	7 months; plaque formation is evident at this age	45%	58
Cyclohexanehexol	Amyloid peptide inhibitor	0.3–30 mg/kg/day oral gavage twice daily	6 months and 1 month	TgCRND8	6 weeks (just before plaques) to 6 months and 5 months full plaques	30–55%	59

[a]Therapeutic agents showed efficacy in reducing, at a minimum, amyloid plaque load after chronic treatment (more than 2 weeks). Although there are different mechanisms of action, all have reported efficacy.[52]

evaluated. Prophylactic treatments started before Aβ deposition reduced Aβ burden to 15.5% and 38.5% of that found in untreated mice at 7 and 18 months of age, respectively. Therapeutic treatment started after Aβ deposition reduced Aβ burden to approximately 50% at the age of 18 months. Importantly, this therapy induced neither neuroinflammation nor T cell responses to Aβ peptide in both APP23 and wild-type B6 mice, even after long-term vaccination. Although it is reported that other anti-Aβ therapies have pharmacological and/or technical difficulties, nonviral DNA vaccines are highly secure and easily controllable and are promising for the treatment of Alzheimer's disease.[51]

A wide range of therapies in addition to immunotherapy has been tested in several different AD transgenic models. Small molecules are orally bioavailable and have shown effectiveness by approaches ranging from natural products that bind to Aβ, metal chelation, lipid metabolism inhibitor, and inflammatory modulators. Preliminary results from these approaches involving more than 2 weeks of chronic treatment using transgenic models are summarized in Table 22–2.[52] The source of these compounds ranges from curry spice to drugs in clinical trials for other indications. These studies vary widely in the choice of model, duration of therapy, and, most importantly, the age/amyloid burden present when therapy was initiated. The great variability in paradigms excludes head-to-head efficacy assessments and predictions. Our experience with immunotherapy suggests that preventing amyloidosis may be easier than reducing existing burdens of older plaques. It is interesting to note in Table 22–2 that none of the tested compounds has the same proposed mechanisms of action or direct inhibition of secretases; this indicates that potential amyloid-directed therapies are quite diverse and effective therapies validated clinically will emerge in the near future.

ACKNOWLEDGMENTS

We thank Drs. Dora Games, Guy A. Higgins, and David Westaway for their kind permission to use tables and for support and encouragement in completing this chapter.

23 Guinea Pigs as Models for Human Cholesterol and Lipoprotein Metabolism

Maria Luz Fernandez and Richard J. Wood

ABSTRACT

Lipoprotein anabolism and catabolism are highly complex when considering the multifaceted aspects that regulate the synthesis and removal of lipoproteins from plasma. In addition, lipoproteins undergo multiple modifications in the intravascular compartment leading to atherogenic or antiatherogenic subclasses. The use of an appropriate animal model mimicking human lipoprotein metabolism is critical to the understanding of how dietary interventions, drug treatment, sex, menopausal state, and exercise regulate these intricate processes. This chapter will discuss in detail the guinea pig as an appropriate animal model to determine the effects of different diets, lipid-lowering drugs, and life style modifications on hepatic and plasma cholesterol metabolism, and atherosclerosis. One of the most salient features of this animal model is that guinea pigs carry the majority of the cholesterol in low-density lipoprotein and possess cholesterol ester transfer protein and lipoprotein lipase activities, which result in reverse cholesterol transport and delipidation cascades equivalent to the human situation. Furthermore, the activities of hepatic enzymes involved in cholesterol metabolism and the mechanisms involved in secretion and removal of lipoproteins mimic those of humans. The similarity in plasma lipid responses to dietary interventions, drug treatment, and exercise between guinea pigs and humans further suggests the relevance of this model to elucidate the mechanisms involved.

Key Words: Guinea pigs, Animal models, Lipoprotein metabolism, Atherosclerosis, Dietary interventions, Drug therapy, Sex, Exercise.

INTRODUCTION

This chapter will provide a useful insight into the suitability of guinea pigs as animal models for cholesterol and lipoprotein metabolism. A discussion of the metabolic advantages plus the usefulness of this model to elucidate mechanisms by which dietary factors, drug therapy, exercise, gender, and menopause alter the regulatory pathways involved in the synthesis, catabolism, and intravascular processing of lipoproteins is presented.

There is some controversy as to whether guinea pigs (*Cavia porcellus*) should be classified as rodents.[1] While this issue is not relevant to the present discussion, there is one aspect of guinea pigs that makes them stand out from other rodents, the fact that they carry the majority of cholesterol in low-density lipoprotein (LDL).[2] This outstanding difference raises the question of whether guinea pigs present other similarities to humans in cholesterol and lipoprotein metabolism. Our laboratory and other investigators have found that indeed guinea pigs do have some analogies to human cholesterol metabolism that merit discussion.

USE OF ANIMAL MODELS FOR CHOLESTEROL AND LIPOPROTEIN METABOLISM

In addition to the guinea pigs, several animal models have been used to study lipoprotein metabolism and atherosclerosis including nonhuman primates, hamsters, mice, rats, and rabbits. Choosing the appropriate model to test a hypothesis is an important decision that should be based on the benefits and limitations of each particular model. In this section of the chapter we outline the advantages and disadvantages of several commonly used animal models in cholesterol and lipoprotein metabolism research. Advantages and disadvantages will be based on similarities and dissimilarities between the particular animal models and humans.

ADVANTAGES AND DISADVANTAGES OF OTHER MODELS

Nonhuman Primates Several types of nonhuman primates have been used in lipoprotein metabolism research including cebus monkeys,[3] squirrel monkeys,[4] baboons,[5] and owl monkeys.[6] One commonly used model for lipoprotein metabolism is the African green monkey, which is known to develop atherosclerosis in a fashion similar to humans with respect to morphology and cytology.[7] Like humans, African green monkeys express only apolipoprotein (apo) B 100 in the liver. A high cholesterol diet leads to a reduction in hepatic LDL receptor mRNA and down-regulation of cholesterol 7α-hydroxylase activity.[8] Feeding African green monkeys an atherogenic diet high in saturated fat led to the enrichment of LDL particles with cholesteryl oleate and predicted the magnitude of atherosclerotic development.[9,10] Atherosclerotic development appears to be less pronounced when these animals consume a diet composed largely of polyunsaturated fats (PUFA) when compared to monounsaturated fats or saturated fatty acids (SFA).[11] However, development of atherosclerosis in this animal model takes years (as opposed to weeks in other models), and these animals are expensive to obtain and maintain. Furthermore, African green monkeys tend to have higher plasma concentrations of HDL cholesterol (HDL-C) than LDL cholesterol (LDL-C), opposite to the human situation.[12]

Rats There are numerous dissimilarities in lipoprotein metabolism between rats and humans. Wild-type rats do not have cholesterol ester transfer protein (CETP) activity,[13] which plays a major role in intravascular lipoprotein particle processing and lipid exchange in humans.[14] As such, CETP transgenic rats have been used.[15] Rats also have a very high activity of cholesterol 7α-hydroxylase (CYP7),[16] thus they readily eliminate excess body cholesterol. Furthermore, rats carry the majority of cholesterol in HDL particles,[17] which also differs from humans. LDL-C does not increase in rats fed saturated fat unless very high cholesterol (0.5–1.0% of diet) is fed in conjunction with cholic acid.[18] The densities of LDL and HDL particles overlap in rats, making isolation of these lipoproteins difficult. As a result of these characteristics of rat lipoprotein metabolism, rats are very resistant to atherosclerosis.

Mice Like rats, wild-type mice are not good models of human lipoprotein metabolism, thus several transgenic and knockout mice have been created. These genetic manipulations can affect the viability of these animals and increase the cost of the experiments. Wild-type mice carry the majority of cholesterol in HDL particles rather than in LDL particles.[17] Two commonly used genetically modified mouse models are the apo E-deficient and LDL receptor-deficient animals, which have been shown to respond to dietary and pharmacological interventions; however, the lipoprotein profile of these models is quite different from humans.[19] Like rats, mice respond to high dietary cholesterol by downregulating cholesterol synthesis and upregulating bile acid synthesis, which serves to maintain plasma cholesterol homeostasis. Mice also express apo B 48 in the liver,[20] which does not occur in humans.

Hamsters Significant research regarding LDL transport has been derived from the hamster model.[21] Compared to the rat, hamsters have moderate levels of expression of CYP7.[22] When fed a high cholesterol diet, hamsters develop hypertriglyceridemia, opposite to humans. Insulin resistance has been induced in hamsters that consumed a high fructose diet for 2 weeks, resulting in an increased mass of microsomal transfer protein (MTP) and increased very-low-density lipoprotein (VLDL) apo B secretion from the liver.[23] When fed a normal chow diet, hamsters carry cholesterol predominantly in HDL particles (56%) rather than in LDL particles (26%), though the majority of triglycerides circulate in VLDL.[24] The hamster is not a good model for dietary fiber since these animals have a forestomach where fiber is fermented prior to reaching the small intestine. Though fibrates function similarly in hamsters and humans,[24] hamsters are not a good model for 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors.[25]

Rabbits Both wild-type and transgenic rabbits are often used in cardiovascular disease research. Rabbits are susceptible to diet-induced atherosclerosis, perhaps due to their high activity of CETP. However, rabbits have almost no hepatic lipase. Like humans, the rabbit liver does not edit apolipoprotein B mRNA. Also, like hypertriglyceridemic patients, rabbits produce β-VLDL, which are large, triglyceride-laden VLDL particles characteristic of hypertriglyceridemia. Rabbits transgenic for lipoprotein (a), apolipoproteins AI, B, E2, and E3, hepatic lipase, and lecithin: cholesterol acyltransferase (LCAT) have all been used to study lipoprotein metabolism. The Watanabe Heritable Hyperlipidemic rabbits are a good model for familial hypercholesterolemia and St. Thomas' Hospital rabbits are a good model for familial combined hyperlipidemia.[26]

GUINEA PIGS

COMPARISONS OF GUINEA PIGS WITH HUMANS

Lipoprotein Metabolism In addition to carrying the majority of cholesterol in LDL, guinea pigs have other similarities in lipoprotein distribution and metabolism including a higher LDL to HDL ratio;[27] they possess plasma CETP,[28] LCAT,[29] and lipoprotein lipase (LPL)[30] activities for intravascular processing of plasma lipoproteins.

Females have higher HDL-C levels than males;[31] ovariectomized guinea pigs, a model for menopause, have elevated triglycerides (TG) and higher LDL-C similar to the plasma lipid profiles of postmenopausal women.[31] Guinea pigs during exercise lower their plasma TG and increase their plasma HDL-C.[32] Guinea pigs also respond to dietary interventions[33–35] and drug treatment[36–38] by lowering plasma LDL-C concentrations.

Hepatic Cholesterol Metabolism Compared to humans, guinea pigs have higher concentrations of free than cholesterol ester (CE) in the liver.[27,39] They also exhibit comparable moderate rates of hepatic cholesterol synthesis[27,40] and catabolism.[41,42] Similar to humans, the binding domain for the LDL receptor differentiates between normal and familial binding defective apo B-100.[43] Most importantly, apo B mRNA editing in liver is present in negligible amounts (<1%) compared to 18–70% in other species.[44] Table 23–1 illustrates the similarities of guinea pigs and humans compared to other animal models in several aspects of cholesterol and lipoprotein metabolism.

USE OF GUINEA PIGS FOR DIETARY INTERVENTIONS

DIETARY FIBER It has been well established that dietary soluble fiber is one of the major components in food, which has been associated with a decreased risk of coronary heart disease.[45] The hypocholesterolemic properties of dietary fiber are a result of the primary action of fiber in the intestinal lumen.[46] These mechanisms involve interruption of the enterohepatic circulation of bile acids and decreased absorption rate of lipids including cholesterol.[47] Based on this action of fiber, plasma LDL-C concentrations are reduced. Guinea pigs have been useful models to elucidate the secondary mechanisms associated with plasma cholesterol lowering.[48,49]

As a result of fiber's primary action in the small intestine, cholesterol delivered to the liver via the chylomicron remnant is reduced.[50] In addition, the interruption of bile acid cycling causes a major effect on hepatic cholesterol. Cholesterol hydroxylation at the alpha position is the initial and rate-limiting step in this process. This step is catalyzed by CYP7, the main regulatory enzyme in the bile acid synthesis pathway.[51] Due to these major alterations in hepatic cholesterol concentrations, CYP7 is upregulated leading to a greater depletion of the hepatic cholesterol pools. To maintain hepatic cholesterol homeostasis, the LDL receptor is upregulated to remove cholesterol from circulation leading to the decreases in LDL-C.

The expression of the LDL receptor gene in liver is regulated by a feedback mechanism involving hepatic cholesterol. When the demand for cholesterol increases, the liver cells express high levels of LDL receptor mRNA and when cholesterol accumulates

Table 23–1
Comparison of humans, guinea pigs, hamsters, mice, rabbits, and African green monkeys in parameters of lipoprotein metabolism[a]

Parameter	*Human*	*Guinea Pig*	*Hamster*	*Rat*	*Mouse*	*Rabbit*	*African Green Monkey*

in the cell, the activity and expression of the LDL receptor are suppressed.[52] Depletion of hepatic cholesterol concentrations as a result of fiber intake leads to an upregulation of LDL receptors as demonstrated by *in vitro* measurements[50] of hepatic LDL receptor or *in vivo* determinations of LDL turnover.[46]

Dietary Fiber and Hepatic Cholesterol Metabolism In guinea pigs, significant reductions of hepatic cholesterol due to intake of different sources of soluble fiber including pectin, guar gum, psyllium,[53,54] or fiber from lime-treated corn husks have been reported.[55] Furthermore, increases in hepatic CYP7 activity and mRNA abundance have also been observed after pectin and psyllium intake,[56] which confirm the postulated mechanisms. Another important metabolic alteration is increased synthesis of cholesterol within the hepatocyte as demonstrated by higher activity of HMG-CoA reductase.[49] Such a compensatory increase in hepatic synthesis occurs when intestinal cholesterol absorption is impaired or when bile acid synthesis is stimulated. Under these conditions, acyl CoA cholesteryl:acyltransferase (ACAT) activity is downregulated[50] because the availability of free cholesterol for esterification is substantially reduced.[57,58]

Dietary Fiber and Lipoprotein Metabolism Lipoprotein metabolism is also altered by dietary fiber as a result of depleted hepatic pools. The decreases in hepatic cholesterol have been related to lower rates of hepatic apo B secretion and to a faster LDL turnover rate in guinea pigs.[46,47] In addition, the compositions of both the VLDL and LDL are significantly altered and these compositional modifications have metabolic implications.[59] Soluble fiber intake results in the formation of a large TG-enriched, CE-depleted VLDL particle, compositional changes associated with less conversion to IDL and LDL in the delipidation cascade.[6] It has also been postulated that large VLDLs are catabolized faster by the apo B/E receptor.[61] In addition, LDL fractional catabolic rates (FCR) *in vivo* are faster in guinea pigs fed soluble fiber.[2] Other important modifications that take place in the intravascular compartment are a significant decrease in CETP activity, which can be associated with the CE-depleted VLDL and LDL.[59] Lower CETP activity may contribute to the mechanisms of hypocholesterolemia attributed to soluble fiber.

The guinea pig model has been useful in elucidating the complex mechanisms by which soluble fiber lowers plasma LDL-C (Figure 23–1).

DIETARY CHOLESTEROL Guinea pigs, similar to humans, present different responses to dietary cholesterol[62] demonstrating

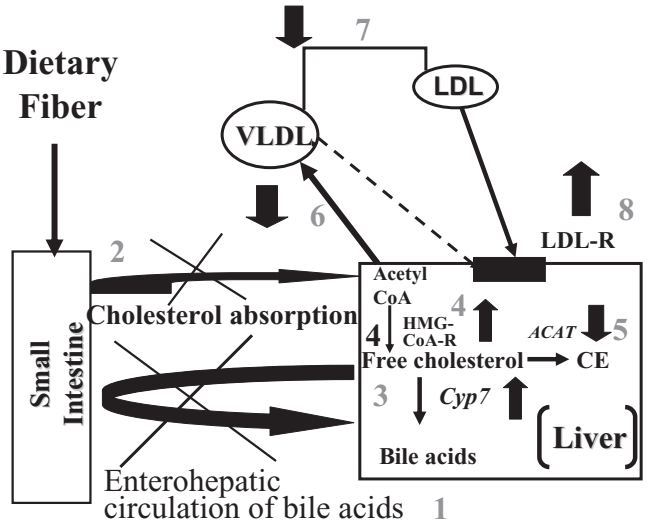

Figure 23–1. Mechanisms by which dietary fiber lowers plasma LDL cholesterol: (**1**) there is an interruption of the enterohepatic circulation of bile acids and (**2**) of cholesterol absorption in the intestinal lumen. As a result (**3**) cholesterol 7α-hydroxylase is upregulated to synthesize more bile acids. At the same time (**4**) HMG-CoA reductase activity is upregulated and (**5**) ACAT activity is reduced because of less substrate (free cholesterol). This leads to (**6**) decreased apo VLDL secretion. In addition, there is (**7**) less conversion of VLDL to LDL and (**8**) an upregulation of LDL receptors. All these mechanisms contribute to the decrease in LDL cholesterol.

that the responses are highly individualized in agreement with clinical studies.[63] Earlier reports on the deleterious effects of dietary cholesterol in guinea pigs, including hemolytic anemia characterized by accelerated destruction of the erythrocytes[64] and death before any considerable plaques have been developed, have precluded the use of guinea pigs for models of cholesterol and lipoprotein metabolism. In addition, these reports focused on the appearance of abnormal lipoproteins and changes in lipid metabolism, which were postulated to be species specific.[65,66] These studies failed to stress the fact that the amount of cholesterol provided to guinea pigs was 1–2%, which is equivalent to 7500–15,000 mg/day of cholesterol in the human situation. Thus the remarks concerning these earlier studies have to be taken with caution and the interpretation of the results viewed on the scope that these experiments cannot possibly have any clinical significance.

The effects of dietary cholesterol on plasma lipids, lipoprotein composition, hepatic LDL receptors, and HDL metabolism have been evaluated in guinea pigs fed 0.08, 0.17, or 0.33% dietary cholesterol, equivalent to 600–2500 mg cholesterol/day in the human situation.[62,67,68] These levels of dietary cholesterol correspond to an amount of absorbed cholesterol equal to one-half, one, and two times the endogenous cholesterol synthesis in guinea pigs.[38] Increasing the concentration of dietary cholesterol resulted in a dose-dependent increase in plasma cholesterol associated with the LDL fraction, which was independent of the dietary fat. HMG-CoA reductase activity was significantly downregulated with an absorbed amount equivalent to one-half times the endogenous cholesterol synthesis (0.08% dietary cholesterol) as a first compensatory mechanism. The amount of cholesterol in liver was also increased in a dose-dependent manner with higher levels of dietary cholesterol. These increases in hepatic cholesterol paralleled the increases in ACAT activity.[69] Hepatic LDL receptor numbers were measured by incubating increasing concentrations of ^{125}LDL with hepatic membranes and the number of receptors was decreased as the amount of dietary cholesterol increased.[67] These studies demonstrate the different compensatory mechanisms of the body when there is a challenge of dietary cholesterol. The effects of different levels of dietary cholesterol on major regulators of plasma cholesterol homeostasis are presented in Table 23–2.

In addition, our laboratory has also demonstrated that guinea pigs do present early atherosclerotic development and fatty streak accumulation after 12 weeks when challenged with amounts of dietary cholesterol in the range of 2000 mg/day human consumption.[70,71]

DIETARY FAT Effects of fatty acids varying in chain length and degree of saturation on cholesterol and lipoprotein metabolism have been studied in guinea pigs. Diets high in PUFA (corn oil) (CO) lower plasma LDL-C concentrations compared to highly SFA palm kernel (PK) rich in short-chain fatty acids or SFA lard rich in long-chain fatty acids.[33,72,73] Other metabolic alterations in lipoprotein assembly and secretion were also associated with the observed changes in plasma LDL-C. For instance, guinea pigs fed the PK diet had the highest apo B secretion rate.[73] The PK group also exhibited the slowest LDL FCR *in vivo*.[72] In contrast, guinea pigs fed the CO diet had the fastest LDL FCR and the highest number of hepatic LDL receptors.[72] Intake of CO also resulted in the smallest mature VLDL particle, as measured by electron microscopy.[74]

The effects of different types of fatty acids on hepatic enzymes involved in cholesterol homeostasis have been evaluated in guinea pigs.[75] Guinea pigs fed the PK diet had the highest plasma LDL-C followed by those fed palm oil rich in palmitic acid and CO intake resulted in the lowest plasma LDL-C concentrations. HMG-CoA reductase activity varied among groups and was independent of plasma LDL-C. In contrast, ACAT activity exhibited a positive correlation with plasma LDL-C concentrations. Two possibilities may account for these correlations: (1) ACAT activity determines rates of incorporation of CE into VLDL, which is subsequently converted into LDL, and (2) ACAT activity changes in response to rates of hepatic cholesterol influx. In support of the first theory, hypercholesterolemic diets are related to the production of a greater number of larger LDL particles in African green monkeys[9] and in guinea pigs.[33] The higher number of CE molecules, incorporated into newly secreted lipoproteins, has been correlated with

Table 23–2
Effects of different doses of dietary cholesterol on plasma and hepatic lipids and parameters of lipoprotein metabolism in guinea pigs[a,b]

Parameter	*0*	*0.08%*	*0.17%*	*0.33%*
LDL-C (mg/dl)[c]	40.0 ± 10.0	54.3 ± 20.9	124.7 ± 65.2	253.8 ± 71.1

[d]Adapted from Sun *et al.*[67]

[e]Adapted from Lin *et al.*[69]

increased ACAT and with a higher number of atherosclerotic lesions in African green monkeys.[51] In support of the second theory, dietary fat saturation and chain length affect LDL absolute catabolic rate.[33,34] In a steady-state condition, LDL flux equals total catabolic rate and assuming 80% of LDL uptake by the liver, guinea pigs having the greatest influx (PK-fed animals) also had the highest ACAT activity. Similar results supporting both theories have been reported for guinea pigs fed low-fat (2.5%) or high-fat (25%) diets.[76]

These studies demonstrate that the mechanisms by which different fatty acids alter lipoprotein levels and composition and possibly atherosclerotic events are related to specific effects of these fatty acids on hepatic cholesterol homeostasis, VLDL secretion, alterations in the intravascular compartment, and LDL catabolic rates. In addition, the cholesterolemic response of guinea pigs to dietary fatty acids is similar to reports from clinical studies[77] and they are in agreement with proposed mechanisms reported in human studies.[78,79]

DIETARY CARBOHYDRATES The role of differing carbohydrate types (simple vs. complex) on lipoprotein metabolism in guinea pigs has been investigated.[80] Guinea pigs were fed isocaloric diets in which 52% of the energy from carbohydrates was derived from either sucrose or starch. Plasma cholesterol concentrations were not different between groups, but triglycerides and VLDL-C levels were significantly higher in the group consuming the sucrose-based diet. Also in the sucrose group, apolipoprotein B secretion was significantly higher, and VLDL contained less triglyceride per apolipoprotein B. This indicates that the higher plasma triglycerides were likely due to an increased quantity of VLDL particles. Guinea pigs consuming a high fat diet with complex carbohydrates display a more rapid removal of VLDL from plasma and less conversion of VLDL to LDL when compared to guinea pigs fed a high-fat diet with sucrose.[81] Similar results have been shown in humans where carbohydrate type affected plasma TG.

With cardiovascular diseases as the leading cause of death in the United States and most industrialized countries, risk management interventions often focus on dietary macronutrient composition. A varying macronutrient composition is known to affect lipoprotein metabolism. Low-fat diets appear to be particularly effective at lowering LDL-C, but may adversely affect TG and HDL-C. Restricting dietary carbohydrate can reduce TG and increase HDL-C, while the effects on LDL-C appear to vary between individuals.[82] We have recently shown that the response of dietary carbohydrate restriction in guinea pigs is similar to the response in humans.

Male Hartley guinea pigs were fed one of three diets for 12 weeks: (1) low cholesterol (0.04 g/100 g) with high carbohydrate (42% of energy), (2) high cholesterol (0.25 g/10 g) with high carbohydrate (42% of energy), or (3) high cholesterol (0.25 g/100 g) with low carbohydrate (11% of energy).[83] The groups consuming high cholesterol had significantly higher VLDL-C and LDL-C than the low-cholesterol group. Using nuclear magnetic resonance, lipoprotein particle size and subclass concentrations were determined. Interestingly, the quantity of total LDL particles and the quantity of medium and small LDL particles were significantly lower in the high-cholesterol, low-carbohydrate group than in the high-cholesterol, high-carbohydrate group. Similar results have been shown in humans[84] where a 12-week carbohydrate-restricted diet decreased LDL particle atherogenicity by reducing the quantity of total, medium, and small LDL particles while increasing mean LDL particle size. While future work is needed to investigate additional facets of lipoprotein metabolism affected by macronutrient distribution in guinea pigs, it appears that LDL metabolism is similarly impacted in humans and guinea pigs with carbohydrate restriction. In addition, as discussed below, carbohydrate restriction in guinea pigs results in improvements in inflammatory markers similar to those experienced by humans.

VITAMIN C DEFICIENCY Like humans, guinea pigs require an exogenous dietary source of vitamin C. Though vitamin C is produced in the liver or kidney of most animals, guinea pigs (like humans) lack the enzyme gulonolactone oxidase, which is required to synthesize it.

Epidemiological studies have shown a negative correlation between vitamin C intake and plasma cholesterol concentration.[85] Guinea pigs are an ideal model to investigate the effects of vitamin C status on hepatic lipid metabolism considering their similarity to humans with respect to ascorbic acid requirement and lipoprotein metabolism.[86] Consuming a diet with suboptimal vitamin C has been shown to negatively affect lipoprotein metabolism in guinea pigs.[87] Guinea pigs were fed diets composed of either high SFA or PUFA, while being fed either adequate (500 mg/kg diet) or suboptimal (50 mg/kg diet) amounts of vitamin C. Guinea pigs that consumed suboptimal vitamin C had 15% lower HMG-CoA reductase activity, a 25% reduction in LDL receptor quantity, 20% higher ACAT activity, a 28% greater hepatic TG and CE content, and a higher VLDL secretion rate in comparison to the vitamin C adequate group. Furthermore, the suboptimal vitamin C group displayed 45% lower plasma HDL-C concentrations, a 40% increase in VLDL-C, a 50% increase in LDL-C, and a 30% increase in CETP activity. Guinea pigs consuming suboptimal vitamin C and higher SFA showed the most pronounced deleterious effects on lipid metabolism. A potential mechanism for the elevations in TG is based on the role of vitamin C in carnitine synthesis. Lower levels of carnitine lead to a reduced transport of fatty acids to the mitochondria for oxidation, causing hepatic triglyceride accumulation.[88] Furthermore, inadequate vitamin C status is associated with reduced hepatic cytochrome P450[89] which results in decreased CYP7 activity and subsequent decreased bile acid formation.[90]

DRUG TREATMENT

Guinea pigs have been used to study drug effects on plasma cholesterol and TG and to clarify their hypocholesterolemic mechanisms. These drugs include probucol,[37] cholestyramine,[91] ACAT inhibitors,[92] HMG-CoA reductase inhibitors such as pravastatin,[93] simvastatin,[94,95] lovastatin,[36,96] and atorvastatin,[59,60,97] apical sodium-dependent bile acid transporter (ASBT) inhibitors,[98] MTP inhibitors,[38] and rapamycin, a drug used in organ transplant patients.[99]

CHOLESTYRAMINE Cholestyramine is very effective in reducing plasma LDL-C concentrations by 55–75% in guinea pigs.[58] Witztum *et al.*[91] measured cholestyramine effects of LDL size and composition and how these affected LDL FCR. Their findings suggest that LDL from cholestyramine-treated guinea pigs, which were smaller in size, had a slower turnover in plasma than LDL derived from control animals. The lowering of plasma LDL-C by cholestyramine was due to increases in LDL receptor in treated guinea pigs, suggesting that compositional changes in LDL have profound metabolic consequences.

3-HYDROXY-3-METHYLGLUTARYL COENZYME A REDUCTASE INHIBITORS Approximately 65% of total cholesterol in the body is endogenously synthesized in extrahepatic tissues.[100] Like humans, guinea pigs have moderate rates of hepatic cholesterol synthesis,[27,101] whereas the major site of cholesterol synthesis in the rat is the liver.[102] HMG-CoA reductase, the rate-limiting enzyme for cholesterol biosynthesis, is largely regulated by cholesterol via negative feedback regulation. Inhibition of HMG-CoA reductase activity results in reductions of plasma total and LDL-C concentrations.

In agreement with humans, guinea pigs treated with reductase inhibitors exhibit significant decreases in plasma LDL-C concentrations.[93–97] Most of these reductase inhibitors have shown that an increase in LDL receptor is a major mechanism for the observed hypocholesterolimia.[36,97] Lovastatin therapy has been shown to increase hepatic LDL receptor activity in guinea pigs and the drug induced compositional changes in the LDL particle, which had significant effects on removal of LDL from plasma.[36] LDL from lovastatin-treated guinea pigs had a slower LDL FCR compared to control LDL. When these studies were repeated in subjects with hyperlipidemia, results similar to those reported for guinea pigs were found, a decrease in particle affinity for the receptor and increases in receptor activity.[103] In our studies with atorvastatin, treatment with this reductase inhibitor resulted in decreased secretion of apo B in combination with increases in apo B/E receptors.[95,97] Our results are in total agreement with the reported mechanisms of LDL-C lowering in hyperlipidemic individuals treated with lovastatin,[103] confirming the suitability of guinea pigs in mimicking metabolic alterations in plasma lipoproteins induced by drug treatment.

APICAL SODIUM-DEPENDENT BILE ACID TRANSPORTER INHIBITORS Apical sodium-dependent bile acid transporter (ASBT) is a 348-amino acid protein localized on the apical surface of epithelial cells lining the ileum[104] and has been shown to mediate approximately 75% of the bile acids recycled in the human body.[105] Interruption of ileal bile acid reclamation leads to a reduction in plasma total and LDL-C levels via a significant increase in cholesterol catabolism.[50] SC-435 is a potent ASBT inhibitor (ASBTi) and has been studied in several animal models[106,107] including guinea pigs.[41,98,108]

West *et al.*[41] reported that guinea pigs treated with 13.4 mg/kg/day SC-435 had 44% lower LDL-C concentrations compared to controls. Hepatic CE were significantly reduced by 43, 56, and 70% in guinea pigs fed 0.8, 3.7, and 13.4 mg/kg/day of the ASBT inhibitor, respectively.[41] In addition, the highest dose of the inhibitor resulted in a 42% increase in the number of VLDL TG molecules and a larger VLDL diameter compared to controls. ACAT activity was 30% lower with the highest dose treatment while CYP7 was 30% higher with the highest ASBT inhibitor dose.[98] Cholesterol in the aortic arch was significantly reduced by 25 and 42% in guinea pigs treated with a monotherapy of 45 mg/day SC-435 and a coadministration of 17 mg/day SC-435 and 16 mg/day simvastatin , respectively.[98] In addition, SC-435 monotherapy and combination therapy also impact important regulatory enzymes of hepatic cholesterol homeostasis, which contribute to the lowering of plasma LDL-C.[98]

Taken together, these results indicate that the interruption of the enterohepatic circulation of bile acids by ASBTi and combination therapy may play a significant role in reducing cholesterol concentrations. This is a key finding since hypercholesterolemia in guinea pigs, like humans, results in an accumulation of cholesterol in the aortic arch, which ultimately leads to the development of atherosclerotic lesions

ACYL COA CHOLESTERYL:ACYLTRANSFERASE INHIBITORS ACAT is the rate-limiting enzyme in the formation of cholesteryl esters from cholesterol and long-chain fatty acyl coenzyme A. ACAT inhibitors have been shown to reduce plasma cholesterol levels by reducing cholesterol absorption[109] and decreasing the formation of VLDL particles. Furthermore, the inhibition of ACAT has been shown to prevent the conversion of macrophages to foam cells in the arterial wall.[110] The guinea pig has been used as a model to examine the effects of two different ACAT inhibitors, PD 321301-2[1] and CL 277,082[2]. At a lower dose (1 mg/kg), PD 321301-2 reduced plasma cholesterol by 21% and triglycerides by 25%. At a higher dose (10 mg/kg), VLDL-C was reduced by 87%, LDL-C by 64%, HDL-C by 75%, and triglycerides by 54%.[111] CL 277,082[2] was effective at lowering cholesterol only at a high dose (136 mg/kg). Junquero *et al.*[112] tested a systemic ACAT inhibitor (F 125113) using guinea pigs and found dose-dependent reductions in plasma cholesterol. These data suggest the potential utility of ACAT inhibitors in reducing plasma cholesterol, though additional work in humans is required. Furthermore, the effects of these drugs on HDL-C are an important consideration.

MICROSOMAL TRANSFER PROTEIN INHIBITORS MTP functions by transferring triglycerides and other lipids into the lumen of the endoplasmic reticulum. MTP is also a key in the assembly of chylomicrons. MTP inhibitors have been used to manage dyslipidemia, particularly because they target a different pathway of lipoprotein generation than HMG-CoA reductase inhibitors. The function of MTP inhibitors is to reduce packaging of lipids into chylomicrons and VLDL particles, decreasing plasma TG and reducing the formation of LDL particles.

An MTP inhibitor, CP-346086, has been administered to healthy humans. A single dose resulted in decreased plasma TG and VLDL cholesterol content, in a dose-dependent fashion. Following a 2-week treatment of 30 mg/day, total cholesterol was reduced by 47%, LDL-C by 72%, and TG by 75%.[113]

Though an MTP inhibitor can have profound effects on plasma lipids and lipoprotein particle lipid content, much concern still existed about hepatic lipid accumulation. JTT-130, an MTP inhibitor, was identified as specifically targeting the intestine. To investigate the effects of this JTT-30, guinea pigs were randomly assigned to consume either a control diet (no JTT-130), a low-dose diet, or a high-dose diet for 4 weeks.[38] In comparison to the control group, the low and high dose JTT-130 groups displayed significantly lower plasma total cholesterol, TG, and LDL-C. Perhaps noteworthy was that no differences between the control, low-dose, or high-dose groups were observed in terms of hepatic free cholesterol, CE, or TG content. It is believed that the JTT-130 reduced TG transfer to chylomicrons, leading to a reduced hepatic TG uptake via chylomicron remnants. Thus, the guinea pig model has been used to demonstrate that an MTP inhibitor specifically targeting the liver can reduce plasma LDL-C and TG without causing deleterious effects on hepatic lipid accumulation. Though further investigation in humans is necessary, the similarities between guinea pigs and humans with respect to lipoprotein metabolism indicate that treatment of humans with an

MTP inhibitor targeted to the intestine has the potential to be effective.

RAPAMYCIN Rapamycin is a natural compound produced by bacteria. Because of its immunosuppressive properties, rapamycin is approved by the FDA for use in preventing organ rejection in transplant patients. Rapamycin functions by binding to the immunophilin FK506 binding protein. Next, this complex interacts with the rapamycin binding domain, which results in the inactivation of a serine-threonine kinase known as the mammalian target of rapamycin (mTOR).[114] mTOR controls proteins that regulate mRNA translation initiation and G1 progression, and is targeted by numerous signals including insulin, growth factors, and amino acids. Through the action of these signals, regulatory cascades are adjusted to impact cell growth and proliferation.

Though these powerful immunosuppressive effects are clearly important in the prevention of transplant rejection, side effects of plasma lipids are known to occur. Specifically, dyslipidemia has been reported in 45% of liver transplant patients[115] and in 40% of kidney transplant patients.[116] Given the relationship between insulin and rapamycin, and the relationship between insulin resistance and dyslipidemia, the mechanisms behind the deleterious effects of rapamycin on lipoprotein metabolism provide insight concerning the risk for cardiovascular disease in transplant patients using this treatment.

The effects of rapamycin on plasma lipids are similar between guinea pigs and humans.[99] As such, the guinea pig model has provided considerable insight into the mechanisms behind the changes in plasma lipids and lipoprotein metabolism resulting from rapamycin prescription. To elucidate these mechanisms, 30 male guinea pigs consumed one of three treatments: control (no rapamycin), low dose, or high dose. The two groups treated with rapamycin displayed a 2-fold higher plasma triglyceride concentration in comparison to controls, with no difference between experimental groups. Guinea pigs treated with rapamycin also displayed large VLDL particle size, which contained a higher percentage of TG compared to the control group. Aortic cholesterol concentration and ACAT activity were significantly lower in the low-dose group as compared to the control and high-dose groups, and aortic triglyceride concentration was higher in the experimental than in the control groups. Also, plasma free-fatty acids and glucose were higher in the low-dose (65%) and high-dose (72%) groups in comparison to the control group. Furthermore, aortic tumor necrosis factor (TNF)-α concentrations were 3.6- and 10.4-fold greater in the low- and high-dose groups in comparison to the control groups.[99] These results indicate that the effects of rapamycin on plasma lipids and atherosclerosis may be due to alterations in the insulin signaling pathway. This appears to have caused an increased secretion of VLDL and VLDL TG, increasing TG accumulation in the aorta. These results also suggest that lower doses of rapamycin may reduce the unfavorable effects of higher doses of the drug.

EXERCISE AND LIPOPROTEIN METABOLISM

Exercise has been shown to favorably alter lipoprotein metabolism by decreasing plasma TG and increasing HDL-C.[117] Guinea pigs doing an exercise protocol consisting of running on a rodent treadmill at a rate of 33.3 revolutions/min for 30–40 min during 6 weeks exhibited lower plasma TG and higher HDL-C concentrations than sedentary animals.[32]

Prolonged exercise results in lowering of fasting plasma TG concentrations.[118] Exercise training increases LPL activity in plasma and in parenchymal cells, suggesting a role of exercise in increasing the capacity to clear TG from the circulation and suggesting that LPL is involved in the restoration of muscle TG stores reduced by exercise.[119] In addition, adipose tissue has increased LPL activity after exercise.[118] In agreement with human studies, exercised guinea pigs have been shown to have higher LPL activity both in heart and adipose tissue.[32] Patients who follow an exercise regimen in addition to dietary recommendations present significant regression and less progression of coronary atherosclerosis compared to usual-care control patients.[120] These results were correlated with significant decreases in plasma LDL-C and TG in the treated group. We have demonstrated that plasma lipid changes due to exercise in guinea pigs are similar to humans and that these animals develop atherosclerosis.[70,71] Based on these observations, the guinea pig could be an appropriate model to further evaluate the beneficial effects of exercise in the treatment of coronary heart disease.

GENDER AND HORMONAL STATUS

Results from the Framingham Heart Study have shown that higher plasma TG and low plasma HDL-C concentrations are highly associated with cardiovascular disease risk in women, while for men the major risk factor is elevated levels of plasma LDL-C.[121] Studies have shown that responses to dietary factors may differ between men and women.[122] In addition, postmenopausal women have significantly higher risk factors for the metabolic syndrome, insulin resistance, and increased plasma LDL-C, apo B, and TG concentrations.[123] Based on these observations, it is important to have an animal model with gender-associated responses to diet similar to humans. In addition, this model should present changes in lipoprotein profile in the absence of estrogen similar to postmenopausal women.

Female guinea pigs are more responsive to dietary cholesterol than males[124] in agreement with reported observations in humans.[125] In addition in females, fiber does not alter the regulatory enzymes of hepatic cholesterol metabolism, as is the case in males.[54] However, a slower apo B secretion rate and faster LDL FCR were observed in females compared to males,[53] indicating important differences in the gender response to dietary treatments.

We have also demonstrated the suitability of the ovariectomized guinea pig to mimic human menopause. Ovariectomized guinea pigs had higher levels of plasma TG than either males or females, higher concentrations of LDL-C, and overall a more detrimental lipoprotein profile.[31,126] In addition, ovariectomized guinea pigs exhibited higher susceptibility of LDL to oxidation compared to intact female animals. It has been shown that estrogen exerts a protective effect against free radical formation,[127] which might explain the higher susceptibility of LDL to oxidation in the ovariectomized guinea pigs. Gender and hormonal status effects on early atherosclerosis development were also evaluated in guinea pigs. Male guinea pigs had the greatest fatty streak accumulations in aortas, followed by ovariectomized animals, and females had the least lesion involvement ($p < 0.001$).[71] A comparison of plasma lipids, parameters of lipoprotein metabolism, and atherosclerosis among male, female, and ovariectomized guinea pigs is presented in Table 23–3.

Table 23–3
Gender/hormonal effects on plasma and hepatic lipids, lipoprotein metabolism, and atherosclerosis in male, female, and ovariectomized guinea pigs[a,b]

Parameter	*Male*	*Female*	*Ovariectomized*
LDL-C (mg/dl)[c]	69.5 ± 34.1	81.5 ± 53.1	123.4 ± 38.4
HDL-C (mg/dl)[c]	13.2 ± 5.4	18.6 ± 8.1	14.7 ± 4.7
Hepatic cholesterol (mg/g)[d]	2.2 ± 0.1	1.3 ± 0.5	2.3 ± 0.9
Hepatic triglycerides (mg/g)[d]	53.7 ± 25.1	24.0 ± 4.1	70.3 ± 35.5
TBARS (nmol MDA/non-HDL protein)[d]	1.4 ± 2.3	2.8 ± 3.4	8.2 ± 4.2
CYP7 activity (pmol/minmg) [e]	1.99 ± 0.63	1.69 ± 1.03	0.98 ± 0.35
LDL apo B FCR (pools/h)[f,g]	0.08 ± 0.01	0.10 ± 0.02	ND
Aortic fatty streak ($\mu m^2/mm^2$)[d]	20705 ± 4752	14771 ± 2999	16576 ± 2094

[a]LDL-C, low-density lipoprotein C; HDL-C, high-density lipoprotein C; FCR, fractional catabolic rate.
[b]Values are expressed as mean ± SD for $n = 6–8$ guinea pigs. Values in the same row with different superscripts are significantly different as determined by one-way ANOVA and the Newman–Keules post hoc test ($p < 0.01$).

GUINEA PIGS AS MODELS FOR ATHEROSCLEROSIS AND INFLAMMATION

Chronic dysfunctions of lipoprotein metabolism contribute to the formation of atherosclerotic plaque, and, potentially, a clinical event. Another important contributing factor to atherosclerosis is inflammation. Validation of an animal model with similarities to humans in terms of the end results of dysfunctional lipid metabolism and inflammation is a valuable resource in atherosclerosis research. Recent evidence suggests that the guinea pig is an appropriate model for the study of inflammation and atherosclerosis.

INFLAMMATION Atherosclerosis has been defined as a chronic, low-grade inflammatory condition. There are several causes of inflammation including vascular injury, lipid peroxidation, and infection.[128] Following such a stimulus, inflammatory cytokines, such as TNF-α, are released, which signal the release of messenger cytokines such as interleukin-6 (IL-6). Subsequently, systemic markers of inflammation like C-reactive protein (CRP) become elevated.[129] CRP has gained much attention recently in terms of cardiovascular disease risk since plasma CRP concentrations have strong predictive power for cardiovascular events.[130]

Our laboratory group has recently validated the guinea pig as a model for inflammation resulting from diet-induced atherosclerosis. Protein levels and mRNA expression of proinflammatory cytokines were measured for guinea pigs that consumed either high or low cholesterol diets that were either high or low in carbohydrate for 12 weeks. Compared with guinea pigs who consumed low-cholesterol diets, the high-cholesterol groups displayed significantly higher aortic cytokine proteins.[131] Another interesting finding was that the high-cholesterol, low-carbohydrate diet group displayed decreased protein and gene expression (assessed using real-time primers for guinea pigs) of interferon-γ, TNF-α, interleukin-1β, interleukin-8, and MCP-1. These results are similar to those reported for humans on a carbohydrate-restricted diet.[132] Furthermore, these results indicate that the guinea pig may be a promising model for the study of human inflammation resulting from diet-induced atherosclerosis.

ATHEROSCLEROSIS Atherosclerotic plaque formation is a complex process initiated via the oxidation of LDL particles. Once taken up by the arterial intima, LDL particles are susceptible to oxidation by free radicals. Oxidized LDLs enhance the adhesion and uptake of monocytes by the arterial intima. Monocytes become macrophages and engulf oxidized LDL particles to form the foam cells characteristic of atherosclerotic plaque.[133] LDL particles carried by guinea pigs are similar to those carried by humans,[134] and the LDL oxidation pattern in guinea pigs is more similar to that of humans (when compared to rats) with familial hypercholesterolemia.[135] Vitamin E has been shown to be protective of the integrity of the arterial intima in guinea pigs.[136] A vitamin C-deficient diet has been shown to increase the severity of atherosclerotic lesions, and the lesions were further exacerbated with high-cholesterol feeding.[137] Soluble fiber supplementation has been shown to reduce lesion development in guinea pigs.[71] Furthermore, guinea pigs have been shown to develop atherosclerosis, and the extent of atherosclerotic lesions is affected by gender and hormonal status.[71] Drug treatment[36] and grape polyphenols[70] can reduce the concentration of cholesterol in the aortic arch even in the presence of high dietary cholesterol.

CONCLUSIONS

This chapter presents compelling evidence regarding the suitability of guinea pigs as excellent models to evaluate the mechanisms by which diet interventions, drug treatments, and other life style factors alter plasma lipids and lipoprotein metabolism. Furthermore, we have shown that guinea pigs have an inflammatory response and develop atherosclerosis when challenged with a high cholesterol diet and that dietary interventions may prove to be beneficial in reducing the expression of inflammatory cytokines and the development of atherosclerosis. In addition, many of the mechanisms by which guinea pigs regulate cholesterol and lipoprotein metabolism as a response to diet or drug treatment are analogous to those reported in clinical experiments. These studies reinforce the importance of the use of guinea pigs rather than those more established and utilized animal models.

24 Reliability of Rodent Models

Dileep Kumar Rohra and Yureeda Qazi

ABSTRACT

Despite the discrepancies observed between data generated from humans and animals, it is common practice to extrapolate data from animal models to humans. This chapter discusses the usefulness of animal models in research and development, but also stresses the need to exercise caution in interpreting the results. Complete reliance on the results from animal experiments can be dangerously misleading, resulting in damage to human health as well as loss of valuable time and resources. Furthermore, we will elaborate on the validity and reliability of rodent models, the role of confounding factors in using animal models, and precautionary advice when extrapolating data obtained from rodent models to a larger, heterogeneous human population.

Key Words: Rodent models, Reliability, Validity, Confounding factors, Transgenic mouse, Genetics.

INTRODUCTION

Animal models are important and essential tools in biomedical research. In 2006 alone, biomedical researchers have used rodent models to explore everything from the pathogenesis of pulmonary contusion to the beneficial effects of fruit extracts on neuronal function and behavior.[1,2] Recently, mouse models that faithfully recapitulate human head and neck small cell carcinoma (HNSCC) at the pathological and molecular levels have been developed, which will potentially allow the specific genes involved in HNSCC to be defined and reveal prospective therapeutic targets.[3]

ISSUE OF RELIABILITY OF RODENT MODELS

In spite of the fact that animal models have contributed considerably to our understanding of the pathological processes of various human diseases and their treatment, in many cases the issue of reliability has prevented results from animal models from being readily used to develop successful clinical treatments. At regular intervals, investigators have reported that animal models do not satisfactorily model the pathophysiology of complex diseases, cardiomyopathy being one of many examples.[4] To fully examine the reliability of such models, it is first necessary to briefly discuss the classification of such models and the means used to evaluate their validity. Using the concepts of validity, we will subsequently assess the reliability of a number of rodent models and indicate, where necessary, that caution should be used when extrapolating the results from such models to human patients.

An animal model is an organism with a genetic, naturally obtained, or induced pathological process that closely resembles the same condition in humans.[5] Animal models bridge *in vitro* laboratory investigations and studies in humans.[6] Useful models are described as either correlational, isomorphic, or homologous.[7] A correlational model, for example, would show that compounds that ameliorate drug-induced seizures in mice are predicted to be anxiolytics in humans.[8] An isomorphic rodent model of a disease would share the signs and symptoms of the human disease but would differ in its etiology.[9] Snell's dwarf mouse model, with a nonfunctional pituitary, is an example of an isomorphic model. Generally, the most successful models have been homologous, where both the etiology and clinical features of a disease in an animal model mirror those found in the human patient, such as the mouse model for HNSCC.

To establish the validity of an animal model, three types of validity have been recognized: face validity, predictive validity, and construct validity.[8] Face validity indicates a degree of similarity between the clinical presentation of a condition seen in the patient and the signs and symptoms of that condition seen in the model. If a rodent model possesses predictive validity, it should correctly predict the results of a particular intervention when applied in a clinical setting. For example, if a mouse modeling hypertension is treated with a particular antihypertensive drug, its response should correctly predict the behavior of the drug when administered to a hypertensive human. Finally, a model possesses construct validity if both the pathogenesis and the clinical features of the disease expressed by the model mimic those of the clinical condition.[8]

Once a model has been established as being theoretically valid, it must also prove itself reliable. We would like to differentiate reliability into two types: experimental and extrapolation. An animal model is experimentally reliable if, under defined test conditions, the results attained can be reproduced by subsequent tests and by different experimenters following an identical protocol.[10] On the other hand, a model is extrapolation reliable if, under defined test conditions, the results produced by the model mirror the results produced by an identical test on a human subject. Refining our definition of "reliable" into two types, experimental and extrapolation, establishes two separate, overarching criteria under which models must be assessed. Depending on the test performed, a model that is experimentally reliable may or may not be extrapolation reliable. A rodent model's experimental reliability may be affected by differing strains of an animal, vendors, environmental conditions, diet, age, gender, and handling practices. However, if these factors are standardized, then a model's

reliability becomes purely a function of its extrapolation validity, which is itself an expression of the model's conceptual validity. Most widely used rodent models such as the spontaneously hypertensive rats (SHR) have already established their experimental reliability. Therefore, when we discuss the reliability of certain findings based on a model like the SHR, it is, in fact, the extrapolation reliability that we wish to examine.

By examining rodent models such as the SHR model and transgenic models such as the APP23 model, we will examine the factors that call into question their general extrapolation reliability. Subsequently, we will examine some possible reasons for the discrepancy in findings between rodent models and the human disease states. Lastly, we will make some recommendations for working with rodent models.

ERRONEOUS EXTRAPOLATION

The SHR is a widely used model of human hypertension. It has been used extensively to study various aspects of hypertension including the complications associated with hypertension such as cardiac hypertrophy and stroke.[11] In recent studies, we showed that an acidic pH induces the contraction of aortas from hypertensive SHR and normotensive Wistar–Kyoto (WKY) rats.[9] Significantly, there was an exaggerated contractile response in the SHRs as compared to the WKY rats.[12] This increased aortic contractility in the SHR due to reduced pH hinted at a possible contributory mechanism for hypertension due to increased blood acidosis (not an uncommon finding where chronic renal failure and diabetes mellitus are comorbidities with hypertension). However, when similar experiments were performed on the precontracted internal mammary artery of normotensive and hypertensive human subjects, an acidic pH caused relaxation of blood vessels.[13] This contradictory finding requires us to define the nature of the extrapolation reliability of the SHR model. While the acidic pH-induced arterial contraction is reproducible between different SHR model organisms, it does not occur in human subjects. However, the SHR does model many other aspects of adult essential hypertension reasonably accurately.[11] It therefore becomes necessary to identify the parameters within which the SHR model remains valid.

SHR has good face validity with respect to hypertension since the symptoms and measurable variables (elevated average blood pressure) seen in the model reflect those seen in human subjects. However, the SHR can be thought to have poor construct validity as the mechanism by which the symptoms of hypertension appear to be established in the rat model do not occur in humans. For the researcher, this means that the SHR is an extrapolation reliable model when considering face valid facts. For example, SHR accurately predicts that humans suffering from uncontrolled hypertension are predisposed to developing strokes. However, we cannot make an a priori assumption that the mechanisms by which hypertension causes stroke in the SHR are the same as those in the human. Thus, while a model may readily acquire face validity, establishing construct validity, especially for models that attempt to represent complex disease states like hypertension, will require careful elucidation of each underlying mechanism and the confirmation that similar mechanisms exist in the human patient.

SHR has also been used to explore the possible genetic contribution to essential hypertension in humans. The SA gene was found to be overexpressed in the SHR kidneys.[14] Multiple F_2 crosses revealed that it was located in a chromosomal region linked to high blood pressure. The SA gene thus generated much interest as a potential candidate for hypertension genes in rats.[15] However, both linkage and association analyses performed on a white population turned out to be negative.[16] As postulated by Nabika, two hypotheses can explain the discrepancy between rat and human results: (1) the population tested lacked a mutation in the SA gene, and (2) the SA gene is a neutral marker and may link with hypertension gene(s) in rats but not in humans.[15] A similar genetic trail went cold after researchers discovered that while an altered atrial natriuretic peptide (ANP) gene was etiologically related to stroke in stroke-prone SHRs, no such etiology could be confirmed for stroke in humans.[17] Given our earlier observation that the SHR model is only face valid, such discrepancies are not unexpected. As we shall reiterate later, it is vital for researchers to understand the validity and extrapolation reliability of the model being used and thus remain wary of assuming that any data from their model are automatically relevant to human patients.

Our discussion of erroneous extrapolation has, until now, dealt with the more subtle case of models that are face valid but lack construct validity. However, there are a number of models whose face validity is questionable. One example is where rodent models are used to represent the human immune response, specifically, the hypersensitivity response seen in asthma.

Murine models for asthma gained widespread acceptance after it was shown that the hallmarks of asthma (epithelial damage, microvascular leakage and edema, and eosinophil activation) could be successfully created in inbred mice.[18–22] However, the extrapolation reliability of these models is called into question by several inconsistencies. In humans, bronchial asthma is well characterized by the presence of plasma exudate surrounding the inflamed bronchial mucosa.[23] In contrast, however, *in vivo* studies in mice show little exudation.[23,24] While eosinophil degranulation is a hallmark of human asthma, degranulation has not been demonstrated in murine models of asthma.[25] The role of mast cells in murine models of asthma further questions the model's validity. In humans, the release of inflammatory mediators from mast cells leads to bronchoconstriction and the influx of inflammatory cells. However, studies with both mast-cell-deficient and IgE-deficient mice have demonstrated that these animals show degrees of bronchial hyperresponsiveness, eosinophilia, and inflammation comparable to those of normal animals.[26] It would thus appear that IgE is not critical for the development of the murine "asthmatic" phenotype. The inconsistencies between the cellular profile and pathology associated with murine asthma as compared to human asthma mean that the murine model is rendered face invalid. Given that inbred mice and outbred humans inhabit different microenvironments and possess a greatly differing genetic background, it is not surprising that a number of researchers have questioned the use of a murine model for asthma.[22,27]

Inconsistencies between rodent models of disease and their human counterparts are especially prevalent when modeling central nervous system (CNS) function and dysfunction. One of the major drawbacks of the mouse model used to model Parkinson's disease (PD) is that it does not represent the progressive neurodegeneration and gradual intensification of motor disability that are the hallmarks of human PD.[28] By a stringent definition of the term, such a model could not even be classified as face valid. In a similar vein, the rodent models for multiple sclerosis (MS) and experimental allergic encephalomyelitis (EAE)

led to false starts in the development of therapies for MS due to an apparent lack of construct validity. Several treatments, though successful in preclinical EAE trials, ended up being less successful when tested on patients or caused unexpected adverse events.[29] It is thought that key differences exist in the pathogenesis of EAE as compared with MS, which consequently limit the extrapolation reliability of data gained from trials with the EAE model.[24] Similarly, discrepancies between the results of rodent model studies and those of clinical trials have prevented the development of successful therapeutic interventions for the treatment of traumatic brain injury.[30] Where a model is unable to satisfactorily represent the symptoms and/or the mechanisms of the pathology, there can be no satisfactory extrapolation of the experimental results.

The study of atherosclerosis in mouse models has also been plagued with results that cannot be sensibly extrapolated to human patients. The inhibition of angiotensin converting enzyme (ACE) has been purported to have antiproliferative, antiinflammatory, and vasodilatory effects that modulate the development of atherosclerosis in experimental rodent models. Yet, no clinical benefit of ACE inhibition has been established and this awaits further clinical trials.[31] Other studies to examine the etiology of atherosclerosis using rodent models have produced counterintuitive results. In apolipoprotein E (apo $E^{-/-}$) mice, obese diabetic mice showed significantly decreased atherosclerosis when compared to lean, nondiabetic control mice.[32]

From our brief examination, it is readily apparent that there are shortcomings in a number of rodent models that prevent experimental results derived from these models from being extrapolated to human trials. The extrapolation reliability is primarily undermined by an incomplete or inaccurate representation of the disease state where the model lacks validity (either face validity or construct validity or both). One attempt to circumvent this problem and accurately model both the symptoms and the mechanism of a particular disease has been the development of transgenic mice.

THE TROUBLE WITH TRANSGENICS

The creation of transgenic rodent models holds out the promise of actually recreating human disease within a mouse's body. In theory, this would immediately render a model both face and construct valid and allow easy extrapolation of results from such models to humans. However, some caveats must be kept in mind.

Most commonly, transgenic rodents are created for the purpose of genotype transformation or for creating gene knockouts. Both approaches are based on the premise that there is congruence between mouse and human gene function and expression. As such, the results of any alteration in rodent gene function or expression by experimental manipulation should predict the results of altered gene function in humans as a result of pathology. With the exception of a few highly conserved genes, the reality is not quite as convenient.

While humans and mice shared a common ancestor at least 100 million years ago, the ensuing years of divergent evolution have left each species' genome significantly different from that of the other. Saliently, even highly conserved protein and regulatory encoding DNA sequences differ between species due to base substitutions in synonymous codons. In addition, human genomes contain a much larger number of introns separating functionally critical protein-encoding sequences.[33] Introns have recently been found to play an important role in gene splicing and transcriptional regulation with an average of 7.8 introns per gene.[34,35] The relative paucity of introns in the mouse genome and the resulting differences in the regulation of expression between human and mouse must be accounted for when extrapolating the results of transgenic studies to humans.

For a transgenic model to be extrapolation reliable, there must be careful confirmation that the symptomatology of a disease is corroborated by expected molecular changes. For example, the validity of the APP23 mouse as a model for Alzheimer's disease (AD) was increased by the finding that along with an AD-like histopathological and behavioral phenotype, the APP23 mice also showed disturbed levels of compounds in cholinergic, adrenergic, and serotonergic systems. However, the APP23 mice still showed discrepancies with postmortem findings on human brains of AD patients, indicating that the model did not yet represent the full spectrum of the disease.[36]

The creation of a more "human" representation of disease in rodent models has yielded promise for cancer therapy. The carcinoembryonic antigen (CEA), an example of a tumor-associated molecule, is one of many potential targets for novel cancer therapies like gene and immunotherapy. Rodents lack CEA and closely related family members, which compromises preclinical testing on such models. To overcome this problem, Chan and Stanners created a transgenic mouse that contained complete CEA genes, with similar spatiotemporal expression patterns.[37] Humanized rodent models will go some way to reducing the discrepancies between the results from transgenic models and those of clinical trials. However, it is likely that intrinsic species differences will remain a significant obstacle to achieving complete extrapolation reliability.

We have highlighted a number of issues with the extrapolation reliability of rodent models, including transgenic models. The discrepancies between rodent models and human trials may result from differences in pathogenesis, genotype, and confounding factors intrinsic to rodent use.

ROLE OF CONFOUNDING FACTORS

The creation of a rodent model often employs chemical or genetic manipulation to induce a disease state. For example, streptozocin (STZ) is used to create a model of type 1 diabetes. In the diabetic state, glucose causes oxidative glycation and free radical production to induce diabetes-related complications.[38] However, the aromatic hydroxylation observed in the STZ-induced diabetic mouse has been attributed, in part, to the action of STZ itself.[39] Thus, confounding factors in the experimental design of the STZ-induced diabetic mouse can undermine the inferences made from this model about the etiology of diabetes-related complications.

In contrast to their expression in rodent models, human disease states are often accompanied by comorbidities. Animal models are often free of comorbidities such as diabetes, hypertension, or cancer and have normal leukocyte counts.[9] In a model to study the pathophysiology of sepsis and test various treatment strategies, a number of confounding factors limited the clinical success rate of using protein C as a therapeutic option. Sepsis in patients with diabetes and atherosclerosis might exhibit lower potency of therapy because of downregulation of protein C and thrombomodulin receptors on endothelial vasculature, associated with these comorbid diseases.[40]

Variation in the etiology of disease between animal models and humans is one of the fundamental confounding factors in using rodent animal models. The induced sepsis and shock models used for drug development highlight the importance for models to be clinically relevant, especially in terms of etiology and mechanism of disease. These models can generally be classified as infection models, intravenous infusion models, and endotoxicosis models.[41,42] In the bolus intravascular bacterial or endotoxin models, short-term, large doses of bacteria are administered to previously healthy rodents, unlike the slowly seeding infective focus found in humans suffering from sepsis (41). This form of sepsis induction bears no clinical correlate.[41,43] To develop more humanized animal models, it is necessary to be cognizant of the pertinent role of the route of infection, the dose, and the virulence of the bacteria.[43] Researchers who use animal models to study cardiovascular, neurological, and immunological disorders must take into account differences in the genetic background, exposure to inciting pathogen, and temporal relation of exposure to pathogen as some of the factors that can affect the validity of the animal model and, consequently, the coherence of results.

Some of the disparities seen between the results from animals and human studies can be ascribed to a paucity of accurate animal models for chronic disease.[28] Such models are imperative to mimic the persistence of conditions such as asthma and the progressive neurodegeneration of human Parkinson's disease. However, headway has been made in improving the murine mouse model for asthma. A model closer to clinical reality, exhibiting airway-specific acute-on-chronic inflammation with cellular features seen in human asthma, has been developed.[44] This brings us closer to bridging the gap between chronic disease states seen in humans and rodents, allowing us to better understand the mechanisms of chronic diseases and investigate possible therapeutic interventions.

Another potential confounding factor is the use of anesthetics in experimental animals. The preparation of rodent models often involves anesthetization in order to provide immobility and analgesia, and reduce physical and mental stress. However, this can confound the results and outcome of drug trials in such animals.[45] When studying the effects of drugs or endogenous chemical compounds in anesthetized animals, it is necessary to consider the effects of anesthetic agents on cell membranes, which can consequently alter the drug's effects on physiological manifestations of the disease.[45] Rodents also have different clearance rates of drugs due to the reduced capillary density of lower animals, which, in turn, affects the free drug bioavailability in tissues.[46] This is a pertinent point to consider for the noncoherence of drug trials.

To produce data that can reliably be applied to humans, researchers must account for both confounders and bias factors. To ensure the validity and reproducibility of results from rodent models, variables such as substrains of rodents used, sources of diet for the rodents, and environmental conditions under which the animals are kept must also be considered.[47] All these precautions must be implemented before the extrapolation reliability of results from rodent models to humans can be assessed. To economize a scientist's time and resources, we propose confirming the preliminary results obtained from animals in humans during the early stages of the study. Failing that, researchers must critically evaluate the results obtained from animals based on a thorough understanding of the extrapolation reliability of the model.

25 The Domestic Cat, *Felis catus*, as a Model of Hereditary and Infectious Disease

Marilyn Menotti-Raymond and Stephen J. O'Brien

ABSTRACT

The domestic cat, currently the most frequent of companion animals, has enjoyed a medical surveillance, as a nonprimate species, second only to the dog. With over 200 hereditary disease pathologies reported in the cat, the clinical and physiological study of these feline hereditary diseases provides a strong comparative medicine opportunity for prevention, diagnostics, and treatment studies in a laboratory setting. Causal mutations have been characterized in 19 felid genes, with the largest representation from lysosomal storage enzyme disorders. Corrective therapeutic strategies for several disorders have been proposed and examined in the cat, including enzyme replacement, heterologous bone marrow transplantation, and substrate reduction therapy. Genomics tools developed in the cat, including the recent completion of the 2-fold whole genome sequence of the cat and genome browser, radiation hybrid map of 1793 integrated coding and microsatellite loci, a 5-cM genetic linkage map, arrayed BAC libraries, and flow sorted chromosomes, are providing resources that are being utilized in mapping and characterization of genes of interest. A recent report of the mapping and characterization of a novel causative gene for feline spinal muscular atrophy marked the first identification of a disease gene purely from positional reasoning. With the development of genomic resources in the cat and the application of complementary comparative tools developed in other species, the domestic cat is emerging as a promising resource of phenotypically defined genetic variation of biomedical significance. Additionally, the cat has provided several useful models for infectious disease. These include feline leukemia and feline sarcoma virus, feline coronavirus, and Type C retroviruses that interact with cellular oncogenes to induce leukemia, lymphoma, and sarcoma.

Key Words: Domestic cat, *Felis catus*, Gene therapy, Whole genome sequence, Radiation hybrid map, Knockout model, FIV, SARS.

INTRODUCTION

Mankind has held a centuries-long fascination with the cat. The earliest arch eological records that have been linked to the domestication of *Felis catus* date to approximately 9500 years ago from Cyprus,[1] with recent molecular genetic analyses in our laboratory suggesting a Middle Eastern origin for domestication (C. Driscoll *et al.*, unpublished observations). Currently the most numerous of companion animals, numbering close to 90 million in households across the United States (http://www.appma.org/press_industrytrends.asp), the cat enjoys a medical surveillance second only to the dog and humankind. In this chapter we review the promise of the cat as an important model for the advancement of human hereditary and infectious disease and the genomic tools that have been developed for the identification, and characterization of genes of interest.

For many years we have sought to characterize genetic organization in the domestic cat and to develop genomic resources that establish *F. catus* as a useful animal model for human hereditary disease analogues, neoplasia, genetic factors associated with host response to infectious disease, and mammalian genome evolution.[2,3] To identify genes associated with inherited pathologies that mirror inherited human conditions and interesting pheno-types in the domestic cat, we have produced genetic maps of sufficient density to allow linkage or association-based mapping exercises.[4–11]

The first genetic map of the cat, a physical map generated from a somatic-cell hybrid panel, demonstrated the cat's high level of conserved synteny with the human genome, which offered much promise for the future application of comparative genomic inference in felid mapping and association exercises.[12] Several radiation hybrid (RH) and genetic linkage (GL) maps have since been published.[4–9,11,13,14]

THE DOMESTIC CAT RADIATION HYBRID MAP

Although previous versions of the cat gene map, based on somatic cell hybrid and ZOO FISH analysis,[15,16] revealed considerable conservation of synteny with the human genome, these maps provided no knowledge of gene order or intrachromosomal genome rearrangement between the two species, information that is critical to applying comparative map inference to gene discovery in gene-poor model systems. Radiation hybrid (RH) mapping has emerged as a powerful tool for constructing moderate- to high-density gene maps in vertebrates by obviating the need to identify interspecific polymorphisms critical for the generation of genetic linkage maps.[7]

The most recent RH map of the cat[8] includes 1793 markers: 662 coding loci, 335 selected markers derived from the cat 2X whole genome sequence targeted at breakpoints in conserved synteny between human and cat, and 797 short tandem repeat (STR) loci. The strategy used in developing the current RH map was to target gaps in the feline–human comparative map, and to provide more definition in breakpoints in regions of conserved synteny between cat and human. The 1793 markers cover the

From: *Sourcebook of Models for Biomedical Research* (P. M. Conn, ed.),

length of the 18 feline autosomes and the X chromosome at an average spacing of one marker every 1.5 Mb (megabase), with fairly uniform marker density.[8] An enhanced comparative map demonstrates that the current map provides 86% and 85% comparative coverage of the human and canine genomes, respectively.[8] Ninety-six percent of the 1793 cat markers have identifiable orthologues in the canine and human genome sequences, providing a rich comparative tool, which is critical in linkage mapping exercises for the identification of genes controlling feline phenotypes. Figure 25–1 presents a graphic display of each cat chromosome and blocks of conserved syntenic order with the human and canine genomes.[8] One hundred and fifty-two cat–human and 134 cat–dog homologous synteny blocks were identified. Alignment of cat, dog, and human chromosomes demonstrated different patterns of chromosomal rearrangement with a marked increase in interchromosomal rearrangements relative to human in the canid lineage (89% of all rearrangements), as opposed to the more frequent intrachromosomal rearrangements in the felid lineage (95% of all rearrangements) since divergence from a common carnivore ancestor 55 My ago.

With an average spacing of 1 marker every 1.5 Mb in the feline euchromatic sequence, the map provided a solid framework for the chromosomal assignment of feline contigs and scaffolds during assembly of the cat genome assembly,[17] and served as a comparative tool to aid in the identification of genes controlling feline phenotypes.

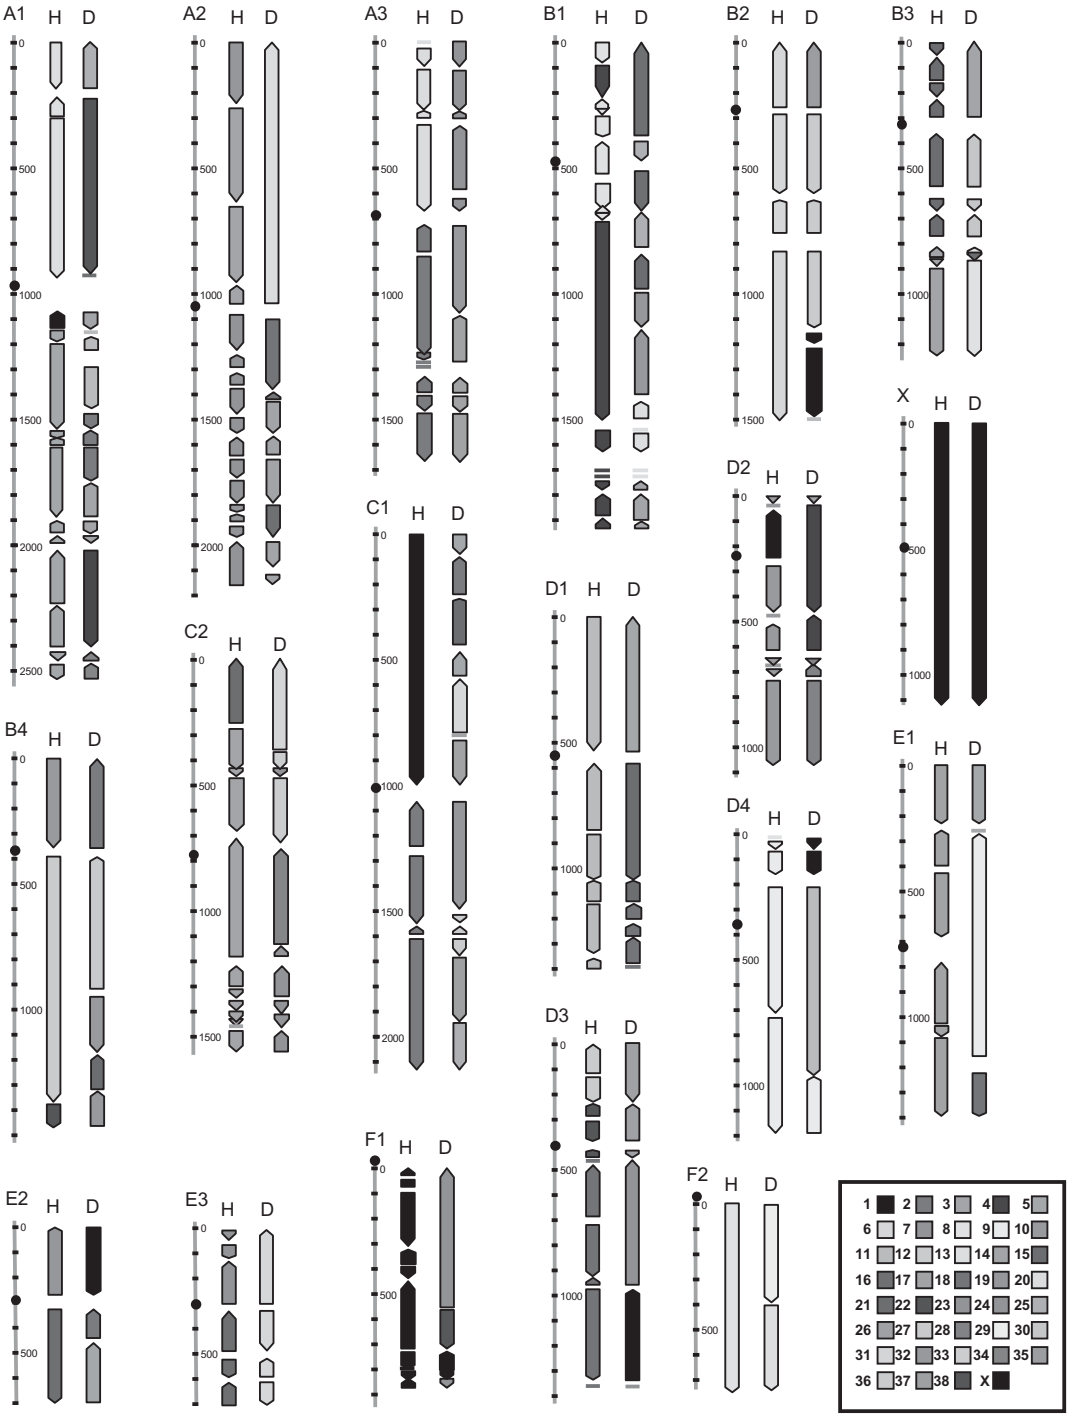

Figure 25–1. Feline chromosome maps (labeled at top) and homologous synteny blocks (HSBs) in the human (H) and dog (D) genomes. HSBs are shown to the right of each cat chromosome map (only the map scale is shown). The dark cross-marks on each cat chromosome correspond to 100-cR$_{5000}$ intervals. The inferred centromere positions are shown by dark circles. HSBs are color coded by human or dog chromosome, defined by the key in the bottom right corner. (Reprinted from Murphy *et al.*[7] Copyright 2007, with permission from Elsevier.) (See color insert.)

THE DOMESTIC CAT GENETIC LINKAGE MAP

As a complement to the RH map of the cat, a third generation linkage map of 625 STRs is currently nearing completion. The map has been generated in a large multigeneration domestic cat pedigree (n = 483 informative meioses).[18] Previous first- and second-generation linkage maps of the cat were generated in a multigeneration interspecies pedigree generated between the domestic cat and the Asian leopard cat, *Prionailurus bengalensis*,[7] to facilitate the mapping and integration of Type I (coding) and Type II (polymorphic STR) loci.[7] The current map, which spans all 18 autosomes with single linkage groups, has twice the STR density of previous maps, providing a 5-cM resolution. There is also greatly expanded coverage of the X chromosome, with some 75 STR loci. Marker order between the current generation RH and GL maps is highly concordant.[8]

Approximately 85% of the STRs are mapped in the most current RH map of the cat,[8] which provides reference and integration with Type I loci. Whereas the third-generation linkage map is composed entirely of STR loci, the sequence homology of extended genomic regions adjacent to the STR loci in the cat 2X whole genome sequence,[17] to the dog's homologous region,[19] has enabled us to obtain identifiable orthologues in the canine and human genome sequences for over 95% of the STRs. Thus, practically every STR acts as a "virtual" Type 1 locus, with both comparative anchoring and linkage map utility. Combined with the cat RH map, these genomic tools provide us with the comparative reference to other mammalian genomes critical for linkage and association mapping.

THE DOMESTIC CAT WHOLE GENOME (2X) SEQUENCE

The domestic cat is one of 26 mammalian species endorsed by the National Human Genome Research Institute (NHGRI) Human Genome Annotation committee for a "light" 2-fold whole genome sequence, largely to capture the pattern of genome variation and divergence that characterizes the mammalian radiations (http://www.hgsc.bcm.tmc.edu/projects/bovine/, http://www.broad.mit.edu/mammals/). Although light genome coverage provides limited sequence representation, (~80%),[20] one of the rationales for these light genome sequences included "enhancing opportunities for research on species providing human medical models." The 2-fold assembly of the domestic cat genome has recently been completed for a female Abyssinian cat, "Cinnamon," [17] and a 7X whole genome sequencing effort is planned in the near future.

A total of 9,161,674 reads were assembled to 817,956 contigs, covering 1.642 Gb with an N50 (i.e., half of the sequenced base pairs are in contigs <N50) contig length of 2378 bp. Assembled supercontigs (N = 217,790) had an N50 length of 117 kb[17] (http://hosted. abcc.ncifcrf.gov/cgi-gin/gbrowse/cat/). The estimated size of the genome was 2.7 Gb and the genome coverage was approximately 2-fold, predicting an average inclusion of 80–85% of the eukaryotic genome sequence.[21]

Feline coding genes were identified using a comparative approach based upon sequence homology and syntenic orthology of neighboring gene homologues in the genomes of six index mammal species (human, chimp, mouse, rat, cow, and dog). The results revealed nearly 21,080 feline genes plus 132,493 conserved sequence blocks (CSBs) used to build the gene map,[17] depending upon the framework RH map of 1794 ordered Type 1 markers.[8] The 2X feline genome sequence detects 83% of human genes, 89% of chimp or cattle genes, and 92% of dog genes based upon sequence identity to approximately 1000 bp of reciprocal base match[17] between the cat sequence and the genome sequence of the six index mammals.

A genome browser has been developed from the cat assembly, named Genome Annotation Region FIELD (GARFIELD), which provides a physical map of the 18 autosomes and the X chromosome, which can be inspected for sequence representation, including genes and the proportion of that gene available in the 2X cover, single nucleotide polymorphisms (SNPs), and STRs, which can be used in linkage and association mapping, and other genome features (http://ccr.cancer.gov/ labs/lab). Figure 25–2 illustrates a

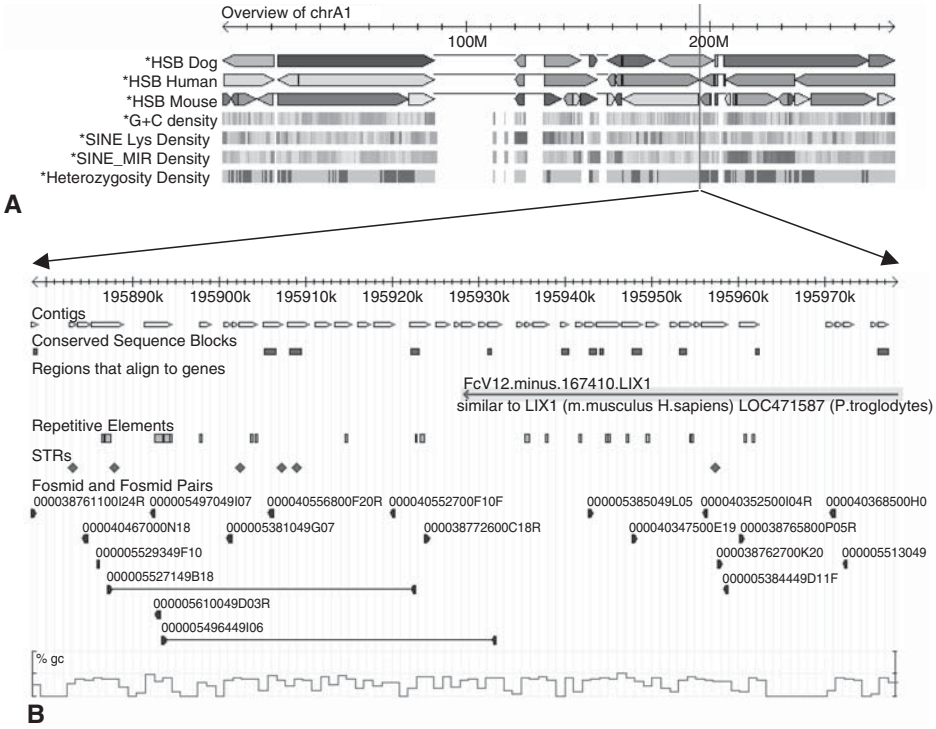

Figure 25–2. Gene annotation region fields (GARFIELD) displayed using Generic Genome Browser at two levels of resolution for the *LIX1* gene on chromosome A1. (A) Chromosome view showing homologous synteny blocks (HSB) for dog, human, and mouse, representation of G + C density, and of SINE, LINE, and SNPs. (B) A 200-kb view showing contigs of the region, conserved sequence blocks (CSB), regions that align to annotated genes in other mammalian genomes, regions masked by repeat masker, single tandem repeats, Fosmid reads with their partners, and a histogram of local GC content.

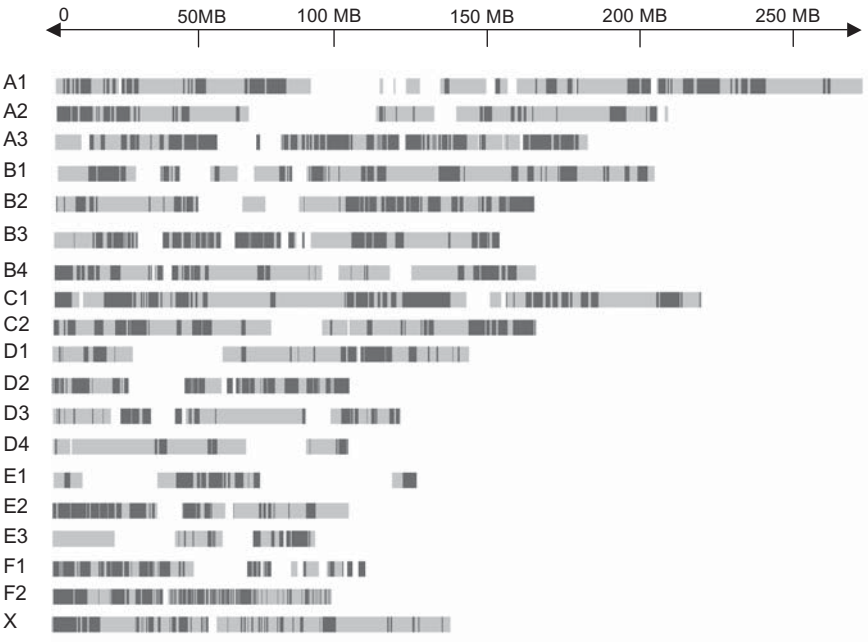

Figure 25–3. SNP profile across the 2X whole genome sequence of the domestic cat, Cinnamon. Heterozygosity across Cinnamon's chromosomes is represented in nonoverlapping windows of 100 kb. Black represents regions with more than two SNPs per 100 kb while gray represents the homozygous region (less than two SNP, 0/100 kb). White represents gaps in the chromosome assembly.

representative view of GARFIELD demonstrating features for the *LIX1* gene on chromosome A1.[17]

SINGLE NUCLEOTIDE POLYMORPHISM ANALYSIS DEMONSTRATES POTENTIAL OF LINKAGE DISEQUILIBRIUM MAPPING IN CAT BREEDS

A total of 421,000 SNP variants were identified in Cinnamon's sequence, representing an incidence of 1/600 bp.[17] Approximately 43% of Cinnamon's genome was heterozygous and 57% homozygous, which was not unexpected in a breed cat that is also the member of a highly inbred pedigree for retinal atrophy.[17,22] Long stretches of alternating homozygous and heterozygous segments were observed (Figure 25–3), which represent the consequences of close inbreeding during the domestication process, and the more recent generation of fancy breeds and inbred disease pedigree.[22] Similar patches of homozygous/heterozygous segments were observed in the recently released whole genome sequence of the dog.[19] The length of the segments is influenced by breed-specific history including effective population sizes, use of popular sires, and population bottlenecks.[23,24]

Linkage disequilibrium (LD) mapping has recently emerged as a powerful approach in humans for association mapping.[25] Long stretches of linkage disequilibrium in the target population greatly facilitate the success of the strategy and decrease the number of markers required for analysis.[25] The extended LDs observed in dog breeds, up to one hundred times the length observed in human populations,[26] is proving to be a powerful mapping strategy for identification of genes associated with breed-specific phenotypes,[27] including hereditary pathologies.[28,29]

The potential of this mapping approach in cat breeds was evaluated by examining breed-specific patterns of common segment homozygosity in 24 Cat Fancier Association (CFA) (http://www.cfainc.org) breeds.[17] The level of homozygosity reflected in a group of 665 SNPs was roughly half that seen in dogs,[26] likely reflecting a more extensive recent inbreeding within dog versus cat breeds.[30] This level of homozygosity was used to estimate[19] that some 45,000 equivalently spaced SNP variants would be required for a linkage disequilibrium/haplotype-based association genome search of a complex heritable disease within cat breeds.

Recently, tyrosinase-related protein 1 (*TYRP1*), one of the key enzymes in the melanogenic pathway, was linked to two coat color variants in the cat by association mapping in 38 cat breeds due to extensive LD.[31] Two DNA polymorphisms in *TYRP1*, an A3G substitution in the signal peptide and an in-frame insertion *TYRP1*–421ins17/18, were associated with the *chocolate* (b) allele. A premature UAG stop codon at position 100 of *TYRP1* was associated with a second allele of the B locus, *cinnamon* (bl).[32] SNP discovery is planned in the 7X whole genome sequencing of the cat through a resequencing strategy of selected genomic regions in several cat breeds as was recently performed in the 7X whole genome sequencing of the dog.[19]

THE MATURITY OF CURRENT FELID MAPPING RESOURCES DEMONSTRATED IN SUCCESSFUL WHOLE GENOME AND ASSOCIATION MAPPING EXERCISES

The majority of hereditary pathologies in the domestic cat for which the gene defect has been elucidated have resulted from the analysis of candidate genes (Table 25–1). However, with the availability of a detailed comparative map, and integration with developing GL and RH maps, and the cat 2X whole genome sequence, linkage and association-based mapping techniques have recently identified causative mutations for hereditary disease genes,[33,34] as well as several feline phenotypes (Table 25–1).[18,32,35–57]

Once a genomic region is implicated from association-based or linkage mapping exercises, fine mapping has been accomplished by development of new STRs or SNPs in the targeted region using the cat 2X whole genome sequence data accessed

[a]Mutation notation according to den Dunnen and Antonarakis.[53]

through the cat genome browser, GARFIELD.[17] A recent report of the mapping and characterization of a novel gene causative of feline spinal muscular atrophy[34] marked the first identification of a disease gene purely from positional reasoning.

Human spinal muscular atrophies (SMAs) are a genetically heterogeneous group of neuropathies that varies in clinical severity, from lethal in infancy to onset of mild weakness in adulthood, but all are characterized by neurogenic muscle atrophy due to degeneration of lower motor neurons of the spinal cord.[58] For approximately 97% of people affected with SMA, disease pathology is attributable to a mutation in the *SMN1* gene, on human chromosome 5q13, which is subject to a high frequency of deletions and gene conversion events with the divergent and only partially functional centromeric copy/copies of the duplicated *SMN2* locus.[59,60]

A domestic cat model of SMA has been described that is a model of autosomal recessive juvenile-onset SMA.[61] With the feline *SMN* gene excluded as the disease locus,[61] a full genome linkage scan was conducted in a pedigree segregating for SMA.[61] The disease phenotype was linked to chromosome A1q,[34] in a region of conserved synteny to human chromosome 5q15. Fine mapping was accomplished with development of new STRs and sequence tagged sites (STS), utilizing sequence information from the cat 2X whole genome sequencing effort, which ultimately identified an ~140 kb deletion and a novel gene candidate, *LIX1*[34] (Figure 25–4). Though the function of *LIX1* is unknown, the predicted secondary structure is compatible with a role in RNA metabolism. An exon sequence screen of 25 human SMA cases, not otherwise explicable by mutations at the *SMN1* locus, failed to identify comparable *LIX1* mutations.[34]

The *SMN1* gene product, SMN, is a ubiquitously expressed protein member of multiple ribonucleoprotein complexes with diverse roles in RNA metabolism, splicing, and transport in all cells.[62,63] A central focus of SMA research remains to discern the disease mechanism(s) and to understand why the primary disease pathology is localized to spinal lower motor neurons when all cells require SMN function. *LIX1* expression is largely restricted to the central nervous system (CNS), primarily in spinal motor neurons, thus offering an explanation of the tissue restriction of pathology in feline SMA. Determination of *LIX1* function may well provide fresh insight into the mechanisms of human SMA pathology, impetus for more targeted therapeutics, and answers to fundamental questions of motor neuron development, maintenance, and/or function.

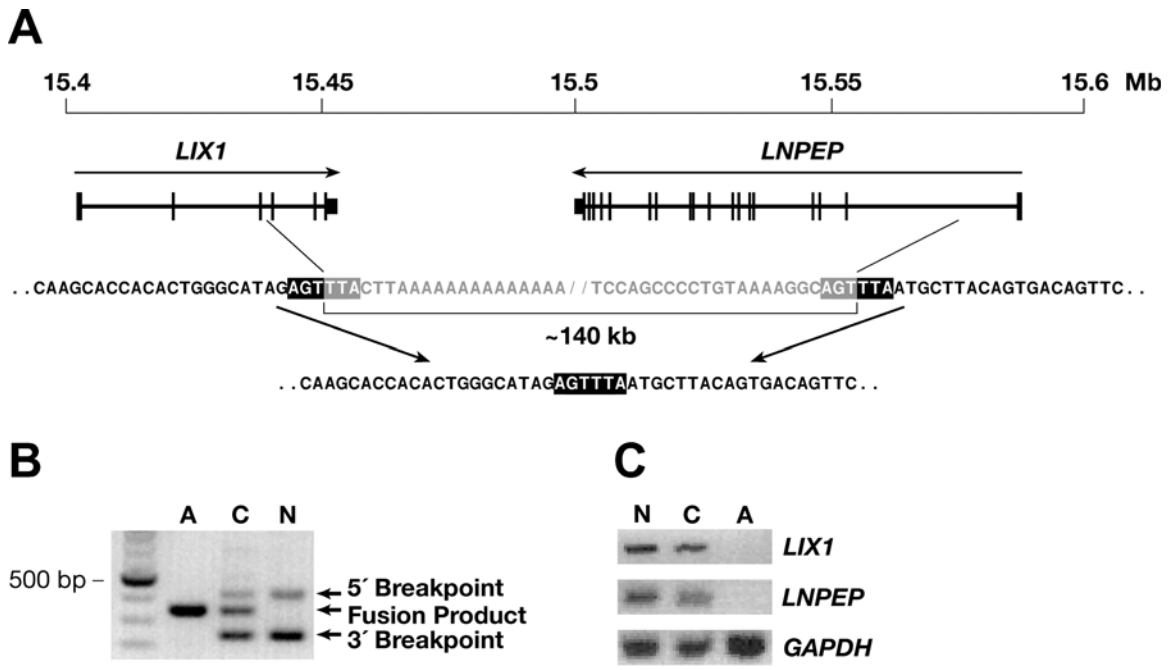

Figure 25–4. An ~140-kb deletion abrogates *LIX1* and *LNPEP* expression in SMA affected cats. (A) A schematic of the genomic organization of *LIX1* and *LNPEP* on FCA A1q. Arrows indicate the direction of transcription of each gene. The scale of chromosome coordinates is from the region of conserved synteny in the dog genome (CFA 3) (UCSC Genome Browser; July 2004 assembly). Sequences of the deleted and normal alleles are aligned showing the precise breakpoints *below* the schematic. The immediately flanking 6-bp sequence, AGTTTA, is in bold. (Note that the genome browser did not itself identify exon 1 of *LNPEP* by homology with RefSeq genes, but limited homology was identified by BLAT search of the dog genome with a cat sequence that was 82% identical over 300 bp of the human exon 1 and flanking 5′-UTR and intron 1 sequences.) (B) PCR products produced from genomic DNA in a multiplex reaction designed to amplify across both deletion breakpoints when the normal allele (lane N) was present. A third product corresponding to the affected cat sequence shown in (A) was amplified when the deleted allele was present, either in homozygous affected (lane A) or heterozygous carrier (lane C) cats. (C) RT-PCR products amplified from cervical spinal cord ventral horn RNA of a genetically normal cat (lane N), a clinically normal carrier (lane C), and an SMA affected cat (lane A). PCR primers for *LIX1* were from exons 1 and 4, *LNPEP* primers were from exons 14 and 15, and *GAPDH* primers were from exons 6 and 8. THE CAT AS ANIMAL MODEL FOR HUMAN HEREDITARY DISEASE

The world's veterinary schools produce thousands of practitioners each year, most of whom carefully document genetic and chronic diseases of our pets. The result is a comprehensive veterinary literature that has described over 200 feline hereditary pathologies[17] (http://www.angis.org.au/). The clinical and physiological study of these feline hereditary diseases provides a strong comparative medicine opportunity for prevention, diagnostics, and treatment studies in a laboratory setting. Additionally, large animal homologues are similar to humans in natural genetic diversity and offer the possibility of evaluating long-term effects of treatment.[64]

To date, causal mutations have been characterized in 19 felid genes that cause hereditary disease (Table 25–1). The largest representation comes from lysosomal storage enzyme disorders that arise from defects in genes playing a role in degradation of macromolecules targeted to the lysosomes. Many of the genes that cause these pathologies have been mapped in the cat.[65]

Corrective therapeutic strategies have been proposed and examined in the cat, including enzyme replacement, heterologous bone marrow transplantation, and substrate reduction therapy.[64,66] Limitations to these treatment strategies include high morbidity and mortality, limited positive outcomes, incomplete response to therapy, cost, and in some cases requirements for continuous lifelong therapy.[66] Gene therapy poses the most recent of intervention strategies. Feline models have been important in elucidating molecular pathogenesis and are now playing a critical role in evaluating and optimizing the range of therapeutic strategies prior to clinical trials in humans.

The mucopolysaccharidoses are disorders that result from the deficiency of lysosomal enzymes involved in the degradation of mucopolysaccharides. The cat offers homologous models for mucopolysaccharidosis Types I, VI, and VII.

Mucopolysaccharidosis Type I (MPS I), which results from a genetic deficient activity of the enzyme α-L-iduronidase (IDUA), can lead to mental retardation, growth abnormalities, and shortened life span in humans.[67] Naturally occurring models have been characterized in the cat[68,69] and dog.[70] Immune responses can nullify the effect of gene corrective therapy. It has been demonstrated that cats, but not dogs, mount a potent CTL response to canine IDUA after neonatal gene therapy, which can be prevented with transient CTLA4-Ig.[71] The efficacy of neonatal retroviral therapy has also been explored in the cat.[66] The cat model, additionally, provides an ideal system to study mechanisms of brain neurodegeneration and neural-directed strategies, especially given a large body of preexisting literature on cat neurology.

MPS VI or Marteaux–Lamy disease, deficient activity of arylsulfatase B (ARSB), is characterized in humans and cats with growth retardation, coarse facial features, corneal opacity, and skeletal deformities.[72–75] The feline model also exhibits abnormal lysosomal storage in occasional neurons and glia distributed throughout the cerebral cortex.[76] Fibroblast-mediated *in vitro* gene therapy has been examined in this cat model.[77] Recently, an adeno-associated vector containing feline *ARSB* has demonstrated gene therapy-based correction of corneal clouding in the MPS VI cat.[78]

MPS VII results from deficiency of β-glucuronidase (GUSB), which in humans manifests as cartilaginous and bony malformations, growth and mental retardation, abdominal organ enlargement, and corneal clouding.[79] Naturally occurring animal models have been described in mice,[80] dogs,[81] and the cat.[82] Enzymatic activity has been restored in fibroblasts and restored by retroviral gene transfer of rat GUSB cDNA. As GUSB is an essential housekeeping enzyme, this feline model is important for examination of exogenous genes and gene product delivery to a variety of tissue types, and could prove especially valuable due to extensive research conducted on the anatomy and physiology of the cat central nervous and visual systems. Three different serotypes of adeno-associated viral constructs of *GUSB* demonstrated the efficacy of this vector to achieve gene transfer in the normal cat brain, as a model for the efficacy of this construct in a large mammalian brain.[83]

Deficiency of lysosomal α-mannosidase leads to an accumulation of mannose-rich oligosaccharides,[84] which leads to mental retardation, recurrent infections, skeletal changes and hearing impairment.[85] This feline model was initially important in achieving bone marrow transplantation as corrective strategy for neuronal storage diseases of the CNS.[86,87] Recently, adeno-associated viral (AAV) constructs of feline α-mannosidase were used to demonstrate the efficacy of CNS gene therapy. Treated cats exhibited widespread improvement of neuropathology, showing the efficacy of this treatment in a large mammalian brain for CNS correction of human lysosomal enzyme deficiencies.[88]

Lipoprotein lipase (LPL) is a crucial enzyme involved in the regulation of lipoprotein and lipid metabolism ability to thrive.[89] Cats with LPL deficiency display a remarkably similar phenotype to humans, including severe pancreatitis, chylomicronemia, and failure to thrive.[46] There is currently no adequate treatment for this pathology in humans. Cats could prove to be the most valuable animal model of LPL deficiency, as of numerous animal model systems examined including the mouse, the cat most closely resembles the lipoprotein pattern and lipid transport system of humans. Recently, AAV-mediated transfer of a human LPL ^{S447X} variant into feline muscle cells demonstrated correction of the hypertriglyceridemia associated with feline pathology; this offers much promise for treatment of human LPL deficiency.[90]

A separate class of lysosomal storage disorder characterized in the cat is the gangliosidoses, G_{M1} and G_{M2}, which are heritable neurodegenerative diseases. A deficiency of lysosomal β-galactosidase results in the neuronal accumulation of the G_{M1} ganglioside, while the degradation of the G_{M2} ganglioside is initiated by coordinated action of at least three gene products, the α and β submits of β-*N*-acetylhexosaminidase and the G_{M2} activator (GM2A) protein.[42,91] Mutations in any of these enzymes result in an accumulation of gangliosides G_{M1} and G_{M2} in the lysosomes of affected neurons, resulting in progressive deterioration of the CNS. Feline models have been especially important in characterizing the pathobiology and molecular biology of these diseases. G_{M2}-gangliosidosis has been characterized in cat models deficient in the G_{M2} activator protein and HexB,[40,42,92,93] exhibiting remarkably similar pathology to human Sandhoff's disease.[91] Limited reduction in G_{M2} neuronal storage has been reported following bone marrow therapy.[86] Feline models will be important in the development of therapeutic strategies for these disorders.

Mucolipidosis II (I-cell disease) is caused by deficient activity of the enzyme *N*-acetylglucosamine-1-phosphotransferase, which leads to a failure to internalize enzymes into lysosomes. The cat is the only known animal model for this pathology.[94]

Congenital diseases of feline muscle and neuromuscular junction have been reviewed by Gashen *et al.*[95] Some pathologies have been observed in isolated breeds, including hypokalemic myopathy of Burmese cats,[96] glycogen storage disease type IV in Norwegian Forest cats,[44] and myopathy observed in the Devon Rex.[97] The cat is the only reported animal model for type IV glycogen storage disease. Myotonia congenital,[95,98] muscular dystrophy (dystrophin deficient),[52] and laminin α_2 deficiency[52,99] have also been reported in the cat.

X-linked muscular dystrophy in humans is characterized by progressive degeneration of skeletal and cardiac muscle. Mutations in humans lead to either an absence of or abnormality in the protein product dystrophin.[100,101] A deletion in the dystrophin muscle promoter characterized in the cat eliminates expression of muscle and Purkinje neuronal dystrophin isoforms.[52] Marked clinical heterogeneity is observed in these models, from severe disability exhibited in human and dog, to minor muscle fibrosis and an actual regenerative process leading to muscle hypertrophy in mouse and cat.[102–104] These different sequellae could be important in characterizing immediate and secondary consequences of the lack of dystrophin[105] and points out the importance of multiple animal models.

Hypertrophic cardiomyopathy is a clinically heterogeneous myocardial disease contributing to one of the most common causes of sudden cardiac death in young adults.[106] The cat represent the first spontaneous large animal model for this familial disease[47] and will prove to be valuable for examining pathophysiological processes and therapeutic interventions.

THE POTENTIAL FOR KNOCKOUT CATS

There is a continued demand for alternative mammalian models for studying human diseases. Compared to traditional murine models, the cat's more similar physiology, increased size, and longevity have made it ideal for testing the safety and efficacy of some therapeutic modalities in naturally occurring feline disease models.[107–110] Additionally, cats have a genetically heterogeneous background, similar to humans. A good example of a human disease in need of a better mammalian model is cystic fibrosis, as mice targeted with the most common human mutation (ΔF508) in the cystic fibrosis transmembrane receptor (*CFTR*) fail to spontaneously develop the same opportunistic lung infections that plague human patients with cystic fibrosis.[111,112] One group has been working to produce a ferret cystic fibrosis model through gene targeting of somatic cells for nuclear transfer.[113,114] While reproductive cloning has a consistently low success rate (1–4%) across mammalian species,[115] targeting genetic loci through homologous recombination in somatic cells is currently the only viable method for producing knockout models in all mammalian species other

than the mouse, for which targeted embryonic stem cells are routinely used. Nuclear transfer of targeted fibroblasts has been successfully used to produce viable α-1,3-galactosyltransferase knockout pig and cow models for xenotransplantation studies.[116,117] With the successful reproductive cloning of cats by several groups,[118–120] the development of gene-targeted cat models through nuclear transfer is now feasible.[121] The imminent release of the annotated feline genome project,[17] integration of recombination and radiation hybrid maps,[5–10,122] and availability of multiple PAC, BAC,[123] flow-sorted autosome, and Y-chromosome libraries[124,125] (J. Pecon-Slattery *et al.*, unpublished observations) at the Laboratory of Genomic Diversity will facilitate efforts by researchers to develop new cat models of specific human genetic diseases.

COAT COLOR GENES IN THE DOMESTIC CAT

The coat color loci influence the development, maturation, and migration of melanocytes as well as the synthesis of melanin and the formation, transport, and transfer of melanosomes. Genes involved in these processes often have pleiotropic effects, which impact other important biochemical pathways. Coat color loci in the mouse have been known to be part of diverse cellular, developmental, and physiological processes and in some cases to be implicated in pathologies such as anemia, sterility, and neurological disorders.[126–128] The cat is an excellent model system with which to study coat color phenotypes. At least nine different coat color loci have been identified in the cat,[129] and several are now characterized on a molecular genetic level including, *a* (nonagouti) responsible for melanism,[18] *b* (Brown), which changes black pigmentation to brown or variants of brown,[32] *c* (color), causing the darker pigmentation at extremities (i.e., ears, tail), observed in Siamese and Burmese cats[32,37] and albinism,[36] and *d* (dilute), which causes dilution of expected color (i.e., black pigmentation appears gray).[35] The cat is also unique in mammalian species in exhibiting a variation in coat pattern, demonstrating agouti (*A*) (nonpatterned coat) and variants of the *T* (tabby) locus, which affect striping and spotting patterns.

VIRAL PATHOGENS OF THE DOMESTIC CAT

The cat has provided several useful models for infectious disease. These include feline leukemia and feline sarcoma virus, feline coronavirus, and Type C retroviruses that interact with cellular oncogenes to induce leukemia, lymphoma, and sarcoma.[130–132] Historically, many of the human oncogenes that define signal transduction pathways were originally discovered in the context of feline leukemia virus interaction in cat models. The cat provides the only naturally occurring model for human AIDS pathogenesis, in its endemic fatal transmissible feline immunodeficiency virus (FIV).[133,134] Similar to its close phylogenetic relative HIV, FIV induces CD4-T lymphocyte depletion in affected cats, an immune system collapse, and susceptibility to adventitious microbial agents as a prelude to wasting disease and death.[133,135] Interestingly, over 10 wildcat species (including lions, leopards, cheetahs, ocelots, pumas and other big cats) are endemic with their own species-specific strain of FIV[136–141]; however, unlike strains in domestic cats, the wildcat FIV strains do not appear to cause acute immunodeficiency in the wildcat species, perhaps a consequence of historic natural selection of host genetic resistance to the fatal virus.[139,142] Lion and puma-specific FIV strains have recently been demonstrated to utilize novel, more promiscuous mechanisms for cell entry than FIV, suggesting a divergent tropism and biological properties of these viruses.[143]

The World Health Organization reported a new human respiratory illness outbreak (severe acute respiratory syndrome, SARS) that emerged in Guangdong Province, China in 2003.[144,145] Sequence analysis demonstrated that the infectious agent was a previously unrecognized coronavirus.[146,147] An animal model demonstrating clinical symptoms and pathology of SARS-infected patients has not been reported.[148] Of interest, the recent report of a highly virulent feline coronavirus epidemic in captive African cheetahs, a disease model for human SARS, illustrates the critical role of ancestral population genetic variation.[132] In addition, cats injected with the SARS virus developed clinical symptoms, an important insight in implicating the virus in the SARS epidemic.[149–152]

The feline panleukopenia (feline distemper) virus has revealed a natural history parable in its abrupt transformation of the cat virus to an epidemic, fatal canine parvovirus, that emerged in the world's puppy population in 1978.[153] In contrast, the canine distemper virus, which is normally restricted to canid species, precipitously adapted to and decimated East African lions in 1994, killing one-third of the lions in the Serengeti ecosystem within a 9-month outbreak.[154] A clear involvement of host defense mecha-

nisms in these and other infectious disease episodes renders the cats and their pathogens an excellent candidate species for characterizing the interaction of microbial adaptation and host disease gene defenses. Given the critical importance of infectious disease in scores of chronic and acute human disease, there are powerful research opportunities in the cat family.[142,155]

Finally, recent concern over the emergence of avian flu H5N1 has shown a strong susceptibility of cats, both domestic and large cats, again raising possibilities for pathogenesis and therapy development.[156,157]

With the development of genomic resources in the cat (Table 25–2) and the application of complementary comparative tools developed in other species, the domestic cat is emerging as a promising resource of phenotypically defined genetic variation of biomedical significance. Exploration of similar resources in other species, particularly the dog and mouse, has provided important insight into otherwise unexplained biomedical disorders.

26 Swine in Biomedical Research

M. Michael Swindle and Alison C. Smith

ABSTRACT

This chapter provides an overview of the use of domestic and miniature breeds of swine in biomedical research. Differences between breeds of pigs and the most significant anatomic and physiological characteristics of the species related to their selection as biomedical research models are discussed. Husbandry and handling techniques that have proven to be beneficial for using these animals in research are detailed. Also included are the key references for developing and using swine and resources for additional training and refinement are listed.

Key Words: Swine, Miniature pig, Surgery, Animal models, Animal husbandry.

INTRODUCTION

Swine (*Sus scrofa domestica*) have been used extensively in biomedical research and have become a standard general surgical model for preclinical studies. Their usage continues to grow while other large animal models are decreasing in number. Since the 1980s there have been a number of conferences held to specifically identify uses of swine in research. There are detailed publications on the technical issues[1–6] involved in the use of this species and reference publications on biology[7–10] and models.[1,2,11–16] Detailed publications on anesthesia, analgesia, and perioperative care are available.[1–3,17–19]

In this chapter their common uses are described as well as some of the technical issues involved in their selection and use as biomedical models. Because of the large number of porcine models utilized, the anatomic and physiological parameters of the various systems that justify their use in biomedical research are detailed.

BREEDS AND SOURCES OF SWINE

Most breeds of swine are animals raised commercially for meat production. These animals are commonly referred to as domestic or farm breeds in the literature. There are hundreds of these breeds and common examples are Yorkshire, Landrace, Duroc, Hampshire, Pietrain, and Poland China. There are over 50 breeds of miniature pigs worldwide but only a few of them are important in biomedical research. Smaller miniature breeds are sometimes referred to as microswine. Some of the most common miniature swine used in research are the Yucatan, Hanford, Sinclair, Göttingen, Ossabaw, Banna, Vietnamese Potbellied, and Meishan.[1,2,4,8]

The most significant difference between miniature and domestic swine is the growth rate. Farm breeds grow from a birth weight of 0.5–1 kg to a weight of >100 kg in 4 months. This is an exponential growth rate that is an economic necessity when raising swine for food consumption. However, in a biomedical research facility this growth rate is a complication for research as well as a potential occupational health hazard. Large swine can be very difficult to handle and lifting anesthetized animals can lead to ergonomic injuries. In the same 4-month period of time miniature pigs grow from 0.25 kg to 7–20 kg depending upon the breed. Of the most commonly used minipigs the size ranges from smallest to largest are Göttingen, Sinclair, Yucatan, and Hanford. The Hanford achieves the body weight of an adult human in a year, while the smaller breeds weigh <30 kg at the same age.[1,2,4,8]

Consequently, using domestic breeds for long-term chronic experiments is discouraged. Unless growth is part of the study, projects using farm pigs for chronic experiments should be limited to 3–6 weeks depending on the size of the animal at the start of the experiment and the housing capabilities of the institution.

Selection of miniature pigs for an experiment is based upon the size and physiological characteristics of the particular breed. Piglets may be weaned from the sow between 3 and 6 weeks of age. Sexual maturity in swine generally is reached between 4 and 6 months of age. Consequently studying animals <4 months of age would be considered to be a study conducted in neonatal or juvenile animals. Depending upon the goals of the study this may be a complication.

In general all pigs of the same weight have similar sized organs and structures. The difference would be the physiological maturity of the organ of interest because the size of the pig is breed dependent. Most organs and systems are physiologically mature by sexual maturity. However, the range of weights between miniature and domestic breeds at sexual maturity may be as much as a 100 kg difference. Consequently, the size of an organ such as the heart may be substantially different at the same age between breeds.

The health status of the source herd is also important.[2,20,21] Pigs purchased from auctions or conventional farms may have complicating diseases and parasites. In fact, their use may be similar to using unconditioned pound source dogs. Large commercial suppliers and operations that specialize in supplying swine for

research will generally have a program for prevention of diseases. In swine there is a designation of specific pathogen free (SPF), which has a proprietary connotation in the United States. These are animals that have been raised to prevent diseases that interfere with weight gain. SPF swine are not necessarily free of all diseases and it should be used as a starting point when evaluating a source of animals. Some pigs are available as Cesarian-derived and barrier-reared animals. Housing of these animals with conventional swine is not appropriate because they will become infected with organisms that may be subclinical in the other animals. The institutional veterinarian should be consulted to preapprove the source of animals after evaluation of the herd health program.

Shipping of swine between facilities may also be a substantial problem that must be overcome.[2,22] There are intense and specific regulations regarding the shipping of swine in interstate commerce within the United States, as regulated by the U.S. Department of Agriculture (USDA), and even more intense regulations need to be followed when shipping between countries. No exceptions are made for animals used in research. The institutional veterinarian should be knowledgeable about the regulations and shipping requirements for animals.

It is important to adequately describe the type of pig used in an experimental study in the materials and methods section of journal articles. This should include the breed, sex, weight, age, and health status of the animal. Hemodynamics should be indexed to the body surface area when they are reported. When making comparisons between studies these factors need to be taken into consideration.

GENETIC MODELS

There are only a handful of spontaneous mutations in swine that have been developed as genetically reproducible models. A colony of swine with ventricular septal defect (VSD) had a high incidence of perimembranous VSD that is similar to the most common form of VSD in humans. Affected animals also had a high incidence of patent foramen ovale. Pedigree studies indicated that the defect was inherited as a polygenic trait.[23] Pigs develop other congenital heart anomalies that occur in humans, but these have generally been described as single case reports and have not been genetically reproducible. Swine with mutations of the predominant bloodborne cholesterol transporter, low-density lipoprotein (LDL), have elevated plasma cholesterol levels and have been used to model familial hypercholesterolemia in humans.[24] Sinclair miniature swine spontaneously develop cutaneous melanoma lesions that are classified histologically as malignant melanomas. Features of the swine model shared with human melanomas are the genetic predisposition, spontaneous appearance, similar histological appearance, capability for malignant transformation, and pattern of metastasis. Unlike human melanomas, tumor development in swine is not related to exposure to ultraviolet radiation, spontaneous tumor regression occurs that is immunologically mediated in most pigs, and the melanomas develop only in darkly pigmented animals.[25] Currently, female Ossabaw swine fed a high fat/cholesterol chow are being developed as a model of the human metabolic syndrome, characterized by central obesity, insulin resistance, impaired glucose tolerance, dyslipidemia, and hypertension.[26]

Current emphasis is on developing transgenic and knockout swine for applications in the areas of xenotransplantation, improving agricultural production, pharmaceutical production, and the development of new animal models. The four primary methods for producing transgenic pigs include pronuclear injection, oocyte transduction, sperm-mediated gene transfer, and nuclear transfer (cloning). The various methods and the pigs that have been produced using these techniques have been summarized by Prather.[27] A transgenic swine model of retinitis pigmentosa has been produced that is characterized by early and severe loss of rod photoreceptors and a slower degeneration of cone photoreceptors, similar to the condition in humans.[28] A major goal in producing genetically modified swine has been focused on overcoming the immunological barriers to xenotransplantation. Cloning technology has been used to produce α-Gal-deficient pigs; however additional immunomodulating strategies will be necessary for xenografting to become clinically feasible.[29]

INDUCED MODELS

Most of the models using swine are induced, many by surgical means, rather than being spontaneous or genetic in origin. The most common use of swine is in cardiovascular research, including atherosclerosis.[2,11,13–15] Investigational surgical procedures of various types are also a very common area of usage. Swine have become the standard general surgical model, having replaced the dog and primates over the past two decades. Included in these invasive procedures would be endoscopy, laparoscopic surgery, interventional catheterization, transplantation, and xenographic technologies.[1–3,5,6,30] In addition to the cardiovascular system, swine have also been used extensively to study diseases of the digestive, urogenital, and integumentary systems.[1,2,13–16,31] Swine have been used to a lesser degree for other systems, but are emerging in a variety of new areas, such as safety pharmacology and toxicology.[2,12,32]

CARDIOVASCULAR Cardiovascular models are based upon shared anatomic and physiological characteristics with humans.[1,2,7,11,13–15] Sexually mature Hanford pigs have a similar sized heart and blood vessels, however, many of the smaller pigs can be used for cardiovascular experimentation if adult sized structures are not important. Anatomically the most significant difference from humans is the presence of a left azygous vein (hemiazygous) that drains the intercostal vessels into the coronary sinus of the heart. Therefore, coronary blood flow return in the pig is mixed systemic and myocardial blood. This vessel may be ligated if total coronary blood flow is required.

The blood supply to the conduction system is right side dominant as in 90% of the human population and significant collateral circulation in the coronary system is not present. If a coronary vessel is obstructed to create a myocardial infarction, a complete infarct is created. Infarcts may be created acutely by ligation of a coronary vessel or by injection or blocking agents such as microspheres. Chronic or gradual infarction may be created by surgically applying osmotic ameroid constrictors around the blood vessel or by creating atherosclerotic lesions in the vessel lumen.[1,2,7,11,13–15,33–35] Myocardial infarction is an intensive area of research in swine because of these characteristics.

None of the cardiac conduction systems in animals exactly matches that of the human. In the case of the pig the conduction tends to be neurogenic rather than myogenic; there are nerve fibers in the atrioventricular node and the bundle branches. The pig has large well-differentiated subendocardial Purkinje cells. However, the anatomy and parameters of the intracardial electro-

gram overlap the values in humans and the pig has been used in studies of cardiac system ablation and pacemaker testing.[36–38]

Pigs are susceptible to development of atherosclerosis in a manner similar to humans. Over time they develop complex lesions. In general, pigs can be fed a diet with 2–4% cholesterol and 40% fat to develop generalized lesions over a period of approximately 6 months. The process can be accelerated by damaging the endothelium with a balloon catheter. This offers the advantage of being able to localize the lesion and decreasing the time to production of a significant lesion to 3 months.[2,39,40]

Almost any model that can be created surgically in other large animal species can be developed in swine.[2] A major category in this area is the production of heart failure and cardiac hypertrophy. Concentric hypertrophy is produced by pressure overload of the ventricle. Pressure overload is created by placement of a Silastic band around one of the great vessels of the heart. The band can be placed without constriction in young animals and the band will produce constriction and overload as the animal grows. Alternatively, it can be placed tightly to produce a constriction and pressure gradient. In either case hypertrophy of the affected ventricle will develop over approximately 3 months.[2,41]

Volume overload can be produced by severance of the tendinous chordae producing mitral regurgitation. It can also be produced by creating an arteriovenous fistula or by creating a patent foramen ovale. The closer to the heart that the shunt is created, the faster is the production of volume overload heart failure and eccentric hypertrophy. Fistulas created in the leg will lead to hypertrophy and heart failure in approximately 3 months. Fistulas between the aorta and pulmonary artery may lead to heart failure within a week.[2]

Rapid epicardial pacing >180 bpm leads to the development of dilative cardiomyopathy and congestive heart failure in approximately 3 weeks. These animals tend to become compromised very quickly and frequently have to be maintained on diuretics because of the rapid development of disease.[42,43]

PULMONARY The pulmonary system consists of three lobes on either side plus an accessory lobe on the right lung. The pulmonary system of the pig is very friable and easily injured. The mediastinum is thin and friable and for practical purposes should be considered incomplete. The lungs are the shock organ for the pig, as in humans. For this reason, pigs have been used as endotoxic shock models. Pigs undergo the same phases of hypodynamic and hyperdynamic shock phases after being exposed to organisms, toxins, or lipopolysaccharides.[2]

Pigs have also been used in studies of adult respiratory distress, asthma, and oxidative stress. Predominately, they have been used in studies of surgical techniques and repair.[2]

INTERVENTIONAL CATHETER AND MINIMALLY INVASIVE SURGERY TECHNIQUES Swine have become the standard model for interventional catheterization, endoscopy, and robotic and laparoscopic surgical procedures.[1,2,34,35,37,38,44–53] At first they were utilized as models for training physicians in the techniques. This evolved into the replacement of dogs and primates as models for testing of these devices and techniques.

Anatomic and physiological characteristics of the vascular system contribute to the selection of this model for testing of intravascular devices.[39,44,46,50,51] The size of the blood vessels in larger minipigs is similar to that of humans. In vascular anastomosis procedures or when intravascular stents are implanted pigs can develop neointimal hyperplasia more readily than other animals at the procedural margin. Neonatal shunts, such as atrial septal defects (ASD) and patent ductus arteriosus (PDA), can be reopened using balloon catheter procedures. These shunts will remain open and can be used for the testing of closure devices. Other models such as aneurysms of various types can be created surgically. Growth of the cardiovascular system from birth until sexual maturity can be used as a model of growth of the human heart into the early third decade of life.[2]

Abdominal, thoracic, and central nervous center minimally invasive techniques are routinely performed in porcine models, mainly as feasibility and training procedures. Long-term testing of devices for preclinical trials are growing in number and the model has gained acceptance by the Food and Drug Administration (FDA).[2]

DIGESTIVE SYSTEM Physiologically the digestive system of the pig is similar to humans probably because pigs are true omnivores. However, the anatomy of the gastrointestinal tract has some significant differences from humans. The stomach has a muscular outpouching called the torus pyloricus that can cause delayed gastric emptying with some substances. The mesenteric vessels form vascular arcades in the subserosa rather than in the mesentery. The cecum and large intestine form a series of centrifugal and centripetal coils that adhere together to form the spiral colon in the left upper quadrant of the abdomen. The bile duct and the pancreatic duct enter the duodenum separately, rather than as a common duct as is found in humans.[2,16,54]

Swine are used in models involving the physiology of digestion and metabolism. They have special importance in the study of diabetes and metabolic syndrome. Pancreatitis and various aspects of islet cell transplantation have also been studied in porcine models. Endoscopic techniques, especially of the biliary system, are routinely studied in porcine models.[2,16,54–57]

UROGENITAL SYSTEM Swine have true multirenculate, multipapillate kidneys making the internal renal anatomy of the calyceal system analogous to humans. Swine have been used extensively in the study of renal function, renal hypertension, hydroureteronephrosis, intrarenal reflux, and the study of interventional devices for the correction of defects.[2,58–62]

The reproductive system of the female is a typical bicornuate type of uterus with epitheliochorial placentation. The fallopian tubes are long and torturous compared to other mammals. The male has the same types of accessory sex glands as the human, except that the dominant glands are the bulbourethral glands rather than the prostate, which is rudimentary. The male also has a corkscrew-shaped tip to the penis, a large preputial diverticulum, and a sigmoid flexure. All of these characteristics of the penis make it impossible to routinely catheterize the male bladder.[2,58–62]

INTEGUMENTARY SYSTEM/WOUND HEALING Swine have been standard models for wound healing and dermal toxicology because of the anatomic and physiological characteristics of the skin. Swine are relatively hairless with a skin that is tightly attached to the subcutaneous tissues as in humans. They have a comparable histology except that they have a paucity of eccrine sweat glands, a fatty subcutis, and a relatively higher pH value. There are similarities in cellular turnover time, permeability, transdermal absorption, and dermal metabolism. The microvascular anatomy is consistent with that of humans and the sizes of flaps, grafts, and dermal wounds have been standardized for comparison of therapeutic agents.[2,63–67]

OTHER SYSTEMS The systems described above represent the majority of the ones in which swine are used as a large animal model. Other organs and systems are utilized to a lesser degree and usually for a specific focus.[2]

For example, the musculoskeletal system is rarely utilized for studies because of the massive structure of the bones and muscle, as would be expected for an animal primarily used for food production. Also the epiphyseal closure may take as long as 4 years in domestic breeds, while the majority of the species are not maintained for that many years. However, some specialized efforts related to studies of bone and cartilage metabolism have been undertaken.[2]

The central nervous system (CNS) and sensory organs are emerging areas of using porcine models.[68–74] Pigs have been used in ophthalmic research, mainly because of characteristics of the retina and vitreous humor. They are being developed as stroke and CNS ischemia models.

The use of swine, miniature breeds in particular, for pharmacokinetic and toxicological studies has been increasing.[12,75,76] Like other species, swine have both similarities and differences from humans and multiple species are used for preclinical studies. In terms of the cytochrome P450 system pigs have CYP1A, CYP2E, and CYP3A activity similar to humans. There is either no information or low activity for CYP2B, CYP2C, and CYP2D. Pigs have high glucuronidation and acetylation activity but low sulfation activity. Pigs have 16 blood types (A–P) with weak blood group antigens. Factors V, VIII, and IX are higher compared to humans and pigs have faster clotting times. As a general rule in our laboratory when we are trying to use a new agent in swine, we use the human pediatric dosage.

Xenotransplantation studies are performed for both tissue and solid organ transplants. The research is mainly related to the transgenic technology issues discussed above. None of the various forms of rejection has been completely conquered. There also exists the issue of poor physiological function posttransplant, even if the rejection issues have been resolved. There is a major interest in protecting against xenozoonoses resulting from either mutation or a combination of viruses in human recipients. The reasons for using swine for this model are their availability as compared to nonhuman primates and because of the anatomic and physiological similarities.[2,77]

HUSBANDRY AND HANDLING

HUSBANDRY Swine are social animals and prefer to have contact with other swine. Laboratory swine can be housed individually or in small groups in pens. Individual housing is common in a research setting. If housed individually pigs should have visual, olfactory, and auditory contact with conspecifics to prevent stress associated with social deprivation.

Proper management practices and knowledge of normal swine behavior are required to successfully group house swine. Group sizes will be based on the size of the pens and the size of the pigs; however, group sizes should be limited to 10–15 animals to maintain a stable social hierarchy. Cage partitions should be provided to allow subordinant animals to avoid more dominant animals. Groups of animals should remain together as long as possible as dominance fighting occurs when new animals are added to the group. In a research setting, new groups should be established when a new shipment of pigs is received. Providing additional troughs or greater trough feeding space will allow all animals to eat simultaneously; however, differences in body weights may occur because of competition during feeding.[3]

In the United States, space recommendations are specified for swine used in biomedical research in the *Guide for the Care and Use of Laboratory Animals*.[69] The Council of Europe has recently revised their housing standards for research swine.[70]

Caging for swine should be sturdy since pigs are strong animals. Although pigs do not climb, they rub their sides along the sides of their cages with considerable force. As an expression of their rooting behavior, they will find and manipulate any loose items in their environment. Consequently, caging should be of solid construction and free of sharp edges and protrusions to prevent injury. Chain link fencing may be used for small swine. Other suitable materials include aluminum and stainless steel caging, which can be configured into vertical bars or solid panels. Regardless of cage material, the fencing should interface with the flooring securely and without gaps to prevent pigs from getting their hooves caught.

Swine require secure footing and can develop stress ulcers if flooring is slippery. Cage flooring can be either solid or on raised grids. If solid concrete or epoxy floors are used they should be textured to provide secure footing, and bedding of wood shavings or straw should be provided for rooting and nesting behavior. Grid floors increase the ease of sanitation since bedding is not usually provided. Spacing of the floor grids should be appropriate to prevent hoof damage. Plastic-coated diamond grids with five-eighths inch openings are suitable for housing swine of multiple sizes; however, swine will chew the plastic off the metal as soon as a tear in the plastic occurs. Fiberglass slatted floors with a slat width of 4.4 cm and a space of 0.64 cm between slats work well in the authors' experience. The slats can be coated with a medium grit to promote hoof wear. Regular hoof trimming at 3–6 month intervals is required for chronically housed animals if flooring does not maintain hoof wear.[2]

Cages that do not use bedding should be hosed daily to remove waste and minimize odors. Daily removal of soiled bedding is recommended when deep bedding is used. A complete change of bedding should be done one or two times a week. Cages should be sanitized no less than every 2 weeks by pressure washing for cleaning units in place or by cage washing modular units after they have been broken down. Pigs should be removed from their cages during routine cleaning to prevent contact with detergents and chilling from being wet. However, they readily accept baths and can be kept clean using a mild soap and warm water.

Swine readily use automatic watering systems, which are preferred to buckets. Swine require approximate 2.5 liters of water/kg of feed and can spill or soil water that is supplied in buckets. Feeders should be securely attached to cage sides to be able to withstand the excitement associated with feeding and the tendency of the pigs to root cage objects. Stainless steel or Teflon feed troughs are easily sanitized and are preferable to bucket feeders used in agricultural settings. Consideration should be given during cage design to the placement of the location of feeders and watering devices since swine will develop a dunging pattern and will defecate at the opposite end of the cage from where they are fed.

Laboratory swine should be provided with environmental enrichment to satisfy their intense need to chew and root, especially if bedding is not provided. We have successfully used large plastic balls, plastic dog toys, items that hang from chains, and

nylon brushes attached to fencing. Hanging items satisfy the need to chew and rub while items provided on the floor are used for rooting. Enrichment items need to be included in routine cage sanitation since pigs will avoid them if they become soiled. Rotation of enrichment items and limiting access to them for several hours a day will help maintain their novelty.

HANDLING Laboratory swine are easily trained using gentle handling techniques and positive reinforcement. Food items such as canned dog food, cookies, apples, and carrots can be used for training. Agricultural methods of handling and restraint, such as snout snares and suspension by the rear legs, are aversive and stressful to swine and are inappropriate in a research setting. Swine adapt readily to daily routines, including special handling practices common to research settings. Small pigs may be carried in the handler's arms, similar to handling a large dog. Larger pigs can be gently restrained against the side of a cage using a swine board. If prolonged restraint is necessary animals can be trained to use a humane restraint sling following a period of acclimation.

Pigs should be approached quietly in a crouched position since bending toward them is perceived as threatening. Rubbing pigs gently on the abdomen has a calming effect and can be used to aid physical examination. Swine can be trained to move out of their cages and guided with the use of a pig board or they can be trained to walk using a harness and leash.[71]

Laboratory swine that are cared for and handled gently interact readily with people. In fact, human–pig interaction is an important part of their environmental enrichment and contributes to their well-being in a research setting.

CONCLUSIONS

Swine will continue to be developed as translational research models and it is expected that their use will continue to outpace the growth of other large animal species in this arena. We receive frequent inquiries to troubleshoot protocols from investigators outside our institution. In the authors' experiences most of the complications that occur in porcine protocols are related to anesthetic, perioperative care and surgical issues. Anesthetic and perioperative care protocols must be designed with specific attention to the physiological effects of the agents and their potential for interference with the experimental goals. Surgical complications are usually related to inadequate aseptic technique or improper wound closure techniques.

There are current courses, CD Rom training programs, and technical publications[2,3,5,6] to help ameliorate these issues. Many of the helpful techniques are located online in various websites, which are listed below:

1. Contains a swine literature database from the Animal Welfare Information Center:

27 The Minipig as an Animal Model in Biomedical Stem Cell Research

Petr Vodicka, Jana Hlucilova, Jiri Klima, Radek Prochazka, Jitka Ourednik, Vaclav Ourednik, and Jan Motlik

ABSTRACT

Pigs and miniature pigs are steadily gaining importance as large animal models in the field of regenerative medicine, including stem cell research. With their size, organ capacity, and physiology resembling in several aspects that of humans, pigs are well suited for preclinical experiments and long-term safety studies. In this chapter, we summarize our experience with the isolation and culture of several somatic stem cell populations from fetal and adult pig tissue and briefly review their potential usefulness in future stem cell-based therapies. We also provide protocols for the isolation of fetal porcine neural stem cells (NSCs), adult bone marrow mesenchymal stem cells (MSCs), and epidermal progenitor cells (EPCs) from adult hair follicles.

Key Words: Animal model, Minipig, Swine, Neural stem cell, Mesenchymal stem cell, Epidermal stem cell, Cell transplantation, Biomedicine, Method(ology).

INTRODUCTION

In basic biomedical research, rodents still remain the first choice as animal models of disease due to their relatively low purchase and maintenance costs, short gestation time, large litter size, and the availability of a large number of genetically well-defined inbred and transgenic strains. However, to apply results obtained from rodent-based research at clinically more relevant levels, larger animals like dogs and nonhuman primates often become necessary. In that respect, pigs offer several advantages in comparison to these more traditional mammalian models:

1. Organ systems (e.g., heart and blood vessels, immune system, liver, kidney, and skin) resemble their human counterparts in size and physiology.
2. Life span is substantially longer than in rodents (10–15 years vs. ~3 years) allowing for long-term safety studies.
3. Easier handling, lower price, and less ethical controversy in comparison to nonhuman primates.

As immunological barriers to xenotransplantation are being overcome[1,2] and despite the recent debate over the risks of porcine endogenous retrovirus (PERV) transmission to humans,[3–5] pigs are considered the most suitable donors of organs and tissues for transplantation-based therapies.[6,7] Being so important in applied biomedical research, it is beyond the scope of this chapter to fully describe all the presently available pig disease models. Therefore, given the recent boom and belief in the promises of new stem cell-based therapeutic approaches, we decided to focus on novel methodologies specifically adapted for the isolation and propagation of several pig-derived stem cell populations and briefly review their possible applications. Although a few reports on the isolation of porcine embryonic stem and germ cells have been published,[8–10] optimal culture conditions for expanding these cells in their undifferentiated state have yet to be determined. Thus, we decided to cover the field of somatic stem cell isolation and culture, for which proven protocols are available.

The Institute of Animal Physiology and Genetics in Libechov imported the first miniature pigs in 1967 from the Hormel Institute, University of Minnesota (two boars and three sows) and from the Institute for Animal Breeding and Genetics, University of Göttingen, Germany (two boars and four sows). During the next 40 years of breeding, animal health and body shape were thoroughly controlled and outbreeding conditions were maintained by imports of several additional boars from Göttingen. The continuous selection made it possible to increase the average litter size (now about 8–10 piglets) and to fix the white color. The animals reach sexual maturity at about 4 months of age, when they weigh about 12–15 kg. While gradually including porcine somatic stem cells in our current research, we have also initiated a minipig inbreeding program. At present, we have two families with an inbreeding index of 0.6–0.7 allowing us, for example, to transplant neural stem cells without immunosuppression. All the experimental procedures described in this chapter were successfully performed on animals from this breed.

ISOLATION AND *IN VITRO* DIFFERENTIATION OF NEURAL STEM CELLS FROM FETAL PORCINE CENTRAL NERVOUS SYSTEM

Neural stem cells (NSCs) capable of self-renewal and differentiation into all major cell types of the neural lineage can be successfully isolated from the fetal and adult central nervous system (CNS) of a variety of mammals. These cells hold an enormous therapeutic potential for the cure of many devastating acquired and hereditary diseases, including spinal cord injuries and neurodegenerative disorders (Parkinson's, Huntington's, and Alzheimer's disease, or multiple sclerosis).[11]

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

Parkinson's disease (PD), in which a specific population of dopaminergic neurons in the brainstem needs to be replenished and sufficient striatal dopamine levels reestablished to achieve a successful therapy, lends itself particularly well for a transplantation approach using fetal neural tissue or expanded neural progenitors. As fetal neural tissue of human origin is not available in sufficient amount and its use is highly controversial ethically, the ontogenesis of fetal porcine brain was studied with the intention to explore its usefulness as a possible source of dopaminergic cells.[12] It was concluded that the 28-day-old porcine fetus is optimal for derivation of brain tissue that could be used for xenotransplantation in PD treatment. The first transfer of mesencephalic tissue isolated from 25- to 28-day-old porcine fetuses occurred unilaterally into the striatum of 12 PD patients, a number of which experienced some improvement of symptoms without major adverse effects of the grafts.[13,14] Nevertheless, despite earlier assumptions that the brain is an absolutely immunoprivileged site, rejection of allogenic and xenogenic grafts can occur without immunosuppression.[15] Consequently, as neural precursors expanded *in vitro* appear to be less immunogenic than primary neural tissue and a recent study demonstrated the potential therapeutic usefulness of NSCs grafted into a rodent model of PD,[16] the survival of xenografted porcine neural precursors in a rat model of PD was investigated[17] and a pig model of MPTP-induced parkinsonism was successfully established for autotransplantation or allotransplantation studies.[18,19]

Huntington's disease (HD) represents another potential target for NSC-based therapy. Unfortunately, a first clinical study using fetal porcine striatal tissue for xenotransplantation into 12 HD patients[13] did not show any significant improvement of the patients' conditions. In 2000, Matsuyama *et al.*[20] identified the porcine huntingtin gene and 1 year later the derivation of the first miniature pig expressing the huntingtin transgene under the control of the neuron-specific enolase promoter was reported by Uchida *et al.*[21] Since no further reports on this topic have been published since, we still lack an effective HD model in the pig. Yet with the recent advances in transgenesis in swine, the establishment of a transgenic HD model in this animal is hopefully not too far away.

The protocol given below was optimized for the isolation of neural precursors from the telencephalon of 27-day-old (E27) porcine fetuses, but can be readily adapted for the isolation and expansion of cells from other parts of the fetal pig CNS and also for E40 neural progenitors. These cells can be significantly expanded in culture and used both for *in vitro* experiments and *in vivo* transplantation studies.

MATERIALS Unless stated otherwise, all media and reagents were purchased from Sigma. Where necessary, catalogue numbers are given in parentheses at the place of the first appearance in the text.

1. Common surgical instruments: forceps, scissors, scalpels, syringes, and needles.

2. Anesthesia: azaperonum (Stresnil, Janssen Animal Health), atropine (Atropin, Biotika), ketamine (Narkamon, Leciva), and halothane (Narcotan, Leciva).

3. Plasticware: 70-µm cell strainers (Falcon), 15-ml and 50-ml centrifuge tubes, plastic pipettes, 10-cm Petri dishes, 24-well culture plates (all TPP), 25-cm^2 low-adhesion culture flasks (Nunc), and cryogenic vials (Corning).

4. Glassware: sterile beakers, Pasteur pipettes, and 12-mm round coverslips.

5. P1000, P200, and P20 micropipettes.

6. Sterile phosphate-buffered saline (PBS), laminin (23017–015, Gibco), and fibronectin (F1141) for coating coverslips, Accutase (A6964) for cell dissociation, and fetal bovine serum (FBS, F7524).

7. NSC culture medium: 500 ml of DME/F12 with 15 mM HEPES (D6421), supplemented with 6.25 ml of 200 mM L-alanyl-L-glutamine (G8541), 0.5 ml of 50 mg/ml gentamicin (G1397), and 2.5 ml of heparin (H3149, 1 U/µl in DME/F12). Freezing medium: NSC medium with 20% dimethyl sulfoxide (DMSO, D2650).

8. Culture supplements and growth factors: B-27 supplement minus vitamin A (12587–010, Gibco), human recombinant basic fibroblast growth factor (bFGF) (100–18B, PeproTech), epidermal growth factor (EGF) (E9644), and all-*trans*-retinoic acid (R2625).

9. Trypan blue (T8154) and hemocytometer.

METHODS

Cell Isolation

1. Euthanize the timed pregnant sow by overdose anesthesia: after premedication with an im injection of 2.0 mg/kg body weight (bw) azaperonum and 1 mg/animal atropine, deeply anesthetize with 20 mg/ kg bw ketamine.
2. Remove the uterus by cesarean section and place on ice.
3. Rinse the uterus briefly with 70% ethanol, liberate the fetuses from their amniotic sacs, and collect them in a beaker with ice-cold phosphate-buffered saline (PBS).
4. From this time on, work in a laminar flow hood.
5. Place the fetus in a 10-cm dish and with sharp scissors or a surgical blade cut off a wedge-shaped head region containing most of the brain as indicated in Figure 27–1A.

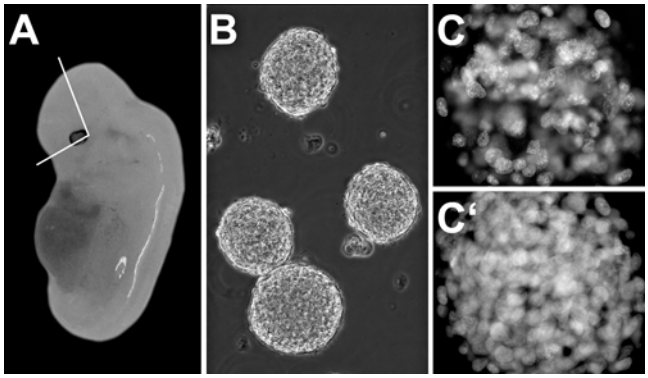

Figure 27–1. Preparation of neurospheres. (A) Example of a 27-day-old porcine fetus. The white line illustrates the cuts necessary to dissect the brain. (B) Phase contrast microphotography of neurospheres after 10 days in culture. (C) A secondary neurosphere 10 days after passage still contains many dividing cells, as indicated by immunolabeling for Ki-67 (C′). The nuclei of cells within the sphere are counterstained with propidium iodide.

6. Remove the brain from the membranous scull, wash with cold PBS, and, with sharp forceps, remove all meningeal membranes and blood vessels (pink color) from the rest of the tissue (white).
7. Collect the dissected brain tissue from all fetuses in ice-cold PBS and cut into small pieces with surgical scissors.
8. Centrifuge at 700 × *g* for 3 min, resuspend in 5 ml of ice-cold NSC culture medium, and break up the tissue by trituration with a Pasteur pipette (bore size 2–3 mm).
9. Centrifuge at 700 × *g* for 3 min, resuspend in 2 ml of ice-cold NSC culture medium, and make a final single-cell suspension by trituration using a P1000 micropipette tip.
10. Pass the cell suspension through a 70-µm Falcon cell strainer, wash the cell strainer with 10 ml of NSC medium, and collect a filtered, single-cell suspension in a 50-ml centrifuge tube.
11. Centrifuge at 700 × *g* for 5 min to collect cells and wash with fresh medium. Repeat three times.
12. Resuspend the cells in NSC medium supplemented with B27 (20 µl/ml), EGF, and bFGF stocks (1 µl/ml, final concentration of 20 ng/ml each).
13. Count the cells using a hemocytometer and either plate them for neurosphere culture or cryopreserve for later use (see below).

Culture and Passaging

1. Plate the cells at a final density of 5–10 × 10^3 cells/cm^2 in low-adhesion 25-cm^2 culture flasks with 8 ml of complete NSC medium (with B27, EGF, and bFGF).

2. Culture at 37°C in a humidified 5% CO_2 incubator.

3. Supplement the cultures every third day with fresh growth factors (EGF and bFGF) and once a week replace half of the culture medium with fresh medium and supplement with B27.

4. Neurospheres should become visible under phase-contrast optics after 7–10 days (Figure 27–1B). They should be of a nearly perfect spherical shape with clearly defined edges and tightly packed cells.

5. Passage spheres, when they reach about 100–150 µm in diameter, usually after 12–14 days in culture, as follows.

6. Transfer the culture medium with neurospheres from the 25-cm^2 flask to a 15-ml centrifuge tube and spin at 700 × *g* for 3 min. Aspirate the culture medium and save as conditioned medium for replating of the cells.

7. Resuspend the pelleted neurospheres in 1 ml of Accutase prewarmed to 37°C and incubate for 5 min at the same temperature.

8. Add 1 ml of fetal bovine serum (FBS) and 10 ml of cold NSC medium to stop the enzyme action. Centrifuge at 120 × *g* for 3 min. Aspirate as much supernatant as possible to remove most of the FBS (can induce cell differentiation).

9. Add 400 µl of fresh NSC medium and finish the dissociation of the neurospheres to a single cell suspension by trituration through a P1000 micropipette tip (10–15 strokes).

10. Dilute a 10-µl aliquot of the cell suspension 1 : 1 with trypan blue and count the viable cells with a hemocytometer.

11. Replate the cells at a final concentration of 5–10 × 10^3 cells/cm^2 in a 1 : 1 mix of fresh and conditioned NSC medium and add fresh B27, EGF, and bFGF.

12. If a clonal origin of secondary neurospheres is desirable, plate the cells at a lower density (about 1000 cells/cm^2) in conditioned medium only, with fresh growth factors and B27 supplement.

Cryopreservation

1. Prepare freezing medium: 20% DMSO in complete NSC medium.

2. Prepare cryovials and label them with cell type, date, and cell passage number.

3. For cryopreservation of cultured cells, freezing of whole neurospheres when they reach a diameter of 50–100 µm usually gives the best results. All spheres from one 25-cm^2 culture flask are frozen in one cryovial.

4. Pellet the neurospheres by centrifugation at 700 × *g* for 3 min, aspirate all but 0.5 ml of the culture medium, and gently resuspend the spheres.

5. Transfer the suspension to cryovial(s) and while gently swirling, add dropwise 0.5 ml of freezing medium.

6. Let the cell suspension equilibrate in the freezing medium for 10 min at room temperature.

7. Transfer the cryovials to a polystyrene box with ~2-cm-thick walls and leave it at −80°C overnight.

8. For long-term storage, transfer the cryovials to liquid nitrogen or a −180°C cryofreezer.

9. For freezing of cell suspensions from fresh isolations, dilute the cells to a final concentration of 2 × 10^7 cells/ml in complete NSC medium and aliquot 0.5 ml per cryovial. Continue from point 5 as with neurosphere freezing.

In Vitro Differentiation

1. Working in a laminar flow hood, place 12-mm round coverslips washed with ethanol into a 24-well culture plate and let them air dry.

2. Dilute the fibronectin stock with PBS to a final concentration of 10 µg/ml and pipette 0.4 ml of the solution per well. Incubate it for 1 h at room temperature.

3. Prepare a laminin solution by thawing the laminin stock slowly on ice and diluting it to 10 µg/ml in NSC medium. Aspirate the fibronectin solution from the wells and immediately add 0.4 ml of laminin to each well. Incubate it for 2–3 h at room temperature.

4. Aspirate the laminin solution and plate 6–10 neurospheres in 50 µl of NSC medium on each coverslip. Incubate the culture plate for 45 min at 37°C/5% CO_2 and let the spheres attach to the coverslips.

5. Add 1 ml of NSC medium with B27 supplement and 1 µM all-*trans*-retinoic acid without growth factors to each well.

6. Culture for 5–10 days.

7. Fix the cells on coverslips with 4% paraformaldehyde and process for standard immunolabeling. Several antibodies against NSCs and differentiated cells have been demonstrated to work on porcine cells; these are summarized in Table 27–1. An example of a whole neurosphere stained for the proliferation marker Ki-67 is shown in Figure 27–1C.

Table 27–1
Antibodies suitable for labeling of porcine neural stem cells and their differentiated progenies

Supplier/catalog number	*Antigen*	*Type*	*Recommended dilution*	*Labels*
Sigma, C5922	CNPase (2′,3′-cyclic nucleotide 3′-phosphodiesterase)	Mouse IgG_1	1 : 100–1 : 500	Oligodendrocytes, Schwann cells

ISOLATION AND *IN VITRO* DIFFERENTIATION OF PORCINE MESENCHYMAL STEM CELLS

Mesenchymal stem cells (MSCs) represent a pluripotent cell population located in the stromal compartment of the bone marrow. These cells can differentiate into cells of mesenchymal lineage and form bone, cartilage, and adipose tissue.[22,23] Differentiation of MSCs into cardiomyocytes was also reported.[24] As MSCs can easily be isolated from a patient's own bone marrow and substantially expanded *in vitro*, they are a very attractive cell source for many cell transplantation-based therapies.

Infarcted myocardium is one of the potential targets for the therapeutic use of MSCs.[25] Many myocardium infarction models exist in the pig[26] and transplantation of allogenic porcine MSCs[27,28] into such models resulted in some improvement in heart function. Several methods of MSC delivery (intravenous, intracoronary, and endocardial) were studied by Freyman *et al.*[29.] Labeling of MSCs with superparamagnetic iron oxide (SPIO) allows targeted delivery and *in vivo* observation of such transplanted cells.[30–32]

MSCs readily differentiate into chondrocytes and osteoblasts and are regarded as an excellent source of cells for bone and cartilage reconstruction and tissue engineering. Thus, a reconstruction of bone by osteoinduction was recently demonstrated in a porcine model[33] where endogenous porcine MSCs were induced to differentiate into osteoblasts by acellular implants of recombinant human bone morphogenetic protein-2 (rhBMP-2) bound to an absorbable collagen sponge. Transplantation of chondrocytes was used for articular cartilage repair in a porcine model[34,35] but with limited amount of autologous donor cartilage available for chondrocyte harvest, MSCs represent an interesting alternative source.

In the following protocol, both isolation and *in vitro* expansion of porcine MSCs are described. *In vitro* differentiation into adipocytes, osteoblasts, and chondrocytes can be used to demonstrate the multilineage potential of isolated cells. A short-term chondrogenic induction protocol can be applied if MSCs are to be used for cartilage tissue therapy experiments.

MATERIALS Unless stated otherwise, all media and reagents were purchased from Sigma. Where necessary, catalogue numbers are given in parentheses at the place of the first appearance in the text.

1. Common surgical instruments: forceps, scissors, scalpels, syringes, and needles; Iliac-Crest 15 G/70-mm bioptic needle (Somatex).
2. Anesthesia: azaperonum (Stresnil, Janssen Animal Health), atropine (Atropin, Biotika), ketamine (Narkamon, Leciva), and halothane (Narcotan, Leciva).
3. Plasticware: injection syringes (Braun), 70-μm cell strainers (Falcon),15-ml and 50-ml centrifuge tubes, plastic pipettes, 10-cm Petri dishes, 75-cm^2 culture flasks, and 24-well plates (all TPP).
4. Glassware: 12-mm round coverslips.
5. P1000, P200, and P20 micropipettes.
6. Ficoll-Paque™ Plus, density 1077 g/ml (Amersham), heparin solution 25,000 IU/ml (Zentiva), PBS, and FBS (F7524).
7. Trypan blue (T8154) and hemocytometer.
8. MSC culture medium: 500 ml of minimal essential medium (MEM)-α (22561–021, Gibco) with 0.55 ml of 50 mg/ml gentamicin (G1397) and 50 ml of FBS. Freezing medium: MSC medium with 20% DMSO (D2650).
9. Trypsin-EDTA solution: 0.25% trypsin (T4799) with 0.02% EDTA in Hanks' balanced salt solution.
10. Chondrogenic medium: MSC medium supplemented with 100 nM dexamethasone (D4902), 50 μg/ml ascorbic acid 2-phosphate, and 1% ITS (Insulin-Transferrin-Selenium, I3146); tumor growth factor (TGF)-β1 (240-B, R&D).
11. Osteogenic medium: MSC medium supplemented with 10 nM dexamethasone, 50 μg/ml ascorbic acid 2-phosphate, and

10 mM β-glycerophosphate; collagen type I 1 mg/ml solution (C8919) and vitronectin (V9881).

12. Adipogenic induction medium: MSC medium supplemented with 1% ITS, 10 mM sodium pyruvate, 0.5 mM IBMX (3-isobutyl-1-methyl-xanthine, I5879), 0.2 mM indomethacin (I7378), and 1 mM dexamethasone.

13. Adipogenic maintenance medium: MSC medium supplemented with 1% ITS and 10 mM sodium pyruvate.

METHODS

Isolation of Bone Marrow Mononuclear Cells

1. Premedicate a pig with an im injection of 1 mg/animal atropine, followed by 2.0 mg/kg bw of azaperonum 15 min later. As soon as sedation is induced, anesthetize the pig with 5 mg/kg bw of ketamine and maintain anesthesia with halothane.
2. Place the pig on its right side. Clean shave, clip, and aseptically prepare an operation field over the left coxal spine (tuber coxae allae ossis illi). Make a narrow scalpel incision through the skin and subcutis up to the coxal spine.
3. With a 15 G/70-mm bioptic needle, penetrate the bone and aspirate 10 ml of bone marrow from the coxal spine pulp chamber into a 20-ml syringe containing 10 ml of PBS with 2% FBS and 25 IU/ml heparin (Figure 27–2A).
4. From this time on, work in a laminar flow hood.
5. Let the Ficoll-Paque equilibrate to room temperature, mix well by inverting the bottle several times, and transfer 15 ml into a 50-ml centrifuge tube.
6. Carefully overlay 20 ml of bone marrow blood mixed 1 : 1 with PBS-FBS-heparin. **It is important not to mix the Ficoll-Paque with the diluted blood sample.**
7. Centrifuge at 400 × *g* for 30 min (20°C).
8. By centrifugation through the Ficoll-Paque density gradient, the cell suspension is separated, with erythrocytes and granulocytes at the bottom of the tube and the mononuclear cells located in a thin opalescent layer on the interface between Ficoll-Paque and blood plasma (Figure 27–2B).
9. Carefully aspirate and discard the blood plasma. Aspirate the opalescent layer of mononuclear cells and transfer into a 15-ml centrifuge tube containing 10 ml of MSC culture medium.

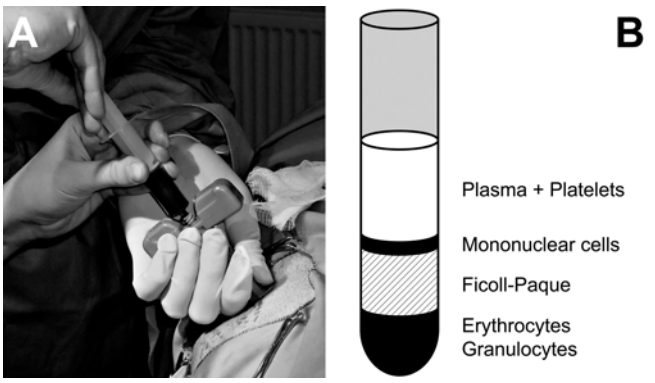

Figure 27–2. Isolation of mesenchymal stem cells. (A) Bone marrow is aspirated from the coxal spine pulp chamber with an iliac crest bioptic needle. (B) Distribution of cells separated by centrifugation through a Ficoll-Paque density gradient. Mesenchymal stem cells are present within the opalescent mononuclear cell layer.

10. Centrifuge at 250 × *g* for 10 min, discard the supernatant, and resuspend in 10 ml of fresh medium. Repeat the wash step once more.
11. Resuspend the cells in 5 ml of MSC medium, mix a 10-µl aliquot with 10 µl of trypan blue, and count the viable cells using a hemocytometer.

Cell Culture and Passaging

1. For initial selection of mesenchymal stem cells, plate isolated bone marrow mononuclear cells at a final density of 5×10^5 cells/cm^2 in MSC medium and culture at 37°C in a humidified 5% CO_2 incubator.
2. After 48 h of culture, aspirate and discard the culture medium with all the nonadherent cells, wash the culture flask with PBS, and feed the cells with fresh MSC medium.
3. Feed the cells with fresh medium every 3 days.
4. The first fibroblast-like colonies should appear in 4–5 days from the start of culture.
5. Passage cells when they reach ~80% confluency (usually 7–10 days from the start of the culture).
6. Aspirate the culture medium and wash the cell monolayer with PBS to remove all traces of FBS.
7. Add 5 ml of a trypsin-EDTA solution per 75-cm^2 culture flask and spread evenly over the cell layer. Leave this for 15–20 sec.
8. Aspirate the trypsin solution from the cells and incubate the flask for 3 min more at 37°C.
9. Add 10 ml of MSC medium and disperse the cells by repeated pipetting of the medium over the monolayer.
10. For routine subculture, split the cell suspension into a new flask 1 : 2 or 1 : 3.

Cryopreservation

1. Prepare freezing medium: 20% DMSO in MSC medium.
2. Prepare cryovials and label them with cell type, date, and cell passage number.
3. Detach the cells as described for passaging, resuspend them in 10 ml of MSC medium, and centrifuge at 700 × *g* for 3 min.
4. Resuspend the cells in 5 ml of MSC medium and count viable cell numbers by the trypan blue exclusion method using a hemocytometer.
5. Adjust the cell density to 1×10^7 cells/ml and aliquot 0.5 ml per cryovial. While gently swirling the cryovial, add dropwise 0.5 ml of freezing medium.
6. Let the aliquots equilibrate for 10 min at room temperature.
7. Transfer the cryovials to a polystyrene box with ~2-cm-thick walls and leave them at −80°C overnight.
8. For long-term storage, transfer the cryovials to liquid nitrogen or a −180°C cryofreezer.

In Vitro Chondrogenic Differentiation of Porcine Mesenchymal Stem Cells

1. For short-term induction of chondrogenic differentiation, resuspend 1×10^7 porcine MSCs in 2.5 ml of chondrogenic medium supplemented with 100 ng/ml of TGF-$ß_1$.
2. Incubate at 37°C for 30 min.
3. Centrifuge the cells at 700 × *g* for 3 min.

4. The cell suspension prepared in this way can be used for cell transplantation or embedding into a scaffold matrix.
5. For long-term *in vitro* chondrogenic differentiation, resuspend 2×10^5 porcine MSCs in 0.5 ml of chondrogenic medium containing 10 ng/ml of TGF-ß$_1$ in a 15-ml centrifuge tube.
6. Centrifuge at $700 \times g$ for 5 min.
7. Culture the pelleted cells in a 15-ml centrifuge tube with loosened cap to allow gas exchange at 37°C in a humidified 5% CO_2 incubator. After 24 h, the cells should form a single spherical cluster.
8. Culture the MSC cell cluster for 14 days and feed every 3 days with fresh chondrogenic MSC medium with 10 ng/ml of TGF-ß$_1$.

In Vitro Osteogenic Differentiation of Porcine Mesenchymal Stem Cells

1. Dissolve vitronectin in sterile ddH_2O to 0.5 mg/ml and mix with collagen in PBS to obtain a final concentration of 12 µg/ml for each ECM molecule. Add 0.5 ml of collagen/vitronectin mixture to each well in a 24-well culture plate and incubate overnight at 37°C in a humidified 5% CO_2 incubator. Just before use, aspirate the collagen/vitronectin solution and wash 1× with PBS.
2. Plate 6×10^4 MSCs in 1 ml of MSC medium per culture well.
3. Culture at 37°C/5% CO_2 until confluency.
4. Replace the MSC medium with osteogenic medium.
5. Continue the culture for 14–17 days. Every 3 days, feed the cells with fresh osteogenic medium.

In Vitro Adipogenic Differentiation of Porcine Mesenchymal Stem Cells

1. Plate MSCs at 1000 cells/cm^2 in adipogenic inducing medium and culture for 3 days at 37°C in a humidified 5% CO_2 incubator.
2. Exchange the medium for the adipogenic maintenance medium. Feed the cells every 3 days with fresh medium, alternating both media types, and continue the incubation for 28 days.

ISOLATION AND CULTURE OF PORCINE EPIDERMAL PROGENITOR CELLS

Pig skin has many similarities to its human counterpart and has been serving for some time as an excellent experimental model for wound healing, skin substitution, and burn treatment. Two extensive reviews addressing the pig as a model for skin wound healing were published recently by Sullivan *et al.*[36] and Middelkoop *et al.*[37]

Acellular porcine dermis can be used to support human epidermal sheet cultures[38] and autologous transplantation of human keratinocytes is currently the main approach for treatment of severe burns and chronic skin wounds. Unfortunately, the amount of autologous tissue that can be harvested for transplantation is limited. Hence, there is great interest in epithelial stem cells, which, after expansion *in vitro*, could produce sufficient numbers of keratinocytes. So far, skin epithelial stem cells and their niche have been studied mainly in the mouse model[39,40] and cells with stem cell characteristics were identified both in interfollicular epidermis and in the bulge region of hair follicles. Because porcine skin is a better model for human wound healing than rodent skin, the isolation of similar stem-like cells of porcine origin is likely to provide new insights and powerful treatment opportunities in the field of burn treatment and skin substitution.

The methodology described below is adapted from the article of Klima *et al.*[41] It allows the isolation of spherical clusters containing high proportions of undifferentiated porcine cells of epidermal origin.

MATERIALS Unless stated otherwise, all media and reagents were purchased from Sigma. Where necessary, catalogue numbers are given in parentheses at the place of the first appearance in the text.

1. Plasticware: 6-cm low adhesive culture dishes (Nunc), 6-cm tissue culture-treated culture dishes, and 15-ml centrifuge tubes (all TPP).
2. Surgical instruments: forceps, scissors, scalpels, and insulin syringe.
3. 70% ethanol, 10% Betadine (Egis Pharmaceuticals), PBS, crude collagenase (Sevapharma) solution: 0.4 mg/ml in Dulbecco's modified Eagle medium (DMEM), trypsin-EDTA solution: 0.25% trypsin (T4799) with 0.02% EDTA in Hanks' balanced salt solution.
4. EPC culture medium: 500 ml of DMEM (D6546) supplemented with 50 ml of FBS (F7524), 20 ml of 200 mM L-alanyl-L-glutamine (G8541), 0.5 ml of 50 mg/ml gentamicin (G1397), and 0.05 mM 2-mercaptoethanol.
5. Mitomycin-inactivated 3T3 fibroblast feeder layer.

METHODS

1. Wash large pieces of full thickness porcine skin briefly in 10% Betadine or 70% EtOH and rinse several times in sterile PBS.
2. From this time point, work in sterile conditions.
3. Using a stereomicroscope, dissect individual hair follicles while keeping the adjacent dermis (Figure 27–3A) and collect in PBS.

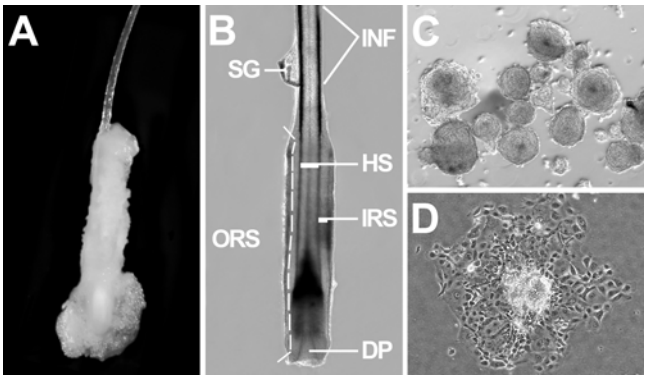

Figure 27–3. Isolation of epidermal progenitor cells from the hair follicle. (A) Photograph of a dissected porcine hair follicle with remnants of dermis. (B) A hair follicle after collagenase treatment and removal of dermal structures. INF, infundibulum; SG, sebaceous gland remnants; HS, hair shaft; ORS, outer root sheath; IRS, inner root sheath; DP, cavity formed by the removal of dermal papilla. The white dotted line demarks ORS, isolated from the hair follicle after trypsin treatment. (C) Phase contrast microphotography of spherical cell clusters formed by ORS cells after overnight culture. (D) Illustration of keratinocytes migrating out of the attached sphere.

4. Transfer approximately 20 dissected hair follicles into 1 ml of collagenase and incubate for 45–60 min at 37°C using a heat chamber.

5. Wash the hair follicles twice with EPC culture medium.

6. Using forceps and an insulin syringe needle, peel away the dermal remnants from the epidermal tissue of the follicle. Collect isolated hair follicles (Figure 27–3B) in PBS.

7. Wash once in PBS.

8. Transfer the follicles into 0.5 ml of trypsin. Incubate for 10–15 min at 37°C using a heat chamber.

9. Aspirate the trypsin solution and cover the hair follicles with EPC culture medium.

10. Using forceps and an insulin syringe needle, scrape the jelly-like outer root sheath (ORS in Figure 27–3B) from the hair follicles.

11. Gently transfer the resulting viscous suspension of the liberated ORS cells into a 15-ml centrifuge tube. Add 10 ml of EPC culture medium and spin down at $500 \times g$ for 5 min.

12. Gently resuspend the resulting cell pellet in EPC culture medium and transfer into low-adhesion culture dishes.

13. Culture at 37°C in a humidified 5% CO_2 incubator. Spherical cell clusters, approximately 50–100 µm in diameter, should appear overnight (Figure 27–3C). The spheres of this size can be easily handled by a micropipette while using a stereomicroscope.

14. Seed the spheres onto an adhesive culture surface or a fibroblast feeder layer. They should adhere, and within 2–3 days keratinocytes should start to migrate out of the sphere (Figure 27–3D).

Note: Vigorous resuspending during steps 11 and 12 will result in more but profoundly smaller spherical colonies, which are not so easy to handle.

CELL-TYPE-SPECIFIC LABELING IN TRANSPLANTATION STUDIES

An important problem of cell transplantation-based therapies remains the unequivocal identification of grafted cells within the host tissue. In xenotransplantation experiments, species-specific antibodies can be used for immunohistochemical cell identification. In allotransplantation and autotransplantation experiments, cells should be prelabeled during *in vitro* culture. Several methods are being used at present for labeling of grafted cells, including the incorporation of fluorescent nuclear (Hoechst) or membrane-bound dyes (CM-DiI) or the DNA marker 5-bromo-2-deoxyuridine (BrdU). A recent publication of Coyne *et al*.,[42] however, shows the potential danger of the transfer of such donor labels into host tissue. Cells transgenic for the green fluorescent protein (GFP) represent an alternative and probably more reliable labeling approach. Recent advances in large animal transgenesis[43,44] allow cell isolation from GFP transgenic pigs and new lentiviral vectors coding for the marker can successfully transduce even nondividing cells right after isolation or during culture.[45] Another alternative approach to visualize donor cells uses SPIO particles as contrast agent for magnetic resonance imaging (MRI). Several types of commercially available SPIO varieties (e.g., Resovist, Endorem, Feridex) were shown to incorporate into stem cell endosomes without affecting cell viability and differentiation potential.[46] The advantage of SPIO-labeled cells is their traceability *in vivo* during and after transplantation[30–32] and their simultaneous detectability in histological sections, where these cells can be identified with a Prussian Blue stain.

A short protocol for MSC labeling is given below. The same protocol can be used for labeling of cells before short-time chondrogenic differentiation. In this case, cells are labeled before chondrogenic induction with TGF-$ß_1$.

MATERIALS AND METHODS

1. Add SPIO particles (Resovist, Schering) to cultured MSCs at 1 µl/ml of culture medium (final concentration of 25 µg Fe/ml medium) 48 h before transplantation and culture in a 37°C/5% CO_2 incubator.
2. Before harvesting of cells, wash the monolayer 1× with fresh culture medium and 3× with sterile PBS to remove nonincorporated particles.
3. Harvest the cells by standard trypsinization, spin down at $700 \times g$ for 3 min, and resuspend in culture medium without FBS at the concentration required for transplantation.
4. Store on ice. Try to minimize the time between cell harvesting and transplantation, and gently resuspend the cells just before transplantation by trituration with a P1000 micropipette tip, as SPIO-labeled cells are sticky and quickly form cell clumps.

ACKNOWLEDGMENTS

This study was supported by the Centre for Cell Therapy and Tissue Repair (1M0538) and the Institutional Research Concept IAPG No. AV0Z50450515.

28 The Nonhuman Primate as a Model for Biomedical Research

DAVID M. ANDERSON

ABSTRACT

This chapter provides a brief summary of issues surrounding the utilization of nonhuman primates in biomedical research. Although a relatively small proportion of the total number of animals utilized in biomedical research, nonhuman primates occupy a unique position as the species most closely related to humans, and thus have the potential to provide highly relevant information regarding human health issues. Nonhuman primates are utilized across a wide diversity of research topics and examples are provided including infectious disease, neuroscience, and genomics. Pertinent information relating to ethical issues, species selection, housing, and specific pathogen-free status are provided as an overview of relevant issues associated with selection of nonhuman primate models. Selected references are provided as a reference for more comprehensive information relating to these topics.

Key Words: Nonhuman primate, Animal model, Macaque, AIDS, Neuroscience, Genomics, Specific pathogen free.

INTRODUCTION

Animal models are an essential component of biomedical research. Over the past century, the overwhelming majority of Nobel prizes awarded in medicine and related sciences have involved significant work utilizing animal models. It is clear that information provided through the use of animal models, and in particular nonhuman primate models, will be essential for continued development of effective solutions to issues affecting the health and well-being of both human and animal populations.

Although nonhuman primates are a relatively small component of the total animal use in biomedical research, they are an extremely important resource for a wide range of investigations. Of over 1.1 million animals[1] (not including rodents, fish, or birds) used in biomedical research annually, less than 0.3% are nonhuman primates.[2] The foundation for this disproportionate significance lies in the quality of information available through nonhuman primate studies. Nonhuman primates are arguably the most applicable animal model to the human condition based on their anatomic, physiological, and genetic similarity to humans. Genetic relatedness with the chimpanzee [*Pan (Homo) troglodytes*], the most closely related nonhuman primate species, approaches 98%, suggesting a high likelihood of correlation for nonhuman primate studies[3,4] Other nonhuman primate species, while less related to humans, still demonstrate important similarities and differences, offering an incredible resource for studies spanning a broad spectrum ranging from infectious disease to evolution.

A wide variety of nonhuman primate species have been developed for biomedical studies.[2,5,6] These include several major families of primates spanning the spectrum from new to old world, apes to prosimians. Examples of commonly used species include the genera *Macaca, Pan (Homo), Papio*, *Aotus*, *Callithrix*, *Saimiri*, *Chlorocebus*, *Saquinus*, and *Cercocebus*. Again, species variations provide the basis for selective advantages between specific nonhuman primate species in certain research applications (Table 28–1).

CONSIDERATIONS FOR USE OF NONHUMAN PRIMATES

Ethical considerations associated with nonhuman primate use in biomedical research are a significant factor in model selection. Nonhuman primates occupy an exceptional position in the hierarchy of animal models due to their close relatedness to humans. As described in earlier chapters, both physical and cognitive needs must be met in order to guarantee appropriate use. Nonhuman primates are recognized as having elevated cognitive requirements in addition to standard physiological needs. Strict minimum housing space requirements as well as dietary and environmental regulations are in place through the Animal Welfare Act and subsequent amendments as well as the Guide for the Care and Use of Laboratory Animals.[7,8] These requirements are enforced through an extensive network of federal, state, and local regulations, scheduled and unscheduled site visits, and oversight by local Institutional Animal Care and Use Committees (IACUC). Use of nonhuman primates, as well as other commonly used laboratory animal species, requires prior justification and approval by the appropriate IACUC to safeguard the appropriate care and use of every animal.

As outlined in other chapters, the selection process utilized to evaluate the appropriateness of nonhuman primates as a model system involves a variety of factors. Of primary importance is the ability of the specific model system to address the biological question posed for each specific investigation. Nonhuman primates typically provide information very relevant to human application and therefore are highly recommended. Other factors, however, must also be considered in the process. If the biological question

Table 28–1
Nonhuman primate species used in biomedical studies

Species name	*Common name*	*Applications*
Macaca nemestrina	Pigtail macaque	AIDS, reproduction, growth and development, behavior, neuroscience
Macaca mulatta	Rhesus macaque	AIDS, reproduction, growth and development, behavior, neuroscience
Macaca fascicularis	Long-tailed crab-eating macaque, cynomolgus	Infectious disease (AIDS, SARS), neuroscience
Papio anubis	Olive baboon	Reproduction, neuroscience, hematology, transplantation
Papio cynocephalus	Yellow baboon	Reproduction, neuroscience, hematology, transplantation
Cercocebus atys	Sooty mangabey	AIDS, leprosy, reproduction
Chlorocebus sabaeus	African green monkey	AIDS, neuroscience
Chlorocebus aethiops	Vervet	AIDS, neuroscience
Sanquinus oedipus	Cotton-top tamarin	Enteric disease, colitis, colorectal cancer
Callithirx jacchus	Common marmoset	Reproduction, endocrinology, vision, behavior
Aotus vociferans	Owl monkey	Vaccines (dengue, malaria), behavior, endocrinology, vision
Aotus nancymaae	Night monkey	Vaccines (dengue, malaria), behavior, endocrinology, vision
Saimiri sciureus	Squirrel monkey	Malaria, neuroscience
Pan (Homo) troglodytes	Common chimpanzee	Infectious disease (AIDS, hepatitis C), behavior

can be addressed through the use of lower species or nonanimal resources, current guidelines require use of these alternative means. In addition, issues such as housing requirements, species availability, and price can be important factors for consideration in the animal model selection process.

The relevancy of information developed in nonhuman primate models is well documented (see Table 28–1). Information developed in nonhuman primate models is critical to the design of subsequent human studies and the evaluation of new medical interventions into human health care. This correlation between human and nonhuman primate studies has application for both positive and negative results. Preliminary studies in nonhuman primate models of new lentiviral vaccines have closely mirrored subsequent results developed in human clinical studies.[9–16] Similarly, results in gene transfer studies have been generally disappointing in both human and nonhuman primates, reinforcing the similarity in response.

INFECTIOUS DISEASE

Nonhuman primates have been a critical resource in biomedical investigations related to infectious disease.[2,5,6] Based on the physiological similarities between species, nonhuman primates and humans share susceptibility to a wide variety of pathogens.[2,5,6] In addition, the balance of the host–pathogen relationship is largely dependent on both innate and adaptive immune responses, both of which are founded in the expression of the genetic code. Nonhuman primates possess a striking similarity to humans, a fact that has formed the basis for development of an extensive range of nonhuman primate models focused on transmission, pathogenesis, therapeutic intervention, and vaccine development for a variety of infectious pathogens.[2,5,6,9–24]

Macaque species are the most commonly utilized nonhuman primate species with the majority of public-funded studies directed toward infectious diseases. Macaques have a history of critical contributions to health concerns including the extensive utilization of rhesus monkeys (*Macaca mulatta*) for the development of the polio vaccine.[24] More recently, extensive use of a variety of species including, but not limited to, *M. mulatta*, *Macaca fascicularis*, and *Macaca nemestrina* has been closely integrated into the research on AIDS on a national and international basis.[10–16] Haigwood *et al.* have provided an excellent overview of this effort in Chapter 58 (this volume).

Of particular note is the expected utilization of nonhuman primate species for research related to "biodefense agents."[25] These agents have been identified by the Centers for Disease Control (CDC) and National Institutes of Health (NIH) as having potential use against the public health. To mitigate this potential, significant resources have been directed toward development of effective means for diagnosis, vaccination, and therapeutic intervention. It is highly likely that macaques will play a pivotal role in the development of these capabilities. This effort will require development and refinement of new nonhuman primate models to provide the necessary information required prior to implementation of human studies. This area of research emphasizes the highly relevant application of nonhuman primates as a precursor and substitute for human clinical studies. Serious ethical considerations accompany the concept of challenging humans with potentially deadly pathogens as part of the development process. Nonhuman primates offer the opportunity to evaluate the safety and efficacy of new vaccines and therapeutic agents with a high degree of confidence, yet without endangering human subjects.

New world nonhuman primate models, although less heavily utilized on a national basis, still provide critical contributions for specific diseases. From an international perspective, malaria is one of the most prevalent and devastating diseases, with a disproportionate impact in developing areas.[26–28] Development of effective malaria vaccines and therapeutics is a high priority for the national and international health care community.[26–30] *Saimiri* and *Aotus* species have proven to be excellent models for these investigations, contributing significant information on transmission, pathogenesis, and therapeutic and vaccine interventions.[22–24] Although availability and maintenance of these species are limiting factors, they will continue to be the most effective models for future translational research.

NEUROSCIENCE

Nonhuman primates have made significant contributions to neuroscience research through utilization of a variety of models over several decades. Nonhuman primates share more anatomic and physiological similarities to humans than any other species, and these factors have been used to provide important advances into the structure and function of the human brain.[31–35]

Nonhuman primates offer several advantages over other animals models, making them a unique resource for neurological investigation. The relatively close behavioral and cognitive abilities of nonhuman primates provide the opportunity to study the anatomic and physiological basis for these characteristics, a capability absent in lower species. In addition, nonhuman primates can be trained to perform a broad range of tasks, allowing development of models designed to investigate very specific neurological activities.[36–38]

As a correlate, many human neurological and cognitive tests have been adapted to nonhuman primates, allowing investigation of developmental aspects of cognition.[39–47] Developmental testing of reflex development, visual acuity, recognition memory, motor development, object concept development, and social interactions has been adapted to evaluate macaque species. These provide exceptional investigative tools and have been effectively utilized to identify important factors affecting cognitive and motor development.

A variety of nonhuman primate models have been developed to explore a broad spectrum of neurological structure and function. Extensive developmental work over several decades has resulted in well-characterized neurophysiological recording models allowing ongoing, active electrical recording from individual neurons within specific neurological networks. Characterization of interrelated neurophysiological function between specific neuronal groups has led to greater understanding of function within both motor and visual systems.[48–51]

Advances in imaging technology have provided exceptional opportunities for investigation of neurological function in nonhuman primate models. A wide variety of imaging modalities have been applied to nonhuman primate models including computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET). These noninvasive techniques offer the opportunity to perform multiple, detailed interrogations of specific neurological, anatomic, and physiological functions without physical disruption of neurological tissues. Additionally, the tractability of nonhuman primates has allowed awake models of neurological function using advanced imaging techniques including fMRI and fPET. These models provide a unique opportunity to investigate higher cognitive functions in species with a high degree of correlation to humans.

FUNCTIONAL GENOMICS

Perhaps the most important similarity between humans and nonhuman primates lies in the relative similarity of the genetic code.[52] In fact, the genomic similarities form the foundation for the physiological, morphological, and phenotypic likeness between species. Similarly, it appears that relatively small differences in either code or expression provide the basis for differences between species.[53–55] Investigation of the genetic code potentially provides an incredible resource for information across a wide spectrum of issues including evolution, cancer, basic physiology, immunology, cognition, and development.

Development of essential investigative resources for genomic studies has proceeded relatively quickly. Taking advantage of the research infrastructure established for sequencing the human genome, subsequent sequencing projects have provided initial full-length sequences for a number of nonhuman primate species including the chimpanzee, bonobo, and rhesus macaque, with sequencing projects underway for additional species.[54,55] Additionally, more limited information is available from a variety of other nonhuman primate species. Consistent with founding principles of the Genome Project, these data and others are available in public reference sites such as GenBank.[56] Microarray chips developed by both Agilent Technologies and Affymetrix have recently become available allowing directed investigation of specific genomic responses across a variety of biological studies. Advances in bioinformatics software capable of distilling complex microarray information into biologically relevant mechanistic pathways have provided a critical link between genome and phenotypic response. Taken together, these resources provide an exceptional opportunity to apply novel, highly sophisticated research methods to important biological issues.

Application of these research resources is rapidly increasing across a variety of biological fields. Evolutionary studies have derived significant benefit through comparative genomic studies of humans and nonhuman primates. Current genomic capabilities allow comparative studies of specific genetic composition and expression, providing important insights on evolutionary pressures underlying the relative divergence or convergence of primate species. In addition, genomic studies can provide significant comparative data for other investigations based on mitochondrial DNA and Y-chromosomal sequencing. Comparative genomic analyses provide the potential for extremely powerful genetic investigations defining the genetic basis for the morphological and phenotypic differences between species.

Infectious disease investigation is likely to be a primary beneficiary of genomic research capabilities. Both innate and adaptive immunity are critical components of the host–pathogen interaction. Recent microarray studies have clearly highlighted the vigorous host inflammatory response in animal models of pathogenic influenza infection.[57–59] It is clear that a more complete understanding of the host response to infection will provide critical information for the development of new generations of therapies and vaccines. As an example, the development of an effective AIDS vaccine has proven to be an exceptional challenge despite more than two decades of intense research. As yet, significant questions remain concerning the transmission events, viral pathogenesis, means of obstructing viral replication, and correlates of protection necessary for effective vaccination. Functional genomic analysis in appropriate nonhuman primate models has the potential to provide important evidence for the resolution of these issues.

In addition to functional genomics, proteomic studies in nonhuman primates have the potential to provide a key link between genome and phenotype. In that the proteome is the sum of expressed proteins based on the genetic composition of the organism and the current environment, the proteome is a critical link in achieving a more complete understanding of the ongoing relationship between genome, proteins, and function. Investigative tools are currently under development and promise to provide

information necessary to fully characterize a wide variety of physiological responses. Efforts are currently underway to provide complementary experimental designs allowing for simultaneous investigation of genomic response, protein expression, and physiological phenotype in nonhuman primate model of infectious disease.[60,61]

HOUSING CONSIDERATIONS

Maintenance of nonhuman primates in laboratory environments presents significant challenges. A considerable commitment in expertise, resources, and effort is required to ensure appropriate care and support for nonhuman primates in research facilities. While outdoors, free-ranging native housing environments might be an ideal for nonhuman primate housing, it is likely that research protocol constraints, existing facilities, and geographic location would render this a nonviable option for most research institutions. Instead, current housing environments are designed to meet the environmental, nutritional, and psychological needs of each animal, allowing individual animals to express species-specific normative behaviors, albeit in a different setting.

While many components of an effective animal care program are similar among species used in biomedical research, nonhuman primate care programs typically must provide additional emphasis on provision for the psychological health of housed animals.[62] Specific elements of a comprehensive animal care program for nonhuman primates include effective health surveillance and veterinary care, husbandry, psychological enrichment/well-being, management of breeding activities, and oversight for research activities. Appropriate documentation of animal-related activities is a critical component of effective management as well as being necessary for regulatory compliance.

In particular, nonhuman primates have special requirements for environmental enrichment, social housing, and mitigation of experimental impacts, both physiological and cognitive. The perceptive and cognitive characteristics of nonhuman primates impose additional responsibility concerning their care and use in biomedical research. Behavioral assessment of nonhuman primates is considered an essential component of health and well-being monitoring programs. Assessment of behavior is considered an indicator of the psychological state of nonhuman primates, with the implication that abnormal behavior may be an outward manifestation of physiological or psychological stress.[63] Novak and Suomi[64] have provided recommendations for the assessment of nonhuman primate well-being, although additional measures may be considered.

The need for positive social interaction between conspecifics is recognized as a critical requirement for the psychological well-being of nonhuman primates. In natural settings, nonhuman primates are generally highly social animals maintaining a range of social relationships. These social interactions are influenced by age, sex, parentage, social standing, as well as a variety of other factors. Social housing of conspecific nonhuman primates is the accepted standard housing configuration unless precluded by specific research or medical or behavioral constraints.[62]

Social housing can take many forms and spans a spectrum of housing configurations. Basic elements of social housing include access to sensory cues from other nonhuman primates including sight, smell, hearing, and touch. The standard cage design for nonhuman primates typically employs spaced bars that restrict the animals to a desired space but also allow extensive interaction with environmental visual, olfactory, and auditory cues.

The highest level of social interaction is achieved through direct physical contact between conspecifics. Group housing configurations such as harem groups, family units, single-sex cohorts, age-matched cohorts, pair housing, or limited contact housing (grooming bars)[65] have all been utilized to provide effective socialization of nonhuman primates. Although a detailed examination of each housing configuration is beyond the scope of this chapter, each has the potential to provide the opportunity for species-specific behavioral interactions, thereby increasing environmental enrichment. Care must be taken, however, in the selection process for social housing partners. Significant differences in the success of social housing configurations can occur based on age, sex, and relatedness of individual animals. While direct social housing has the potential to provide significant environmental enrichment, unsuccessful social interactions can result in significant psychological and physical trauma, including death. Additionally, social interactions can precipitously change from stable, positive physical interactions to aggressive, potentially traumatic interactions without identification of a precipitating cause. Experience and ongoing close observation of socially housed nonhuman primates is necessary to establish and maintain positive social interactions.

Maintenance of health care for nonhuman primates is central to an effective animal care program. This point is substantiated in the Animal Welfare Act through placement of independent judgment and final decision authority in the Institutional Veterinarian. An effective health care program has several components including well-defined programs for preventive health care, health surveillance, and treatment of health issues. These components must be effectively combined into a seamless program that not only meets the spontaneous health needs of each animal but actively intercedes to avoid potential health care issues. Specific components are (1) preventive health care, including quarantine, isolation, annual physical examination, dentistry, and vaccination when appropriate; (2) health surveillance, including viral testing, microbiological testing, daily observations, behavioral assessment, and weight monitoring; and (3) treatment/veterinary care, including veterinary care and surgery support, treatment of spontaneous disease, and treatment of health issues associated with research activities.

CHARACTERIZATION

As the complexity of biomedical research increases, so too does the demand for better characterization of the nonhuman primate resource. Increasing sophistication of scientific investigation requires a more thorough knowledge of potentially confounding factors, including the health status and genetic profile of the experimental animals. Most recently, AIDS-related research in nonhuman primate models has provided the overriding impetus to characterize and segregate animals based on health status and genotype.[66–69] The heavy reliance on normal immune function in AIDS-related research studies requires well-characterized research animals capable of exhibiting a normal immune response to viral infection or vaccination.

Both ethical and financial considerations provide additional motivation for characterization of individual animals prior to recruitment into research projects. Ethical guidelines require the use of minimum numbers of animals to meet experimental objec-

tives, typically the demonstration of the experimental hypothesis with statistically significant results.[70] Biostatistical consultation during the study design is a common part of the protocol development process. Additionally, nonhuman primate studies require a significant financial commitment for purchase and appropriate maintenance of experimental animals. These factors combine to produce an experimental design that includes the minimum number of animals necessary to produce statistically significant results. The dropout of individual animals due to unknown pathogen status can be the difference between experimental results that are statistically significant and results that are merely suggestive. Therefore, significant effort is directed toward the designation of specific health status prior to inclusion in research projects.

In addition to research requirements, significant motivation exists to eliminate agents with the potential for zoonotic transmission. Investigative and animal care staff typically work in close proximity to housed animals, providing the potential for transmission events between species. Several nonhuman primate pathogens have the potential to induce significant morbidity or mortality when transmitted into human hosts.[71–74] Although rare, a number of documented incidents of mortality associated with zoonotic transmission of herpes B virus from nonhuman primates to human hosts are available in the literature. Based on this potential, many facilities now require documented negative status of nonhuman primates for several infectious agents.

Genetic characterization of nonhuman primates has proven to be an important factor in studies involving immune response to infectious agents. Characterization of the MHC Class I alleles in the rhesus monkey has revealed a pattern of differential response to lentiviral infection based on the presence or absence of specific alleles.[66,67] It is therefore important to characterize the genetic composition of study animals prior to study onset either to avoid undesirable and unintended impacts to the study results or to provide important information for the interpretation of the results. As an important correlate, identification of these alleles may provide valuable information regarding relative susceptibility or resistance to disease progression following lentivirus infection.

Genetic characterization can extend beyond individual differences to important differences between subspecies. At one point in time, rhesus monkeys from either Indian or Chinese origin were largely considered interchangeable for infectious disease studies. Detailed comparative studies have revealed, however, that although both species appear to be equally susceptible to lentiviral infection, a significant difference exists in their ability to support ongoing, long-term viral replication.[75] Current recommendations therefore include segregation of subspecies for these studies, or equal distribution in experimental groups to avoid spurious distortion of experimental results.

Of note is the historically imprecise confirmation of the genetic origin of many domestic breeding colonies. Breeding records for many domestic nonhuman primate breeding colonies have depended on imprecise observational methods for documentation of parentage. Long-term productive management of breeding colonies requires accurate, ongoing genetic characterization to avoid undesirable inbreeding and to confirm the genotype for individual animals. Recent advances in genetic sequencing have provided more precise methods for confirmation of parentage and genetic origin. Techniques such as single nucleotide polymorphisms (SNPs) and microsatellite assays have made it possible to determine with relative certainty the parentage and general genetic stock and subspecies of individual animals.[76–79]

SPECIFIC PATHOGEN FREE

The characterization of the health status of nonhuman primates is critically important for a wide variety of experimental applications. In particular, studies involving exposure to infectious diseases or characterization of immunological response have the potential for unintended distortion due to coinfection with spurious pathogens. To avoid this potential confounding effect, significant efforts have been directed toward the development and characterization of nonhuman primates guaranteed negative for specific pathogens, designated specific pathogen free (SPF).

The SPF designation indicates negative status for one or more infectious agents. Although the SPF designation can technically be used for any pathogen, standard use refers to viral pathogens with a negative status for *Mycobacterium tuberculosis* assumed. Several different levels of SPF status exist; however, the most common designation refers to animals negative for simian retrovirus (SRV), simian T-lymphotrophic virus (STLV), simian immunodeficiency virus (SIV), and herpes B virus (B virus, CHV-1). This SPF designation has been established by the National Center for Research Resources (NCRR) and the Office of AIDS Research (OAR) through the development and support of SPF macaque colonies for AIDS-related research. This designation reflects the need to have animals free of indigenous retroviruses potentially capable of skewing immune function while at the same time providing protection for investigative and husbandry staffs against potential exposure to a significant zoonotic agent, herpes B virus.

Effective maintenance of SPF status requires ongoing surveillance, typically provided by strict viral testing programs. SPF status can be documented through a variety of techniques; however, several constraints exist for use of laboratory assays for colony surveillance screening. Sensitivity and specificity are key parameters for any laboratory assay and each should be quantitated and confirmed through a rigorous, ongoing quality control program. Additionally, colony surveillance assays must be relatively easy to perform and must be cost effective for efficient inclusion in a colony management program.

Under these considerations, a spectrum of screening tests has been developed to survey the viral status of macaques in breeding and research colonies. Serology is an industry standard with enzyme-linked immunosorbent assay (ELISA) and, more recently, multiplexed bead assays[80–86] utilized to identify antibody response to previous viral exposure. In addition, standard confirmatory tests such as Western blot, polymerase chain reaction (PCR), and virus isolation are utilized to confirm positive tests and resolve indeterminate results. While some institutions maintain proprietary diagnostic laboratories, commercial laboratories are available for support of viral surveillance programs.

Management of SPF colonies depends heavily on the surveillance of colony viral status. Typical management strategies include the means to test all animals with removal of individual animals testing positive or indeterminate for specified pathogens. Management protocols are available in the literature for the derivation of SPF nonhuman primate colonies from non-SPF founder stock as well as expansion of current SPF colonies.[87] These protocols rely heavily on rigorous adherence to surveillance testing schedules with exclusion of animals from the SPF colony until negative

pathogen status is confirmed. Subsequent monitoring of the colony is maintained on a continuing basis to ensure identification and isolation of individual animals demonstrating conversion to positive status.

CONCLUSIONS

Nonhuman primates are a critical resource for biomedical research. The genetic, morphological, and physiological similarity to humans provides an invaluable resource for information directly applicable to both human and nonhuman primates. Although housing and maintenance of these species are challenging, well-defined programs are in place to meet the physiological and psychological needs of animals in research settings. Ongoing efforts continue to better characterize nonhuman primate genetics and pathogen status, thereby improving the application of these models to biomedical research questions. Given the current emphasis on translational research, it is highly likely that demand for these extremely relevant animal models will continue to increase in the foreseeable future.

29 Primates as Models of Behavior in Biomedical Research

STEVEN J. SCHAPIRO

ABSTRACT

Much can be learned about behaviors with biomedical relevance from behavioral studies of the seemingly uncomplicated prosimians to the seemingly complex great apes. This chapter will concentrate on providing insight into suitable, and perhaps even ideal, nonhuman primate (NHP) models that can be used, or that have been used, to attempt to answer specific behaviorally oriented biomedical research questions. Prosimians, monkeys, and apes are all organisms whose behavior has been investigated in the laboratory in an attempt to model, to simulate, to understand, or to change behavior. One of the primary biomedical uses of behavioral research with NHP is to identify, study, and treat behavioral abnormalities. A second important biomedical use of behavior is as an assay. Normal behavior can be assessed during a baseline condition and then an experimental manipulation can be implemented, with any significant changes in behavior being indicative of a meaningful effect of the manipulation. Nonhuman primate subjects can also be trained to perform specific tasks until they have reached target criteria and the effects of manipulations on performance can then be measured. For investigations focusing on the evolution of behavior, primate behavioral capabilities can be studied to better understand the evolution and/or development of human capabilities. Rhesus and cynomolgus macaques are the two most commonly utilized nonhuman primate models in studies of behavior. These medium-sized animals appear to represent a valuable compromise model, retaining many of the most attractive and useful characteristics of NHP as behavioral models, while simultaneously demonstrating many of the convenient and utilitarian characteristics required for successful laboratory animal models. Although specialized studies will require more specialized nonhuman primate models, rhesus and cynomolgus macaques appear to be exceptionally useful models for a variety of types of behavioral research.

Key Words: Animal models, Nonhuman primates, Behavior, Behavioral assays, Conditioning, Cynomolgus macaques, Rhesus macaques, Chimpanzees, Baboons.

INTRODUCTION

This chapter will focus on the use of nonhuman primates (NHP) as behavioral models in biomedical research. Other chapters within this volume will examine the behavior of other species[1] and other uses of nonhuman primates as models.[2,3] From studies of infants[4] to studies of the aged,[5] from studies of normal individuals[6] to studies of extremely abnormal subjects,[7] from studies of simple individual behaviors[8] to studies of extremely complex social behaviors,[9] nonhuman primates serve as important behavioral models in the biomedical research enterprise. Much can be learned about behaviors with biomedical relevance from studies of the seemingly uncomplicated prosimians to the seemingly complex great apes. Since the emphasis of this volume is on identifying appropriate models to address specific research questions, this chapter will concentrate on providing insight into suitable, and perhaps even ideal, NHP models that can be used, or that have been used, to attempt to answer specific behaviorally oriented biomedical research questions.

One of the primary biomedical uses of behavioral research with NHP is to identify, study, and treat behavioral abnormalities. Most behavioral studies of NHP have as their goal the exploration, explanation, prediction, and/or modification of behavior. Prosimians, monkeys, and apes are all organisms whose behavior has been investigated in the laboratory in an attempt to model, to simulate, to understand, or to change behavior. For example, Harlow demonstrated in considerable detail the behavioral abnormalities that result from inadequate mother–infant attachment.[4] Others continued this research and were able to identify methods to compensate for, and more importantly prevent, poor mother–infant relationships and their behavioral outcomes in the laboratory.[10–12] Addiction research shows that primates will work for "drugs," sometimes to the exclusion of food.[13] This work identifies the reinforcing components of drug use and abuse. Some studies of pharmaceuticals examine changes in abnormal behavior as a function of drug administration[14]—changes are good if the drug is having the desired effect and changes are bad if the drug is not supposed to affect behavior or is supposed to affect abnormal behavior differently. This chapter will highlight studies that have taken place in the laboratory setting, but will also include occasional mention of relevant work conducted with primates in natural settings (the field). This will be especially evident when examining the evolution of biomedically relevant behaviors.

A second important biomedical use of behavior is as an assay. There are two different, but related ways in which behavior can serve as an assay. First, normal behavior can be assessed during a baseline condition (or in control groups), and then an experimental manipulation can be implemented. Behavior can then be

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

assessed again during the experimental condition, with any significant changes in behavior being indicative of a (hopefully biologically) meaningful effect of the manipulation. As an example, Kaplan, Shively, and their colleagues have studied the effects of a variety of manipulations (social stress, atherogenic diets, oral contraceptives) on the behavior of captive cynomolgus macaques,[15–20] primarily using between-subjects designs. Many studies of environmental enrichment involve multiple manipulations and control conditions and are most effectively conducted using within-subjects designs.[21,22]

Trained behaviors can also be used as assays. NHP subjects can be trained to perform specific tasks[23–26] until they have reached target criteria or have established stable patterns of responding. Once responding has stabilized, an experimental manipulation (i.e., administration of a pharmaceutical agent) can be implemented and changes in responding can be assessed. In many studies of psychoactive compounds, the effects of various doses of these compounds are measured on macaques or baboons that have been trained to reliably perform sophisticated operant tasks.[23] In addition to providing information about the behavioral effects of the manipulation, this experimental approach can also provide information about the sensory effects of the manipulation through the use of the techniques of psychophysics.[24,25]

A less biomedically oriented but still important use of studies of primate behavior involves investigations of the evolution of behavior. In this type of work, primate capabilities are studied to better understand the evolution and/or development of human capabilities. Studies of aggressive behaviors are one clear example[27] Cognitive behavior, especially the social cognition that is involved in the complex amalgamation of behaviors that yields "culture," is another example.[28] This chapter will stress behaviors that have considerable biomedical relevance. By doing so, we will be neglecting/ignoring a large, interesting, and useful component of the primate behavioral literature (e.g., studies of NHP: in space flight,[29] temperament/personality,[30,31] laterality,[32] and culture[28,33]). In a short chapter such as this one, it is inevitable that arbitrary decisions must be made and some subsets of the potential subject matter will not be treated in adequate detail.

One of the strongest justifications for using NHP as behavioral models in biomedical research is that it is possible to perform certain experimental manipulations with NHP subjects that cannot be performed with human subjects. This does not mean that potentially damaging or harmful research can be conducted without restrictions using NHP. All animal research, and especially primate research, is carefully regulated and approved by a variety of bodies with oversight responsibilities (i.e., IACUC, USDA, etc.). The similarity of NHP to humans makes them both desirable and problematic choices as animal models. In fact, NHP may be especially high fidelity models for behavioral investigations, as groups of subjects can be easily "randomized" and individuals are less likely to exhibit several potential confounding tendencies that may be unique to human subjects (noncompliance,[15] deception, biased behavior,[34] logically inconsistent preferences,[35] and spiteful behavior[36]). Of course, data from NHP are not as valid for generalizations to human behavior as are data from humans.

Although retrospective analyses can provide considerable insight into the understanding of behavior, prospective experimental investigations using appropriately selected,[37] conditioned,[38] desensitized,[39] and trained[40] primate models can more systematically, directly, and reliably address experimental hypotheses. Thus, assessments of the behavioral effects (natural or experimental) of glucocorticoids on the hippocampus in aged primate brains[41] are extremely relevant for studies of the behavioral effects of Alzheimer's disease in humans.

Inherent in any discussion of appropriate NHP models in biomedical research is the understanding that the care the animals receive while in captivity must be of the highest quality. In addition to outstanding husbandry and veterinary care, it is especially important for NHP maintained as models for behavioral research to be appropriately behaviorally managed.[42–44]

The different models and approaches used with nonhuman primates to study behaviors of biomedical relevance have been rather arbitrarily divided into several categories (see Table 29–1). These categories are intended to be neither exhaustive nor mutually exclusive. Since entire books and issues of journals have been devoted to topics relevant to this chapter, the reader is directed to additional sources, including the *ILAR Journal*, several recent books,[45–47] and an issue of the journal *Methods*[48] for more complete discussions of some of the topics treated in the present chapter.

NONHUMAN PRIMATE MODELS TO IDENTIFY AND TREAT BEHAVIORAL ABNORMALITIES

Nonhuman primate models have played a critical role in the study of abnormal behavior.[49–52] This applies to a variety of abnormal activities, including those behaviors that do not occur in natural circumstances, those behaviors that occur at abnormal frequencies under captive conditions, and those behaviors that are considered indicative of psychopathology. In all of these circumstances, NHP can and have been used to better understand, create, and treat abnormalities similar to those of clinical significance in humans.[50,51] Harlow's studies of poor/abnormal mother–infant attachment in rhesus monkeys (*Macaca mulatta*[4,53]) have probably made the largest contribution to our understanding of the development of a variety of abnormal behaviors, both in NHP and in humans. While Harlow is perhaps best known for his work that created rhesus monkeys that behaved abnormally, his research and the ongoing work of his academic descendants also demonstrate that it is possible (1) to mitigate abnormal behaviors once they have developed, but more importantly, (2) to prevent certain abnormalities from developing at all.[10–12] Much of what we know about proper mother–infant attachment and its lifelong consequences in NHP and humans comes from the laboratories of Harry Harlow and his colleagues[4,11,12,53,54] and the more human-focused John Bowlby.[55] In addition to the rhesus monkeys observed by Harlow, important contributions to the study of mother–infant attachment and abnormal behavior were made using squirrel monkey[56] and chimpanzee[57] models.

A number of abnormal behaviors may develop in laboratory primates that are housed singly for long periods of time, especially among those socially deprived when very young.[4,53,57] One of the most interesting and most relevant is self-injurious behavior (SIB).[7,58] As the name implies, SIB occurs when an individual injures itself, in the case of rhesus monkeys, typically through acts of self-directed biting. Aside from any parallels to human SIB, NHP SIB is of considerable importance in biomedical research because SIB can adversely affect the NHP and the study in which

Table 29–1
Research questions and appropriate model species

Research question	*Model species (references)*	*Special characteristics*
Assess and/or treat behavioral abnormalities		
Depression	Cynomolgus macaques[18–19]	Females and social stress
Self-injurious behavior	Rhesus[7,14,58]	Singly housed males
Abnormal development	Rhesus,[4,53] chimpanzees,[57] squirrel monkeys[56]	Socially isolated infants
Behavior as an assay		
Normal behaviors		
Effects of oral contraceptives	Cynomolgus macaques[15,17]	Females in captivity
Effects of diet	Cynomolgus macaques[17,20]	Laboratory setting
Environmental enrichment	Rhesus,[14,21,44] baboons[22]	Laboratory setting
Trained behaviors		
Drug effects	Rhesus,[8,3] baboons[23–25]	Laboratory trained to lever press
Brain manipulations	Rhesus,[26] squirrel monkeys[61]	Laboratory trained to lever press
Learning and memory	Many species[68,71–72,74]	Many circumstances
Control by thought	Rhesus[76,77]	Laboratory setting
Space flight	Rhesus,[29] chimpanzees[29]	Experimental settings
Study decrements to understand normal behavior		
Affiliative behavior	Cynomolgus,[63] rhesus[64]	Adults in unstable groups
AIDS susceptibility	Rhesus[64]	Subadult males in unstable groups
Alloparental	Marmosets,[86] Blue monkeys[87]	Naturalistic social groups
Response to capture	Vervets[66]	From wild to laboratory quarantine
Sexual behavior	Bonobos,[83–85] mandrills[81]	Naturalistic social groups
Study occurrence to understand evolution of behavior		
Aggression	Many species[27]	Laboratory and natural settings
Murder	Chimpanzees[79–80]	Natural setting
Rape	Orangutans[97]	Experimental settings
Cannibalism	Chimpanzees[98]	Natural setting
Infant abuse	Rhesus[10,53]	Socially isolated individuals
Social stress	Baboons[41,65,99]	Natural setting
	Cynomolgus macaques[16,19,59]	Laboratory setting
Eating	Rhesus[103–104]	Caloric restriction, obesity
	Cynomolgus macaques[105]	High cholesterol diets
Addiction	Baboons[23,25]	Laboratory setting
Infanticide	Proboscis monkeys[78]	Natural setting
Laterality	Chimpanzees[32]	All settings
Personality/temperament	Bushbabies[31]	Laboratory setting
Adoption	Capuchins[96]	Natural setting
Aging	Rhesus[5,106]	Laboratory settings
Culture	Chimpanzees[28,33]	Laboratory and natural settings
Self-medication	Chimpanzees[6]	Natural settings
Emerging techniques and new frontiers		
fMRI[a]	Rhesus,[108] marmosets[111]	Laboratory setting
PET[a] scans	Rhesus[54,109]	Laboratory setting
Gaze tracking	Ring-tailed lemurs[112]	Laboratory, but group-housed

[a]fMRI, functional magnetic resonance imaging; PET, positron emission tomography.

the animal is participating.[58] The focus of this volume is on identifying appropriate models for research questions. Therefore it should be obvious that singly caged male rhesus macaques are an appropriate model for studies of SIB and that SIB may make them inappropriate subjects for investigations requiring early and long-term social isolation. Because SIB is a condition that already exists among a subset of captive male rhesus,[7,58] there is little, if any, need to attempt to experimentally induce SIB.

Recent studies suggest that female cynomolgus macaques are particularly good models for investigations of depression,[19] demonstrating many useful similarities to human depression. These similarities appear to be relatively unique among animal models, and even NHP models, for depression. This research group has also profitably studied the effects of stress on behavior in this species.[59,60]

Nonhuman primates as models for abnormal behavior are probably the best known and reported use of NHP as behavioral biomedical models. Recent, excellent reviews of this topic are available from a number of sources.[50–52]

NONHUMAN PRIMATE BEHAVIOR AS AN ASSAY

As with many laboratory animal species, the behavior of NHP can be used as an assay to measure the effects of particular manipulations. These manipulations can be behavioral or nonbehavioral in nature. Typically, behavior during baseline periods is compared to behavior during experimental conditions or behavior in control groups of NHP is compared to behavior in experimental groups of NHP. Depending on the species and the experimental question, either natural behavior or trained behavior can be used as the assay.

CHANGES TO NORMAL NONHUMAN PRIMATE BEHAVIOR Perhaps the easiest way to view this approach to behavioral assays is to consider studies that are designed to establish relationships between particular brain structures and particular behaviors. Effects of a variety of brain manipulations (lesions, stimulation, pharmaceutical treatments, etc.) can be assessed by comparing behavior with and without the manipulation.[26,61] Macaques, primarily rhesus and cynomolgus macaques, are the most frequently utilized NHP models in neuroscience research.[62]

Unstable social settings have been shown to have a variety of adverse behavioral and physiological consequences on laboratory NHP, especially several macaque species *(M. mulatta* and *M. fascicularis*).[60,63,64] Similar findings exist for baboons in the wild[65] and for vervet monkeys recently captured from the wild and housed individually in captivity.[66] These studies are extremely relevant to biomedical research, as they compare stable to unstable social conditions and demonstrate that behavioral factors/manipulations can have profound physiological and behavioral consequences. In addition to opportunities to study these types of manipulations and their consequences as phenomena, it is important to be aware of factors such as potential confounds when developing and using NHP models in research. There are strong data describing the physiological and especially the immunological consequences of unstable social settings.[60,63,64] For example, rhesus macaques infected with simian immunodeficiency virus (SIV) get sicker faster when housed in unstable social groups than when housed in stable social groups.[64]

Cynomolgus macaques have also served as extremely important models in a long series of research projects that have examined the effects of a variety of behavioral and physiological manipulations, including social stress, atherogenic diets, alcohol consumption, ovariectomy, and oral contraceptives[15–20] on "normal" behavior. Most of these studies have taken advantage of between-subjects designs in which the behavior of the experimental group(s) is compared with the baseline behavior of the control group, which did not receive the atherogenic diet,[17] the oral contraceptives,[15] or the ovariectomy.[16]

USING TRAINED BEHAVIOR Nonhuman primates can be trained to perform a variety of simple and sophisticated operant responses.[8,13,23–26] Once trained, the response patterns of the NHP can be used to assess the effects of a variety of manipulations. Animals that respond in one way during control conditions but respond differently during experimental sessions provide important behavioral data to address research questions. For example, an NHP that has been trained to successfully avoid shock under baseline conditions, but fails to avoid shock while under the influence of alcohol,[67] provides a useful model for alterations in behavior as a function of alcohol consumption. The techniques of psychophysics can be applied to determine whether a subject's responses to target stimuli have changed, rather than its ability to perceive/sense the stimuli.[24,25]

Macaques, baboons, and chimpanzees can be trained to perform many different behaviors using food or fluid (water or juice) as the primary reinforcer.[68] Some of these experimental paradigms are conducted under conditions of food or water control, in which subjects receive much of their food or fluid as a function of performing the experimental task.[69] In these types of studies, food or water is often available only during, and shortly after, the experimental session, resulting in reasonably long periods of food or water restriction for the NHP.[23] These types of procedures are typically thought to increase the motivation of the subjects to perform the operant response, but may simultaneously adversely affect the validity of the experiment.[69,70]

NHP subjects can be trained to perform many different responses, including simple lever presses, making choices on touch screens, and using joysticks.[68,71,72] Similarly, the effects of a variety of manipulations can be examined using these behavioral responses, including the psychoactive effects of pharmaceutical compounds and the effects of brain lesions or brain stimulation.[8,13,23–26,61,67–69] NHP can also be trained to perform multiple operant responses with each response coupled to a different reinforcer in order to compare the value of the different reinforcers.[23,24] The most enlightening of these studies are ones that involve comparisons between food and psychoactive reinforcers (drugs or brain stimulation), providing substantial insight into the behavioral components of drug addiction.[23] The use of trained behaviors may be particularly valuable for assessing longitudinal effects of manipulations, including developmental, maturational, and aging processes.

Studies of Learning and Memory Trained behaviors are especially useful in studies of NHP learning and memory. Although memory is not really a behavior, learning is a constellation of behaviors with considerable biomedical relevance and learning and memory are so closely related that both learning and memory are important to include in the current discussion. Learning and memory have been studied in many primate species using naturalistic and artificial methods of assessment under both laboratory and field conditions.[73–75] The study of NHP learning and memory is likely to be limited, not by the capabilities of the animals, but by the ability of human experimenters to develop technology to adequately assess NHP learning and memory. Once again, macaques and baboons are the most frequently used NHP models for studies of learning and memory.[62] Chimpanzees, given their considerable cognitive abilities, are also attractive, well utilized, and productive models.[75]

Macaques have also been quite profitably utilized in research programs that have focused on training NHP to control body movements via thought (primarily hand movements).[76,77] Although

neither a training manipulation in the strict operant conditioning sense nor a standard approach to examining learning and memory, these studies have successfully trained rhesus monkeys to control movements with thoughts. The data from these experiments are impressive and have many implications for therapeutic behavioral applications.

NONHUMAN PRIMATE MODELS OF THE EVOLUTION OF BEHAVIOR

When the behaviors of NHP are typically explained, evolutionary justifications for behavioral patterns are often provided. Although evolutionary explanations fit certain patterns of human and NHP behavior, explanations of human behavior are not limited solely to adaptations of NHP patterns. While male NHP may kill infants (infanticide) sired by rival males to increase their own likelihood of siring infants,[78] this type of explanation is unlikely to be invoked in human situations. On the other hand, male chimpanzees will systematically attack and kill other chimpanzees, a fact that some use to explain human tendencies toward murder and war.[79,80]

SEXUAL BEHAVIOR Ovulation is clearly signaled in some species of NHP[81] and concealed in others.[82,83] As reproductive strategies, both signaled and concealed ovulation impact patterns of sexual and paternal behavior. In NHP species with signaled ovulation,[81] males may be able to adopt behavioral strategies designed to monopolize females' breeding opportunities during fertile periods. If successful, males may then have some certainty of parenthood and should invest in the care of offspring they have "calculated" to be theirs. Alternatively, usurper males would know that they were not the father of any infants and might try to eliminate the offspring of a rival through infanticide. In NHP species with concealed ovulation, males may be more likely to invest in the infants of all females they mated with, since they cannot be completely certain that they sired any particular infant. NHP females may take advantage of this. Bonobos may be a particularly important model for studies of sexual behavior, since their ovulation appears to be concealed[83] and unlike many NHP species, sexual behavior is not strictly under "hormonal control."[84] In fact, bonobo sexual behavior appears to function both for reproductive and for nonreproductive purposes,[85] serving as a critical, human-like component of this species' repertoire of social behaviors.

CAREGIVING BEHAVIOR Nonhuman primates typically take very good care of their offspring, investing great quantities of time and resources in their young. As with most of the topics in this chapter, much has been learned about all types of caregiving behavior from studies of NHP caregiving.

Offspring of NHP are typically altricial, requiring considerable care from one or both parents (and sometimes additional individuals) during long developmental periods.[86,87] Mothers and fathers differ considerably in their initial investment in offspring, and much has been made of this discrepancy as an explanation for differences in parenting behavior.[88] In general, there is a positive correlation between an NHP male's certainty of paternity and his tendency to engage in paternal behavior.[89] As one example, males of species with typically monogamous mating systems (marmosets), on average, are considerably more paternal than males of species with typically polygamous mating systems (macaques[90]), providing a wide spectrum of potential NHP model species for studies of paternal behavior.

Nonhuman primate parents often rely on caregivers other than themselves to assist in the raising of offspring. Examples of these alloparenting situations include older siblings helping to care for younger siblings in several marmoset species,[91] and aunts and cousins caring for infants in many other species of nonhuman primates.[92–94] Grandparents are relatively infrequent alternate caregivers among NHP.[90] There are even examples of individuals purposely "adopting" and raising unrelated conspecific orphans (at significant costs to themselves and/or their own offspring[95]) or members of other species.[96]

AGGRESSIVE BEHAVIOR The vast array of aggressive, violent, and destructive behaviors of which humans are capable is at times unbelievable, but always of biomedical relevance. Clearly, examples of similar aggressive/violent tendencies exist among species of NHP.[79,80] Natural selection is typically posited as the cause of most aggression in wild populations of NHP, with animals competing with one another over the availability of resources and opportunities to pass their genes on to future generations. Competition among NHP may be aggressive and/or violent, but it is less frequently lethal, and according to evolutionarily based arguments, is rarely performed for "no apparent reason." It is of interest then that rape occurs among orangutans,[97] infanticide occurs in several species,[78,98] chimpanzees engage in war[79,80] and cannibalism,[98] and mother macaques will abuse their infants.[10] Clearly, rape, infanticide, war, cannibalism, and infant abuse are all behaviors that lend themselves to examination in a biomedical research context.

STRESS-RELATED BEHAVIOR AND DOMINANCE STATUS Several aspects of NHP agonistic interactions (dominance and subordinate behaviors) are affected by, and affect, multiple behavior patterns in many social circumstances and are thus relevant to biomedical investigations of behavior. Studies of chronic subordinate status in wild baboons serve as particularly relevant models in this regard. In addition to behaviors indicative of chronic stress, low-ranking male baboons suffer from persistently high levels of glucocorticoids that are frequently associated with a variety of physiological impairments with behavioral implications, including most importantly, death of neurons in the hippocampus.[65,99]

EATING BEHAVIOR Clearly, NHP eat in the wild[100] and in the laboratory.[101] Similarly, given the epidemic of obesity and diabetes that currently plagues many Western societies,[102] eating behavior is of great interest in biomedical research. The consumption of food by NHP has been studied in a variety of contexts, including normal foraging behavior and diet in wild NHP,[100] the effects of calorie restriction on longevity and behavior in captive NHP,[103] and the effects of different "human-like" diets on weight gain, behavior, and a variety of physiological parameters in captive NHP.[17,20,104] From the standpoint of this chapter in this volume, the most relevant body of work focuses on the effects of dietary manipulations (primarily the use of atherogenic diets) on the behavior of adult cynomolgus monkeys;[17,20,105] however there are many other useful NHP models for eating, obesity/diabetes,[104,106,107] and caloric restriction.[103]

EMERGING MODELS/QUESTIONS/FRONTIERS

Noninvasive imaging techniques are likely to increase in importance in studies of behavior in the biomedical research enterprise. Although few fully developed NHP models for use with these techniques currently exist, a number of promising

models are currently under development, including rhesus monkeys for functional magnetic resonance imaging (fMRI)[108] and positron emission tomography (PET),[54,109] chimpanzees for MRI,[110] and marmosets for fMRI.[111]

Monitoring of the visual attention (gaze direction) of NHP is often an important dependent measure in biomedical research. In one of the few prosimian models in biomedicine, a system is currently under development to measure the visual orientation of socially living *Lemur catta*.[112]

CONCLUSIONS

This has been a very brief and very selective review that sought to identify some available and developing NHP behavioral models. The references in this chapter contain data from at least 20 different NHP taxa. A complete treatment of all NHP behavioral research that might be relevant to questions of biomedical interest is simply not possible in a short chapter. Many issues have not been treated, including extremely interesting topics such as NHP social cognition, language, culture, laterality, personality, and emotions,[28–33] and the reader is directed to several recent publications[45–48] for more detailed treatments of these and related topics.

For some behaviors, there is considerable justification for studying the behavior in NHP for its own sake, while for other behaviors, the primary, and perhaps only, justification for studying the behavior is to better understand human behavior. It should be obvious that there are numerous examples of behaviors in NHP that are useful for modeling, predicting, or understanding behaviors relevant to biomedical research investigations. In fact, it is probably difficult to think of a behavior that could not be studied with some face validity in biomedicine using an NHP model. Even many of the most sophisticated (language, learning, culture) and the most abnormal (self-aggression, infant abuse) patterns of behavior can be studied and/or induced in nonhuman primates.

Rhesus monkeys and cynomolgus macaques are the two most commonly utilized NHP models in studies of behavior.[62] While not all behavioral studies are biomedically oriented, the literature cited above suggests that these two species are among the most commonly utilized NHP models in biomedical behavioral research. These medium-sized animals appear to represent a valuable compromise model, retaining many of the most attractive and useful characteristics of NHP as behavioral models while simultaneously demonstrating many of the convenient and utilitarian characteristics required for successful laboratory animal models. While some specialized studies may require more specialized models like marmosets[86,91] or chimpanzees,[71,80,98,110] rhesus and cynomolgus macaques appear to be exceptionally useful models for a variety of types of behavioral research.

30 Primate Models for Understanding Brain Mechanisms of Cognitive Behavior

Ronald E. Kettner, M. Lysetskiy, and M. Suh

ABSTRACT

An approach to understanding cognitive brain function is described for behaviors that are best studied in primates. The approach begins with the development of an experimental paradigm that exhibits important aspects of the cognitive behavior, can be learned by a monkey, and allows quantification and experimental control. Behavioral and neural responses during task performance are then recorded and analyzed. Finally, biologically realistic neural network models of specific brain regions are created that generate appropriate behavioral and neural outputs. This approach is ambitious and depends on the combined efforts of many laboratories, but has a high payoff in providing a mechanistic explanation of cognitive function. To illustrate this approach, we discuss work that seeks to understand the neural basis of predictive control during smooth eye pursuit of visible, as well as imagined, targets in monkeys. This is a cognitive process that facilitates eye tracking based on the prediction of upcoming target motions from memory. Neural recording takes place in the flocculus/paraflocculus regions of the cerebellum and the frontal eye fields of the frontal lobe, regions that are involved in predictive eye pursuit. Mathematical modeling of neural/behavioral processing is done at several levels. Single-neuron-firing models are used to quantify single-neuron responses during task performance in terms of sensory, motor, and cognitive variables. Local-circuit models describe how these neural firing patterns might be processed using local synaptic and intracellular mechanisms. Finally, a neural network model is presented that describes how predictive eye tracking could be generated in the cerebellum.

Key Words: Primate, Monkey, Model, Pursuit, Eye, Neuron, Behavior, Prediction, Cognition.

INTRODUCTION

A primary goal of neuroscience research is the understanding of how brain systems generate cognitive behaviors such as memory, perception, prediction, dance, music, and rational thought at the single-neuron level. In this chapter we describe a multilevel approach to understanding cognitive brain function using a combination of experimental and mathematical modeling techniques. The goal is a mechanistic description of the brain processes that create cognitive behavior. Mechanistic descriptions go beyond simple correlative descriptions that merely point to the involvement of particular brain areas in mental function. They make it possible to understand at a very fundamental level how specific brain areas might produce cognitive performance, how disruptions in this processing might produce mental dysfunction, and how processing can be changed to improve cognition. Mechanistic explanations of how biological systems might produce cognitive performance have also proven useful to computer scientists and engineers who want to create robots and intelligent computer systems with cognitive abilities.

To study a specific cognitive behavior, it is necessary first to develop an experimental paradigm that allows the control and quantification needed for scientific study while still retaining the most important aspects of the behavior. Experimental paradigms are also called animal models, behavioral models, or model systems (see other chapters in this book). In this chapter, which explores behavioral, neural recording, and mathematical approaches to understanding cognition, "model" will refer to mathematical models and "experimental paradigm" will refer to the animal preparation and associated experimental tasks used to study a specific behavior.

We have been interested in the cognitive abilities that underlie predictive behaviors. Real world examples include the quarterback who throws a football to the predicted future location of his receiver, the dancer who moves elegantly and in perfect synchrony with the beat of the music, and the Formula 1 driver who skillfully anticipates a turn in the road before it becomes visible. At a more mechanistic level, predictive motor control allows language production based on a rich variety of internal and external inputs that are not driven by auditory feedback control. Finally, predictive eye movements keep the eye on a target when it moves behind a tree or when it moves along an erratic but remembered trajectory.

Our experimental paradigm for the study of predictive control utilizes macaque monkeys as experimental subjects and experimental tasks that examine eye pursuit along predictable and nonpredictable visual target trajectories. We first train the monkeys to perform pursuit tasks and then characterize this behavior quantitatively using behavioral models. Once trained, single-neuron responses are recorded during task performance.

Our modeling approach strives for biological realism at each processing stage without abandoning the primary goal of developing models of cognitive brain function. We do not follow a strict "bottom-up" approach that requires a complete knowledge of

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.),

low-level function at the cellular level before creating theories of higher-level function at the cognitive level. Nor do we adhere to a strict "top-down" philosophy that builds models of higher-level function with minimal anchoring in empirical data. Instead we use a combination of top-down and bottom-up approaches. Single-neuron and behavioral data provide measures of input, output, and internal signaling that guide the construction and evaluation of our modeling work. The architecture of the neural network model used to generate high-level performance is based on neuroanatomical data. Finally, and perhaps most importantly, the processing performed by the simulated neurons and local neural circuits within the model are biologically reasonable. For example, individual neurons can sum inputs from other neurons but cannot perform a Fourier or Laplace transform on input signals. This construction of higher-level performance from large numbers of units with simple input–output transformations is central to the spirit of the neural network modeling approach to understanding brain function.

THE USE OF MONKEYS TO STUDY COGNITIVE BRAIN PROCESSING

Like many other investigators of cognitive function, our empirical studies utilize macaque monkeys as experimental subjects because they are easily trained to perform a variety of interesting cognitive behaviors that cannot be studied in other animals. Primate investigations also tend to study important motor behaviors that can be studied only in primates. For example, studies of hand and finger movement require primate subjects. Our own work focuses on smooth pursuit eye movements, a class of behaviors unique to primates.

Monkeys also have several methodological advantages for experiments that correlate behavioral performance with single-neuron recording. Monkeys enjoy doing complex tasks for juice reward and once trained perform reliably for several hours while sitting comfortably in a primate chair that maintains their head in a fixed position. This quiet pattern of behavior coupled with neurons that are relatively large in size makes it possible to record from a single neuron for about 1 h while the monkey performs under a variety of test and control conditions.

Although there are obvious concerns about the expense of using monkey subjects, this cost is offset by the fact that a great deal of information can be obtained from each monkey. From 100 to 200 neurons are typically studied in a single monkey during a series of recording sessions lasting a month or more. This means that detailed analyses of a specific brain region generally require only two or three monkeys. This small number of subjects contrasts with other animal studies that use many more subjects. Perhaps most importantly for cognitive studies, the ability to collect large amounts of data from each monkey makes it possible to study cognitive tasks that require months of training. It would not be feasible to train an animal for 3 months and then obtain data during a single test day. Thus, for many types of experiment, primates are the species of choice in terms of cost and efficiency.

Repeated recording sessions across days are made possible by experimental procedures that have become standard in the field. During sterile surgery conducted under deep anesthesia, a recording chamber is surgically implanted over a skull opening that provides access to the brain region of interest. The exposed brain is protected from infection and damage between recording sessions by preserving the membrane that encloses and protects the brain, flooding the chamber with an antibiotic solution, and sealing the chamber with a cap. On the day of an experiment, the chamber cap is removed and a microdrive system is attached to the chamber. This allows accurate positioning of a microelectrode at a specified chamber location. The microelectrode is then slowly lowered into the brain until a stable, single neuron is encountered. At this time, the monkey is allowed to perform in one or more tasks while action potential events are recorded from the isolated neuron. This process is repeated for other neurons until the monkey indicates that he wants to go back to his cage. This generally occurs when the monkey has had his fill of juice.

BEHAVIORAL PARADIGMS FOR STUDYING PREDICTIVE EYE PURSUIT

In the laboratory setting, several experimental paradigms have been developed to study predictive eye movements.[1–3] Perhaps the simplest requires the subject to track a target that moves back and forth at a fixed sinusoidal amplitude and frequency. Subjects quickly lock onto the target so that the lag between eye and target is essentially zero. This result cannot be explained by direct visual control because the brain processes visual information with a delay of ~100 msec. That is, if direct visual control were the only resource available to the primate there would be a 100-msec delay between eye and target during sinusoidal pursuit, a delay that is not observed. To produce the performance that is actually observed, the brain must utilize cognitive processes that predict changes in target motion well before information about these changes can be processed by the visual system.

Our first behavioral studies[4,5] demonstrated that predictive control was more complex than previously thought: it could also be used to generate accurate eye pursuit along more complex sum-of-sines trajectories. Figure 30–1A illustrates this result using a sum-of-sines task that required tracking of a trajectory created by combining two sinusoidal motions with different frequencies along horizontal and vertical axes. Notice that repeated cycles of eye pursuit (thin lines) were relatively accurate, albeit with some variability about the target trajectory (thick lines). In particular, changes in eye direction were well timed with little overshoot following relatively abrupt changes in target motion. The use of predictive control was indicated by quantitative measurements that showed a delay between eye and target of essentially zero, far better than would have been possible using visual inputs processed with a 100-msec delay on this and a variety of other complex trajectories.

Our next studies[5–7] utilized half-circle trajectories that are less complex than sum-of-sines trajectories but more demanding in requiring right angle changes in the pursuit direction. The abrupt changes in target direction also facilitate the viewing and measurement of pursuit delays. For example, Figure 30–1B shows eye tracking performance during the random-half-circle task where the half-circle trajectory is presented randomly on 25% of cycles intermixed with circle trajectories on the remaining 75% of cycles. As expected, a consistent overshoot was observed on the cycles that contained the half-circle perturbation because its occurrence was unpredictable. The system had to rely on visual information about changes in target direction that was processed with a 100-msec delay. This idea was supported by quantitative analyses that indicated an average lag of 95 msec following the top right angle transition.

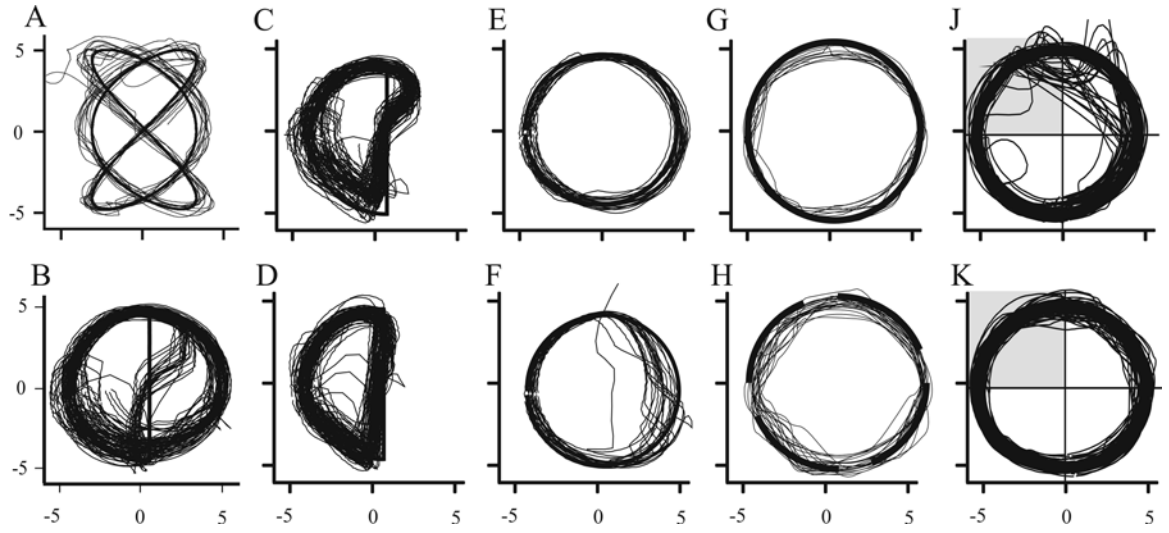

Figure 30–1. Behavioral results during (A) the sum-of-sines task, (B) the random-half-circle task, (C, D) the repeated-half-circle task before and after training, (E, F) the circle task before and after training in the repeated-half-circle task, (G, H) the circle task versus the circle-with-four-gaps task, and (J, K) the circle-with-random-gaps task before and after training. Thin lines represent multiple cycles of eye pursuit along a target trajectory indicated by thicker lines. Axes indicate eye position in degrees.

To see whether predictive control could be used to improve performance on this demanding half-circle trajectory, its occurrence was made highly predictable by presenting it on every cycle in the repeated-half-circle task.[6,7] As expected, overshoot errors were initially observed (Figure 30–1C). However, after several hundred repeated presentations a highly accurate pursuit profile developed (Figure 30–1D). This repeated presentation schedule allowed the monkey to utilize predictive control that appropriately decelerated his eye in anticipation of the top change in target direction. Deceleration occurred well before visual information about the change in target direction became available. Interestingly, the ability to use predictive control during the repeated-half-circle task develops rather slowly across hundreds of repeated cycles. This suggests that predictive control in this task results from permanent alterations in the brain pursuit systems. This idea was verified by the presence of aftereffect errors in comparisons of circle tracking before (Figure 30–1E) and after (Figure 30–1F) training. Notice that after training the eye consistently decelerated at the top to the circle in anticipation of the expected right angle change in direction. These aftereffect errors continued for hundreds of cycles.

Other behavioral paradigms developed for the study of nonvisual predictive control turn the target off briefly during ongoing pursuit.[8–13] In these "gap" tasks the subject is required to maintain pursuit when the target goes off. It is argued that any pursuit during target gaps cannot result from direct visual drive, but must instead result from predictive signals that maintain target motion in the absence of a visual target. In short 100-msec target gaps during linear pursuit, the eye continues to move with little reduction in ongoing velocity.[8] Here the level of required predictive control is relatively simple: the maintenance of ongoing eye speed and direction. We extended this result using a circle-with-four-gaps task that introduces four gaps (of either 100 or 200 msec) at constant positions along a repeated circle trajectory.[14] The monkey subjects showed good pursuit continuation during circle trajectories both with (Figure 30–1G) and without (Figure 30–1H) target gaps under conditions that required the prediction of a target that was continually changing direction.

When the duration of a target gap is increased beyond 100 msec during linear target pursuit declines in pursuit velocity are observed at about 200 msec, although some residual eye velocity is maintained.[9] This result is based on task conditions designed to make the time and duration of gap events unpredictable. We have extended these studies using a circle-with-random-gaps task that turned the target off on random cycles of circle pursuit but always during the same 312-msec period in the upper left quadrant of the circle trajectory.[15,16] Our goal was to study pursuit during longer gap periods for a trajectory that constantly changed direction and thereby put higher demands on a predictive controller. In these experiments, the monkeys initially did quite badly (Figure 30–1J) showing severe declines in pursuit ~100 msec after the target light was switched off. When the target reappeared, a large catch-up saccade was then generated after ~200 msec that pulled the eye back on target. Both results are what would be expected based on past experiments. A new finding (Figure 30–1K) was that performance during these longer gaps improved markedly with extended training, indicating the presence of predictive pursuit during these longer gap periods.

NEURAL PARADIGMS FOR STUDYING PREDICTIVE EYE PURSUIT

Studies of smooth eye pursuit have focused on three brain regions: the flocculus and ventral paraflocculus of the cerebellum, the frontal eye field of the frontal neocortex, and the superior colliculus. Their involvement in smooth eye pursuit has been established by a number of recording, stimulation, and lesion studies.[17–34] Other brain sites are also likely to be involved and deserve further study including the middle-temporal, middle-superior-temporal, lateral-intraparietal, and supplementary-eye-field regions of the neocortex.[1,8,17] The contribution of brain systems closer to motor output or sensory input are less likely involved in higher-level predictive processing, but their

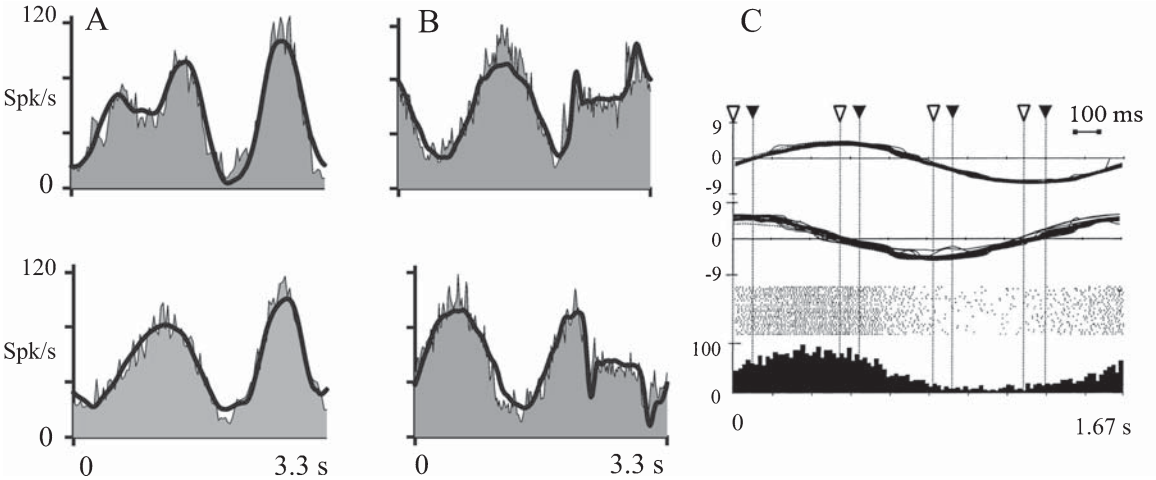

Figure 30–2. Cerebellar neural responses during (A) the sum-of-sines task, (B) the random-half-circle task, and (C) the circle-with-four-gaps task. In (A) and (B), the gray histogram represents averaged neural responses and the dark line indicates fits of the eye-motion model to the data. (C) Horizontal and vertical eye positions are shown at the top and neural raster and average neural response data at the bottom. Vertical lines indicate the start and stop of the 100-msec gap periods.

contribution needs to be studied to understand the complete system.

One approach that we have used to understand the brain mechanisms of predictive pursuit is to record from single neurons while a monkey performs behavioral tasks designed to contrast predictive versus nonpredictive control. For example, in studies of the cerebellum[14] we recorded activity from single neurons during performance in both the sum-of-sines task (see Figure 30–2A) and in the random-half-circle tasks (see Figure 30–2B) to contrast responses related to predictive and nonpredictive pursuit, respectively. Our analyses produced two important results. First, these cerebellar regions are most directly involved in predictive control and only secondarily involved in nonpredictive control. Second, predictive control is derived from nonvisual signals.

Evidence for predictive control in the cerebellar flocculus and ventral paraflocculus was based on a timing analysis that compared changes in neural firing to changes in eye movement. Put briefly, we found that average neural responses led eye motion by 3 msec during predictive pursuit in the sum-of-sines task, but lagged eye motion by 7 msec during nonpredictive pursuit in the random-half-circle task. Because activity in brain areas responsible for generating pursuit must lead eye motion while those playing a follow-up role will show response lags, we concluded that the cerebellar flocculus and ventral paraflocculus were more strongly involved in generating predictive pursuit than in generating nonpredictive pursuit.

Our second finding was that predictive processing was based on nonvisual input. During performance in the circle-with-four-gaps task designed specifically to test for the presence of visual input, no modulation in firing rate was observed when the target was turned on and off (see Figure 30–2C). Any system involved in direct visual control should have shown some response to these dramatic on–off changes in visual input. An absence of visual drive was also shown using the modeling analyses described in the next section. These analyses showed strong correlations with eye movement and negligible influence from retinal-slip inputs during the sum-of-sines, random-half-circle, and circle-with-four-gaps tasks. This result is particularly compelling for data obtained from the random-half-circle task that generated reliable periods of visual input when the target image on the retina was moved away from the fovea following unexpected right angle changes in target direction.

MATHEMATICAL MODELING OF SINGLE-NEURON FIRING PATTERNS

Our modeling work begins with the quantitative modeling of single-neuron responses. This is important for our later models that must be supplied with appropriate inputs. A standard approach to modeling neural responses with multilinear equations is used.[25,27,35,36] We model two types of neural response: the first related to eye motion input and the second related to visual input variables.

The eye-motion firing-rate model defines the neural firing rate due to eye motion, $R_M(t)$, by the following equation:

$$R_M(t) = b_M + \mathbf{e}_P \cdot \mathbf{E}_P(t) + \mathbf{e}_V \cdot \mathbf{E}_V(t) \qquad (30\text{–}1)$$

It states that at a given time, t, the firing rate of a neuron can be determined by adding a baseline firing rate, b_M, to weighted influences due to eye position, $\mathbf{E}_P(t)$, and eye velocity, $\mathbf{E}_V(t)$. The weights are constants that define sensitivities to eye position, $\mathbf{e}_P$, and eye velocity, $\mathbf{e}_V$. In all instances, bold letters indicate vectors and their multiplication is by the dot product. In this vector formulation the length and direction of the sensitivity vector define the magnitude and direction of the variable it specifies. This equation is often reexpressed in terms of x and y components. For example, $\mathbf{e}_P \cdot \mathbf{E}_P(t) = e_{PX} E_{PX} + e_{PY} E_{PY}$ based on the dot product operation on $\mathbf{e}_P = (e_{PX}, e_{PY})$ and $\mathbf{E}_P = (E_{PX}, E_{PY})$.

The dark lines in Figure 30–2A and B show the excellent fits provided by the eye-motion model for cerebellar responses during performance in the sum-of-sines and random-half-circle tasks. Further support is provided in Figure 30–3A and B by model descriptions of frontal-eye-field neurons during a circles task that alternates six cycles of CW (clockwise) pursuit with six cycles of CCW (counterclockwise) pursuit.[34] Interestingly, the neuron shown in Figure 30–3B fired more strongly during CCW cycles, a result obtained when position and velocity sensitivity vectors

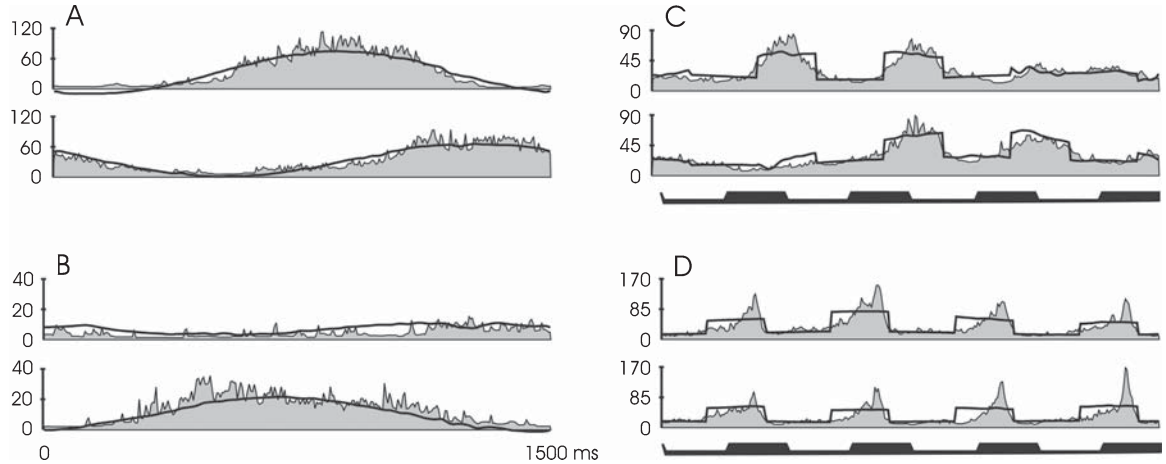

Figure 30–3. Comparisons between model fits (thick lines) and average firing rate (thin lines) for four single neurons recorded from the frontal eye field. (A, B) Responses during the circle task. (C, D) Responses during the circle-with-four-gaps task. Target on times are indicated by bars. In each panel, the top and bottom plots show CW and CCW pursuit along a circle of radius 5°, a period of 1500 msec, and a tangential velocity of 20.9°/sec.

point in different directions. Rotation-specific neurons were also observed in our cerebellar studies.[27]

The visual-input firing-rate model defines the neural firing rate due to visual input, $R_V(t)$, by the following equation:

$$R_V(t) = L(t)\ [b_V + R_S(t) + R_G(t)] \qquad (30–2)$$

Because visual input is defined only when the target light is on, its contribution to firing rate is modulated by the variable, $L(t)$, which depends on the intensity of the target light. Here, it is defined to be one when the light is on and zero otherwise. Thus, the baseline value, b_V, indicates the average increase in firing rate due to the presence to the target light. Variations in neural firing rate result from two factors.

The first factor, $R_S(t)$, defines changes in visual input that result from movement of the target image on the retina:

$$R_S(t) = \mathbf{s}_P \cdot \mathbf{S}_P(t) + \mathbf{s}_V \cdot \mathbf{S}_V(t) \qquad (30–3)$$

Although slip position, $\mathbf{S}_P(t)$, cannot be measured directly, it can be computed by subtracting eye position from target position, $\mathbf{T}_P(t)$, using the equation $\mathbf{S}_P(t) = \mathbf{E}_p(t) - \mathbf{T}_P(t)$. Slip velocity, $\mathbf{S}_V(t)$, is defined similarly.

A second factor, $R_G(t)$, defines gain-field changes in visual input due to eye motion:

$$R_G(t) = \mathbf{g}_P \cdot \mathbf{E}_P(t) + \mathbf{g}_V \cdot \mathbf{E}_V(t) \qquad (30–4)$$

Several investigators have reported visual responses that vary with the position of the eye and have described these results in terms of gain fields. In our work, we have found it useful to extend this idea to include an additional dependence on eye velocity.

The addition of the eye-motion and visual-input firing-rate models produces the total firing-rate model that defines the total firing rate, $R_{Total}(t)$, using the following equation:

$$R_{Total}(t) = R_M(t + \Delta_M) + R_V(t + \Delta_V) \qquad (30–5)$$

Here we have introduced two delay constants: a movement delay, Δ_M, and a visual delay, Δ_V. Estimates of the movement delay allow us to determine whether neural activity leads or lags eye motion. As noted in the previous section, leads and lags are important criteria for determining whether a brain area is creating a behavior (response lead) or simply monitoring a behavior after it has been created elsewhere in the brain (response lag). The visual delay is needed to compensate for observed delays in visual processing of ~100 msec during visual pursuit tasks. Both delay terms can be used to identify cognitive events that precede motor and visual signals and therefore cannot be explained by these signals.

The total firing-rate model makes it possible to quantify the relative contributions of movement and visual variables in terms of both magnitude and preferred direction. Figure 30–3C and D shows fits of the total firing-rate model for two frontal-eye-field neurons during the circle-with-four-gaps task.[34] One neuron (Figure 30–3C) shows responses related to a combination of eye-motion and visual-input variables as indicated by modulation during both target-on and target-off periods. Responses from another neuron (Figure 30–3D) show a stronger reliance on visual input with minimal variation in firing when the target was off. Interestingly, the responses related to visual input began before the target turned on. Thus, they reflect cognitive processes that anticipate the appearance of the target in the absence of direct visual drive and that could be useful in predictive control.

LOCAL-CIRCUIT MODELS

Sometimes information key to the creation of a systems-level model is not available. For example, it has proven difficult to record from cerebellar granule cells in performing monkeys because of their small size. Neuroscientists have also made slow progress in studying the synaptic mechanisms of learning because intracellular recordings are difficult to maintain during the course of learning in behaving animals. Because of these difficulties, modelers sometimes make hypotheses about the nature of missing information. This is a useful approach that produces testable model predictions that can be evaluated experimentally.

A more direct approach is to use local-circuit models to generate the needed information from data that are available. For

example, we use local-circuit models to generate granule cell responses that are difficult to study in behaving monkeys using the mossy-fiber data that are available. Another local-circuit model is used to describe changes in the efficacy of parallel-fiber-to-Purkinje-cell synapses during learning. Local-circuit models are based on cellular-level information that describes the anatomical, electrical, and chemical characteristics of a small group of interconnected neurons. Their implementation is facilitated by computer programs (e.g., NEURON, GENESIS) that provide a standard framework to which the cellular modeler can add electrophysiological and neurochemical response data specific to the local circuit being modeled. The primary use of this type of modeling has been to explain intracellular responses to simple electrical or chemical inputs. However, there is increasing interest in using cellular models to study responses to more realistic input streams.

Thus, local-circuit models allow systems-level models to benefit from the very large base of information available from "reduced preparations." For instance, the "slice" preparation has revolutionized neuroscience by providing the access and stability required for intracellular recording using patch-clamp, sharp-electrode, and imaging techniques, as well as the controlled study of responses elicited by intracellular current injection, extracellular stimulation of axonal and dendritic inputs, and the application of chemical agents. Of course, slice experiments necessarily eliminate much of the brain circuitry and input at play in intact organisms. Thus, they have been most useful for the analysis of specific channels and/or receptor subtypes. However, the use of this information to simulate natural conditions using local-circuit models provides an important bridge between these highly specialized cellular experiments and systems-level analyses. From a philosophical point of view, the use of local-circuit models to facilitate systems-level modeling represents an elegant combination of top-down and bottom-up approaches to understanding and modeling brain function.

CEREBELLAR LOCAL-CIRCUIT MODELS

To illustrate the use of local-circuit models we first describe a model of the cerebellar glomerulus that has been developed by Dr. Lysetskiy and its use in creating a local-circuit model that implements onset detection in our network model. His analyses indicate that local processing within the glomerulus produces granule cell activation only during the initial few milliseconds of a sustained mossy-fiber input. This onset-response transformation greatly reduces the fraction of active granule cells at any given time relative to the fraction of active mossy-fiber inputs. At the systems level, the result is a sparser coding of eye motion information within the granule cell population as compared with the highly overlapping coding of eye motion information observed experimentally for the mossy-fiber population. The importance of this sparse recoding will be discussed in the context of our neural network model of the cerebellum.

The glomerular model is shown schematically in Figure 30–4. It models synaptic interactions among the triad of neural processes within each cerebellar glomerulus: mossy-fiber input, Golgi-dendrite input, and granule-dendrite output. The model was developed in the NEURON modeling environment by constructing the glomerular triad and inserting into each neural process the large number of membrane-channel and receptor properties that have been described in the cellular literature (e.g., D'Angelo *et al.*[37]). A primary finding was the production of a phasic burst of granule cell action potentials (upper-left graph) in response to a

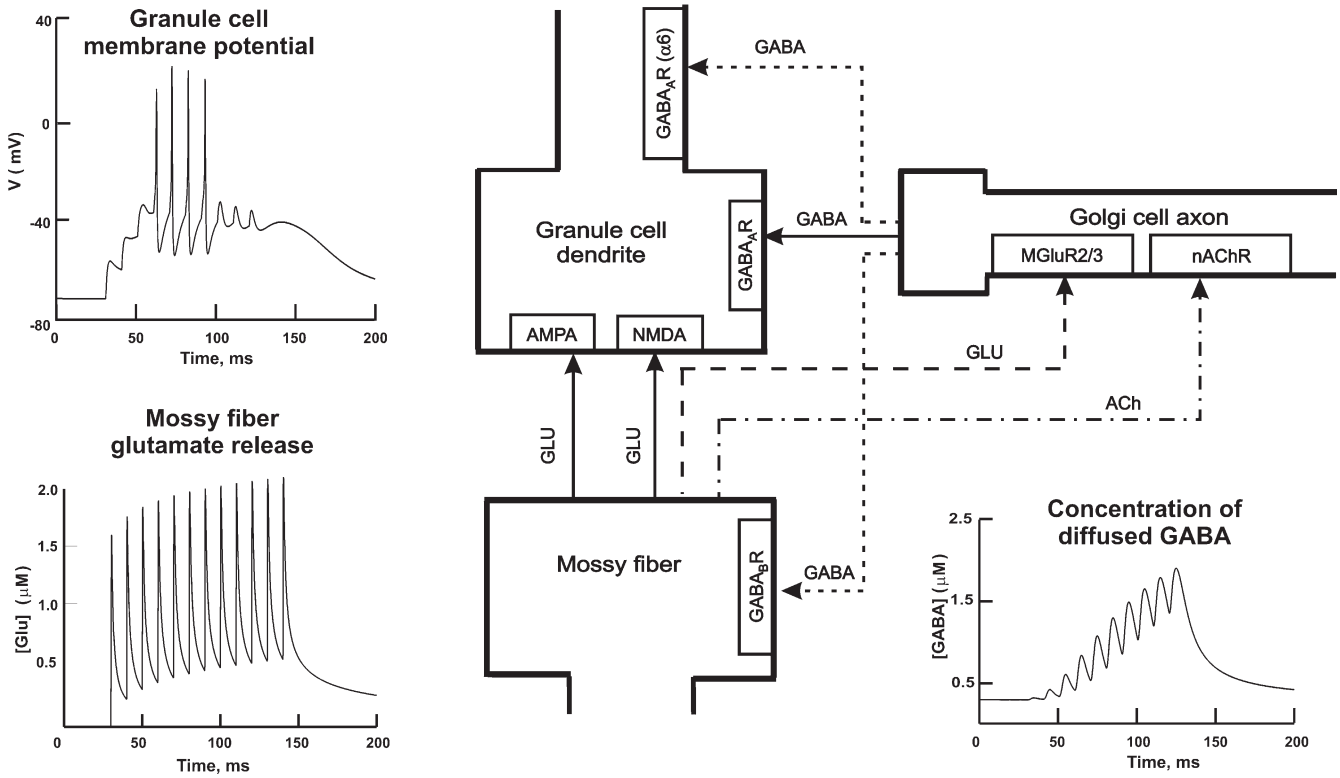

Figure 30–4. Local-circuit model of the cerebellar glomerulus. See the text for additional details.

sustained pattern of mossy-fiber glutamate release (lower-left graph). The on phase of the response was generated by the expected direct activation of sodium channels via activation of glutamate receptors. The off phase was more surprising. It resulted from several factors that acted in combination including sustained inactivation of spike-generating sodium currents, membrane hyperpolarization induced by slow (I_M like) potassium currents, and increased inhibition due to accumulated GABA (lower-right graph). The idea that granule cells might produce phasic responses also has initial support from empirical studies that show burst responses under some conditions.[37]

Another important local-circuit model implements a coincidence-detection mechanism that further refines the mossy-fiber input signal at the granule cell soma. Put simply, more than one dendritic input to a granule cell must be active simultaneously before an action-potential output is generated. This model is motivated by slice experiments[38] that indicate that granule cells show no spontaneous firing and require more than one input pulse in close temporal proximity before an action potential is generated. Because glomerular processing causes individual dendrites to generate a single onset burst in response to mossy-fiber input, it is likely that more than one dendrite must be active at any given time before an action potential is generated at the granule cell soma. This coincidence detection is implemented by a local-circuit model that limits the maximum contribution of each dendritic input to the membrane potential at the granule cell soma so that more than one input must be active before action-potential generation can occur. At the system level, this coincidence detection mechanism further enhances sparse coding and the computational capacity of our neural network model.

A final local-circuit model specifies the synaptic learning rule that we use to modify the influence of parallel-fiber axons on Purkinje cell dendrites. Granule cell axons ascend and then bifurcate to form parallel fibers that innervate Purkinje cell dendrites. Plasticity at the parallel-fiber-to-Purkinje-dendrite synapse has been studied extensively in slice preparations.[39–43] Initial studies focused on conditions that cause a long-term depression (LTD) of synaptic strength, but more recent studies have established additional conditions that produce long-term potentiation (LTP) of the same synapse. This dual mechanism is important for the training of our neural network. Without the ability to drive synaptic strength both up and down, a synapse that becomes too strong cannot be pulled back to an appropriate level. A simple learning rule based on the combined occurrence of recent parallel-fiber activation and climbing-fiber input allows our cerebellar network model to learn.

BIOLOGICALLY REALISTIC NEURAL NETWORK MODELS

Several central concepts distinguish biologically realistic neural network models from other brain models. First, neural networks contain a large number of computational units. The original idea was to mimic the large number of neurons observed experimentally in brain systems. For example, our cerebellar models utilize from 10,000 to 40,000 computational units depending on the pursuit accuracy that is required. Over time, network research has indicated the advantages associated with processors with large numbers of units computing in parallel: they are faster than serial processors and are better able to handle the large number of sensory and feedback signals received by real brain systems. Thus, evolution has increased the size of the primate brain for important reasons.

A second guiding idea used in the construction of neural network models is that each unit performs a relatively simple computation. Again, the original idea was to mimic biological neurons that were then assumed to perform relatively simple computations. This computation has most frequently been the weighted summation of inputs coupled with a "squashing function" that smoothly limits output levels. Later, slightly more complex operations involving multiplication and spiking events have also been used. The simplicity of the unit computations in network models is in sharp contrast to the complexity of unit computations in models containing only a handful of interconnected units. The units in these models are sometimes labeled "black boxes" to indicate the complexity of the operations they perform and a lack of interest in understanding the mechanisms that create this complexity. For those interested in brain mechanisms, these black box models are unappealing. However, they can prove useful for dissecting a complex process into subprocesses.

A third guiding principal is that the computational unit is often the synapse. This principle acknowledges the fact that simple operations beyond the simple multiplication of input by a synaptic weight can sometimes occur. For example, the glomerular transformation at the mossy-to-granule synapse results in the conversion of a sustained input into a phasic output. This principle implies that relatively complex operations are performed by neurons that receive thousands of synaptic inputs and that less complex operations are performed by neurons with only a few synaptic contacts. In the cerebellar model described below, two Purkinje units perform predictive control by driving horizontal and vertical eye muscles respectively. These complex operations arise from the convergence on each Purkinje cell of more than 5000 synaptic inputs from parallel fibers. In contrast, each granule cell performs a relatively simple coincidence detection operation based on input from four dendrites.

A final defining concept is that a biologically realistic neural network model should be constrained by neural data. This is not the same as saying that such a model needs to be a simple, bottom-up reconstruction of a brain system. This is a very tedious exercise that produces a result that is already known: that the complete system can generate responses observed experimentally. Rather, the goal of the modeler is to help us understand how a brain system works by creating a simpler version of the system that retains biologically realistic connectivity and processing. One simplifying idea is that brain systems consist of thousands of nearly identical modules each consisting of a few cells. It is then possible to understand the larger system by understanding processing within a module. Another useful approach is the deletion of neural elements that are not needed for the generation of a particular function. Here it is presumed that these discarded elements are used only to refine the processing of the simple model. It is also possible that excluded elements play their role in other functions performed by the network.

Of course there are differences in opinion regarding how schematic a model can become before it stops being useful to biologists. For this reason there has been a split between those interested in creating biologically realistic neural network models and others interested in computational networks without the constraints required for realistic biological modeling. The result is a healthy

and synergistic interaction between two perspectives that facilitates a common goal of understanding complex, highly parallel, computational systems in multiple contexts. That said, we place ourselves in the group interested in using neural networks to understand brain function.

A NEURAL NETWORK MODEL OF CEREBELLAR PREDICTIVE CONTROL

A neural network model will now be described that puts these pieces together to provide a mechanistic explanation of how the cerebellum could generate predictive smooth eye pursuit. It benefits from a variety of other approaches to cerebellar modeling.[44–48] A schematic diagram of the model's architecture is shown in Figure 30–5. It follows well-established anatomical connections between the primary neural elements in the model, although the precise anatomical positioning of these neural elements has been altered. For example, the exit direction for Purkinje cell axons has been reversed to allow a more orderly left-to-right presentation of information flow through the model. The number of neural elements is also underrepresented: the model contains 240 mossy fibers and 7200 granule cells that provide input to two Purkinje cells and one Golgi cell.

Mossy fibers entering the cerebellum at the left of the diagram provide the primary input to the model. Their signals are then processed within cerebellar glomeruli before activating multiple granule cells. Each granule cell, in turn, receives input from multiple glomeruli. This produces an expansive recoding of the mossy-fiber population into a much larger granule cell population with a more diverse pattern of activation. Granule cell axons then travel to the molecular layer where they bifurcate at right angles to form the parallel fibers. The Golgi cell also receives input from parallel fibers and in turn influences granule cell responses within the glomeruli.

Purkinje cells provide the sole output for the cerebellar model. They receive their primary input from parallel fibers and climbing fibers that arise from the inferior olivary nucleus. The climbing fibers provide a training signal[24,49,50] that is used to modify the strength of parallel-to-Purkinje synapses using the biologically based learning rule described above. The Purkinje cells provide predictive output that activates a well-established system of brainstem nuclei that further process the signal before activating eye muscles. A rudimentary model of saccadic generation and a visual-pursuit model based on existing pursuit models[51–53] have been included to complete the model environment. They are needed in the initial training of the cerebellar network and to provide contrasts between what is expected from visual control alone and what can be achieved with the addition of predictive signals.

Figure 30–6A and C shows the excellent performance of the model during sum-of-sines and circle pursuit. Figure 30–6B and D shows the much poorer levels of performance observed without predictive control using only delayed visual control. The jagged appearance of the pursuit results from a saccade generator that pulls the eye back on target at intermittent times that never exceed the saccade refractory time of ~200 msec. Between saccades, the eye continues the pursuit, but in the wrong direction, based on information about the direction of target motion that is delayed by 100 msec. Figure 30–6E shows how the sparse activation of the granule cell population provides a good representation of eye position at the top of the circle trajectory. Figure 30–6F shows the much broader pattern of activation across the granule cell population that would have been observed without the local-circuit refinements that produce sparse recoding. Without this sparse representation the model is unable to learn predictive tracking.

Put simply, the model creates predictive pursuit at a given point along a predictable trajectory by using the currently active subpopulation of granule cells to drive Purkinje cells in a fashion that generates correct eye motion at that position. This drive varies as first one subpopulation of granule cells and then another subpopulation is activated along the trajectory so that a changing drive signal is created across the entire trajectory. This process requires the sparse coding of trajectory location by the granule cell population. Otherwise it would be impossible to assign the unique drive pattern required at each point along the trajectory. Put another way, the network model creates predictive eye pursuit by using the active granule cell subpopulation to retrieve

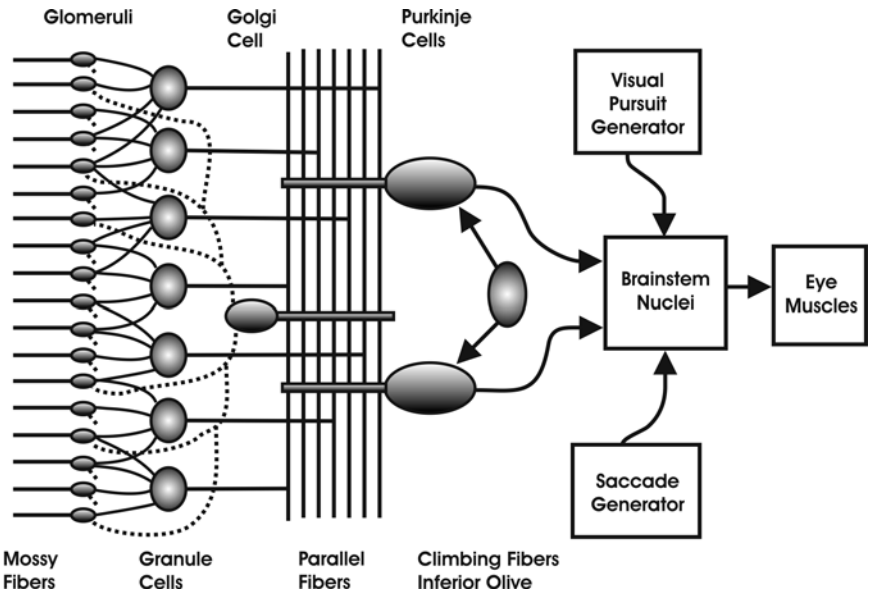

Figure 30–5. Architecture of the neural network model of the cerebellum described. Although Golgi cell axons innervate each glomerulus, these connections are indicated in complete detail for only a subset of glomeruli. See the text for additional details.

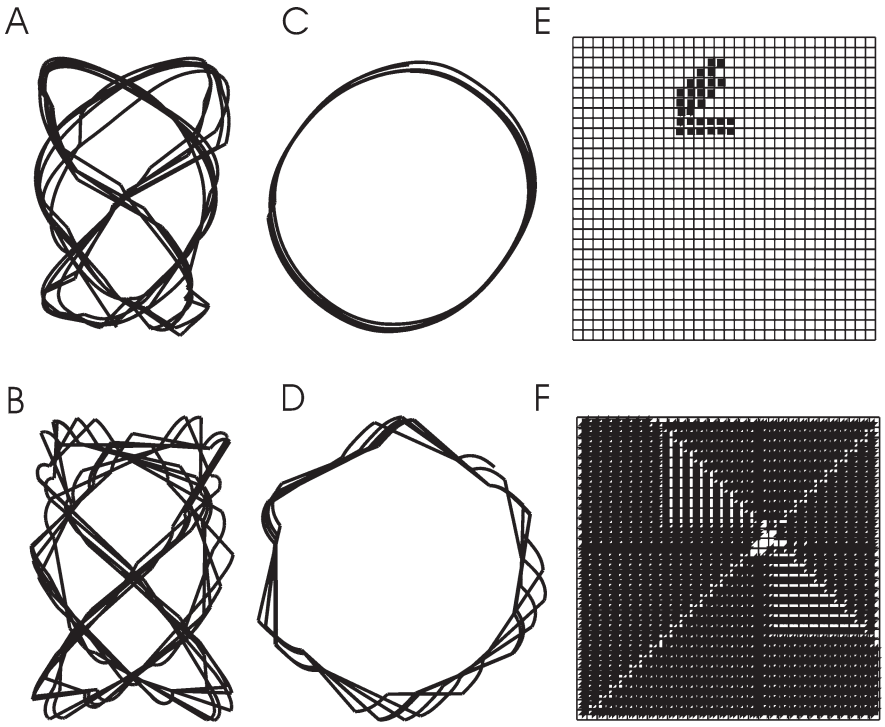

Figure 30–6. Neural network processing. (A, B) Eye movements during sum-of-sines pursuit with and without predictive control. (C, D) Eye movements during circular pursuit with and without predictive control. (E, F) Activation of the granule cell population of 7200 units with and without sparse coding. Each of the 900 boxes corresponds to a specific eye position and contains eight granule cells with different preferred directions. In the top panel, cells in black indicate the granule cell subpopulation active when the eye is at the top of the circle trajectory. The bottom panel shows that most of the population is active when the glomerular onset-detection mechanism is turned off at the same top eye position.

remembered control information stored by granule-to-Purkinje synapses. Importantly, the model does not rely on visual input because the mossy-fiber population is activated exclusively by signals related to eye motion.

CONCLUSIONS

This chapter describes how monkeys are used to study the neural mechanisms of cognitive processing. The approach is multipronged using information from behavioral studies that test the limits of cognitive performance in primates, neural recording studies that examine brain responses in performing monkeys, and modeling studies that attempt to pull this information together in a biologically realistic fashion. Examples of this approach are presented based on our own work that seeks to understand the cognitive processing that results in predictive control. We first present evidence that predictive processing is used by monkey subjects during eye pursuit in a variety of experimental tasks. Single-neuron recording experiments indicate that the cerebellum and frontal eye fields show responses correlated with predictive control. Finally, a biologically realistic neural network model is presented that generates predictive control and explains the experimental data.

IV Models for Specific Purposes

A Visual and Auditory Disease

31 Animal Models for Eye Diseases and Therapeutics

Takeshi Iwata and Stanislav Tomarev

ABSTRACT

It is believed that more than 80% of the information our brain receives comes from the visual system. Dysfunction of the visual system can significantly lower the quality of life. The most prevalent causes of visual impairment are cataracts, glaucoma, and age-related macular degeneration (AMD), which are responsible for 69% of blindness globally. In spite of the high incidence of AMD and glaucoma, a limited amount of information is available on the underlying pathological mechanisms causing these diseases. Because experimental studies of AMD and glaucoma are limited in humans, the availability of animal models is very valuable to investigate molecular mechanisms and to test new therapeutic interventions. Appropriate animal models, such as monkey, mouse, rat, and zebrafish, facilitate the identification of new genes involved in the pathology and elucidate the genetic relationships between causative and modifier genes. In this chapter the advantages and difficulties of using animal models for vision research will be discussed. Several animal models including a primate model with defined macula for AMD research and genetically modified mice models for glaucoma research will be introduced.

Key Words: Vision, Age-related macular degeneration, Retina, Macula, Drusen, Glaucoma, Retinal ganglion cells, Optic nerve.

VISUAL IMPAIRMENT AND IMPORTANCE OF ANIMAL MODELS FOR EYE DISEASES

It is believed that more than 80% of the information our brain receives comes from the visual system. Dysfunction of the visual system can alter the normal human life style and significantly lower the quality of life. The causes of visual impairments and blindness vary among ethnic groups and the global regions where they live. There are many causes of visual impairments including diabetic complications, infections, and trauma; however the most prevalent causes of visual impairment are cataracts, glaucoma, and AMD. According to the World Health Organization, there were more than 161 million visually impaired individuals in 2002; 124 million of this group had low vision and 37 million were blind (http://www.who.int/mediacentre/factsheets/fs282/en/index.html) (Figure 31–1).

Cataract, glaucoma, and AMD are responsible for 69% of blindness globally. Although cataracts are the leading cause of blindness worldwide, recent advances in cataract surgery have significantly reduced the visual impairments caused by cataracts, especially in developed countries. Glaucoma, an optic neuropathy, is often associated with elevated intraocular pressure and is responsible for blindness in 6.7 million people across the world. Glaucoma is more common in individuals of African ancestry, and the incidence of glaucoma increases with age.

The most prevalent eye disease for elderly Europeans and Americans is AMD. This degenerative disease progresses from retinal deposits called drusen to neovascularization and retinal hemorrhages resulting in irreversible loss of central vision.

In spite of the high incidence of AMD and glaucoma, a limited amount of information is available on the underlying pathological mechanisms causing these diseases. Obtaining tissues for any disease is often difficult, and even when obtained, they may not be informative because the tissues are usually collected many hours or even days after death. Because experimental studies of AMD and glaucoma are limited in humans, the availability of animal models is very valuable because they can be used to investigate the molecular mechanisms causing these diseases and to test new therapeutic interventions. Animal models, compared to other experimental methods, e.g., cell and organ cultures or postmortem models, allow the study of different pathological factors and therapeutic treatments under *in vivo* conditions, i.e., with the visual and other systems of the body intact. Appropriate animal models, e.g., monkey, mouse, and zebrafish, also facilitate the identification of new genes involved in the pathology as well as elucidate the genetic relationships between causative and modifier genes. Equally important, specific genes can be altered in these models. Thus, it is possible to induce mutations in animals, and then search for specific phenotypes, e.g., abnormal intraocular pressure (IOP) and retinal ganglion cell degeneration. Subsequently, the affected genes can be identified by standard genetic procedures.

Many animal models of AMD and glaucoma have been developed in different mammalian and nonmammalian species. None of these models is a perfect reproduction of the human disease, and when choosing the animal model for research, the investigator should evaluate the following: (1) the similarity of the visual system of the model to that of humans, especially the eye; (2) the similarity of the time course of pathological changes in the model and in human eyes; (3) the ability to perform genetic manipulations; (4) the training required to produce affected animals; (5) the size of the eye; (6) the availability and difficulties in the

methods of analysis; (7) the availability of animals; and (8) the cost.

AGE-RELATED MACULAR DEGENERATION

INTRODUCTION The retina is composed of nine layers of neural and glial cells that are arranged concentrically at the posterior pole of the eye. Incoming light is focused on the central area of the retina called the fovea, which is located in the center of the macular area (Figure 31–2). In humans, the size of the macula is approximately 6 mm in diameter (Figure 31–3). The outer (posterior) surface of the retina is covered by a monolayer of retinal pigment epithelial (RPE) cells that forms a diffusion barrier between the neural retina and the choroidal blood supply. The RPE regulates the transport of proteins to the retina and controls the hydration and ionic composition of the subretinal space. The physiological condition of the RPE is closely associated with the pathogenesis of AMD.

AMD is a blinding disorder characterized by a marked decrease in central vision associated with RPE atrophy with or without choroidal neovascularization (CNV). Many factors, including genetic, behavioral, and environmental, are involved in this disease. AMD is characterized by the degeneration of cone photoreceptors in the foveal region of the retina resulting in a decrease of central visual acuity. The progressive impairment of the RPE cells and damage to Bruch's membrane and choriocapillaris results in retinal atrophy and photoreceptor dysfunction. In some cases, CNV develops, and the new vessels penetrate Bruch's membrane and pass into the subretinal space.

Two types of AMD are recognized: the nonneovascular type is called the dry-type AMD and includes more than 80% of the cases; the neovascular type is called the wet-type AMD and it is progressive with a higher probability of blindness. The prevalence of AMD differs considerably among the different ethnic groups, but the incidence increases with age in all groups. A lower prevalence of AMD has been reported in individuals of African ancestry than of Anglo-Saxon ancestry. Other risk factors for AMD are cigarette smoking, obesity, hypertension, and atherosclerosis.

EPIDEMIOLOGY AND GENETICS Extensive epidemiological studies have shown a genetic component for AMD. Thus, twin studies have shown a higher concordance for AMD in monozygotic twins than in dizygotic twins.[1–3] In addition, first-degree relatives of individuals with AMD have a 2- to 4-fold higher incidence of AMD than individuals without a family history of AMD. Genetic segregation studies have also shown a genetic effect that accounts for approximately 60% of AMD with a single major gene accounting for about 55% of the risk of developing

AMD. Overall, the data have suggested that the etiology of AMD has a significant genetic component. Only a small proportion of the families with AMD shows Mendelian inheritance, and the majority of the individuals inherit AMD in a complex multigene pattern.

There have been a number of attempts to identify the genes that cause AMD. With the help of the haplotype marker project (HapMap Project), genome-wide scanning has identified at least 13 loci linked to AMD on different chromosomes.[4–6]

Recently, a polymorphism of complement factor H gene (*Y402H*) was shown to be associated with an increased risk for AMD.[7–10] These results were confirmed in many of the countries with large white populations but not in Japan.[11,12] This gene is located on chromosome 1q25-31 where one of the candidate loci was identified by linkage studies. Another recent study reported that a haplotype association of tandemly located complement 2 and factor B was protective for AMD.[13]

PATHOLOGY AND BIOCHEMISTRY The early stage of the dry-type AMD is characterized by a thickening of Bruch's membrane, aggregation of pigment granules, and increasing numbers of drusen. The thickening of Bruch's membrane obstructs its function as a "barrier" between the choroid and the RPE that protects the neural retina from the choriocapillary. Drusen are small yellowish-white deposits that are composed of lipids, proteins, glycoproteins, and glycosaminoglycans. They accumulate in the extracellular space and the inner aspects of Bruch's membrane (Figure 31–4). Drusen are not directly associated with visual loss but represent a risk factor for both the dry-type and wet-type AMD. The classification of hard and soft drusen is based on their size, shape, and color; hard drusen are yellowish with diameters <50 μm and are found in eyes that are less likely to progress to advanced stages of the disease, while soft drusen are darker yellow and larger in size, and are found in eyes more likely to progress to more advanced stages of AMD. A small percentage of dry-type AMD patients progress to the late stage of the wet-type AMD that is characterized by geographic atrophy or detachment of RPE and the development of CNV in the macular region. The presence of a CNV is the factor that most damages the neural retina because the newly developed vessels grow from the choriocapillaris through Bruch's membrane and extend laterally through the RPE cell layer (classic CNV) or extend between the inner Bruch's membrane and RPE (occult CNV). In advanced stages of AMD, the CNV and fluid leaked into the subretinal or intraretinal regions lead to cell death and retinal detachment.

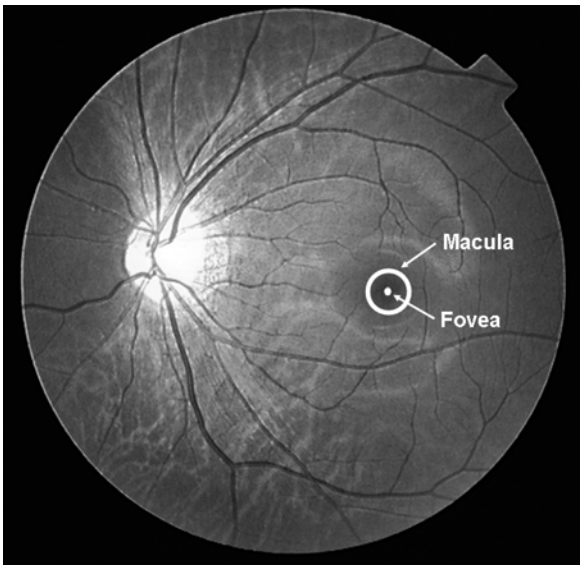

Figure 31–3. Fundus photograph of a normal human retina showing the location of the macula and the fovea.

Recent analyses of the progression of drusen have provided important clues that help understand the molecular pathology of AMD. Using both immunohistochemistry and proteomic techniques, the materials in drusen were found to be composed of molecules that mediate inflammatory and immune processes.[14,15] These molecules include components of the complement pathway and modulators of complement activation, viz. vitronectin, clusterin, membrane cofactor protein, and complement receptor-1. In addition, molecules triggering inflammation, viz. amyloid P component, α_1-antitrypsin, and apolipoprotein E, were identified in drusen. Cellular debris from macrophages, RPE cells, and choroidal dendritic cells has also been identified in drusen. On the other hand, crystallins, EEFMP1, and amyloid-β have been found at

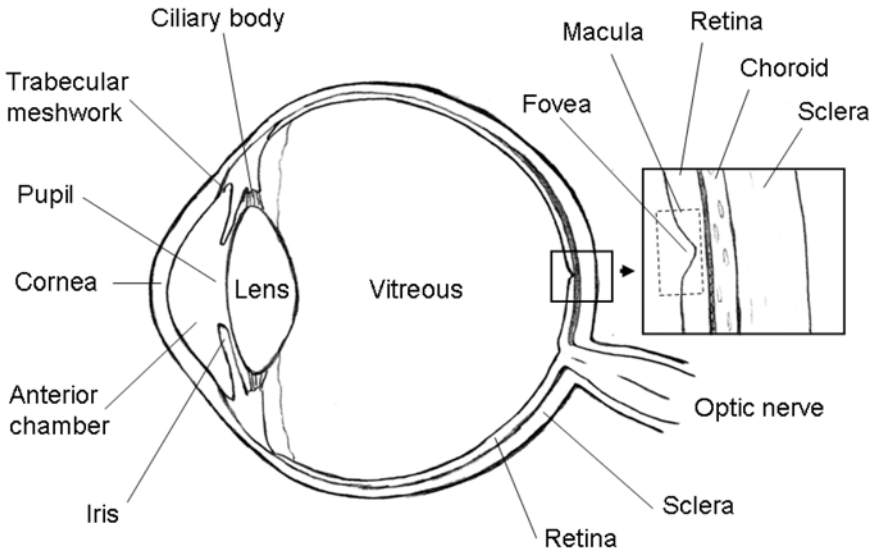

Figure 31–2. Schematic diagram of the human eye.

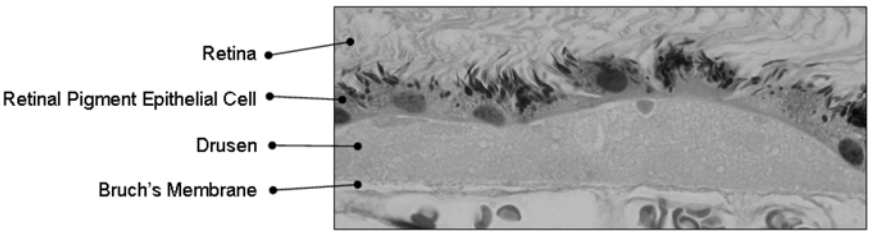

Figure 31–4. Retinal histological section showing the accumulation of drusen between the retinal pigment epithelium and Bruch's membrane in a primate model of AMD.

higher levels in drusen from individuals unaffected by AMD. The presence of immunoreactive proteins and the oxidative modifications of many proteins in drusen imply that both oxidation and immune functions are involved in the pathogenesis of AMD.

All of these findings suggest that complement activation triggers innate immune responses in the subretinal space. The codistribution of immunoglobulin G (IgG) and terminal complement complexes in drusen indicate that immune responses that directly target antigens in retinal cells might also be occurring. Antiretinal autoantibodies have been reported in a number of ocular disorders, e.g., macular degeneration in an aged monkey model.

ANIMAL MODELS Access to appropriate biological materials from affected donors at different stages of a disease is an absolute necessity for the study of mechanisms underlying the disease process. However, because it is nearly impossible to obtain retinal tissues from patients or controls, the development of animal models becomes crucial for investigating the biological pathways involved in the progression of the disease and for the development of therapeutic strategies.

Over the past few years, genetic engineering techniques have generated a number of animal models of AMD in mice, rats, rabbits, pigs, and dogs.[16] However, in mammals, a well-defined fovea is found only in primates (humans and monkeys), and a search for a monkey line affected with macular degeneration has been persistent for a long time.

A monkey with macular degeneration was first described by Stafford *et al*. in 1974. They reported that 6.6% of the elderly monkeys they examined showed pigmentary disorders and drusen-like spots.[17] El-Mofty *et al*. reported that the incidence of maculopathy was 50% in a colony of rhesus monkeys at the Caribbean Primate Research Center of the University of Puerto Rico.[18] At the Tsukuba Primate Research Center (Tsukuba City, Japan), Suzuki *et al.* found a single cynomolgus monkey (*Macaca fascicularis*) in 1986 with a large number of small drusen around the macular region (Figure 31–5).[19–21] This single affected monkey has multiplied to a large pedigree of more than 65 affected and 210 unaffected monkeys. Drusen were observed in the macular region as early as 1 year after birth, and the numbers increased and spread toward the peripheral retina throughout life. No histological abnormalities have been found in the retina, retinal vessels, or choroidal vasculatures of the eyes with drusen. Immunohistochemical and proteomic analyses of the drusen from these monkeys showed that the drusen were very similar to those in other monkeys with aged macular degeneration sporadically found in older monkeys and also with human drusen.[22,23] These observations by Umeda *et al.* have shown that the Tsukuba monkeys produce drusen that are biochemically similar to those in human AMD patients, but the development of the drusen occurs at an accelerated rate of over 25 times. Currently, 240 loci of the cynomolgus monkey are being investigated to try to identify the disease-causing gene and to understand the biological pathways leading to complement activation.

The eyes of monkey are structurally similar to human eyes, which make them extremely valuable for macular degeneration studies. However, there are limitations in using this species over other laboratory animals. Monkeys have a relatively longer life span, have a longer gestation period, have lower birth numbers resulting in a slower rate of expanding the pedigree, and are more difficult to genetically manipulate; in addition, the cost of maintenance is high. In other laboratory animals, the differences in the eye structure, lack of a fovea, and a low cone-to-rod ratio compared to humans have been considered to be a disadvantage for using them as AMD models. However, they are easier to manipulate genetically and easier and less expensive to maintain. This has made the development of a mouse model of AMD very attractive, and a number of mouse AMD models have been reported recently.

The mouse model described by Ambati *et al*. is deficient either in monocyte chemoattractant protein-1 or its cognate C–C chemokine receptor-2. These mice were found to develop the cardinal

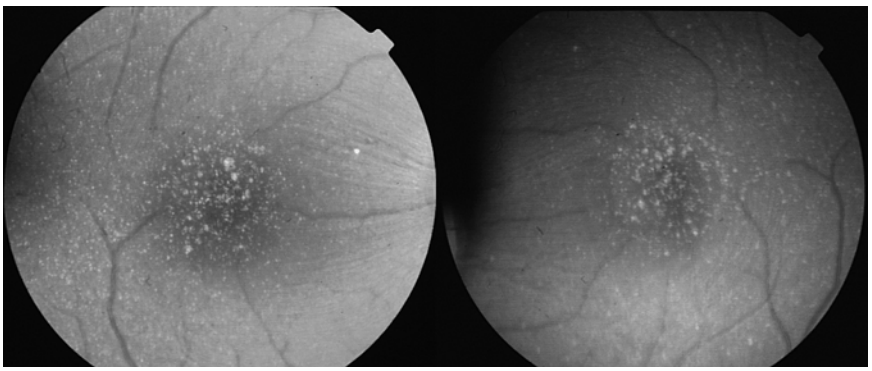

Figure 31–5. Photographs of the fundus of two monkeys with AMD in the Tsukuba Primate Research Center showing drusen.

features of AMD including accumulation of lipofuscin in drusen beneath the RPE, photoreceptor atrophy, and CNV.[24] An impairment of macrophage recruitment allowed the accumulation of C5a and IgG, which leads to the production of vascular endothelial growth factor by the RPE cells and the development of CNVs.

Another mouse model that has three known AMD risk factors—age, high-fat cholesterol-rich diet, and expression of human apolipoprotein E (apoE2, apoE3, andapoE4)—has been developed.[25] ApoE4-deficient mice are severely affected showing diffuse subretinal pigment epithelial deposits, drusen, thickened Bruch's membrane, and atrophy, hypopigmentation, and hyperpigmentation of the RPE.

Oxidative stress has long been linked to the pathogenesis of AMD. Imamura*, et al.* reported Cu, Zn-superoxide dismutase (SOD1)-deficient mice that had features typical of AMD in humans. Senescent $Sod1^{-/-}$ mice had drusen, thickened Bruch's membrane, and choroidal neovascularization.[26] The number of drusen increased with age and also after exposure of young $Sod1^{-/-}$ mice to excess light. The retinal pigment epithelial cells of $Sod1^{-/-}$ mice showed oxidative damage, and their β-catenin-mediated cellular integrity was disrupted. These findings suggested that oxidative stress may affect the junctional proteins necessary for the barrier integrity of the RPE. These observations strongly suggested that oxidative stress may play a major role in AMD.

The complement components, C3a and C5a, are present in drusen, and were observed in Bruch's membrane of a laser-induced CNV mice model. Neutralization of C3a or C5a by antibody or by blockade of their receptors by a complement inhibitor significantly reduced the CNV. These observations revealed a role of immunological mechanisms for angiogenesis and provided evidence for future therapeutic strategies for AMD.

Although the pathology of AMD is pronounced in the macula area, it is not confined to this region. Characteristics of human AMD such as thickening of Bruch's membrane, accumulation of drusen, and CNV have been observed in mouse models. Nevertheless, the primate model will still be the choice for AMD studies, especially at the stage when new therapeutic methods are tested and evaluated for the first time. However, it would be wise and more productive to study both primate and mouse models in AMD research. This will be necessary to determine the mechanisms underlying the disease and to identify clinical and molecular markers for the early stages of AMD. The findings from these studies will provide critical information needed to develop therapies for AMD.

GLAUCOMA

OVERVIEW Glaucoma is a heterogeneous group of complex neurodegenerative disorders that is characterized by the constriction of the visual field, death of retinal ganglion cells (RGCs), and a pathognomonic deformation of the optic nerve head (ONH) known as glaucomatous cupping. Glaucomas are classified into three main types: open-angle, closed-angle, and congenital glaucoma. Each of these types is subdivided into primary and secondary types.

EPIDEMIOLOGY AND GENETICS Primary open-angle glaucoma (POAG) is the most common form of glaucoma; it occurs in about 4.5 million people worldwide and accounts for 12% of all global blindness. By the year 2020, over 11 million people will be blind from primary glaucoma.[28] POAG is often, but not always, associated with elevated IOP, which is one of the main risk factors in glaucoma. However, about a third of all patients with POAG develop the disease without an IOP elevation, and in these patients, the IOP is continuously below 21 mm Hg. This form of POAG is called normal tension or low tension glaucoma (NTG). A reduction of the IOP, even in cases of NTG, is the main, clinically proven, treatment for glaucoma.

ANIMAL MODELS Among the different animal models of glaucoma, the monkey models are superior because of the anatomical similarity of the monkey eyes to human eyes and the phylogenetic similarities of these two species. At the same time, monkeys are extremely expensive and experiments on them require a highly skilled team of investigators.

Most of the existing animal models of POAG, including the monkey models, are based on the elevation of the IOP. An elevation of the IOP develops from an imbalance between aqueous humor production and outflow. Aqueous humor, a fluid produced by the ciliary body of the eye, drains out of the eye and into the blood circulatory system. The eye's outflow system consists of a series of endothelial cell-lined structures that include the trabecular meshwork (TM), Schlemm's canal (SC), which serves as a collector vessel, and the episcleral venous system (Figure 31–6). In most glaucoma models, the IOP is elevated as a result of a reduction or blockage of the aqueous humor outflow. In monkeys, an elevation of IOP is commonly induced by laser photocoagulation of the TM.[29,30] Several days after the laser treatment, the IOP increases and this elevation may last for more than a year, although more than one laser session is usually required to achieve a sustained elevation of the IOP. The IOP in treated eyes is usually between 25 and 60 mm Hg.

Other methods to elevate the IOP in monkey eyes include the anterior chamber injection of ghost red cells,[31] latex microspheres,[32] cross-linked polyacrylamide gels,[33] and enzymes.[34] Topical steroids have also been shown to elevate the IOP.[35] These latter treatments produce less consistent elevations than laser photocoagulation.[36]

Monkey glaucoma models have been shown to have changes in the optic disk, optic nerve, RGC, and nerve fiber layers similar to those observed in glaucomatous human eyes. Apoptosis was shown to be the cause of the RGCs death in a monkey photocoagulation model,[37] and apoptosis was later confirmed to be the cause in other animal models and in humans with glaucoma. Monkey glaucoma models have also been successfully used to study changes in the retinal gene expression pattern 30 days after laser photocoagulation of the TM,[38] and to test the effectiveness of new classes of hypotensive drugs.[36]

Rodent became the animal of choice when large numbers of animals were required, e.g., when examining the mechanism of RGC degeneration and neuroprotection. Several rat models of elevated pressure-induced optic nerve damage have been developed during the past decade, and they have been used to study changes in the retina and the optic nerve. Rats are easy to handle and the relatively large size of their eyes allows multiple, awake measurements of the IOP with commercially available equipment.[39] This latter is important because it is well documented that general anesthesia induces a rapid decrease in the IOP. Although there are certain differences in the structure of the rat and human eyes, all of the eye structures affected in glaucomatous human eyes exist in the rat eye.

In rat models, the IOP elevation is achieved by injection of concentrated saline solution into the episcleral veins,[40] laser

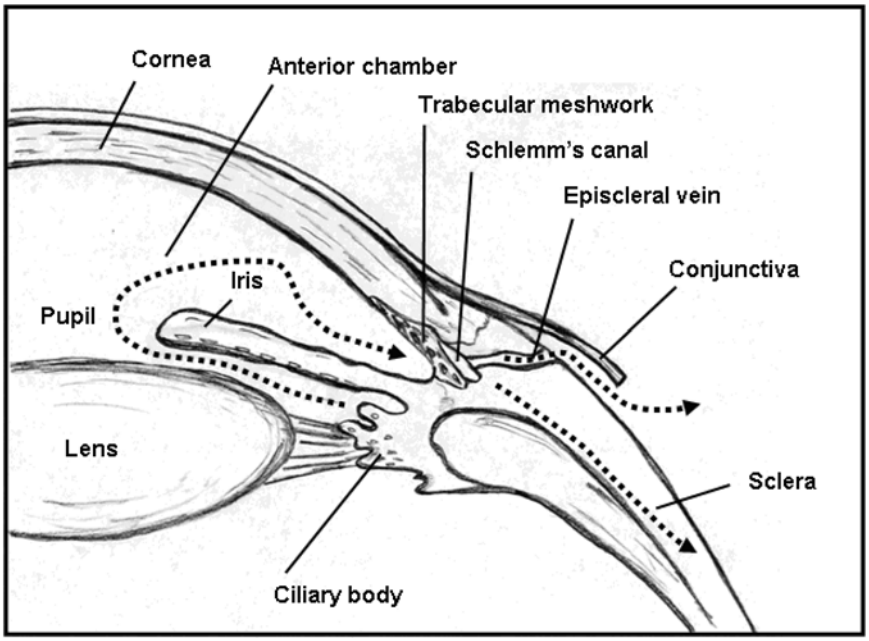

Figure 31–6. Schematic diagram of the anterior segment of the eye showing the trabecular meshwork and uveoscleral outflow pathways of aqueous humor.

photocoagulation of the TM after an injection of Indian ink into the anterior chamber,[41] laser photocoagulation of the TM,[42] and laser cauterization of episcleral veins.[43] All of these methods that lead to an elevation of the IOP require special training of the investigators.

Successful treatment of the eye leads to a rapid elevation of the IOP, although the level of elevation varies from eye to eye. Saline injection generally produces a wide range of IOP elevation from a very minimal rise to a 2-fold increase over the IOP in control eyes. The elevation of the IOP generally lasts for several weeks, and a second laser treatment is often required in the photocoagulation method to maintain an elevated IOP for more than 3 weeks.

A chronic elevation of the IOP in rats leads to apoptosis of the RGCs, degeneration of the optic nerve fibers, and remodeling of the ONH similar to those observed in human glaucomatous eyes.[40,44–45] Rat models of glaucoma have been used to study the effects of elevated IOP on the electroretinogram,[46] neuroprotective drugs,[47] and molecular changes in the retina and optic nerve using the candidate gene approach and array hybridization.[48]

A mutant rat strain was reported to have unilateral or bilateral enlargement of the eyes with an IOP ranging from 25 to 45 mm Hg. In this strain of rat, cupping of the optic nerve head was detected by funduscopic examination, and the cupping was more pronounced in older animals. The number of RGCs also declined with age.[49] Unfortunately, this strain was obtained from the Royal College of Surgeons colony that has a mutation in the receptor tyrosine kinase gene, leading to degeneration of the photoreceptors. Therefore, this strain can hardly be considered a good glaucoma model.

The construction of mouse models of glaucoma has lagged behind rat glaucoma models for a long time despite the advantages of mice over rats and other mammalian species for cost-effective genetic manipulations, availability of a wide spectrum of methods, and the existence of many genetically modified strains. However, it should be remembered that mouse and human eyes have certain important differences including the arterial blood supply to the optic nerve head and the absence of a lamina cribrosa.[50] The lamina cribrosa, a collagenous scaffold supporting the optic nerve, plays a critical role in the damage/protection of the human optic nerve.

One of the main difficulties working with mice is that their eyes are much smaller than the eyes of humans and rats, and new methods had to be developed to measure the IOPs in mice. To date, several invasive and noninvasive methods of IOP measurements have been developed for mice. The first remains one of the most reliable and accurate methods and does not depend upon the mechanical properties of the cornea. It involves the insertion of a glass microneedle connected to a pressure transducer into the anterior chamber of the eye. Using this method, it was shown that common mouse strains have different IOP between 10 and 20 mm Hg.[51] Other methods of IOP measurements in mice were later developed including noninvasive techniques. Noninvasive methods allow multiple IOP measurements to be completed in a short period of time, but the results of these measurements may depend upon mechanical properties of the cornea. To obtain reliable IOP readings, all of the described techniques require training.

Transgenic and gene-targeted knockout approaches have been used to develop several mouse models of glaucoma. The main advantage of these models is that the animals with the mutated gene provide a more uniform elevation of the IOP and damage to the retina and optic nerve similar to that found with surgically induced elevated IOPs. A large number of animals can be produced, and once a mutant mouse line is obtained, no special training is needed to produce more affected mice.

Several lines of transgenic mice have been developed that contained BAC DNAs with a mouse Tyr423His point mutation and Tyr437His point mutation of the human myocilin (Myoc) genes. The Tyr437His mutation in the Myoc gene leads to severe glaucoma in humans, and the mouse Tyr423His mutation corresponds to this human mutation. Expression of mutated mouse Myoc in the ocular drainage structures led to moderate (about 2 mm Hg during the day and 4 mm Hg at night) elevation of the

IOP and progressive degenerative changes in the peripheral RGC layer and optic nerve that resembled glaucomatous changes in human eyes.[52] In 1-year-old animals, the peripheral retina of transgenic mice had approximately 20% fewer RGCs than the peripheral retina of control littermates.

Transgenic mice with a targeted mutation in the gene for the α_1-subunit of collagen type I have also been constructed. This mutation blocks the cleavage of collagen by matrix metalloproteinase-1. Transgenic mice expressing mutated collagen had elevated IOPs. The difference in the IOP between control and transgenic mice gradually increased to a maximum of 4.8 mm Hg at 36 weeks. Because these mice had progressive optic nerve axon loss with normal organization of the drainage structures, it has been suggested that they may be used as a mouse model of POAG.[53]

Recent data have demonstrated that transgenic mice expressing mutated optineurin under the control of the ubiquitous ROSA26 promoter develop optic nerve cupping and death of the RGCs without elevation of the IOP.[54] These transgenic mice may represent the first animal model of NTG.

The surgical methods used to produce rat glaucoma models have also been used in mice. However, performing surgery on the mouse eye is even more challenging than on rat eyes because of the difference in size. A significant elevation of the IOP was found in the eyes of C57BL/6J mice that had an injection of indocyanine green dye into the anterior chamber and diode laser treatment of the TM and episcleral vein region.[55] At 10 days after the surgery, the mean IOP in the operated eyes was 33.6 ± 1.5 mm Hg versus 15.2 ± 0.6 mm Hg in the control eyes. However, the IOP returned to normal 60 days after the surgery. Histological examination of the treated eyes 65 day after the surgery revealed anterior synechia, a decrease in the number of RGCs, thinning of all retinal layers, and damage to the optic nerve structures without evidence of prominent cupping.[55] A reduction in the function of the outer retinal layers, confirmed by electroretinographic studies, may indicate that this model produces more extensive changes in the retina compared to the glaucoma in humans.

Similar to the above model, an elevation of IOP was induced by argon laser photocoagulation of the episcleral and limbal veins in C57BL/6J mouse eyes[56] or by cauterization of three episcleral veins in CD1 mouse eyes.[57] During the first 4 weeks following laser treatment, the mean IOP in the treated eyes was about 1.5 times higher than in control eyes. The number of RGCs had decreased by $22.4 \pm 7.5\%$ of that in the controls at 4 weeks after treatment. Most of the TUNEL-positive apoptotic cells were detected in the peripheral retina.[56]

Cauterization of the episcleral veins led to a maximum IOP elevation within 2–9 days, and the IOP decreased progressively thereafter to reach more or less normal values after 24–33 days. There was a 20% decrease in the number of RGCs 2 weeks after the surgery.[57]

The DBA/2J strain has high IOP and has become a popular mouse model to study secondary angle-closure glaucoma. This mouse strain has mutations in two genes, *Tyrp1* and *Gpnmb*.[58] DBA/2J mice develop pigment dispersion, iris transillumination, iris atrophy, and anterior synechia. At the age of 9 months, the IOP was elevated in most mice and the elevation was accompanied by the death of the RGCs, optic nerve atrophy, and optic nerve cupping. Although no group of the RGCs was especially vulnerable or resistant to degeneration, fan-shaped sectors of dead or surviving RGC radiated from the ONH.[59] It has been suggested that axon damage at the ONH might be a primary lesion in this model.[59]

Several important observations were made from the studies on the DBA/2J model. It was shown that the proapoptotic protein BAX is required for the survival of RGCs but not for RGC axon degeneration, suggesting that BAX may be a candidate human glaucoma susceptibility gene.[60] Unexpectedly, a high dose of γ-irradiation accompanied by syngeneic bone marrow transfer protected the RGCs in DBA/2J mice.[61] Similar to the results obtained with rat and monkey models, genes involved in the glial activation and immune response were activated in DBA/2J retina as shown by array hybridization.[62]

Complement component, 1Q, was upregulated in the retina of several animal models of glaucoma as it is in human glaucoma with the timing suggesting that complement activation plays a significant role in the pathogenesis of glaucoma.[63]

Taken together, these findings confirm that animal models might be used to look for a molecular mechanism involved in glaucoma in humans.

The modulation of the activity of genes involved in the development of the anterior segment of the eye may lead to relatively rare developmental glaucomas that account for less than 1% of all glaucoma cases. Several genes have been implicated in congenital glaucoma and anterior segment disgenesis. They include *Cyp1b1*, *Foxc1*, *Foxc2*, *Pitx2*, *Lmx1b*, and *Pax6*. Several lines of mice with defects in these genes have been studied with glaucoma in mind (see Gould *et al.*[64] for a review). For example, mutation in the *CYP1B1* gene (cytochrome P450, family 1, subfamily b, polypeptide 1) may lead to primary congenital glaucoma (PCG) in humans. Although Cyp1b1 knockout mice did not develop elevated IOP, they had ocular abnormalities similar to the defects in humans with PCG, viz. small or absent Schlemm's canal, defects in the TM, and attachment of the iris to the TM and anterior synechia.

Mutations in the *FOXC1* gene, which encodes a transcription factor with a forkhead-winged-helix DNA binding domain, cause a range of eye abnormalities associated with glaucoma, e.g., iris hypoplasia, Axenfeld and Rieger anomaly, and Rieger syndrome. $Foxc1^{-/-}$ mice die at birth, while $Foxc1^{+/-}$ animals are viable but have defects in the eye drainage structures without changes in IOP. Similar eye defects were observed in $Foxc2^{+/-}$ mice. It has been suggested that $Foxc1^{+/-}$ and $Foxc2^{+/-}$ mice are useful models for studying anterior segment development and anomalies, and may allow the identification of genes that interact with *Foxc1* and *Foxc2* (or *FKHL7* and *FKHL14*) to produce a phenotype with elevated IOP and glaucoma.

Other animals, including rabbit, pig, and bovine, have also been used to develop animal models of glaucoma, but none of them is widely used for different reasons. Zebrafish became a powerful model for advanced genetic studies in vertebrates, especially in the case of complex diseases, and was proposed as a model for identification of modifier genes for glaucoma.[65]

CONCLUSIONS

In summary, animal models of glaucoma, including the most widely used rodent and monkey models, have already provided interesting new information about mechanisms of glaucoma in humans. However, it should be remembered that even in monkey models the time course of changes in the glaucomatous eyes may

be significantly accelerated compared to that in human glaucomatous eyes, and all discussed models are indeed just models of glaucoma in humans. Results obtained with these models should not be automatically applied to human glaucoma and should be confirmed by testing in humans whenever possible. It has become clear that reaction to the same insult, e.g., elevated IOP, may be somewhat different in different animal models. Glaucoma studies in animals may help us identify the molecular mechanisms involved in the development of glaucoma in each particular model. By comparing these mechanisms, it may be possible to find some common mechanism that might be involved in glaucoma formation in humans. This will be extremely valuable for the development of new therapeutic approaches for the treatment and prevention of glaucoma in humans.

32 Animal Models of Noise-Induced Hearing Loss

Richard Salvi and Flint A. Boettcher

ABSTRACT

Animal models have played a major role in understanding noise-induced hearing loss, a major cause of hearing loss in industrialized societies. Behavioral models using positive and negative reinforcement techniques have played an important role in delineating the relationship between the physical characteristic of the noise, namely intensity, spectral content, and duration, and the magnitude of the resulting hearing loss. An important contribution from these studies was the discovery that the hearing loss reaches an asymptotic value of threshold shift for exposures lasting 24 h or more. Animal models of noise-induced hearing loss have revealed a significant loss of frequency sensitivity, making it difficult to discriminate signals in noise, and a breakdown in temporal resolution that makes it difficult to perceive the temporal information contained in complex signals such as speech. Animal models have shown that prolonged exposure to high-level noise mainly damages the sensory hair cells in the inner ear. The stereocilia bundles on the sensory hair cells, which contain the mechanically gated ion channels responsible for converting sound into neural activity, are especially vulnerable to acoustic overstimulation. High-level noise can obliterate or damage the stereocilia. More severe sound exposures can result in degeneration of the hair cell body, beginning with the outer hair cells followed by the inner hair cells. The functional status of the outer hair cells can be evaluated in noise-exposed animals using distortion product otoacoustic emissions. When healthy ears are stimulated with two primary tones, f1 and f2, the inner ear generates a distortion tone, the most prominent of which occurs at 2f1–f2. Acoustic overstimulation that primarily damages the outer hair cells and leads to mild to moderate hearing loss almost completely abolishes the distortion product otoacoustic emission. The type I spiral ganglion neurons, which make synaptic contact with single inner hair cells, can be used to assess the functional status of a very narrow region of the cochlea. The functional status of small populations of type I neurons can be evaluated using tone bursts to elicit the compound action potential. Narrow band noise exposures that damage specific regions of the cochlea cause an increase in the compound action potential threshold at frequencies associated with the region of cochlear pathology. Microelectrode recordings from single type I auditory nerve fibers can be used to delineate the pathophysiology at specific sites along the cochlea. Sound exposures that selectively damage the outer hair cells lead to an elevation of threshold and loss of tuning. In cases in which acoustic overstimulation destroys both the outer hair cells and inner hair cells, nerve fibers associated with the damaged region are unresponsive to sound resulting in a dead region. The biological mechanisms that lead to noise-induced degeneration of hair cells is not fully understood, but there is growing awareness that hair cell death may be initiated by oxidative stress that leads to hair cell death by necrosis or apoptosis.

Key Words: Chinchilla, Gerbil, Mice, Noise exposure, Hearing loss, Tuning, Oxidative stress, Hair cells, Auditory nerve.

NOISE-INDUCED HEARING LOSS

In industrialized countries where recreational and work place noise are increasing, noise-induced hearing loss (NIHL) has become the leading cause of hearing loss among those under 50 years of age.[1] The early studies of NIHL in humans between 1940 and late 1960 helped to establish a basic understanding of the magnitude of the hearing loss resulting from noise exposures of a given intensity, duration, and spectral content; however, because of ethical constraints and the difficulty of carrying out long-term noise exposure with humans, most of the early human studies focused on sound exposures that resulted in temporary threshold shifts (TTS). With the growing concern that TTS-inducing sound exposures might cause permanent damage to the sensory cells, supporting cells, and spiral ganglion neurons in the inner ear, more recent work on NIHL has turned to animal models, in particular, studies aimed at understanding the basic neuroanatomical, neurophysiological, and biochemical mechanisms underlying NIHL.

Which animal model is the most useful for investigating NIHL and to what extent is it possible to extrapolate from animal models to humans? The answer to the question is complex and probably depends on the specific issue or problem being investigated. Most biological studies of sensorineural hearing loss have been conducted on cat, chinchilla, gerbil, guinea pig, mouse, and rat. Because cats are particularly hardy animals, they have proved especially useful for long-term electrophysiological recording.[2] Chinchillas have often been used because their range of hearing is nearly identical to that of humans;[3] however, they may be more susceptible to acoustic trauma than humans.[4] The upper range of hearing in guinea pigs and gerbils is slightly

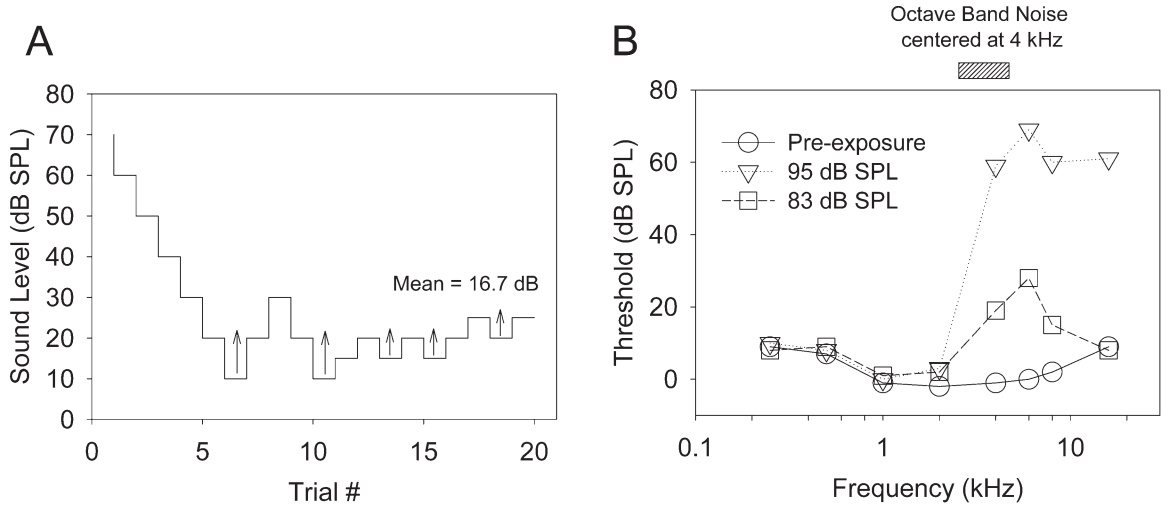

Figure 32–1. (A) Behavioral threshold tracking algorithm in which the sound level is initially decreased in 10-dB steps after a response is made on a tone trial (hit) and increased in 10-dB steps if no response is made on a tone trial (miss). The step size is reduced to 5 dB after two 10-dB reversals. The threshold is calculated as the mean of the last three reversals with a 5-dB step size. (B) Behavioral thresholds between 0.25 and 16 kHz preexposure and after long-term noise exposure to an octave band noise centered at 4 kHz and presented at 83 and 95 dB SPL. Note the large increase in high-frequency behavioral thresholds and normal low-frequency thresholds after the exposure. (Modified from Salvi *et al.*[9])

higher than in humans, but their cochlea is accessible for physiological recordings and anatomical analysis.[5,6] With the rapid developments in molecular biology and genomics, research has shifted toward the use of rats and mice, in particular, inbred strains in which the effects of genetic variability are greatly reduced.[7] A wide range of techniques has been used to assess the effects of NIHL in animal models. The following sections will review some of the most commonly used techniques that have provided fundamental insights into questions such as the following: How much noise is too much noise? What anatomical structures in the inner ear are damaged by noise? What physiological changes are associated with NIHL? Are there any therapeutic treatments for NIHL?

BEHAVIORAL ASSESSMENT OF NOISE-INDUCED HEARING LOSS Behavioral measures, although time consuming, allow for the most comprehensive assessment of the full range of hearing deficits associated with NIHL. Animal psychophysical techniques for assessing hearing fall into two broad categories: those involving positive reinforcement and those utilizing negative reinforcement.[8,9] Regardless of the technique, sufficient training must occur so that the animal's behavior is under stimulus control. The psychophysical procedures used to define threshold in quiet typically involve the method of limits, method of constant stimuli, or a tracking algorithm in which the sound level is decreased or increased by a specified dB step size after a correct or incorrect response, respectively (Figure 32–1). For example, chinchillas have been trained to press and hold down a key and wait for a variable time interval until a tone is presented. If the tone is detected, the animal releases the bar and receives a food pellet (hit). Failure to release the bar on tone trials is scored as a miss resulting in a time out indicted by turning off the house lights. Blank (no tone) trials are presented on 50% of the trials. If the bar hold is maintained throughout the trial, a food pellet is administered and the trial is scored as a correct rejection. Release of the bar on a no-tone trial is scored as a false alarm. To more accurately define threshold, the step size can be reduced after a certain number of threshold reversals has occurred. In the example shown in Figure 32–1A, threshold was defined as the mean of the last three reversals, 16.7 dB sound pressure level (SPL), with a step size of 5 dB. Threshold can be measured over a broad range of frequencies to obtain a plot of threshold versus frequency, or the audiogram. Figure 32–1B illustrates the audiogram of the chinchilla, an animal model that has been used extensively in behavioral studies of NIHL. Thresholds in quiet are lowest in the 2–4 kHz range and begin to increase near the lower and upper range of hearing for this species.[9]

Procedures similar to those used to measure the audiogram have also been used to assess suprathreshold measures of hearing such as frequency discrimination, frequency tuning curves, temporal resolution, intensity discrimination, masking patterns, and the critical band.[10–13]

BEHAVIORAL ASSESSMENT OF NOISE-INDUCED HEARING LOSS Chinchillas have been used extensively to map out the relationship between the three main parameters of the noise exposure (intensity, frequency, and exposure frequency) and degree of TTS and/or permanent threshold shifts (PTS).[14–18] Figure 32–1B illustrates the pattern of TTS that would result from exposure to an octave band of noise (OBN) centered at 4 kHz at a low level (83 dB SPL) and a high level (95 dB SPL). The hearing loss is typically greatest one-half to one octave above the center frequency of the noise exposure, a phenomenon referred to as the one-half octave shift. At low exposure levels, the hearing loss drops off rapidly above and below the exposure frequency; consequently, there is little or no threshold shift at 16 or 2 kHz. However, at high exposure levels, the hearing loss spreads extensively toward the high frequencies, but comparatively little toward the low frequencies. The spread of TTS and PTS toward the high frequency results mainly from the traveling wave vibration pattern that spreads from the point of maximum vibration toward the basal high-frequency region of the cochlea.[19]

EXPOSURE LEVEL AND DURATION A major advantage of animal models is that it is possible to use long-term, well-controlled noise exposures that extend over days, weeks, months, or years, something that is impossible to do in human laboratory studies. Prior to the 1970s, it was not clear if the degree of hearing loss would continue to increase with exposure duration or if it would reach an asymptotic value. When the experiments were finally carried out, a major revelation was that the degree of hearing loss increased with exposure duration, but reached an asymptotic value after 18–24 h. Figure 32–2A illustrates the growth of TTS at 715 Hz in the chinchilla resulting from a 7-day exposure to an octave band of noise centered at 500 Hz.[20] The level of the octave band noise was set at 75, 85, 95, or 105 dB SPL. Hearing loss was measured approximately 4 min after the animal was removed from the noise. When hearing loss is plotted on a logarithmic time scale, TTS increased approximately linearly with exposure duration over the first 24 h and then reached a plateau, or asymptotic threshold shift (ATS). This plateau remains stable for exposure durations as long as 3 years.[21] The ATS value increased according to the following equation: $TTS_{4\,min} = m(OBL - k)$, where OBL is the octave band noise level in dB, k is the exposure level that must be exceeded for a hearing loss to occur, and m is the rate of growth of hearing loss. For an octave band noise centered at 500 Hz, $TTS_{4\,min} = 1.6(OBL - 65)$. That is, the ATS value will increase at 1.6 dB/dB once the OBN level exceeds 65 dB SPL. The variables m and k vary with species and/or frequency. It was originally assumed that if the noise exposure went on indefinitely, ATS would go on to become PTS. If this assumption were correct, then this would be theoretically important because ATS could be used to predict the maximum PTS that could result from a given noise exposure. However, 5–20 dB of recovery has been observed even after a 3-year period of ATS. Thus, ATS is a combination of TTS and PTS where the PTS component increases with exposure duration and level.[21]

RECOVERY Following the end of a noise exposure, thresholds typically recover over a period of approximately 10–15 days. Thresholds can fully or partially recover depending on the exposure level and exposure duration. Figure 32–2B shows the pattern of threshold recovery at 5.7 kHz following an intermittent (6 h/day for 9 days) exposure to an octave band noise centered at 4 kHz.[15] The exposure resulted in an ATS that ranged from 10 dB with an exposure level of 52 dB SPL to approximately 70 dB when the exposure level increased to 92 dB SPL. On a log-recovery time scale, three phases are seen: an early phase during the first 200 min (~3 h) where there is little recovery, a rapid recovery phase extending from approximately 200 to 7000 min (~5 days), and finally a very slow recovery phase followed by a plateau. In general, small ATS values produced by low exposure levels are associated with a shorter recovery time and little or no PTS, whereas large ATS values produced by high exposure levels resulted in longer recovery times and PTS.

FREQUENCY SELECTIVITY If NIHL simply resulted in a loss in hearing sensitivity, then correcting the problem would simply entail turning up the volume on your hearing aid or stereo amplifier. Unfortunately, NIHL also disrupts a listener's frequency selectivity, that is, the ability to extract out and hear the signal of interest from nearby frequencies in the background noise.[12,22] Behavioral psychophysical tuning curves can be measured by having animals respond when they hear a fixed-frequency, short-duration probe tone burst, for example, a 20-msec tone burst at 2000 Hz presented 10–15 dB above the threshold. The low-intensity probe tone presumably excites a limited group of neurons that is tuned to the frequency of the probe signal. Next, a continuous pure tone masker is added to the background. The frequency of the masker is set to a frequency far below the probe-tone frequency, for example, 500 Hz, and then the level of the 500-Hz continuous masker is increased until the animal can no longer hear the 2000-Hz probe tone. The intensity of the 500-Hz

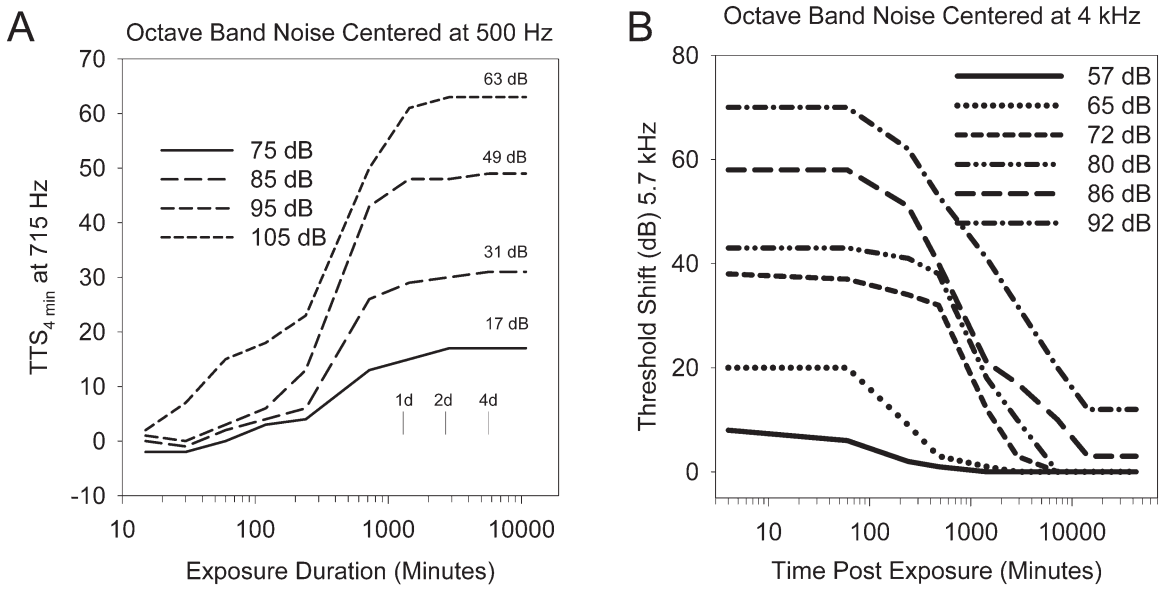

Figure 32–2. (A) The amount of TTS at 715 Hz that occurred 4 min after chinchillas are removed from an octave band noise centered at 500 Hz. Exposure levels were 75, 85, 95, and 105 dB SPL; the ATS values associated with these exposure values were 17, 31, 49, and 63 dB. (B) The recovery of threshold as a function of log recovery time following exposure to an octave band noise centered at 4 kHz. Exposure levels ranged from 57 to 102 dB SPL as shown in the inset. (Modified from Clark.[21])

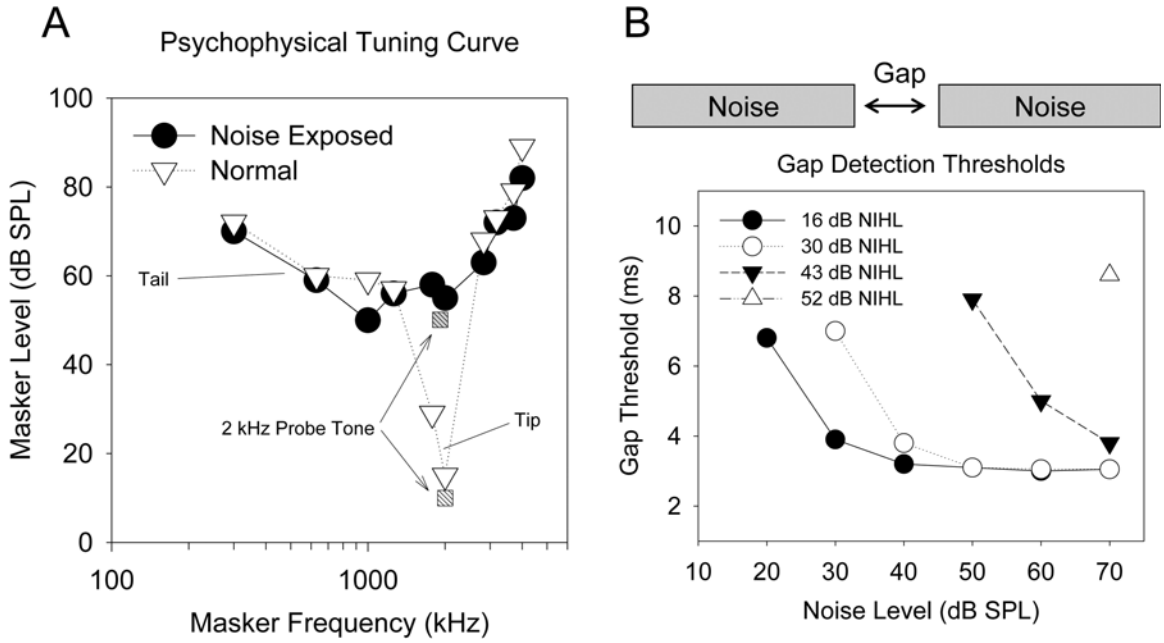

Figure 32–3. (A) Psychophysical tuning curves from a chinchilla using a 2-kHz probe tone presented approximately 10 dB above threshold before and after a noise exposure that resulted in approximately 30 dB of permanent NIHL. The normal psychophysical tuning curve has a narrow, V-shaped, low-level tip near the 2-kHz probe tone frequency and a high-level, low-frequency tail that extends toward the low frequencies. After a noise exposure, the level of the 2-kHz probe tone must be increased so that it is again 10 dB above threshold and the psychophysical tuning curve is remeasured. In animals with NIHL, the psychophysical tuning curve has a broad U-shaped or blunt W-shaped tip due to the increased masked threshold near the probe frequency. Masked thresholds in the tail of the psychophysical tuning curve show little change or sometimes become hypersensitive. (Modified from Salvi *et al.*[47]) (B) Changes in gap thresholds as a function of stimulus level in chinchillas with a flat NIHL of approximately 16, 30, 43 or 52 dB. (Modified from Giraudi-Perry *et al.*[13])

masker that prevents the detection of the 2000 Hz tone bursts represents the masked threshold at 500 Hz. The frequency of the masker is change to another frequency, and the masked threshold is remeasured to obtain a second point on the psychophysical tuning curve. When the masked threshold is measured over a wide range of frequencies below, near, and above the frequency of the probe tone, the entire psychophysical tuning curve can be mapped out. Figure 32–3A shows a normal psychophysical tuning curve measured in a chinchilla using a 2-kHz probe tone presented approximately 10 dB above threshold. The masked thresholds are lowest near the probe tone frequency; masked thresholds increase rapidly as masker frequency increases resulting in a steep high-frequency edge to the tuning curve. Masked thresholds also increase rapidly as the masker frequency decreases; however, at about one octave below the probe frequency, masked thresholds reach a plateau. Thus, normal psychophysical tuning curves consist of two distinct regions, a narrowly tuned V-shaped tip centered at the probe frequency and a high-threshold, broadly tuned tail region. The shape of the psychophysical tuning curve changes significantly in subjects with NIHL as shown in Figure 32–3A. In subjects with approximately 30 dB of NIHL, the probe tone intensity must be increased so that it is 10 dB above the threshold in the impaired ear. When the psychophysical tuning curve is measured in an ear with NIHL, the masked thresholds in the vicinity of the tip are found to increase (hyposensitive), whereas masked thresholds in the tail of the tuning curve remain the same or sometime decrease (hypersensitive). Thus, psychophysical tuning curves in animals with NIHL have a high-threshold, broadly tuned tip connected to a high-threshold tail region, which give rise to a blunt W- or U-shaped tuning curve. Consequently, sounds far below the probe tone, which normally would have little effect on its detection, become almost as effective at masking the signal as those located near the probe signal.

TEMPORAL RESOLUTION The information content of sounds such as speech and music is largely contained in the temporal fluctuations in sound frequency and intensity. Thus, it is possible to ask whether NIHL has any impact on the ability of listeners to extract out and respond to the temporal fluctuations present in sounds. One simple task that can be used to assess the temporal resolving power is the ability to hear a brief silent gap in an otherwise continuous background noise (Figure 32–3B).[13,23] An animal is placed in a continuous background noise and trained to make a behavioral response when a silent gap appears in the ongoing background noise. As shown in Figure 32–3B, the shortest silent gap that can be detected in broadband noise is on the order of 3 msec at moderate to high sound levels. When the background noise intensity falls below 40 dB SPL, the gap threshold decreases to around 7 msec when the background noise is just above the threshold of hearing.

When chinchillas were exposed for many days to a broadband noise that induced relatively flat hearing loss across all frequencies, gap thresholds systematically increased as the noise-induced ATS increased.[13] With a 16-dB ATS, gap thresholds were longer than normal only when the gap thresholds were measured in low-level background noise. With higher levels of background noise gap thresholds were essentially normal. However, as the noise-induced ATS increased from 30 to 43 and then 52 dB, the gap threshold became longer than normal and could be measured at

high levels of background noise only when the stimulus was above threshold. Since it is possible to systematically manipulate the degree of NIHL in animal models and assess the deterioration in hearing performance, animal models have been especially useful in determining exactly how auditory temporal resolution changes as the degree of NIHL increases.

HISTOPATHOLOGIES ASSOCIATED WITH NOISE-INDUCED HEARING LOSS

The major histopathologies associated with NIHL occur in the inner ear (cochlea). The spiral-shaped sensory epithelium is encased in a fluid-filled, bony labyrinth located in the temporal bone (Figure 32–4A). Sounds that are collected by the external ear are channeled toward the tympanic membrane that is coupled to the middle ear ossicles, which consist of a chain of three small bones, the malleus, incus, and stapes. Sound-induced vibrations of the tympanic membrane are transmitted through the middle ear to the stapes, a piston-like bone that is loosely coupled by ligaments to the oval window, the point of entry of sounds into the fluid-filled cochlea. Complex sounds entering the cochlea are spatially filtered and set up a traveling wave such that high-frequency sounds produce maximal vibration in the base of the cochlea; lower frequencies produce maximal vibration further toward the apex.[19] The spiral tube of bone that forms the cochlea is subdivided along its entire length by three parallel, fluid-filled compartments, scala tympani, scala vestibuli, and scala media, as shown in Figure 32–3B. The cochlea spirals around the modiolus, a centrally located, hollow bony core that contains the spiral ganglion neurons whose axons give rise to the auditory nerve fibers. The sensory cells, which transduce the incoming sounds, rest on supporting cells of the basilar membrane. The basilar membrane is attached medially to the bony modiolus and laterally near the spiral limbus along the lateral bony wall of the cochlea. The outer hair cells (OHC) form three rows and the inner hair cells (IHC) form a single row that spiral along the length of the cochlea from base to apex. Although there are roughly three times as many OHC as IHC, the majority, 95%, of auditory nerve fibers make synaptic contact with the IHC. Only about 5% of auditory nerve fibers contact the OHC.[24] The sensory hair cells can be subdivided into three main regions, the cell body, a cuticular plate containing a stereocilia bundle on the cell's apical surface facing the endolymph, and a basal pole where the afferent dendrites from the spiral ganglion neurons make synaptic contact. The stereocilia bundles that protrude from the apical pole of the hair cells are most easily visualized using scanning electron microscopy (SEM).

SCANNING ELECTRON MICROSCOPY AND STEREOCILIA DAMAGE Our procedure for visualizing the stereocilia

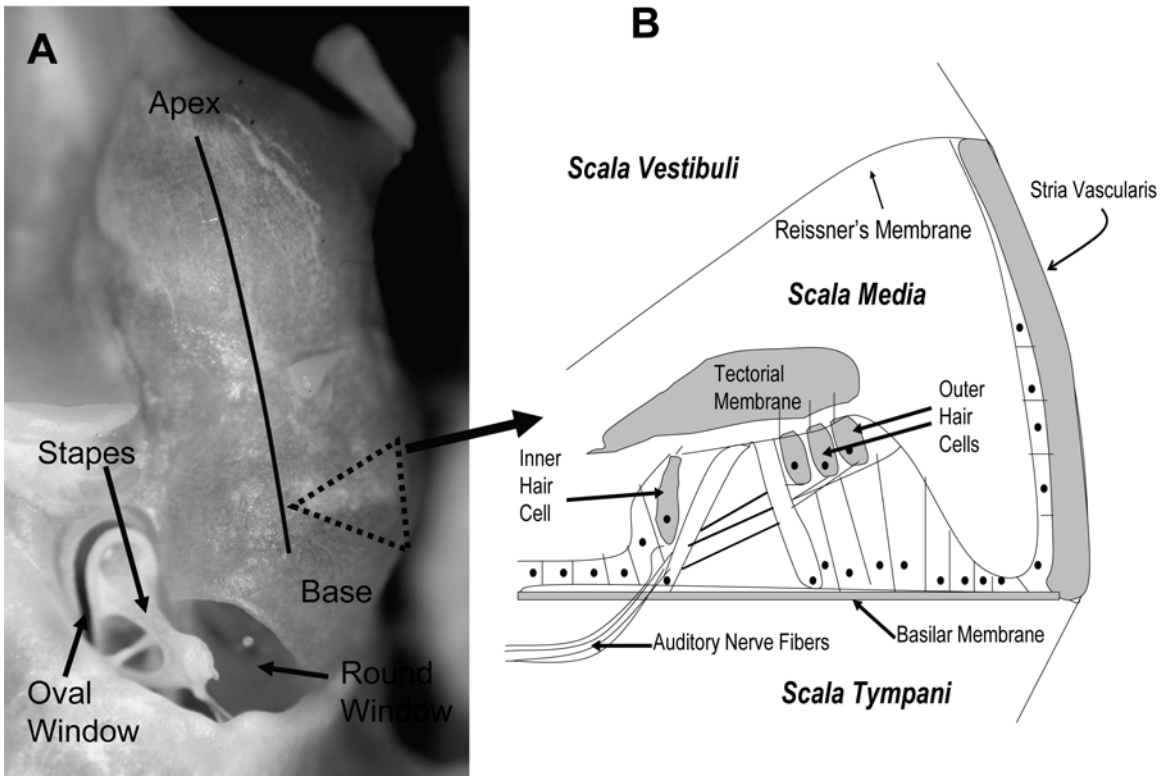

Figure 32–4. (A) Photomicrograph of the chinchilla cochlea showing the stapes plugged into the oval window in the base of the cochlea next to the round window. The cochlea spirals from base to apex around the modiolus, a central bony core containing the spiral ganglion neurons whose fibers give rise to the auditory nerve. The solid line depicts the axis of the modiolus within the cochlea; the dotted triangle depicts a cross section through the basal turn of the cochlea. (B) Schematic cross section of one turn of the cochlea showing the three fluid-filled compartments, the scala media, scala vestibuli, and scala tympani. The scala media is separated from the scala vestibuli by Reissner's membrane; the stria vascularis lies along the lateral wall of the cochlea. The organ of Corti containing the sensory hair cells and supporting cells rests on the basilar membrane. The tectorial membrane, an acellular structure, lies above the outer hair cells and inner hair cells. Approximately 95% of the auditory nerve fibers contact the IHC; the remaining 5% contact the OHC.

Figure 32–5. (A) The apical surface of the sensory epithelium from a normal control animal with three rows of OHC and a single row of IHC. The stereocilia bundle on each OHC is arranged in a W-shaped pattern with the bottom of the W oriented toward the lateral wall and the interior of the W facing the modiolus. The IHC stereocilia bundle is arranged in a gently curving arc. (B) High-level sound exposures primarily damage the sensory hair cells. In some cases, the entire stereocilia bundle is destroyed leaving behind the W-shaped imprint of the stereocilia rootlets on the apical surface of the OHC (white arrowheads). In other cases, the stereocilia bundle can be partially obliterated, in disarray, or the stereocilia can be fused together or bent over (black arrowheads).

with SEM involves euthanizing the animal; afterward, the cochlea is quickly removed, the stapes and oval windows are opened, and fixative (e.g., 2.5% glutaraldehyde) is slowly perfused through the round window.[25] The cochlea is immersed in fixative for 24 h, postfixed in 1% osmium tetroxide, and dehydrated with ethyl alcohol (ETOH). Afterward, the bony shell surrounding the sensory epithelium is dissected away along with the stria vascularis. Segments of the cochlea are removed, rehydrated, immersed in thiocarbohydrazide, dehydrated, rinsed in acetone, critically point dried in CO_2, mounted on aluminum stubs coated with conductive graphite, sputter coated with gold (25 nm), and examined on an SEM at an accelerating voltage between 10 and 25 kV. Figure 32–5A shows the apical surface of the sensory epithelium from a normal control animal with three rows of OHC and a single row of IHC. The stereocilia bundle on each OHC is arranged in a W-shaped pattern with the bottom of the W oriented toward the lateral wall and the interior of the W facing the modiolus. The IHC stereocilia bundle is arranged in a gently curving arc.

High-level sound exposures primarily damage the sensory hair cells, although secondary damage has been seen in auditory nerve fibers, stria vascularis, or fibrocytes in the sensory epithelium.[26,27] With low-intensity or short-duration sound exposures that primarily lead to TTS or a low level of PTS, damage appears to be largely confined to the stereocilia bundles on the OHC.[28,29] In some cases, the damage is confined to the tip links that contain the mechanically gated ion channels.[30] As the intensity and/or duration of the noise increases, the amount of stereocilia damage increases.[25] In some cases, the entire stereocilia bundle is destroyed leaving behind the W-shaped imprint of the stereocilia rootlets on the apical surface of the OHC (Figure 32–5B, white arrowheads). In other cases, the stereocilia bundle can be partially obliterated, in disarray, or the stereocilia can be fused together or bent over (Figure 32–5B, black arrowhead). Since the transduction channels on the stereocilia play an essential role in the mechanical-to-electrical transduction process that leads to depolarization of the hair cells, significant damage to the stereocilia bundle could result in nonfunctional, but surviving hair cells. With careful sample preparation that reduces the risk of preparation artifacts, it is possible to quantify the amount of stereocilia damage following acoustic overstimulation;[25] however, the technique can be difficult and time consuming, especially if it is necessary to evaluate the condition of the stereocilia over the entire length of the cochlea.

SURFACE PREPARATION TECHNIQUE AND COCHLEOGRAM One of the most useful techniques for surveying the degree of hair cell damage along the entire length of the cochlea is the surface preparation technique. Detailed methods for preparing and staining surface preparations of the cochlea can be found in Ding *et al.*[31] Briefly, the cochlea is removed, stained, and/or fixed using a procedure similar to those described above. Afterward, the bony shell and lateral wall surrounding the cochlea are carefully dissected away and then the sensory epithelium containing the organ of Corti with the IHC and OHC is carefully removed as a surface preparation. Sections of the cochlea are typically removed in half turns. The half turns are mounted in glycerin or other medium on glass slides in sequential order, coverslipped, and then observed through a light microscope typically at 400× magnification. Two of the staining techniques we have found to be especially useful are Harris's hematoxylin and succinate dehydrogenase histochemistry (SDH). For Harris's hematoxylin staining, the cochleas are first fixed with 10% formalin for approximately 4 h and then immersed in hematoxylin staining solution for approximately 5 min. Afterward, specimens are dipped in 0.3% hydrochloric acid for 3 min to remove excess stain followed by immersion for a few seconds in ammonium aluminum sulfate until the tissue turns blue. This is an inexpensive, reliable, and convenient method that intensely labels the nuclei of hair cells and supporting cells. SDH staining is a particularly useful method for selectively staining just the IHC and OHC since SDH and other dehydrogenase enzymes are heavily expressed in the hair cells, but not in the surrounding supporting cells. The SDH technique utilizes colorless tetrazolium salts that are reduced to colored formazans in the presence of hydrogen donors. Briefly, after removing the cochlea, the round and oval windows are opened and a small hole is made in the apex. Then SDH staining solution is gently perfused through the round window followed by immersion in SDH for approximately 45 min at 37°C. Afterward, the cochlea is fixed with 10% formalin, dissected out as a flat surface preparation, and mounted on glass slides for analysis.

Figure 32–6A shows two segments of surface preparations from SDH-stained cochleas, one from a leupeptin-protected ear and the other from the opposite unprotected ear of a chinchilla that had been exposed for 48 h to a 105 dB SPL OBN centered at 4 kHz. The IHC and OHC in the protected ear (Figure 32–6A,

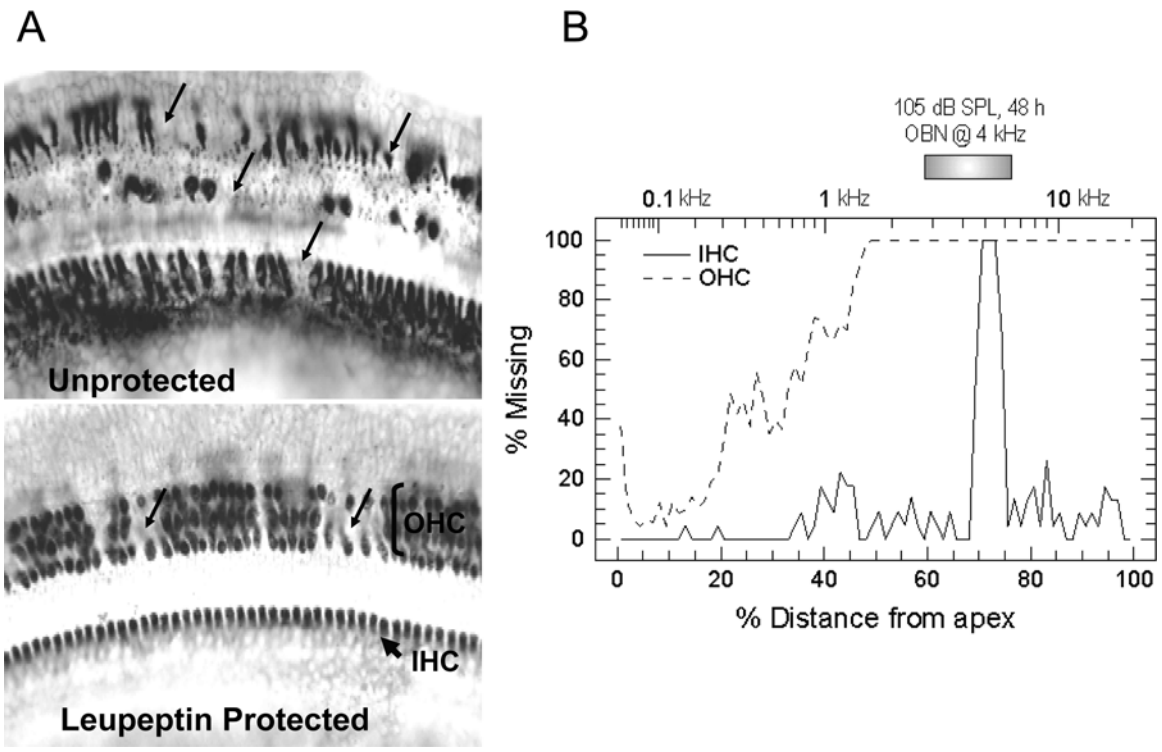

Figure 32–6. (A) Segment of a surface preparation of chinchilla cochlea stained with SDH. Surface preparations were obtained from a chinchilla that had been exposed for 48 h to an octave band noise centered at 4 kHz at 105 dB SPL. One ear (bottom, left panel) had been infused with a protective agent, leupeptin; the opposite ear (upper, left panel) was unprotected (no treatment). The protected ear shows intense dark purple staining of the single row of IHC and three rows of OHC; all of the IHC are present in the protected ear whereas a few OHC are missing (arrows). Many OHC are missing (arrows) in the unprotected ear as well as some IHC. (B) Cochleogram showing the percentage of missing IHC and OHC as a function of percent distance from the apex of the cochlea from a chinchilla that had been exposed to a 105-dB SPL octave band noise (OBN) centered at 4 kHz for 48 h. The position along the length of the cochlea is related to frequency using a frequency–position map for the chinchilla.[32] The horizontal bar at the top shows the approximate bandwidth of the OBN on the frequency–place map. A large IHC loss was present near the 4-kHz place in the cochlea. Note the large widespread loss of OHC extending from the base of the cochlea up to 30% distance from the apex.

bottom, left) are darkly stained while the surrounding supporting cells are unstained, making it especially easy to identify the hair cells. All of the IHC are present in the protected ear and most of the OHC are present in three parallel rows, except for the scattered loss of a few OHC (arrows). In the unprotected ear from the opposite cochlea (Figure 32–6A, upper left), many OHC are missing as well as a few missing IHC.

The degree of IHC and OHC loss can be quantified by counting the number of hair cells that are present or absent at each cochlear location from the apex and proceeding toward the base. For ease of comparison, hair cell loss can be converted to percentage loss; however, this requires that the hair cell density be determined for each cochlear location in the species being studied.[31] Figure 32–6B is a cochleogram from a noise-exposed chinchilla (105 dB SPL, OBN at 4 kHz, 48 h) showing the percentage of missing OHC and IHC as a function of the percent distance from the apex (lower abscissa) of the chinchilla cochlea. Using the frequency-position map developed for the chinchilla, percent distance from the apex of the cochlea can be related to frequency as shown in the upper abscissa.[32] The cochleogram in Figure 32–6B shows a large, discrete lesion located at a distance of 70–75% from the apex; the location of the IHC lesion lies near the 4 kHz region on the chinchilla frequency-place map. This chinchilla sustained a 100% loss of OHC extending from the base of the cochlea down to the middle of the cochlea (~1.8 kHz) followed by a decline of the OHC lesion in the apical half of the cochlea.

PHYSIOLOGICAL MEASURES OF NOISE-INDUCED HEARING LOSS

While behavioral measures have been extremely useful in delineating the perceptual changes that are associated with NIHL, the assessment technique is time consuming and provides little insight regarding the functional changes that are occurring in the cochlea. Consequently, researchers have developed a number of useful physiological tools for evaluating the functional status of the hair cells in ears with NIHL. Three of the most useful tools are discussed below.

OTOACOUSTIC EMISSIONS Otoacoustic emissions, discovered by Kemp in the late 1970s, refer to sounds generated by an active process within the inner ear. Otoacoustic emissions can be recorded by a sensitive microphone placed in the ear canal.[33,34] The biological source of the spontaneous and sound-evoked otoacoustic emissions remained a mystery until it was discovery that OHC possess an electromotile response. Changes in the membrane potential of the OHC cause extremely rapid, cycle-by-cycle longitudinal movements of the OHC body.[35,36] OHC elongate

during membrane hyperpolarization and contract during depolarization. The electromotile response is asymmetric with contraction being substantially larger than elongation. The electromotile response arises from the voltage-sensitive motor protein prestin, which is heavily expressed in the lateral wall of the OHC.[37] Knockout mice lacking prestin fail to produce otoacoustic emissions, even though the OHC appear normal, and show hearing loss on the order of 50 dB.[38] Furthermore, destruction of the OHC, but not the IHC, leads to substantial or complete loss of otoacoustic emissions.[39,40] Thus, otoacoustic emissions provide a sensitive and selective tool for assessing the status of the OHC in NIHL.

Distortion Product Otoacoustic Emissions Distortion product otoacoustic emissions (DPOAE) can be evoked from a normal, healthy ear by presenting two primary tones, f1 (lower frequency) and f2 (higher frequency), through a pair of loudspeakers. DPOAE amplitudes are largest when the f2/f1 ratio is on the order of 1.2 and the intensity level of the lower frequency, L1, is slightly greater than the intensity level of the higher tone, L2. When the primary tones, f1 and f2, are delivered to the ear canal, they propagate in the forward direction into the inner ear where each tone sets up a traveling wave with a peak at its characteristic place along the cochlear (Figure 32–7A). The two primary tones produce maximum activation of OHC in the region of the cochlear where the peaks of the two traveling waves overlap. Since the mechanical response of the cochlear partition vibrates nonlinearly at its characteristic place, presumably due to the nonlinear electromotile response of the OHC, distortion tones, the most prominent of which is 2f1–f2, are generated in the vicinity of the primaries. The distortion tones generated in the cochlea propagate in two directions, in the forward direction to the characteristic place associated with 2f1–f2 and in the reverse direction, back through the middle ear and into the ear canal. As shown in Figure 32–7B, the two primary tones together with the distortion tone, 2f1–f2, can be recorded with a sensitive microphone in the ear canal and analyzed with a spectrum analyzer to identify the amplitude of f1, f2, and 2f1–f2. When the OHC are healthy, then a robust 2f1–f2 DPOAE can be recorded as schematized in Figure 32–7B. The functional status of OHC located at high, mid, or low frequencies can be assessed simply by sweeping the f1, f2 pairs from high to low frequencies and measuring the amplitude of the DPOAE at each frequency location. A plot of DPOAE amplitude versus the geometric mean of each f1, f2 pair is sometimes referred to as a DPgram, somewhat akin to a behavioral audiogram. When the OHC are damaged or destroyed, DPOAE amplitude is greatly reduced or absent.

Distortion Product Otoacoustic Emission Amplitude and Noise-Induced Hearing Loss The amplitude of the DPOAE can be evaluated at each f1, f2 pair as the level of the two primary

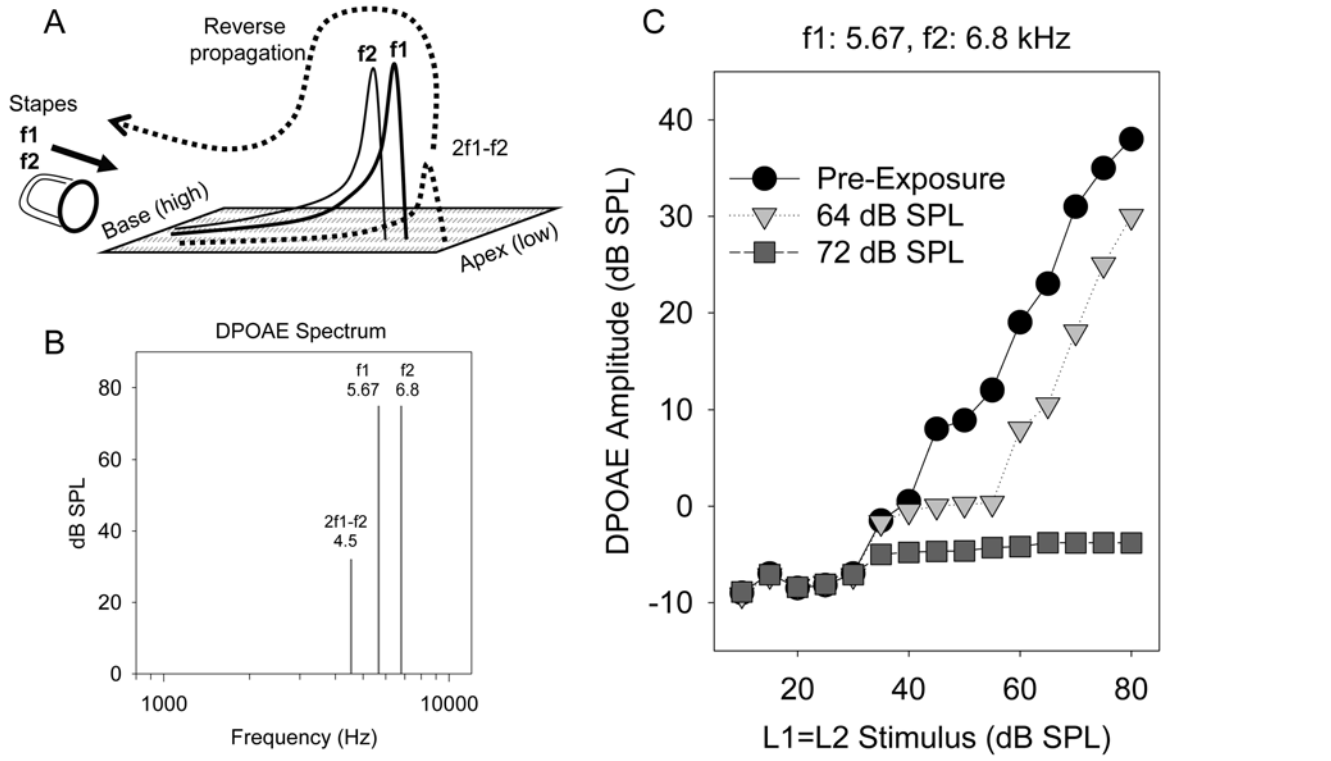

Figure 32–7. (A) Basilar membrane vibration pattern (forward transduction) to f1 (lower) and f2 (higher) primary input tones with an f2/f1 ratio of 1.2. Primary tones generate a distortion signal, 2f1–f2, that propagates in the forward direction from the region of the primaries to its characteristic place in the cochlea; the distortion tone also propagates in the reverse direction back toward the stapes, through the middle ear, and into the external ear canal, where it is detected with a sensitive microphone. The high-frequency base of the cochlea is shown on the left and the low-frequency apex of the cochlea is shown on the right. (B) Sound spectrum recorded with a sensitive microphone in the ear canal of a healthy ear. Primary tones f1 (5.67 kHz) and f2 (6.8 kHz) were presented at 75 dB SPL. Note the distortion production otoacoustic emission (DPOAE) signal, 2f1–f2, at 4.5 kHz at an intensity of approximately 35 dB SPL. (C) DPOAE input/output functions measured preexposure and after a 2–3 day exposure to an octave band of noise centered at 4 kHz presented at 64 dB SPL and then 72 dB SPL. (Redrawn from Eddins *et al.*[41])

tones, L1 and L2 (L1 = L2), are increased. DPOAE input/output functions can be used to assess the functional status of the OHC in the vicinity of f1 (5.67 kHz) and f2 (6.8 kHz) before and after a noise-induced ATS using an octave band noise centered at 4 kHz (see Figure 32–9C). Prior to the noise exposure, DPOAE amplitude begins to rise above the measurement noise floor when the stimulus level exceeds 30 dB SPL. Between 40 and 80 dB SPL, DPOAE amplitude increases from approximately 0 to nearly 40 dB, that is, a growth rate of 1 dB output per dB of input. When chinchillas are exposed to a long-duration (several days) noise that leads to ATS, DPOAE amplitude drops precipitously as the level of the octave band noise centered at 4 kHz increases.[41] Exposure to an octave band noise of 64 dB SPL, which induces ~30 dB of ATS, results in roughly a 10 dB decrease in DPOAE amplitude at nearly all stimulus levels. When the level of the octave band noise was increased to 72 dB SPL, an exposure level that induces 40 dB of ATS, the DPOAE was almost completely abolished. Importantly, the DPOAE remained essentially normal at low frequencies where there was little or no hearing loss from the exposure. A set of six to eight DPOAE input/output functions between 1000, and 12,000 Hz can be measured in about 30 min or less. In some species such as the chinchilla, DPOAE can be measured while the animals are awake and lightly restrained avoiding potential confounding effects associated with anesthesia. These results indicate the DPOAE are an extremely useful tool for assessing NIHL and the functional status of the OHC; however, otoacoustic emissions have a number of limitations. First, DPOAE are almost completely abolished once the hearing loss exceeds 30–35 dB; thus otoacoustic emissions cannot differentiate between large NIHL in the range of 35 and 100 dB. Second, DPOAE cannot assess the functional status of the IHC and the auditory nerve, which provide the main conduit for transmitting information to the central auditory system. Therefore two additional electrophysiological techniques, the compound action potential (CAP) and single fiber recordings from the auditory nerve, provide important insight on the output transmitted through the IHC and into the central auditory system.

Compound Action Potential and Noise-Induced Hearing Loss The CAP represents the local field potential that originates from the synchronous response of the type I auditory nerve fibers that make synaptic contact with the IHC. The CAP onset response can be elicited with a click or short duration (1–2 msec) tone bursts with a rapid rise–fall time (1 msec). CAP recordings can be obtained relatively easily by making a small opening in the middle ear space and placing a silver ball wire electrode on or near the round window (Figure 32–4A) and a ground electrode at some remote location. In most cases, the CAP is recorded from acute surgical preparations; however, it is possible to chronically implant the recording electrode on the round window, seal the opening in the middle ear space with dental cement, and then thread the output of the electrode to a connector permanently mounted on the skull.[25]

The output of an electrode contains the cochlear microphonic (CM) potential, mainly arising from the OHC, the summating potential (SP) mainly coming from the IHC, and the CAP from the type I neurons that contact the IHC. The CAP response can be isolated by filtering (100–3000 Hz) to eliminate the SP and reversing the phase of the stimulus 180° on every other stimulus presentation to cancel the CM.[42,43] Figure 32–8A shows the main features of the CAP waveform recorded from the round window. The CAP consists of two negative peaks, N1 and N2, separated by approximately 1 msec. The latency between stimulus onset and the N1 peak is approximately 1.5 msec; however, latency increases as the intensity and frequency of the stimulus decrease. The amplitude of the N1 component (baseline to negative peak) can be measured as a function of stimulus intensity to obtain the CAP input/output function to a click stimulus or tone burst. Figure 32–8B shows the CAP input/output function for a tone burst under normal conditions and after an NIHL. As stimulus intensity is increased, the amplitude of the N1 response rises above the noise floor of the recording system. In normal animals, the visual detection threshold for the CAP is on the order of 20–25 dB. In animals with NIHL, the CAP amplitude is reduced and the intensity needed to produce a just noticeable response is shifted toward higher intensities to reflect the degree of NIHL. In the example shown in Figure 32–8B, the noise exposure resulted in a threshold shift of the CAP of approximately 25 dB and a roughly 50% reduction in the maximum amplitude.

The tone burst-evoked CAP is useful for assessing the degree of NIHL because the tone burst frequency can be varied to determine the CAP threshold in different frequency regions thereby obtaining a CAP "audiogram." Figure 32–8C shows what the CAP thresholds might look like in a normal chinchilla and one that had been exposed for 24 h to an OBN centered at 4 kHz and an intensity of 86 dB SPL. The CAP thresholds in the normal control are lowest in the mid-frequencies (~20–25 dB) and increase to around 40 dB at the highest and lowest frequencies. Animals that have been exposed to the OBN centered at 4 kHz show elevated CAP thresholds above 2 kHz and normal thresholds at the low frequencies. The CAP threshold shifts are on the order of 50 dB at 4 and 8 kHz and slightly less at 16 kHz. Thus, the CAP can provide a global look at the degree of hearing loss.

Single Auditory Nerve Fibers and Noise-Induced Hearing Loss The auditory nerve forms the only pathway by which acoustic information transduced by the hair cells can be relayed to the central auditory system. The auditory nerve is composed of type I and type II nerve fibers arising from the spiral ganglion neurons that lie within the modiolus. Dye-labeling studies indicate that the type I fibers, which comprise 95% of the total population, appear to be the only fibers that respond to sound stimuli.[44,45] Since each type I nerve fiber makes one-to-one synaptic contact with a single IHC at some point along the length of the cochlea, the response properties recorded from a type I fiber reflect the combined output of the OHC, IHC, and supporting cells from a discrete region of the cochlea. The fibers are tonotopically organized; those innervating hair cells in the apex of the cochlea are most sensitive to low frequencies and those located progressively closer to the base of the cochlea respond best to progressively higher frequencies.

Glass micropipettes with diameters less than 1 μm are typically used to record the all or none spike discharges from single fibers in the stump of the auditory nerve as it passes out of the cochlea through the internal auditory meatus and into the brainstem where the fibers synapse on neurons in the cochlear nuclei.[46,47] Figure 32–9A shows the spike discharge pattern that would occur when a tone burst is presented at a frequency and intensity sufficient to activate the neuron. The number of spike discharges is highest during the onset of the tone burst and gradually declines to a steady-state level; after the tone burst is turned off the spontaneous spike rate is low and gradually returns to the baseline

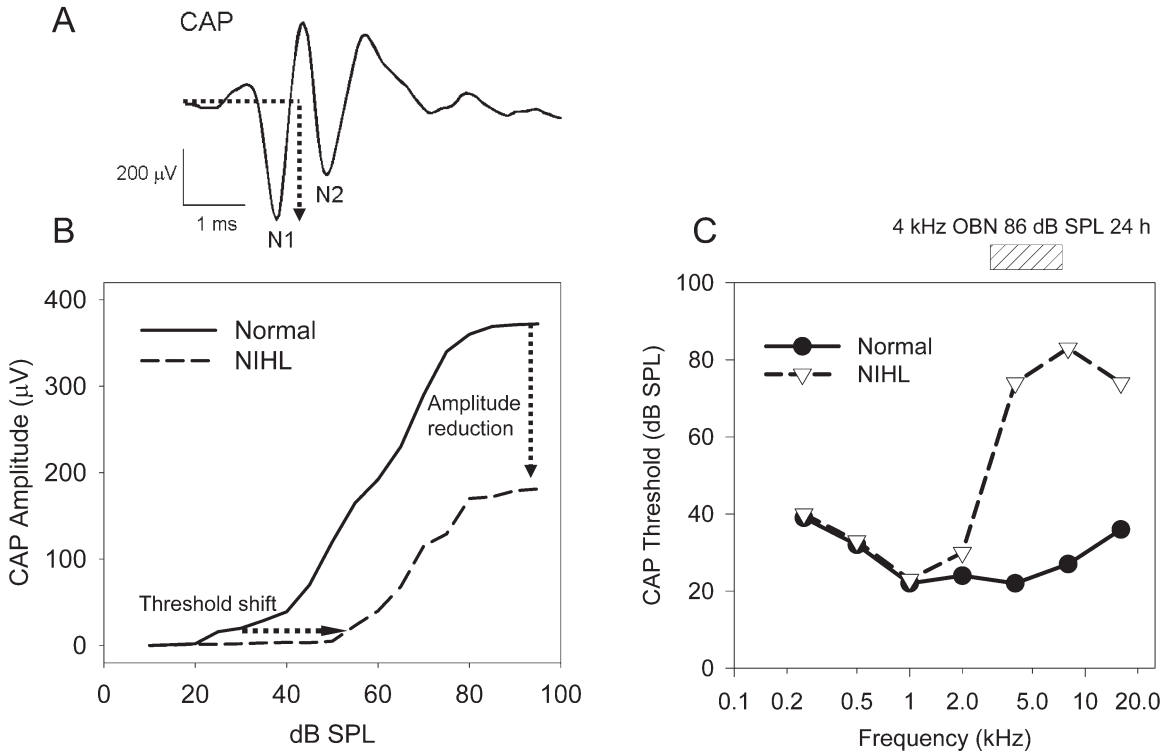

Figure 32–8. (A) CAP waveform with N1 and N2 components. (B) CAP input/output function before and after NIHL. Note the reduction in CAP amplitude and the increase in CAP threshold resulting in threshold shift. (C) CAP threshold versus tone burst frequency in the normal control group and in the group exposed for 24 h to octave band noise centered at 4 kHz at 86 dB SPL.

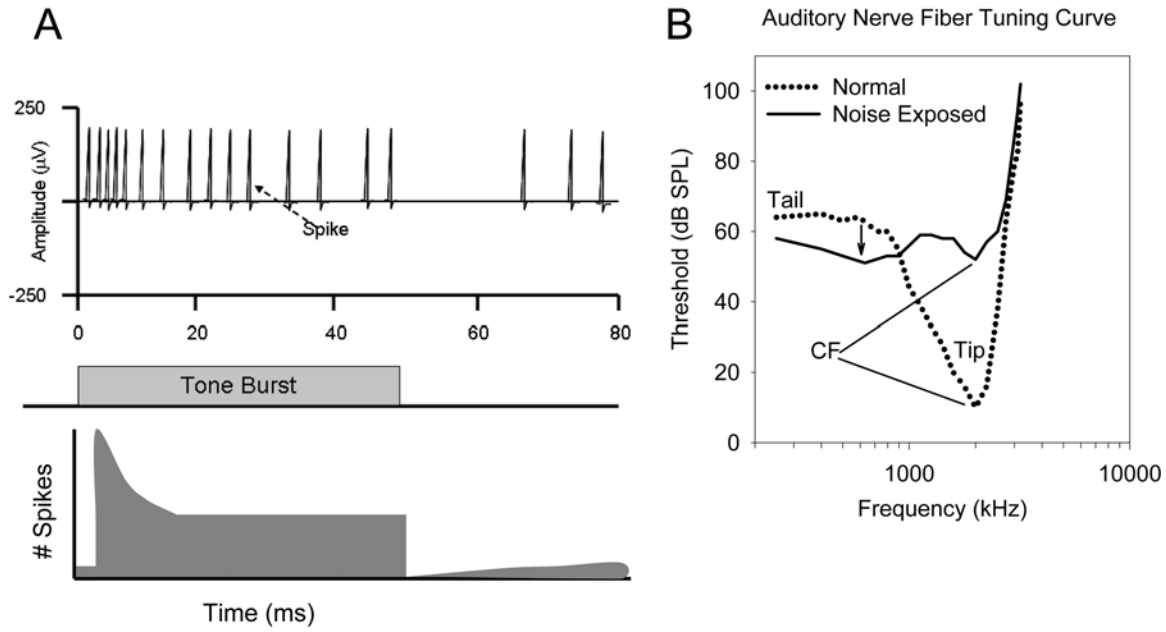

Figure 32–9. (A) Action potentials from an auditory nerve fiber during the presentation of a tone burst at a frequency–intensity combination that caused an increase in spike rate during the presentation of the tone burst. The lower panel is a poststimulus time histogram showing the number of spike discharges occurring during and after the tone burst. (B) Frequency–threshold tuning curves from an auditory nerve fiber in a normal chinchilla (dotted line) and one from a noise-exposed animal (solid line). The normal tuning curve has a low-threshold, sharply tuned tip with a characteristic frequency (CF, frequency with lowest threshold) near 2 kHz; the normal tuning curve has a high-threshold, broadly tuned tail beginning roughly one octave below CF. The tuning curve from the noise-exposed chinchilla has elevated thresholds and broad tuning at the CF region located along the high-frequency side of the tuning curve. Thresholds in the low-frequency tail of the tuning curve are somewhat lower than normal (hyposensitive). Below the high-frequency cutoff, the threshold is nearly constant across the frequency resulting in poor frequency selectivity. (Redrawn from Salvi *et al.*[47])

spontaneous rate. The average spike discharge pattern during and following the tone burst can be measured by presenting the tone burst many times and counting the number of spikes that occur at specific time bins during and following the stimulus; this type of plot is referred to as a poststimulus time histogram and is shown below the tone burst in Figure 32–9A.

Tone burst frequency and intensity can be varied to determine which frequency–intensity combinations are just able to produce a significant increase in discharge rate above the spontaneous rate; this information is used to construct a frequency–threshold tuning curve for each fiber. The dotted line in Figure 32–9B shows the frequency–threshold tuning curve of an auditory nerve fiber in the chinchilla that has a characteristic frequency (CF) of 2 kHz; the CF is defined as the frequency with the lowest threshold. This fiber presumably innervates an IHC located near the middle of the chinchilla cochlea. The auditory nerve fiber tuning curves are similar in shape to psychophysical tuning curves (Figure 32–3A). Physiological tuning curves have a low-threshold, narrowly tuned tip at CF, a steep high-frequency slope, and a threshold plateau in the low-frequency tail. If recordings are obtained from many neurons, auditory nerve fiber tuning curves can be found with CFs spanning the entire range of hearing of the animal.[47] That is, the auditory nerve contains fibers tuned to a frequency range covering the entire range of hearing.

Auditory nerve fiber tuning curves have been evaluated in animals with varying degrees of NIHL and varying amounts of OHC and IHC damage. When animals are exposed to high-level noise that causes 40–50 dB of hearing loss and primarily damages the OHC, then fiber thresholds increase significantly around the CF and the tip of the tuning curve (Figure 32–9B). In addition, thresholds in the tail of the tuning curve sometimes decrease (hyposensitive). Thus, the fiber not only becomes less sensitive, but more broadly tuned responding with almost equal sensitivity to most frequencies from the tail up to the high-frequency cutoff of the tuning curve. These results indicate that OHC are largely responsible for giving each fiber its extraordinary sensitivity and exquisite tuning. In cases in which both the OHC and IHC are destroyed, acoustic information can no longer be relayed to the auditory nerve fibers innervating the region of total hair cell damage. In cases in which there is total loss of OHC and IHC, a gap appears in the CF distribution.[47] Psychoacousticians often refer to regions with complete loss of IHC and OHC as cochlear "dead regions" since sound-induced vibrations from these regions fail to produce any neural activity.[48,49]

BIOLOGICAL BASIS OF NOISE-INDUCED HEARING LOSS

Over the past 30 years, much has been learned about how intense sounds affect hearing, the anatomical structures in the ear, and the physiological properties of the cochlea. In the past few years, research has focused on understanding the cellular basis of NIHL with the long-term goal of developing intervention strategies that might protect the hair cells from noise-induced damage and reduce the risk of NIHL.

CELL DEATH, OXIDATIVE STRESS, AND NOISE-INDUCED HEARING LOSS As with many other forms of tissue injury, noise-induced hair cell loss can occur through necrosis or apoptosis.[50,51] Necrotic cell death is characterized by swelling of the cell body and lyses of the cell membrane leading to leakage of the cell's content into the surrounding intercellular space, which can generate an inflammatory response. In cases of extremely high levels of noise, the mechanical vibrations in the inner ear may rip apart sections of the sensory epithelium leading to the rupture of cell membranes and necrotic cell death.[52–54] Apoptosis, or programmed cell death, is characterized morphologically by chromatin condensation, nuclear condensation and fragmentation, membrane blebbing, and formation of apoptotic bodies. Hair cell death associated with lower level noise exposures that do not lead to direct mechanical injury to the hair cells may arise from the overproduction of reactive oxygen species arising from metabolic stress.[55] Reactive oxygen species implicated in NIHL include the superoxide radical, hydrogen peroxide, the hydroxyl radical, and peroxynitrite. The metabolic stress associated with acoustic overstimulation has been shown to lead to the overproduction of reactive oxygen species.[56,57] Since acoustic overstimulation can decrease blood flow to the cochlea, the subsequent reperfusion of blood may be a major source of reactive oxygen species.[57]

PHARMACOLOGICAL STRATEGIES FOR PREVENTING NOISE-INDUCED HEARING LOSS Armed with the fact that noise may induce the overproduction of reactive oxygen species in the cochlea, numerous animal studies have been undertaken to identify pharmacological strategies that can prevent NIHL and block hair cell death by suppressing the production of reactive oxygen species. For example, *R*-phenylisopropyladenosine (*R*-PIA), which upregulates glutathione and superoxide dismutase, endogenous antioxidants, reduces NIHL and hair cell loss.[58] Similarly, acetyl-L-carnitine, which enhances the function of mitochondria during oxidative stress, and D-methionine, which enhances the production of the endogenous antioxidant, glutathione, reduce NIHL and hair cell loss.[59] Likewise, when glutathione monoethyl ester, a precursor of glutathione, is applied to the round window, it reduced the amount of NIHL and hair cell loss.[60]

CONCLUSIONS

Animal models have played an important role in determining how the intensity, duration, and spectrum of a noise affects the amount of hearing loss and how hearing perception changes when the OHC and IHC are damaged. High-level noise exposures tend to damage OHC before IHC. The first signs of damage are often seen on the stereocilia bundles that contain the mechanical-to-electrical transduction apparatus. Noise-induced destruction of the OHC results in a 40–50 threshold elevation plus a loss of frequency selectivity and temporal resolution. OHC damage leads to a significant reduction or complete loss of DPOAE, whereas auditory nerve fibers show a selective elevation of threshold near CF and significant loss of tuning. When the noise exposure is severe enough to destroy both the IHC and OHC, neural activity can no longer be relayed to the central nervous system resulting in a cochlear "dead region." Since the hair cells in the mammalian inner ear do not spontaneously regenerate, preventing NIHL hearing loss from occurring has become a major research focus. Since high-level noise exposures appear to generate toxic reactive oxygen species such as the superoxide radical, hydrogen peroxide, and the hydroxyl radical, a promising approach to preventing NIHL is to enhance the antioxidant capacity of the inner ear using endogenous or exogenous therapeutic agents. Positive results obtained in animal models of NIHL are therefore likely to lead to translational research aimed at preventing NIHL in humans who are routinely exposed to high-level noise.

33 Human and Animal Models for the Study of Muscle Pain

Norman F. Capra and Jin Y. Ro

ABSTRACT

Muscle pain typically results from engaging in novel or unaccustomed levels of muscle activity. It may also result from a sharp blow or other direct trauma. Typically this type of pain resolves over a few days. However, several clinical conditions are associated with muscle pain that may range in severity from an intermittent but recurring distraction, to a debilitating disorder lasting for months that is accompanied by severe stress and in some cases significant motor impairment. The cost of medical treatment and lost work productivity runs in the billions of dollars, yet little is known about the etiology of chronic muscle pain. This chapter will explore how experimental approaches have been used in an effort to model clinical pain in humans and in experimental animals, and provide practical information regarding the implementation, interpretation, and limitations of these methods. Parallels between human and animal experiments will be emphasized.

Key Words: Chronic muscle pain, Hyperalgesia, Allodynia, Experimental models, Intramuscular injection, Exercise, Ischemic contraction, Induction, Assessment.

INTRODUCTION

The costs of medical treatment, lost work productivity, and suffering resulting from chronic musculoskeletal pain conditions run in the billions of dollars, yet relatively little is known about the underlying mechanisms of chronic muscle pain. Chronic muscular pain conditions may be regional [e.g., temporomandibular disorders (TMD) and low back pain] or widespread, involving multiple tender points distributed over most of the body [e.g., fibromyalgia syndrome (FMS)]. Progress in understanding the pathophysiological basis for these disorders has been limited by the lack of adequate human and animal models to study chronic muscle pain. However, renewed interest in the subject has led to refinements to early methods and the development of promising new approaches for the study of chronic muscle pain.

Several strategies have been used to experimentally induce muscle pain including ischemic contraction, novel or prolonged exercising, mechanical stimulation, electrical stimulation, and intramuscular injection of algesic substances (i.e., chemical stimulation) in humans. Each of these methods has also been adapted to study peripheral and central nociceptive mechanisms in experimental animals. The judicious implementation of experimental tools that are not feasible in humans and the development of novel methods for the assessment of nociceptive processing in animal models have provided insight into the mechanisms of persistent pain in humans. This chapter will consider several experimental approaches in which parallels between the results of human and animal experiments have enhanced the understanding of the mechanisms of chronic muscle pain.

Muscle pain produces characteristic sensory and sensorimotor manifestations. Precise assessment of these characteristic features is necessary to evaluate therapeutic efficacy and to study underlying mechanisms. Pain of muscle origin is generally more diffuse than cutaneous pain, it spreads to adjacent muscles, and it is commonly referred to remote sites. Assessing the distribution of pain in patients with chronic muscle pain is clinically useful. The quality of pain originating in muscles differs from superficial pain and is often described by patients as aching, tender, and throbbing. Tenderness, a characteristic symptom of persistent muscle pain, results from sensitization of peripheral afferents and central neurons. Sensitization results in lowering of the mechanical threshold of muscle afferent receptors to noxious and innocuous mechanical stimuli leading to hyperalgesia and allodynia, respectively. In addition, complex emotional signs and autonomic symptoms[1] often accompany chronic muscle pain.

Pain arising in muscle and associated deep tissues (e.g., investing fascia, blood vessels) begins with the activation of small-diameter group III and group IV afferent nerve fibers. The morphology and distribution of muscle afferents contribute to the characteristic properties of muscle pain. They are diffusely distributed and terminate in unmyelinated (free) nerve endings. Many of these afferents are polymodal, responding to a wide range of stimuli. The neurobiology of muscle pain, a glossary of pain terminology, and a wealth of information on clinical muscle pain conditions are provided by Mense and colleagues.[1–3]

EXPERIMENTAL MUSCLE PAIN: INDUCTION

In the 1930s, Kellgren introduced the technique of making intramuscular injections with hypertonic saline (HS; 5%) to model deep pain.[4] This method is recognized as a safe, reliable, and reproducible experimental procedure. Most importantly, subjects report that pain resulting from a single intramuscular HS injection is similar in quality and intensity to clinical pain of muscle origin Each of these conditions—safety, reliability, reproducibility, and clinical relevance—is an essential ingredient for the study of experimentally induced muscle pain in humans.

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

Also in the 1930s, Lewis introduced the technique of ischemic contraction to produce muscle pain.[5,6] This method has been used successfully to address certain multidimensional aspects of deep tissue pain[7] and is appropriate for the study of clinical pain disorders that appear to be primarily related to vascular insufficiency.

Exercise-based models, which produce pain in response to unaccustomed muscle activity, have been widely used by sports physiologists to produce delayed onset muscle soreness (DOMS).[8] The cause, the onset, and the time course for resolution of DOMS are well characterized. As more is learned about the mechanism of DOMS, it is becoming increasingly clear that it is connected to inflammatory processes similar to those associated with chronic inflammatory pain.[9,10] As a result, the potential of this method to address clinically relevant questions is being recognized by experimentalists.

INTRAMUSCULAR INJECTION Of the methods described above, intramuscular injection of algesic and inflammatory agents is the most common method of induction. This method involves either injecting a discrete bolus of a sterile solution containing an algogen (pain-producing agent) or the continuous infusion of an algogen (usually HS) over a period of minutes into the muscle of interest. Pain assessments are typically made before, during, and after algesic administration.

Algogens In addition to the advantages described above, HS may be injected several times in the same muscle or it may be preceded or followed by injection with isotonic saline, which serves as a vehicle to control nonspecific effects. This is possible because single injections of HS do not produce sensitization or "tenderness," a characteristic feature of clinical muscle pain. To study sensitization, an alternate algogen or injection strategy must be considered.

A number of *endogenous* and *exogenous* algogens have been used for making intramuscular injections in human and animal experiments (Table 33–1).[11–16] Endogenous algogens are substances found naturally in the body such as the metabolites of exercising muscle or substances that accumulate in the interstitial tissues subsequent to injury or with inflammation (i.e., myositis). Most algogens produce measurable sensitization (e.g., a reduction in mechanical threshold) following a single injection and when combined, endogenous algogens may synergize to produce greater pain and sensitization than injection of either substance alone.[17] In addition to algogens tested in humans, exogenous agents not considered safe for human use have been used to study nociceptive mechanisms in animals. For example, complete Freund's adjuvant (CFA) produces significant and prolonged inflammation and is used to model persistent muscle pain.

Many algogens operate through specific receptor-mediated mechanisms. Capsaicin, which activates C fiber (group IV) nociceptors, binds to the TRPV1 receptor and is present in a subpopulation of muscle afferents. Capsaicin is one of the few exogenous algogens that have been used to induce muscle pain in human studies.[18] Sequential intramuscular injection strategies, involving injection with specific receptor agonists and antagonists prior to algesic injections, have been exploited to study the involvement of specific membrane receptors in peripheral aspects of muscle pain. A list of algogens is provided in Table 33–1 with references to selected literature describing how they were used to study muscle pain.

Table 33–1
Algogens used for intramuscular injection[a]

Substance	*Site of action*
Endogenous	
Acid saline (pH)[26,27]	ASICS receptors
Adenosine[11]	P2X receptors
Bradykinin[17]	B1 and B2 receptors
Potassium chloride[12,13]	NS
Glutamate[22,23]	NMDA, AMPA, MGluR receptors
Hypertonic saline[28,35,37]	NS
NGF[14]	Trk A receptor
PGE_2[9]	EP 1–4 receptors
Serotonin[17]	5-HT receptors
Substance P[17]	NK-1 receptors
TNF-α [15]	TNFA R1 and RII
Exogenous	
Capsaicin[18]	TRPV1
Carrageenan[44,56]	NS
Formalin[54]	NS
Complete Freund's adjuvant[50]	NS
Mustard oil[16,22,23]	TRPA1

[a]NS, nonselective; NMDA, *N*-methyl-D-aspartate; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; NGF, nerve growth factor; PGE_2, prostaglandin E_2; 5-HT, 5-hydroxytryptamine; TNF, tumor necrosis factor.

Bolus Injections

Injection Volume In most cases, injection volume has been empirically determined based on the size and morphology of the muscle under study. For animal experiments, adequacy of the injection volume and intramuscular location may be confirmed by including an inert dye in the injection solution and performing careful postmortem dissection. Following injection of algogens that produce significant tissue edema, Evan's Blue may be administered near the end of the experiment. Localization of the injection site can be inferred from the distribution of Evans Blue and the extent of edema can be determined by measures of plasma extravasation.[19,20] Cairns *et al.*[21] used magnetic resonance imaging to determine edema volume in the masseter muscle following injection with glutamate.

Injection Parameters Consideration must also be given to the duration, timing, and sequencing of injections. Injections are usually made slowly to limit effects due to increases in local tissue pressure. If multiple injections of algogen are to be performed, sufficient time must be allowed for the effects of each injection to clear. If drugs are injected prior to algogen the timing is critical to maximize the drug effect. By carefully timing the injection of antagonists prior to injections with glutamate, Ro and others have provided compelling evidence that glutamate has important actions at peripheral receptors in muscle nociception.[22–25] Algesic injections are evaluated against isovolemic injections with vehicle and observations are made with the experimenter blind to the injection condition.

The initial effect and the duration of algesic action are also important considerations. For example, the primary effects of injecting a bolus of HS (e.g., a pain report in humans or increased neuronal activity in animals) dissipate within several minutes and vehicle or another dose of HS can be reinjected into the same site in the same subject. In contrast to HS, glutamate produces post-injection sensitization and edema. In such cases, reinjection into the same muscle is not practical, so experiments must involve separate experimental and control groups.

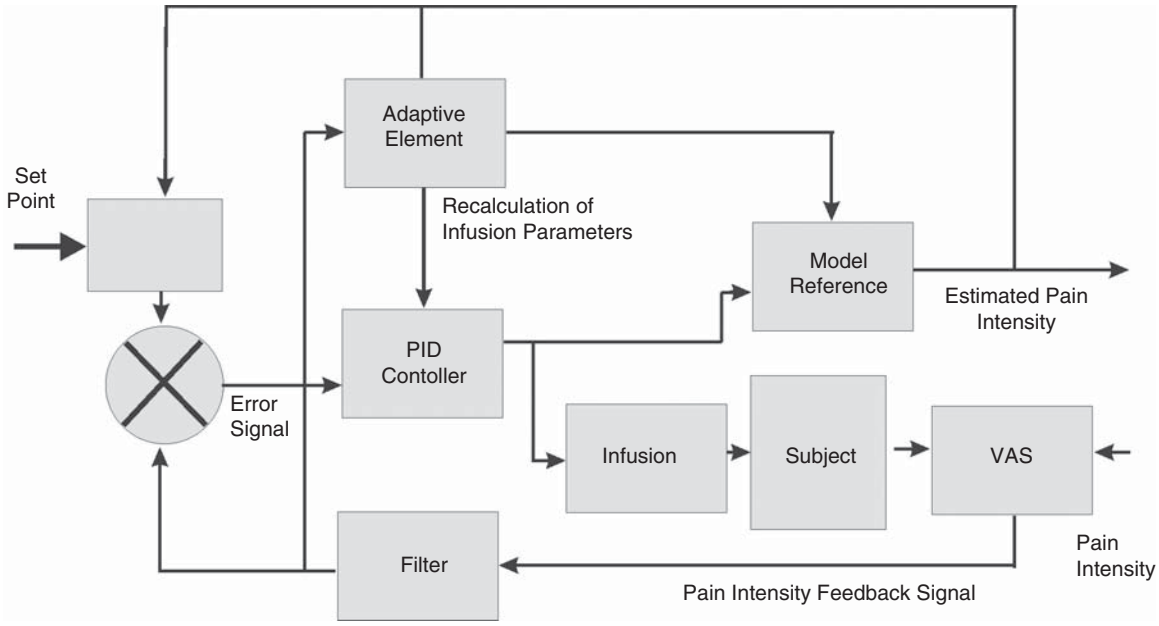

Figure 33–1. Block diagram of the closed loop system designed to induce and maintain pain intensity. (Adapted from Stohler.[31])

An interesting approach developed by Sluka and co-workers[26,27] involved making repeated intramuscular injections of acid saline buffered to pH 5.0. In contrast to HS in a "normal" pH range, repeated injections with acid saline produced a prolonged reduction in withdrawal threshold to cutaneous mechanical stimuli and direct muscle pressure, with forceps attached to a force transducer. The long-term behavioral changes observed in animals after repeated acid injection may be equated with allodynia and hyperalgesia in humans.

Intramuscular Infusion Zhang and colleagues[28] developed an infusion system based on closed-loop drug delivery systems to model chronic masseter muscle pain, a common complaint of patients with TMD. Feedback from continuously rated visual analog pain ratings (a measure of pain intensity) was used to adjust HS infusion rates and maintain a constant pain level for as long as 20 minutes.[29,30] The major elements of the system include a microprocessor-controlled infusion pump interfaced with a PC, a proportional integral derivative (PID) controller, a strain gage pressure transducer, an electronic visual analog scale (VAS), and a tubing delivery system with meticulously defined mechanical properties to account for factors such as compliance and dead space (Figure 33–1). Complete methodological details are provided in the original publications.[28]

For the experiment, an infusion needle was placed in a standard location (i.e., in the "middle" of the masseter muscle). Once any pain produced by placing the needle subsided, subjects received an initial standard algesic injection and pain intensity ratings were obtained every 15 sec until it dissipated. The overall magnitude and time to peak pain for the initial response were recorded (i.e., the open loop response) and compared to a preestablished group mean response. A control algorithm used these values to calculate an initial infusion rate. The infusion was started and updated pain intensity values were used as feedback to adjust and maintain a constant pain level (VAS score).

Sustained infusion of HS produced complex patterns of pain-related states including primary and secondary muscle hyperalgesia and altered cutaneous sensibility. Importantly, this approach also evoked emotional and autonomic responses similar to those observed in chronic pain conditions. This method has provided insight into opioid mechanisms in the sensory and affective dimensions of pain,[30] revealed sex differences in opioid sensitivity,[32] and provided evidence that genetic factors underlie differential muscle pain sensitivity.[33] Based on the system described above, others have developed a standard set of infusion protocols referenced to the subject's initial pain report,[34–36] and further characterized the sensory and sensorimotor manifestations of persistent muscle pain.

To the best of our knowledge only one study employed HS infusion in an animal model.[37] This experiment clearly showed an enhanced activation of central nociceptive neurons compared to bolus injections. This response was clearly attenuated in a dose-dependent manner by preinjection into the muscle with MK-801, a noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist.

ISCHEMIC CONTRACTION Originally described by Lewis,[5,6] ischemic contraction was the first method developed to systematically produce deep tissue pain in humans. A modification known as the submaximum effort tourniquet technique was introduced by Smith and colleagues.[38] Following venous exsanguination of the forearm with an Esmarch bandage, a pressure cuff was inflated to occlude arterial flow. Subjects were instructed to perform a sequence of repeated contractions (squeeze a hand exerciser) at approximately half of their predetermined maximum voluntary contraction force and then to rest until they registered a maximum pain rating or reached a predetermined time limit before deflating the cuff.

This procedure is very effective in producing muscle pain. However, Graven-Neilsen *et al.*[39] reported that the quality of pain produced by ischemic contraction differed from pain reports following HS or adenosine injections and suggested that these methods activated different subpopulations of muscle nociceptors. Rainville *et al.*[7] compared four different types of phasic and tonic pain and found that in addition to producing intense pain, ischemic pain tended to be more "unpleasant" than other types of experimental pain.

A potential disadvantage of the ischemic contraction method is that ischemia is not limited to one muscle or muscle group so that there are concomitant changes in the afferent input from other nonmuscle deep tissues and from cutaneous sources. This may, in part, contribute to the observation that the pressure pain threshold[39] increases over the ischemic muscle, whereas it is generally reduced over the site of intramuscular algesic injection. Although the method lacks the selectivity of intramuscular injection, to model conditions with muscle pain in the face of reduced blood flow (e.g., compartment syndromes or intermittent claudication) this may be the best approach.

Ischemic contraction has not been used widely to study muscle pain in animals, but this method was important in the initial electrophysiological characterization of muscle nociceptive afferents. Bessou and Laporte[40] used a contraction model to demonstrate that group IV muscle afferents were specifically activated under ischemic conditions. Chabel applied a tourniquet to the hindlimb of rats and recorded nerve fiber activity from the proximal sciatic nerve.[41] While this study was not specifically directed toward the identification of muscle afferents, it revealed the gradual onset of spontaneous activity in slowly conducting afferents during the ischemia.

DELAYED ONSET MUSCLE SORENESS Exercise protocols used to produce delayed-onset muscle soreness (DOMS) typically involve a significant amount of eccentric contraction (i.e., muscle contraction during lengthening movements of the muscle) along with concentric contraction (shortening contractions). Onset of pain generally develops within 24–72 h after exercise and is associated with loss of strength, reduced range of motion, and elevated creatinine kinase levels.[8]

Although many strategies can be implemented to produce DOMS, the technique is well illustrated by the work of Tedeger and colleagues[9] who utilized a simple "stepping" protocol to produce DOMS. Subjects were instructed to stand with one foot on a 45° sloped step, lifted on the tip of the toes (concentric contraction), and then to slowly lower the heel until the sole of the foot made full contact on the sloped surface of the step (eccentric contraction). The tips of the toes were lifted again and contractions were repeated until subjects completed two sets of 50 combined concentric/eccentric contractions separated by a 5-min rest

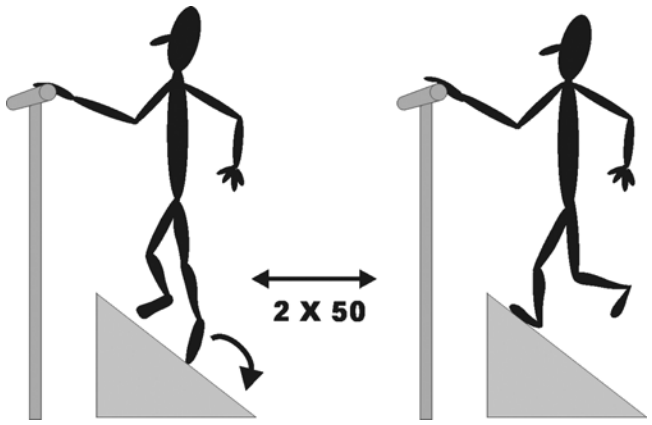

Figure 33–2. Illustration of the exercise protocol used by Tegeder *et al.*[9] to produce delayed onset of muscle soreness. (Adapted from Tegeder *et al.*,[9] with permission.)

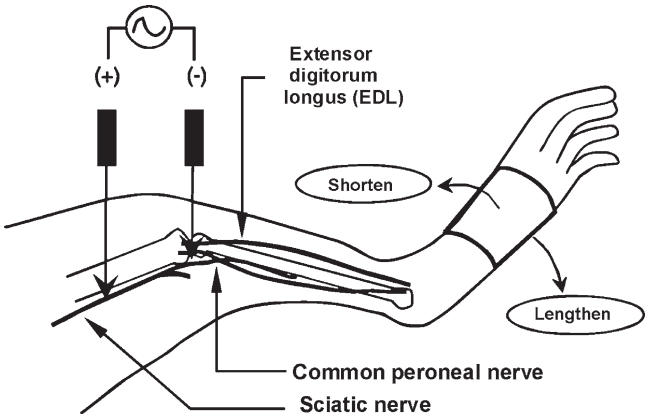

Figure 33–3. Schematic illustrating the experimental setup used by Taguchi *et al.*[43] to produce eccentric contraction in an animal model. (Adapted from Taguchi *et al.*,[43] with permission.)

(Figure 33–2). Pain intensity was measured prior to the exercise, immediately after, and 24 h after the exercise. Pain assessments were made in the DOMS and the control leg was assessed at rest, walking, going downstairs, and tiptoeing.

There is an impressive literature utilizing "exercise" or controlled muscle contraction (concentric and eccentric) in animals, but relatively few animal studies have used this strategy to explore mechanisms of deep tissue nociception. Taguchi and co-workers[42,43] have shown that repeated bouts of muscle contractions, which include an eccentric component, yield evidence for primary muscle hyperalgesia and sensitization in a rat model. In their model, the hindpaw was fixed to a bar, which in turn was connected to a linear motor. Transcutaneous needle electrodes were inserted near the sciatic nerve and the common peroneal nerve, respectively (Figure 33–3). Repetitive contractions of the muscle were induced by cyclic electrical stimulation of the nerve at three times the threshold for twitch contraction. The stimulus frequency was set at 50 Hz to produce tetanic contractions. Stimulus trains (1 sec duration) alternated with 3 sec of rest. Timing of the lengthening movements were synchronized with the electrical stimuli to produce contractions during lengthening. The control group was subjected to stretching without contraction. This procedure reliably resulted in reduction of the mechanical threshold to noxious and innocuous stimuli. Kehl and Fairbanks[44] ran rats on a treadmill with a 30° downhill incline to produce eccentric contraction of the limb muscles. This method produced a measurable reduction in grip force (an index of hyperalgesia, see below) compared to animals running on a level treadmill.

EXPERIMENTAL MUSCLE PAIN ASSESSMENT

HUMANS The sensory manifestations of muscle pain are commonly assessed with psychophysical tools that measure the intensity, the quality, and the distribution or location of the pain. Pain intensity is commonly assessed with magnitude rating scales. An ordinal rating scale numbered from 0 to 10, with 0 representing no pain and 10 being the worst pain imaginable, allows subjects to score their pain. Alternately, a subject or patient may rate pain by extending a line along a fixed distance (e.g., 0–10 cm) with a pencil on paper or on a computer monitor using a "mouse" or other pointing device. Computerized or electronic measures may be time stamped and the ratings may be saved in a spread-

sheet or database during the course of an experiment. Although there is a great deal of intersubject variability, magnitude rating scales have been shown to be very reliable indicators of within-subject muscle pain.[45]

The McGill Pain Questionnaire (MPQ) and comparable instruments that involve verbal descriptors are used to assess the quality of muscle pain. Melzak and colleagues demonstrated that it was possible to correctly classify 91% of patients with facial pain conditions using seven verbal descriptors.[46] The discriminative capacity of the MPQ can be improved by the addition of terms uniquely suited for the type of pain condition. This is a particularly valuable suggestion when attempting to characterize pain of deep tissue origin. Discrimination of muscle pain would benefit from inclusion of both temporal and spatial descriptors. For example, it is important to ask whether the pain is constant or intermittent (temporal) or if it is local or diffuse (spatial).

Since muscle pain is commonly referred to other deep tissue sites, it is important to identify the distribution of the pain. This may be done with simple body maps in which the patient or subject is asked to draw or otherwise indicate the location or distribution of spontaneous or experimentally evoked pain. In addition to identification of spontaneous sites of muscle pain, palpation is commonly used to demonstrate areas of reduced mechanical threshold. The diagnosis of FMS depends upon the ability to demonstrate a minimum of 11 out of 18 "tender" points as described by Wolfe and others.[47] Although palpation can be performed manually to identify these areas, there are increasing efforts to obtain a quantitative measure of palpation pressure with algometry.

Hand-held algometers are widely used to assess muscle sensitivity. Several types are available ranging from a simple "analog" version to more sophisticated digital instruments. Most have a circular footplate with a diameter of $1\,cm^2$. Regardless of the design, all algometers provide a numerical value of the force (e.g., kg/cm^2) necessary for the subject to report pain. This value is referred to as the pressure pain threshold or PPT. Several caveats must be considered with the use of algometry. The PPT is strongly influenced by the method of application (most instruments are designed to be applied perpendicularly over the test site) and the composition of the tissue at the test site (e.g., the amount of body fat). Physical considerations such as the size of the footplate and the rate of application are also critical variables that influence PPT values. Last, but not least, the skill and experience of the examiner are essential in order to obtain reproducible results.

Evaluation of the sensorimotor response to pain has been the subject of much research and has led to a better understanding of the relationships between muscle pain and motor function. During voluntary motor activity muscle pain is generally accompanied by reduced motor activity when the sore or injured muscle is working as an agonist. This is often accompanied by increased activity in the antagonist muscles. This response, referred to as pain adaptation,[48] serves to protect the injured muscle. In contrast, myofascial pain is associated with focal regions of increased muscle activity (i.e., trigger points) characterized by the demonstration of "taut bands." It is important to distinguish between these two quite distinct entities when attempting to generalize about the relationships of muscle pain and motor function. This topic has been thoroughly reviewed by Mense and Simons.[1]

ANIMAL MODELS

Although animals cannot report the subjective experience that we refer to as pain, methods for the induction of muscle pain in humans characteristically produce activation of nociceptors, recruitment of central nociceptive pathways, and predictable nocifensive behaviors in animals. In addition to the general ethical issues associated with the use of animals in research, the study of nociception in animal models requires special consideration. Extreme care must be taken to minimize exposure of animals to nociceptive stimuli, to recognize symptoms of unacceptable morbidity, and whenever possible to provide an "escape" from prolonged intense noxious stimuli. These and other important considerations are highlighted in *Definition of Pain and Distress and Reporting Requirements for Laboratory Animals* 42 http://www.nap.edu/catalog/10035.html.

Assessment of Muscle Nociception in Anesthetized Animals Many insights regarding muscle nociceptive mechanisms can be obtained from studies in anesthetized animals. Nociceptive afferents and their central target show changes in firing to graded noxious stimulation and are the electrophysiological correlate of intensity. Changes in the receptive field size of nociceptive neurons in response to experimental manipulations (e.g., intramuscular algesic injection) provide an assessment of spatial changes related to noxious stimuli. An anatomical approach to assess the intensity and extent of nociceptive activation is to study the pattern of expression of the immediate-early gene *c-fos* after noxious stimulation. Fos protein expression shows predictable increases, under carefully controlled conditions, and has been widely used as a measure of nociceptive activation in muscle.[23,37,50,51]

Behavioral Assessment of Muscle Pain in a Lightly Anesthetized Model A useful strategy to minimize discomfort in animals is to study nocifensive behaviors that are elicited under conditions of light anesthesia. Monitoring electromyogram (EMG) activity following intramuscular injection[52] has been used successfully as a method to document nociceptive activation in orofacial muscles following injection of the masseter muscle with algesic chemicals in halothane-anesthetized animals. Lightly anesthetized animals are often employed to assess changes in the magnitude of muscle reflexes, and the production of nocifensive behavior in response to noxious deep tissue stimulation. However, nocifensive reflexes and behaviors documented under light anesthesia must be carefully assessed and validated. Responses obtained with one anesthetic agent may be qualitatively and quantitatively different from those obtained with another agent in the same species.

Examination of nocifensive behaviors in lightly anesthetized animals has been used successfully by Ro and colleagues to make inferences about the intensity and the duration of algesic stimuli injected into the masseter muscle.[53] Algesic injections made into the masseter muscle of lightly anesthetized rats elicited a brisk repetitive hindpaw shaking that appeared to reflect an attempt to rub the site of injection while injection with vehicle produced minimal hindpaw shaking behavior. This behavior is similar to previously described orofacial pain-induced grooming behavior in awake rats.[54] The anesthetic level was maintained by infusing a constant rate of sodium pentobarbital (Nembutal; 3–5 mg/h). Animals in the light anesthetic state typically responded to noxious tail pinch with an abdominal contraction and noxious hindpaw pinch with a calibrated clip (600 g) produced a brisk single withdrawal response. Core temperature and heart rate were monitored continuously to ensure the animals were within a normal physiological range throughout the experiment.

Once the animals were stable, selected algogens were injected into the masseter muscle. The behavior was recorded with a

digital camera and stored on compact disc for subsequent analysis. Hindpaw shakes were counted by an individual, blinded to the experimental condition. Counts were distributed into 30-sec bins for the duration of the behavior. The mean peak count, which usually occurred in the first 30 sec, and area under the curve were calculated from the resulting histograms. Both parameters varied in a concentration-dependent manner following injection with mustard oil. Systemic administration of morphine sulfate (3 and 0.3 mg/kg), ip, dose-dependently attenuated the shaking behavior. Lidocaine injected locally 5 min prior to mustard oil injection also significantly decreased the behavior. Similar results have been obtained with injection of glutamate, capsaicin, acid saline, and complete Freund's adjuvant. Regardless of the algogen used, this method produced a relatively finite stereotypical hindpaw shaking response that lasted no more than 4 or 5 min following injection. These experiments validate this model for assessing the intensity and duration of acute nociceptive activation and may also be a useful test of novel pharmacological interventions.

Postinjection Sensitization in a Lightly Anesthetized Model It is possible to rekindle the hindpaw shaking behavior by mechanical stimulation with von Frey filaments or an electronic von Frey in lightly anesthetized rats. Approximately 5 min after the hindpaw behavior subsides, application of von Frey monofilaments of relatively high bending forces generates a few cycles of shaking behavior in animals injected with sensitizing agents (e.g., glutamate, capsaicin, acid saline). Monofilaments are applied perpendicular to the injection site in a stepwise fashion and the smallest diameter von Frey capable of "rekindling" the hindpaw shaking behavior in response to four consecutive applications at bending force was considered threshold. Repeating the procedure periodically (e.g., every 5–10 min) resulted in the demonstration of a treatment-dependent reduction in threshold that persisted for at least an hour after injection.

Behavioral Assessment in Awake Animals It is possible to condition animals to sit quietly for measurements in response to stimulation with manual or electronic von Frey filaments to determine changes in mechanical threshold.[20,55] This approach has been used to study changes in mechanical threshold following intramuscular injection with algesic chemicals.[20] Sensorimotor manifestations of muscle inflammation and nociceptive stimulation may be assessed by indirect approaches such as monitoring locomotor behavior or studying feeding behavior. Recently, however, behavioral assays based on the predictions of the pain adaptation model have been used to assess muscle hyperalgesia and allodynia in animals.

Grip Force as a Model for Muscle Hyperalgesia Rats and mice exhibit an innate grasping behavior when suspended over a surface like a cage top or wire grid. Kehl *et al.*[56] took advantage of this behavior to develop a rodent model for assessment of muscle hyperalgesia. They postulated that injection of carrageenan into the triceps muscles would produce an "anatomically" specific reduction of grip force with respect to preinjection values. During testing, each animal was held by the tail, just above wire mesh grids attached to force transducers and gently pulled in a rostrocaudal direction. Output from the force transducers was digitized and led to a computer that display force versus time traces. Initially, three experimental groups were examined. One group received bilateral carrageenan injections (3%, 75 µl), a second received bilateral vehicle injections [phosphate-buffered saline (PBS), 75 µl], and a third received carrageenan in one triceps and vehicle (PBS) in the contralateral triceps. Carrageenan injections produced a significant time- and treatment-dependent

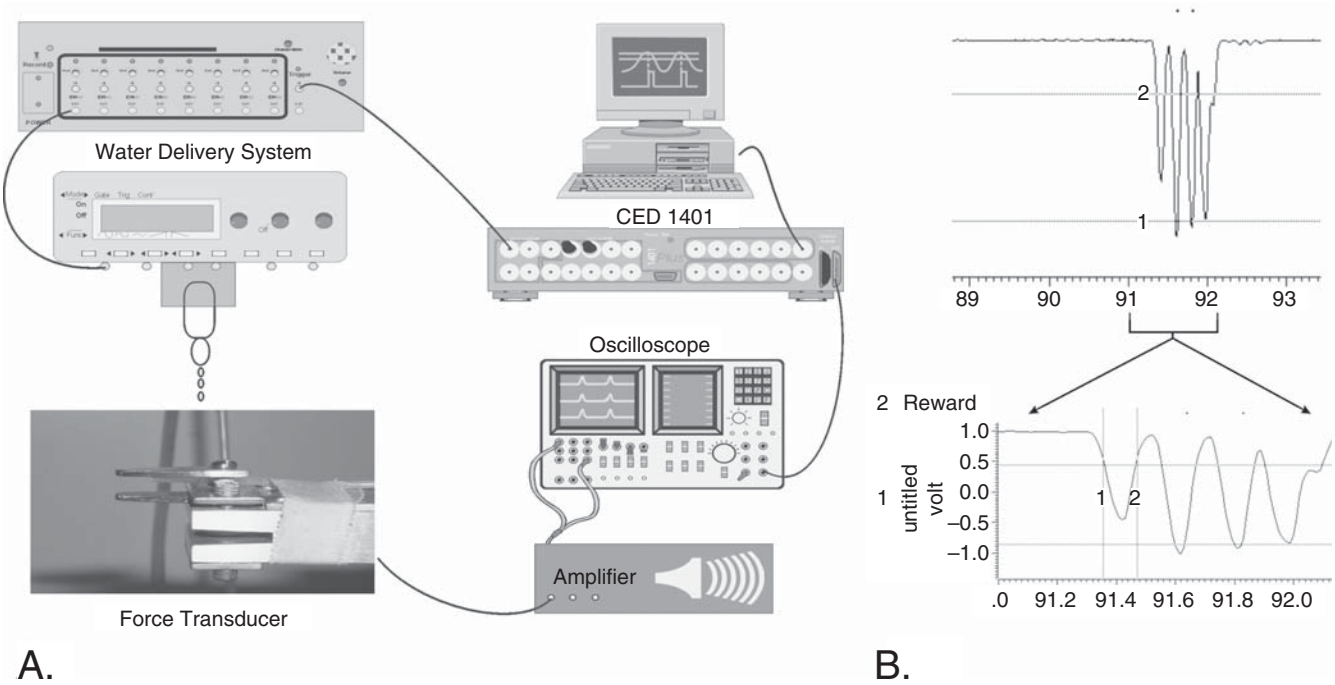

Figure 33–4. Schematic illustrating the bite force apparatus. In addition to the description in the text, full methodological descriptions are provided in Nies and Ro.[57] (A) The signal from the bite plates is led to a device to provide water and the output of the transducer is led to an A/D to record the bite force. (B) A software program is used to set horizontal and vertical (1 and 2) cursors to measure the bite force and duration.

reduction in gripping force that peaked at 12 h but remained significantly reduced at 36 h. Treatment with six different concentrations (0–6 mg) produced dose-dependent reductions in the grasp strength measured at 24 h after injection.

The demonstration that significant recovery of grip force was obtained by treatment with levorphanol (a μ-opioid selective agonist) provided compelling evidence that the reduction of threshold was a specific response. The reduction in grip strength was also attenuated in animals with significantly reduced unmyelinated afferents (produced by neonatal capsaicin treatment). These observations, which were consistent with the predictions of the pain adaptation model (i.e., reduced activity to protect the injured muscle), were interpreted as behavioral indications of reduced mechanical threshold and therefore a measure of muscle hyperalgesia. Additional details about the grasp-force device, manufacturer information, and source of drugs are provided in the original manuscript and a subsequent review of methodology for study of muscle pain in animals.[44]

Bite Force as a Measure for Craniofacial Muscle Hyperalgesia Nies and Ro[57] developed an operant conditioning protocol in which rats are trained to generate higher than normal bite force in order to obtain water reinforcement. On the basis of the pain adaptation model, they hypothesized that animals with sore or inflamed jaw muscles would not be able to generate the same bite force as normal animals.[24] Sprague–Dawley rats were positioned so they could bite on a pair of brass plates attached to a force transducer with the incisors. A water tube placed between the bite plates was connected to a Schmitt trigger-activated delivery system to provide water reinforcement for successful biting trials. The output of the transducer was led to a CED 1401 laboratory interface and data were stored on the hard drive for offline analysis (Figure 33–4A).

Training was initiated after determining the average weight and water consumption for each animal. During the training and the experimental phase, water intake was limited but was sufficient to maintain body weight within 80% of normal. After some exploratory behavior, rats gradually learned to associate biting with water reinforcement. Once this association was made they were rewarded for bite forces 400 g or greater and only the rewarded trials were saved for analysis (bites below this "cutoff value" were difficult to distinguish as discrete bites).

Once rats successfully learned the task, they were trained to generate gradually increasing target forces by rewarding only bites whose force exceeded the target. Animals were trained until a stable success rate (>70%) was attained at the final target force (>1.3 kg). Although there were individual differences in biting pattern (e.g., multiple bites versus single bites), the learning curves were similar and rats generally reached target force within 3 weeks.

Bite force data for each session were analyzed using Bite Analysis, a "script" program designed for use with Spike 2. The program is interactive so that users can manipulate cursors to specify cutoff and target forces and select the duration of the data sample (Figure 33–4B). The program automatically computes parameters such as the success rate and maximum and mean bite force and stores these values for subsequent analysis.

CONCLUSIONS

Lewis proposed that pain produced by ischemic contraction resulted from a "factor P". This factor, which acted in the interstitial (tissue) spaces under ischemic conditions, was dependent upon processes occurring within the muscle fiber as a result of contraction. An interesting aspect of the methods considered in this review is that each involves the introduction, the production, or the accumulation of algesic metabolites at some time throughout the course of the experiment. Many of the endogenous algogens have been shown to produce a significant level of muscle pain and nociceptive activation. Beyond the initial insult it is clear that both peripheral and central factors are likely players in the maintenance of persistent pain and there is substantial evidence that both are involved. Through the further evolution of models that specifically address the problem of muscle pain, we may one day unravel the complexly timed chain of biological events from the initial injury to the chronic pain condition and use this information to develop meaningful treatment strategies.

34 Animal Models of Parkinson's Disease

Emma L. Lane, Thomas Carlsson, Deniz Kirik, and Stephen B. Dunnett

ABSTRACT

Parkinson's disease is a movement disorder, caused predominantly by the degeneration of the dopaminergic nigrostriatal pathway. Various animal models have been developed in both rodents and nonhuman primates that have been used successfully in the evaluation of pharmacotherapeutics. The most commonly used animal models are generated through the administration of toxins; those most extensively characterized with a view to analyzing motor deficits are the 6-hydroxydopamine (6-OHDA) lesioned rat and the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated nonhuman primate. We review how these models are developed and the most common behavioral tests used to discern motor impairments and the improvements afforded by both pharmacological and surgical interventions. A major problem in the treatment of Parkinson's disease is the generation of dyskinesia, or abnormal involuntary movements following the long-term administration of L-DOPA. Until recently, research on dyskinesia was restricted to the use of the MPTP-treated nonhuman primate, but the development of a rodent model has improved understanding of the mechanisms responsible and expedited screening of drugs for their dyskinesiogenic potential. Although both rodent and nonhuman primate models have significantly furthered our understanding of the mechanisms behind Parkinson's disease and the associated motor complications, both still have significant limitations. Therefore, the search continues for a model that can reproduce not just the neuropathology and symptoms of the disease, but also recreate more faithfully the progressive pathogenic aspects of the disease.

Key Words: Parkinson's disease, MPTP-treated nonhuman primate, 6-hydroxydopamine lesioned rat, Abnormal involuntary movements.

INTRODUCTION

Parkinson's disease (PD) is a neurodegenerative motor disorder that presents as a loss or paucity of movement (akinesia/bradykinesia), postural instability, resting tremor, rigidity, and altered gait. The primary cause of these symptoms is the continuous deterioration of dopaminergic (DAergic) neurons of the substantia nigra pars compacta (SNc) that project to the striatum via the nigrostriatal pathway. To study the pathogenic mechanisms and evaluate potential therapies of PD, a range of animal models has been used, based on the administration of toxins, either locally (6-hydroxydopamine, 6-OHDA; 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, MPTP) or systemically (reserpine, MPTP, rotenone, proteosomal inhibitors). These models are used to test potential therapeutic strategies, such as drugs, cell replacement, and gene therapy, and it is predominantly their overt behavioral phenotypes, correlated to aspects of the human disorder, that make them so useful. The primary aim of this chapter is to detail the animal models that are most widely used to evaluate potential therapies to improve motor function in PD. Thus, transgenic mouse models based on specific mutations identified in a small number of patients, which have not yet been used effectively in therapeutic development, will not be covered (although some of the mouse behavioral tests described can also be applied in that context[1]).

This chapter will focus on the use of two classical toxin-based models of PD, the unilateral 6-OHDA-lesioned rodent and the MPTP-treated primate. The use of these toxins in alternative species, i.e., the 6-OHDA-lesioned primate and the MPTP-treated mouse, will be considered and we also include a brief description of the other toxin-based rodent models. These are less well established and are still to be fully characterized, but are contributing a new dimension to toxin-based models of PD.

6-HYDROXYDOPAMINE-LESIONED RAT

The first use of 6-OHDA to obliterate a catecholaminergic pathway in the search for a model of Parkinson's disease was described in 1968 by Ungerstedt.[2] 6-OHDA is taken up through the catecholamine transporter on DAergic and noradrenergic neurons where it accumulates in the cytosol. Here it inhibits mitochondrial complexes in the respiratory chain and also produces reactive hydroxyl radicals that contribute to the induction of a nonapoptotic cell death.[3] As it does not cross the blood–brain barrier, it is administered directly into the required area (in this case along the nigrostriatal tract) using stereotaxic procedures. Animals are placed in a stereotaxic frame (Figure 34–1) and using a sagittal cut the skull and bregma are exposed. The location of the appropriate target track is determined on the surface of the skull in coordinates from the interaural line and bregma using a rat brain atlas, and a small burr hole is drilled. A cannula is then lowered to the correct depth and the toxin is slowly infused either manually or using an automated pump. The cannulas are typically made of fine stainless-steel tubing (0.2–0.4 mm o.d.), but alternatively glass capillaries can be pulled to much finer tips (~50 μm)

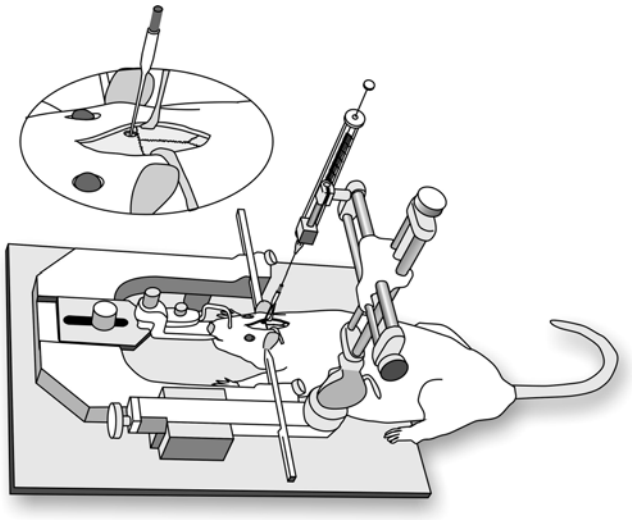

Figure 34–1. Schematic representation of a rat in a stereotaxic frame. The head is secured in position with ear and tooth bars. This frame holds a Hamilton syringe with a glass capillary attached through which the toxin is injected; alternatively, metal cannulas can be used connected to a syringe placed in a syringe pump.

to minimize tissue damage, especially where multiple injection sites are used. After the injection, the cannula should remain in place for a short time to allow the toxin to diffuse into the surrounding tissue before it is retracted and the wound sutured. When using 6-OHDA it is important to remember that it oxidizes easily and should be dissolved in saline containing 0.02% ascorbic acid as an antioxidant. The powder and solution should be kept cold and in the dark as far as is practically possible, with fresh solutions made up at regular intervals (every 1–2 h), which should be discarded as soon as a brown or pink coloration is observed. The cannula should be loaded just prior to each injection to minimize exposure to light.

The extent of the lesion produced by 6-OHDA is dependent on the location at which the toxin is applied and the concentration used. The most common lesion model is the complete destruction of the nigrostriatal pathway in which 6-OHDA is injected into the median forebrain bundle (MFB). This protocol produces a >97% depletion of the DA neurons in the SNc and up to 80% in the ventral tegmental area (VTA). A more restricted, progressive, partial lesion of the nigrostriatal pathway can also be achieved by injecting the 6-OHDA into the striatum.[4] DAergic terminals take up the toxin and retrogradely transport it to the cell bodies in the SNc. The extent of the partial lesion can range from a 30% to 90% loss of DA neurons of the SNc, dependent upon the number of striatal injection sites and the quantity of 6-OHDA administered.[6] A four-site striatal lesion gives rise to about an 80–90% loss of the DA neurons in the SNc, but only 15% of VTA neurons are affected.[4] Partial lesions can also be achieved by targeting the MFB with lower concentrations of the toxin,[5] although this strategy is typically more variable. In addition, 6-OHDA has also been directly injected in the SNc, resulting in substantial degeneration of the nigrostriatal pathway, but this lesion method is less commonly used.

BEHAVIORAL TESTS FOR UNILATERAL 6-HYDROXYDOPAMINE LESIONS The unilateral denervation produces a number of deficits on the side contralateral to the lesion, displayed as spontaneous circling toward the (ipsilateral) lesioned side, reduced use of the contralateral forelimb, and a neglect of the contralateral side. A very wide range of behavioral tests has been described in the nearly four decades since 6-OHDA came into widespread use. We describe below a selected range of behavioral tests in widespread use, which have been found by ourselves and others to be sensitive, objective, and easily quantified. The list is of course not exhaustive, and other tests can be found elsewhere.[1,6–8]

Rotational Behavior Circling behavior is the most frequently used behavioral test, largely due to its simplicity.[9] It is affected differentially by the administration of dopaminomimetics, the direction and nature of the behavior being related to their respective modes of action. The number of rotations can be counted manually, although commonly this is done with the use of automated rotometers. The output is the total number of rotations in either direction over a predetermined period of time, which can also be expressed as net rotations. Some days after receiving a unilateral lesion, rats exhibit a tendency to turn during spontaneous locomotion to the (ipsilateral) side of the lesion. This ipsilateral bias is markedly enhanced by activating the animal, for example, by exposure to mildly stressful stimuli or injection with a stimulant drug. Thus, amphetamine will increase DA release on the intact side to a greater extent than the DA-depleted lesioned side, and will enhance marked turning toward the side ipsilateral to the lesion. Significant asymmetry can be induced by amphetamine with more than a 30% loss of the DA neurons in the SN or a 40–50% depletion of the DA content in the striatum. In contrast, direct acting dopamine receptor agonists will induce a contralateral circling behavior by acting predominantly on the DA receptors on the postsynaptic striatal neurons, made supersensitive by the deafferenting lesion. More extensive lesions are required to induce high levels of rotation with apomorphine. Many studies have reported a close correlation between the rates of amphetamine and apomorphine-induced rotation and the extent of denervation, such that rotation scores can be used to determine the extent of lesions on an animal-by-animal basis, allowing exclusion from further study of animals with inadequate lesions and allocation of the remainder to matched groups prior to subsequent investigations. Generally, 14 days postlesion, in excess of five ipsilateral rotations per minute induced by *d*-amphetamine sulfate (2–5 mg/kg ip or sc in saline) measured over 90 min is used to indicate >90% denervation. Similarly, over 90% dopamine depletion is assumed from >5 contralateral rotations per minute following the administration of apomorphine (0.5 mg/kg sc in 0.02% ascorbic acid) over 40–60 min. It should be noted that apomorphine can sensitize the circling response and should be avoided if the animals are intended for use in studies of striatal sensitivity; in addition, compared to amphetamine, apomorphine is less responsive to dopamine replacement measures.

Compounds inducing contralateral rotations, such as direct acting DA agonists and L-DOPA, are predicted to have antiparkinsonian effects, while a reduction in amphetamine-induced ipsilateral rotations is frequently used to demonstrate improved DAergic function on the lesioned side following cell transplantation or treatment with viral vectors.[10,11]

Spontaneous Forelimb Test (Cylinder Test) The cylinder test evaluates forelimb akinesia by determining the animals' ability to support their body weight against the wall of a glass cylinder during explorative behavior. The cylinder test was first

described by Schallert and Lindner[12] and further modified by Schallert and Tillerson.[7] The animals are placed in a transparent glass cylinder (approximately 20 cm in diameter for rats and 10 cm for mice) and videotaped; two mirrors are placed at a 90° angle behind the cylinder to allow visualization of the whole surface. An observer blinded to the treatment of the animals counts the number of independent weight-bearing touches made with each forelimb, usually expressed as percent touches with the lesioned paw of the total performed. A normal animal will, on average, achieve a score of 50% (Figure 34–2A, "normal"), while animals with DA depletion of the nigrostriatal fibers will exhibit a marked reduction in the use of the contralateral paw (Figure 34–2A, "lesion"). To improve the sensitivity of this test Schallert and Tillerson[7] describe a more detailed analysis where the first touches during rearing and landing and differential counting of simultaneous versus lateralized paw use are separately scored.

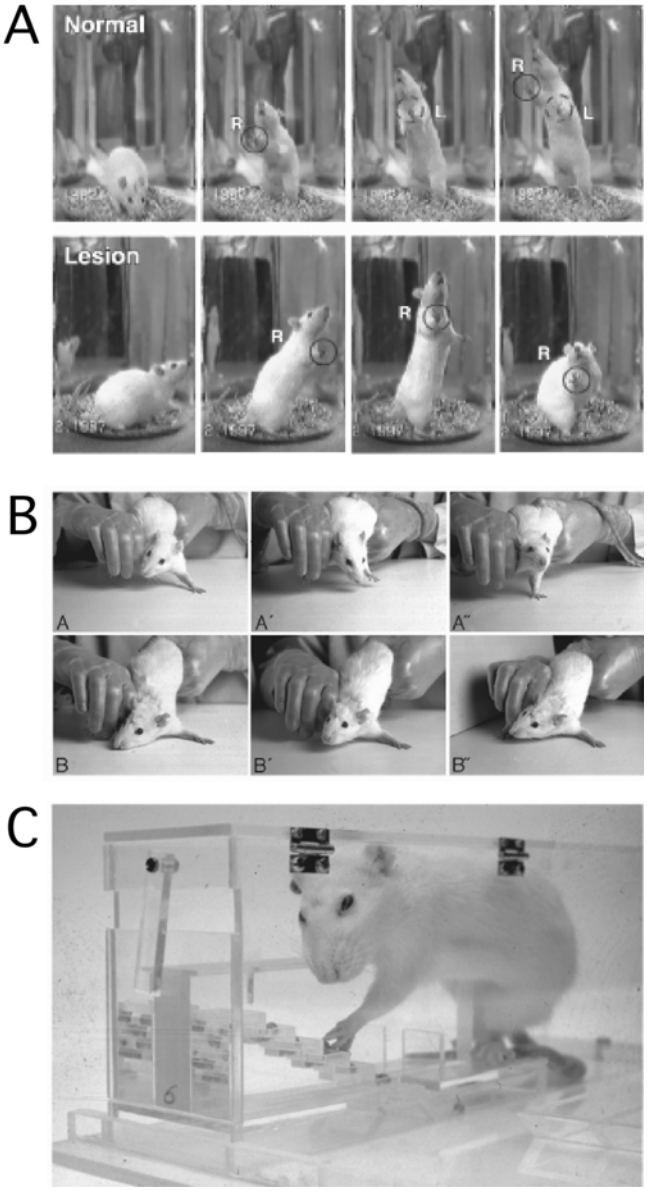

Figure 34–2. Photographic demonstration of (A) the cylinder test of forepaw asymmetry. A "normal" rat will use both forepaws to explore the cylinder, but a 6-OHDA "lesion" will cause a predominant use of the paw on the ipsilateral side to the lesion. (B) The stepping test, in which normal rats (A, A′, A″) will make adjusting steps with the weight-bearing forepaw as it is moved across a surface, but a lesioned animal (B, B′, B″) will not. (C) A rat in the paw-reaching "staircase" apparatus.

There are several advantages of the cylinder test, in that no drug administration is required, food restriction is not necessary, and there is no or limited handling by the experimenter, reducing the influence of external parameters. However, especially where repeat testing is necessary, the animals can become habituated and more reticent to explore the cylinder. To encourage a good performance, the test should be carried out in the latter part of the light cycle, and the following can also be applied: (1) turning the light off and/or switching the light on and off two or three times (requires a video camera with infrared recording capability), (2) mildly shaking the cylinder for a few seconds, (3) removing the animals from the cylinder for 10–30 sec and returning them, and (4) exposing the animals to female/male odors or mild stressors.

Stepping Test The stepping test forces the use of individual forelimbs and determines the rats' ability to perform adjusting steps when moved sideways. The design was first described by Schallert *et al.*[13] and further defined by Olsson *et al.*[14] The experimenter supports the animal lightly round the waist, restraining the hind limbs and the forelimb that is not being tested. The animal is lowered to the table surface and the free forepaw is allowed to provide placing support. The animal is then moved sideways over a 90 cm surface, from one edge to the other, over about 5 sec, during which time the tested paw is touching the surface (Figure 34–2B). The number of steps, while the animal is moved over the surface, is counted. The test is repeated twice per day for three consecutive days for each forepaw in both a forehand and backhand direction. Prior to testing, a habituation trial period of 3–7 days is required to ensure that the animals perform the test properly and to give consistent results. A normal rat will perform about 9–13 adjusting steps in the forehand direction and a few more, 12–16, in the backhand direction. Rats with extensive 6-OHDA lesions of the nigrostriatal pathway (>80%) show a marked reduction in adjusting steps for the contralateral forepaw to only 0–2[4,14,15] (Figure 34–2B, B′). Stepping in the backhand direction tends to be much less affected than stepping in the forehand direction, and may be only marginally impaired in rats with less completed intrastriatal 6-OHDA lesions. Intermediate 6-OHDA lesions, 50–80%, will make intermittent forelimb steps, while a lesion of less than 40% will not significantly alter forelimb stepping.[4,15] In conducting this test it should be noted that a subjective element is introduced when there is direct interaction between experimenter and animal. This makes comparing the results between different experimenters and studies difficult and the same experimenter should conduct all the testing within a study. Other factors such as strain used, testing environment, and stress can also influence the rats' performance.

Skilled Forelimb Use in the Staircase Test This test, also called the *paw reaching test*, was introduced by Montoya *et al.*[16] to independently evaluate individual forepaws in a skilled test and is based on the animals' ability to successfully retrieve and eat sugar pellets with different levels of difficulty. The apparatus is generally a transparent Plexiglas box with a central platform separating two staircases such that the animal can reach down into the staircase on each side only with the forepaw on the same side (Figure 34–2C). This configuration allows the animal's performance to be assessed separately for the two forelimbs without

having to restrain the animal. Each staircase has a well on each step in which a predefined number of sugar pellets is placed (between 2 and 10 are used in different laboratories). The animals are placed in the box and allowed to collect and eat the pellets for 10–15 min.[4,16] The number of pellets taken from each well and the number of displaced ("missed") pellets are counted, giving the total number of successfully eaten pellets for each forepaw. For the animals to perform well in this task they should be food deprived prior to starting the test (1–3 days) and be maintained at around 90% of their body weight during the testing period; sugar pellets can be introduced as food during this time. On the first day of testing, the animals generally explore the test box and begin to associate the task with the sugar pellets, and with repeated sessions on subsequent days begin to learn the task. The time required for training varies between groups of animals and can be up to 2 weeks in older rats before a stable performance is reached. When more than 50% of DA is lost in the SNc and greater than 80% in the striatum[4,17,18] the animals start to show significant deficits. Complete unilateral 6-OHDA lesions reduce performance in this test by about 50–70% taken pellets and 30–50% eaten pellets compared to intact rats.[14,16,17,19,20] It should be noted that lesioned animal usually improve on their intact paw and retrieve up to 10% more pellets than intact control animals. The test can also be used as a forced paw choice test, where sugar pellets are placed only on one side of the staircase, forcing the use of the paw on that side.[21]

Other less widely used but validated tests include the rotarod and forelimb-placing test. The rotarod is a rotating cylinder on which the rats (or mice[22]) are trained to walk. There are two main approaches: the first uses a fixed-speed protocol in which rats perform on set speeds (increments between 4 and 40 rpm) and their time to stay on the drum at different speeds is measured. In the second approach accelerating paradigms have the rod increasing in speed (4–44 rpm) at a fixed rate (increasing over 90–300 sec)[23–25]; the time at which the rat falls off the drum is recorded and can be directly related to a speed. A comparative study between the two protocols found that the fixed-speed assay was more predictive of therapeutic efficacy, but accelerating protocols could be used more efficiently and easily to test lesion extent.[23] Again, animals do require some training on this apparatus to reach a stable performance in the task before any testing can be carried out, but this can be as little as one or two training sessions.[25]

These tests were primarily developed in rats, but have been adapted for other species, most notably mice and primates. Thus, unilateral nigrostriatal lesions induce similar postural and rotation asymmetries in mice, although their size typically makes it easier to monitor rotation by direct observation or using automated video tracking devices than mechanical rotometers.[22] Similarly, mice show performances akin to rats in staircase and other paw-reaching tasks with the apparatus scaled down to be suitable for the smaller species.[26] Whereas the effects of DAergic lesions in large primates have been more extensively explored using peripheral administration of MPTP (see below), the brains of small New World marmoset monkeys are sufficiently consistent to allow stereotaxic positioning using external reference landmarks to produce reliable nigrostriatal lesions with 6-OHDA, which, as in rats, produce a range of lateralized motor and sensorimotor impairments. Rotation is less consistent because these monkeys typically move in a three-dimensional space, but contralateral postural and head-turning biases are prominent and easy to measure by video recording.[27] Moreover, Marshall, Ridley, and Kendall have developed primate analogues of the staircase test in which the monkeys reach through slots behind transparent vertical baffles that constrain them to use just one arm in reaching to retrieve palatable foods from staircase wells behind the barrier.[28,29] In each of these tasks, marmosets exhibit lateralized changes in response to unilateral nigrostriatal lesions and to pharmacological and cellular therapeutic interventions directly comparable to rats.[30,31]

1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE

A byproduct of the illicit manufacture of a pethidine analogue, MPTP was identified as the cause of rapidly developing parkinsonism in a group of drug addicts in the United States in the early 1980s.[32] Postmortem analysis revealed that MPTP had induced a self-perpetuating cell death of DAergic neurons in the SNc, with few other anatomical changes. It was found to have similar effects in nonhuman primates;[33–35] this has developed into what is currently considered the best available model for PD, providing both a similar behavioral profile and neuropathology. MPTP has also been used in a wide range of other species from the mouse to the worm and zebra fish. In a series of enzyme steps, non-DAergic cells such as glia and serotonergic neurons convert MPTP into the active metabolite MPP^+. It is then released into the synaptic space and subsequently taken up by DAergic neurons through the DA transporter. Although the mechanism through which it induces selective DAergic cell death has not been fully elucidated, it is known to act as an inhibitor of complex I of the mitochondrial respiratory chain, producing a decrease in tissue ATP content and an increase in oxidative stress.

1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE-TREATED PRIMATE The behavioral effects of MPTP have been well characterized in various nonhuman primates including the squirrel, rhesus, and cynomolgus monkey, and the common marmoset.[33–35] The progression of the degeneration can be controlled by the paradigm of administration. Most protocols use a relatively acute regime of administration for convenience, but a more prolonged administration of regular small doses of weeks or months is required to reproduce the slow progressive deterioration and the absence of spontaneous recovery seen in patients. The mode of administration to give a bilateral lesion can be subcutaneous, intraperitoneal, intravenous, or intramuscular. For example, a common acute bilateral paradigm in marmosets is the subcutaneous administration of MPTP at 2 mg/kg over 5 days.[34] With this regime the nigrostriatal DAergic cell loss is upward of 90%, representing late stage PD. After a few days of treatment the primates show akinesia, limb rigidity, reduced vocalization in the marmosets, and reduced grooming. Although resting tremor is not common, it can occasionally be seen as a whole body tremor. A regime of 1 mg/kg for 3 days has also been described recently in the marmoset, in which a subthreshold DA loss produces more limited behavioral deficits that more closely represent presymptomatic to early stage disease states.[36] The more chronic treatment protocols that have been described use between 0.2 and 4.5 mg/kg MPTP repeatedly over weeks or months.[37–39] However, there appears to be an optimum treatment regime to create a stable cell death, as recovery of the DAergic losses has been described with protocols of 29 days,[37] while with 15 days a reportedly nonrecoverable DAergic deficiency is induced.[38]

MPTP is highly toxic, and the literature reports a number of cases of permanent neurological impairment in laboratory person-

nel working with it.[40] Supreme care should therefore be taken when working with MPTP, typically to category III standard, to avoid self-administration or any contact with animal products during the administration period and for a washout period of a few days afterward. The animals require careful observation over several weeks following administration and hand feeding is advisable until the animals can eat unaided and sustain their body weight. Occasionally antiparkinsonian medication such as L-DOPA is given to increase their ability for self-care.

The bilateral MPTP-treated primate model is commonly used to screen pharmaceuticals for their antiparkinsonian potential. Following treatment, animals are observed either in their home cages or in specialized locomotor cages to independently determine their activity levels, while subjective rating scales for activity and disability are also used. Several different scales are used by different research groups, each with its own criteria and grading system, often based on clinical rating scales such as the UPDRS (United Parkinson's Disease Rating Scale). Many of these scales include criteria such as bradykinesia, freezing, rigidity, tremor, alertness, reaction to external stimuli/interaction, posture, balance/coordination, and vocalization (for comparisons of different scales see Imbert *et al.*[41]).

In Old World primates such as the macaque and rhesus monkeys, the toxin may be administered though the intracarotid artery, giving a predominantly unilateral syndrome. This surgery is more invasive but, as with bilateral versus unilateral lesion with 6-OHDA, the unilateral lesion results in improved survival and requires less posttreatment care. The behaviors are evaluated using rating scales similar to the bilateral model but there are individual scores for the gross motor skills for each limb. The fine motor skills of each forelimb can also be evaluated in food retrieval tasks.[42,43]

1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE-TREATED MOUSE Rats have a relative insensitivity to MPTP that may be the result of a species-specific metabolism or sequestration of MPP^+.[44] Very high doses are required to induce DAergic cell death compared to mice and the administration of guanethidine is required to prevent peripheral catecholamine release and mortality.[45] Mice, however, are susceptible to the effect of MPTP and have provided a useful small animal model of MPTP-induced parkinsonism. There are caveats to this model, as mice are not as sensitive as primates to the toxin and susceptibility is also hugely variable between mouse strains. Furthermore, with some treatment regimes, cell death is not complete and the mice can show a spontaneous functional recovery. This is more often seen with acute paradigms, while longer-term treatment may provide a more stable DAergic loss. The toxin is usually injected subcutaneously (although it can be given via other routes) typically in the range of 2–45 mg/kg/day for up to 10 days (for a full summary see Seledis *et al.*[46]). As in the primate, this produces a bilateral lesion and therefore the behavioral tests that are applied are distinct from those used for the unilateral 6-OHDA lesioned rodents.

BEHAVIOR TESTS WITH THE 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE-TREATED MOUSE

ACTIVITY Depending on the paradigm of administration, MPTP-treated mice may develop a hypokinesia that can be assessed using simple tests of locomotor activity and catalepsy. The simplest test of akinesia involves placing the animal of a flat surface and timing how long it takes to move all four limbs (akinesia), while for catalepsy the animals are placed with their fore or hind limbs supporting them on an elevated block or a raised bar, and the latency to restore normal posture is recorded.[1] More generally, activity can be monitored in a large square open field (typically 100 cm × 100 cm). In the manual version of the task, the field is divided into squares by lines on the floor and the number of squares entered in a fixed time interval is recorded by direct observation. Frequently, the total counts are subdivided into central squares and squares adjacent to the wall of the open field, as an index of exploratory activity (more anxious animals will spend more time at the edge). The open field test can be readily automated by mounting an array of infrared beams to traverse the open field or a standard cage. The number of beam breaks is used to calculate the time spent locomoting and the total distance traveled. In addition, the location and pattern of beam breaks can also be interpreted, i.e., whether the central beams are broken or just in the peripheral areas of the cage, or if single beams are repeatedly broken, indicating stereotypic behaviors, and with a decline of counts over time taken as an index of "habituation." Higher beams can also be used to measure vertical rearing activity, as a second measure of exploration. As mice are nocturnal, better results are achieved if they are tested during the dark cycle, as their spontaneous activity is higher. Placing a novel object in a center square of the open field and recording the rise in the time spent and number of entries in the squares immediately adjacent to the object can further assay exploration more directly.

POLE TEST The pole test[47] is very sensitive to changes in nigrostriatal function as it requires maneuvering and grip function. The mouse is placed head up near the top of a vertical pole (1 cm in diameter, approximately 50 cm in height) and the time to rotate 180° and time to descend are used as measures of motor function. Similarly, tests of grip strength are also sensitive to changes in nigrostriatal DA.

The rotarod, as described above, in the 6-OHDA rat model has been very widely used for assessing motor abnormalities in mutant mice.[1,48] However, MPTP has been reported to have variable effects on the rotarod,[46] and the use of different protocols in the administration of the toxin as well as in the ways the rotarod test is conducted makes comparisons difficult. Other tests used in the evaluation of motor function in the MPTP-treated mouse include swim tests (set in a narrow tank of water at 22–25°C for 30 min) assessing active swimming versus passive floating over a period of time both in the presence and absence of an escape platform, grip strength, and apomorphine-induced climbing.

DYSKINESIA IN ANIMAL MODELS OF PARKINSON'S DISEASE

The gold standard for pharmacological dopamine replacement in PD is L-DOPA, the metabolic precursor to DA. This is a highly effective treatment, but within 10 years of initiating L-DOPA therapy abnormal involuntary movements (AIMs), known as dyskinesia, develop in most patients limiting its use.[49] Thus, a major area of research using animal models of PD has involved identifying the cause of dyskinesia and evaluating the potential of new compounds to elicit, exacerbate, or reduce this side effect.

DYSKINESIA TESTING IN THE 6-HYDROXYDOPAMINE-LESIONED RAT The ability of drugs to induce contralateral rotations in the 6-OHDA-lesioned rat is taken as an indicator of

The amplitude ratings for the abnormal involuntary movement scale in rodents given in addition to scores of duration[a]

Score	*Axial*	*Limb*	*Orolingual*
1	Persistent deviation of the head to a 30° angle	Small movements of the paw and distal forelimb around a fixed position	Chewing and repeated jaw movements
2	Lateral deviation of the head and neck at an angle between 30° and 60°	Low-amplitude movements of the distal and proximal forelimb	With tongue protrusion
3	Lateral deviation of greater than 60° without loss of balance	Translocation of the whole limb with the shoulder muscle	N/A
4	Twisting of the head and neck such that balance is lost	Vigorous limb and shoulder movements to their maximum extent	N/A

[a]Axial and limb movements are scored 1–4 and orolingual 1–2.

their antiparkinsonian potential, but with repeated administration the circling in response to L-DOPA changes in profile.[50] This sensitivity of the locomotor response was considered an indicator of dyskinesiogenic potential. However, this model has been further developed by the extensive characterization of the simultaneous development of abnormal involuntary movement of the torso, fore and hind limbs, and orolingual area; this is considered to be rodent correlates of the L-DOPA-induced dyskinesia seen in patients.[51,52] Rating scales have been devised for these behaviors based on their duration and the magnitude to which they are expressed. To evaluate these behaviors, rats are individually observed in sawdust-free, transparent cages without food or water. Each animal is injected with the compound of interest at 1 min intervals and then observed at regular intervals (10–30 min) for 1–2 min each and rated. Some researchers prefer to take fewer time points and video the behaviors, permitting scores of additional parameters such as head nodding, and also to distinguish between choreic and dystonic movements of the forelimb. However, care should be taken to ensure that enough time points are evaluated as differences between single time points could be attributed to shifts in the time course, rather than a change in the severity of the response. There is a three-tier 1–4 point rating scale based on the duration, class, and amplitude of dyskinetic behaviors, as follows for the duration of behaviors of each class:

1. The behavior is present for less than half the observation time.
2. The behavior is present for more than half but not all the time.
3. The behavior is continuously present but interruptible by external stimuli, e.g., a sharp rap on the outside of the cage.
4. The behavior is uninterruptible by external stimuli.

Scores for amplitude in each category are listed in Table 34–1.[20] Duration and amplitude ratings are combined to give an overall score of severity for each category at each time point, which were accumulated to give a cumulative severity score. The same methodology and rating scales can also be applied to 6-OHDA-lesioned mice.[53]

DYSKINESIA TESTING THE 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE-TREATED MARMOSET The MPTP-treated primate has been extensively used to determine the neural mechanisms underlying the development of L-DOPA-induced dyskinesia and to assess the dyskinesiogenic potential of new compounds in addition to the antiparkinsonian activity. The dyskinesia takes the form of choreic movements of the fore and hind limbs, athetosis, and dystonic posturing and a separate dyskinesia rating scale based on the clinical UPDRS is used. The scoring occurs at repeated intervals (generally every 30 min), often for the duration of drug action, on several days during the treatment regime. A rater blind to the treatment received by each animal, as these are subjective scales, should carry these out.

CHOOSING THE RIGHT MODEL

UNILATERAL VERSUS BILATERAL LESIONS 6-OHDA and to a certain extent MPTP can produce either unilateral or bilateral lesions. PD generally affects patients on both sides, although the symptoms are generally worse on one side. In the early stages of disease, PD is often observed to be asymmetric with greater symptoms on one side, but the degree of lateralization observed in extensive unilateral lesions in animals is seldom seen, with both sides affected significantly in advanced disease. Therefore the bilateral models can be seen as more closely representative of the human disease. However, generally the bilateral lesions are more problematic in terms of the health of the animal. Extensive bilateral lesions in rats, whether induced by intraventricular or intracerebral injections of 6-OHDA, typically result in profound inanition, with the animals failing to eat, drink, or groom spontaneously, requiring prolonged and intensive care to maintain basic health status.[54] By contrast, both primates and rodents with unilateral lesions can feed and drink adequately to sustain their own body weight and maintain basic health, although MPTP-treated primates with severe bilateral lesions will often require feeding by hand for the first few weeks following treatment and may require antiparkinsonian medication. Partial, bilateral, striatal, and nigral 6-OHDA lesions have been used successfully and the rats are then able to sustain themselves,[55,56] but because the deficit is then bilateral, a different combination of behavior tests is then used including open field and operant tests such as the reaction time task (this is described in more detail elsewhere).[8,56]

In terms of the behavioral tasks that can be used to assess motor function and recovery, in the bilateral primate models especially, qualitative observational parameters are predominantly used to evaluate changes in motor function. In contrast, the tests that utilize the asymmetry of the unilateral models generally provide a more quantitative assessment. A further advantage to the unilateral model is that it enables comparisons of the physiological events in damaged and intact hemispheres, allowing functional deficits to be related to physiological changes. The intact

side may therefore be used as an internal control, but caution must be exercised, as there are some changes to the intact side as a result of the lesion.

6-HYDROXYDOPAMINE VERSUS 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE MPTP is a highly dangerous, lipophilic toxin and special care has to be taken in all aspects of handling and injecting it and when cleaning out the cages during and shortly after the toxin-administration period. 6-OHDA should also be handled with care, but the main concern, as detailed above, is in keeping the toxin fresh. MPTP (in the bilateral model) can be given as a simple systemic injection and in the unilateral model by peripheral intracarotid injection, but 6-OHDA must be centrally injected by stereotactic surgery, which requires a greater level of skill and equipment, is more time consuming, and because of the accuracy of stereotactic placement adds an additional degree of variability. Ultimately, however, central injection of either toxin is required to achieve extensive unilateral lesion in the absence of any depletion on the contralateral side.

Using the modes of administration described above, both 6-OHDA and MPTP are relatively selective for the DAergic nigrostriatal pathway. Indeed, although 6-OHDA can also be taken up by and can kill noradrenergic neurons, there is only sparse noradrenergic innervation of the striatum such that these lesions should have little impact. If this is a concern, desipramine can be administered 30 min prior to surgery, which will block the noradrenaline transporter, thereby increasing the selectivity for DAergic neurons. The actions of MPTP and 6-OHDA on the serotonin system have been debated, and both toxins have been claimed to leave the serotonin system unaffected, induce serotonergic sprouting, or decrease levels of serotonin in the striatum following DAergic denervation.[57–60] This may depend on the mode of administration in the case of 6-OHDA (striatal vs. mfb) or the time course of treatment for MPTP.[37,61,62]

One of the pathological hallmarks of PD is the presence of intracellular inclusions termed Lewy bodies, now known to be attributable to the abnormal aggregation of the α-synuclein protein.[63] The administration of 6-OHDA does not result in the development of inclusions. However, MPTP has been reported to induce protein accumulation in the SN of aged primates that resembles some features of Lewy bodies.[64–66]

RODENT VERSUS PRIMATE The main considerations in deciding between rodent and primate models are both ethical and practical. Both legislative and welfare considerations require use of the least advanced species to address the specific experimental hypotheses. Moreover, primates are more expensive and have limited availability, and the level of care is higher than for rodents as they require larger and more specialized housing facilities.[67] In addition, larger equipment for recording activity is also required, while rodents are easier to handle, house, and care for. Nevertheless, some experimental questions can be addressed only in the larger primate brain. A major advantage of the use of nonhuman primates, especially in the testing of pharmaceuticals, is their phylogenetic similarity to humans and the expression of PD pathology. Rodents do not have a distinguishable caudate and putamen, which are instead combined in a singular structure, the neostriatum, and thus in this regard nonhuman primates have a closer structural arrangement to humans. Aside from the pathology, the expression of parkinsonian symptoms in primates is more similar to the movement disorder in humans, and so has greater face validity in preclinical studies. Indeed many of the movement disorder rating scales used in primates are adapted from those used clinically to assess patients. By contrast, while many of the behaviors observed in rodents are less clearly recognizable as "parkinsonism," there are multiple behavioral tasks that can be applied in order to probe different components of the underlying motor deficits such as neglect versus motor function. When comparing rodent species, rats are larger, more docile, and more amenable to both surgical manipulation and behavioral analysis than are mice. Nevertheless, there has been greater interest in recent years to developing mouse models also, because of the greater numbers of mutant strains and the opportunities provided by new transgenic and knockout technologies to probe specific genetic and molecular influences on degeneration and behavior.

OTHER TOXIN MODELS One of the earliest toxins to be used in PD research is reserpine, a toxin that induces the release of catecholamines from their stores in the nerve terminals. This induces a hypokinetic state in most rodents and drugs can then be administered systemically or into selected brain regions through implanted cannulas. Reduced akinesia and increased activity and grooming can be observed when drugs are administered systemically, or the induction of a locomotor side bias when drugs are injected unilaterally. However, unlike the disease state, the depletion of the catecholamine stores and thus the resulting behavioral deficits are only temporary, and the stores are replenished and locomotor activity restored over a few days. It is therefore difficult to investigate experimental deficits such as dyskinesia that accumulate over time, or to evaluate chronic therapeutic treatments against a stable baseline. Furthermore, there are no morphological effects on the DAergic neurons, no permanent cell death or damage is observed, and no inclusions are documented. There is no selectivity for nigrostriatal as opposed to mesolimbic DAergic neurons, and other monoamine neurotransmitters are also severely depleted. Despite these failings, this model has been successfully used to evaluate pharmacotherapeutics and was fundamental in demonstrating the efficacy of L-DOPA in restoring motor function following DA depletion.[68]

In the past few years, models have been proposed based on rotenone and paraquat, two agricultural chemicals that have both been associated with an increased incidence of PD. However, these models produce a high mortality and decidedly variable results, and the induced degeneration is not specific to the SNc.[69–72] More recently, abnormalities of protein processing by the proteosome have been identified as a possible mechanism for inducing PD and the accumulation of proteins such as α-synuclein. McNaught *et al.*[73] reported that chronic administration of PSI, a synthetic peptide aldehyde that inhibits proteasomal function, reproduced both the motor and pathological consequences of PD in rats. They describe specific degeneration of dopaminergic neurons, proteinous deposits akin to Lewy bodies, in addition to bradykinesia, tremor, and rigidity. However, although similar results have been reported by other researchers,[74] equally many have not been able to reproduce these findings.[75,76] Each of these models still has to be fully and reliably characterized before being used to evaluate therapeutic or neuroprotective approaches to the treatment of PD.

CONCLUSIONS

6-OHDA and MPTP are the tools most frequently used to induce selective and effective degeneration of the DAergic nigrostriatal pathway in experimental animals, and thereby model the

primary pathology and symptoms of PD in the laboratory. In deciding which model to use, the focus should be on first selecting the most appropriate model and, more importantly, the behavioral tests most appropriate for that model for the specific experimental hypotheses or preclinical strategies to be evaluated. The alternatives will be weighed according to a range of criteria involving dimensions of practicality, efficiency, validity, and animal welfare. Generally, several tests are used to determine the generality of results and the extent and limitations of their application. Treatments may not necessarily improve function in all of them. For example, transplants of DAergic tissue produce improved forepaw asymmetry in the cylinder test but not in the more complex paw-reaching task. However, while the 6-OHDA-lesioned rat and MPTP-treated primate are well-established models of PD that have provided considerable insight into the disease, it should be remembered that both still have significant limitations and the search continues for a model that can not just reproduce the neuropathology and symptoms of the disease, but also recreate more faithfully the progressive pathogenic aspects of the disease.

35 Transgenic Animal Models of Neurodegenerative Diseases

ANTHONY W.S. CHAN AND YUKSEL AGCA

ABSTRACT

Neurodegenerative diseases are complex disorders involving neuropathological and psychiatric alterations. Transgenic mice expressing mutant human Alzheimer precursor protein (βAPP), α-synuclein, and mutant huntingtin genes have been developed for Alzheimer's, Parkinson's, and Huntington's disease (AD, PD, and HD), respectively. However, none of the existing mouse models completely represents the pathology of these diseases, including neuronal loss, cerebral atrophy, widespread neurofibrillary tangles, and neuropil threads in AD, formation of Lewy bodies and the extensive loss of dopaminergic neurons in PD, and neuronal loss and aggregate formation in HD. Although rat models have been shown to be superior to mouse models because of the brain size and the availability of more sophisticated behavioral testing, a common disadvantage in rodent models is the lack of neurodegeneration. Furthermore, rodents have relatively smaller brains and thus provide a limited behavioral repertoire for assessing transgene-associated structural and cognitive deficits. Nonhuman primates are ideally suited for modeling the neuropathology of neurodegenerative diseases because of their biological proximity to humans, size, and age-related development of lesions. Thus the development of a transgenic nonhuman primate model of neurodegenerative diseases holds greater promise for success in the discovery of diagnoses, treatments, and cures than approaches using other animal species. Nevertheless, it is undeniable that rodent models contribute significantly to the understanding of neurodegenerative diseases and the development of cures. A transgenic nonhuman primate model will be able to mimic human conditions not only physiologically but also genetically. However, the development of transgenic rodent and nonhuman primate models of neurodegenerative diseases is equally important for unraveling the mystery of neurodegeneration and the development of early diagnosis and cures.

Key Words: Neurodegenerative disease, Neurodegeneration, Animal model, Transgenic rodent, Transgenic nonhuman primates.

INTRODUCTION

Animal models of neurodegenerative diseases (NDs) have been developed quickly in the past decades because of the advancement in molecular genetics and the latest development of gene transfer technology. Parkinson's disease (PD), Alzheimer's disease (AD), and Huntington's disease (HD) are the most common NDs and affect more than six million people in the United States. Compared to HD, which is caused by the extension of the polyglutamine [poly(Q)] tract at the 5′ region of the huntingtin (htt) gene, PD and AD are more complex.[1–6] Extensive effort has been made to determine the genetic and environmental components that lead to complex genetic disorders such as PD and AD.[7,8] Candidate genes are often identified in a small number of families that are scattered around the globe.[3,7,9] Although candidate genes have been identified, no single gene is unanimously linked to PD and AD. The latest discovery of the leucine-rich repeat kinase 2 (LRRK2) gene has the greatest link to familial parkinsonism (FP), which contributes to only 2–10% of these cases.[1,2,9,10] Several mutations have also been identified in the Alzheimer precursor protein (APP) gene that are linked to the development of AD.[3,11–13] However, no single mutation leads to neuropathology and cognitive behavioral declines in animal models equivalent to that seen in human patients.[3,10]

Transgenic animal technology has revolutionized animal modeling, which becomes a very useful tool for elucidating the link between genetics and human diseases.[3,10,14–18] The development of a new animal model is not only important for a better understanding of human diseases, but also important for the development of diagnostic tools and treatments.[18,19] Unfortunately, animals that carry genetic defects similar to those found in patients do not develop identical patterns.[20–21] This suggests fundamental differences between human and other mammalian species such as rodents and nonhuman primates (NHPs).[19] Physiological differences include life span, brain complexity, cellular metabolism, and endocrine and reproductive function, which could be the result of genetic redundancy or variations in biochemical pathways.[22–24] Hence, a good animal model is not only dependent on the genetic constitution of the transgene but also the genetic and physiological background of the animal species.[25] It is particularly important for NDs because of the complexity in genetic composition, the unknown neuropathological mechanisms, and the gradual decline in cognitive and behavioral function. For example, most of the transgenic HD mice do not develop identical neuropathology. Although brain size was reduced by 20%, specific neuronal cell loss was not found in the striatal region or cortex.[26] A similar phenomenon was also observed in AD and PD mice.

Due to physiological differences between species, the rat has certain advantages over the mouse because of brain

From: *Sourcebook of Models for Biomedical Research*
(P. M. Conn, ed.),

size, neurocircuitry, and availability of cognitive–behavioral testing.[12,13,27–31] Additionally, NHPs are considered the best animal models, especially for NDs, because of the complex correlation between aging and progressive neurodegeneration, which leads to deleterious alterations in behavior and psychiatric status associated with diseases such as AD, PD, and HD in humans.[19,32,33] NHPs are the only animal model providing accessibility to a wide range of cognitive–behavioral testing including the possibility for high-resolution brain imaging such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET).[19,32] Thus, a transgenic animal with a genetic alteration that leads to human inherited NDs might best mimic patient conditions; this could increase our understanding of disease development, thereby paving the way for the development of cures.[32]

Besides the selection of target genes and animal species, promoter is also an important factor for the development of a transgenic model. Promoter regulates the expression of disease-related genes, which affects the etiological pattern of the animals.[3,10,16] The R6/2 mouse model of HD has good representation in neuropathology and motor deficits; however, mutant *htt* expressed under the control of the human *htt* promoter results in an excessive decline in health and sudden death with no known cause.[34–36] On the other hand, transgenic mice that carry mutant *htt* with 82Q under the control of the prion protein promoter have neuron-specific pathology with distinctive stages of disease development, which mimics the course of HD progression.[37] These studies suggest that promoter is important in determining disease development, neuropathology, and cognitive–behavioral patterns in transgenic animal models.

Here we will focus on animal model development of AD, PD, and HD as a representative of NDs. Our goal is to provide a brief overview of currently available animal models and new methodology for creating transgenic rat and NHP models.

METHODS FOR CREATING TRANSGENIC ANIMALS

The method for creating transgenic animals has a significant impact on the application of the disease model.[14,18] In general, transgenic animals can be categorized by the expression pattern, which includes (1) overexpression, (2) gene targeting: knockin, knockout, and knockdown, (3) conditional expression, and (4) inducible expression. Although the expression pattern could be manipulated by strategies such as the tetracycline-inducible system, the Cre-lox conditional expression system, and artificial chromosome (AC), an exogenous gene construct has to be inserted into the target cell genome in order to achieve long-term expression. Additionally, there are three fundamental criteria determining the success of a transgenic animal: (1) germline transmission, (2) stable expression, and (3) all body cells must carry the transgene.[38] Two exceptions are chimeric mice generated by blastocyst injection of genetically modified embryonic stem cells and local gene transfer such as stereotaxic viral injection in a selected brain region.[33,39–41]

Several methods have been used to generate transgenic animals. Among these methods, pronuclear microinjection (PI) is the most commonly used method in creating transgenic mice and rats. A similar method has also been used to generate transgenic livestock; however, somatic cell nuclear transplantation (SCNT; cloning), a recent development, is slowly replacing PI in livestock because more versatile genetic manipulation could be achieved.

Table 35–1
Focal transgenesis versus germline transgenesis

	Focal transgenesis	*Germline transgenesis*
Number of transgenic cells	Regional and limited	All body and germ cells
Expression pattern	Regional	Whole body (dependent on promoter)
Inheritance	No	Yes
Timeline	1–6 months	6–24 months (dependent on species)

SCNT will not be discussed in detail because it is not commonly used in ND models. Compared to PI, viral vectors such as retrovirus and lentivirus have been developed with high efficiency in generating transgenic animals.[14,42,43] Retroviral gene transfer was first described by Jaenisch and colleagues in 1976. However, retrovirus was not widely used for the production of transgenic animals because of biosafety concerns. Not until the mid-1990s was a replication-defective pseudotyped retroviral vector developed.[44,45] Pseudotyped retroviral vectors have the advantage of achieving a high titer and broad host cell range, which are the two major limitations of conventional retroviral vector systems. Chan and colleagues have successfully generated transgenic cattle and the first transgenic monkey using pseudotyped retrovirus at high efficiency.[14,42] However, due to the life cycle of retroviruses, efficient gene transfer could be achieved only in actively dividing cells.[14,42]

The recent development of the lentiviral vector has led to a new era of *in vivo* genetic manipulation.[46,47] Nondividing cells could be transfected efficiently using pseudotyped lentivirus.[46,48] Replication-defective lentivirus is derived from HIV-1 with most of the viral structural genes removed. Vesicular stomatitis virus envelope glycoprotein protein G (VSVG) pseudotyped lentivirus is widely used in neurological research because gene transfer in neuronal cell types that are not actively dividing could be achieved at high efficiency.[49] Stereotaxic injection of lentivirus at selected brain regions provides an efficient[46,48] and effective method for studying gene function in a relatively short time compared to germline transgenesis[43,47,50] (Table 35–1). There are significant differences between focal and germline transgenesis. Focal transgenesis is limited to a small region in the brain and is able to transfect only a limited number of neuronal cell types in an individual. Therefore, each model has to be generated independently and variation between animals is expected. This technique offers the opportunity for an *in vivo* gene function study in species that are highly relevant to humans but for which efficient gene transfer techniques are not available for the creation of transgenic models such as rat and NHPs.[14,19] The development of transgenic rat and NHP models of NDs will also be discussed.

TRANSGENIC MOUSE MODEL OF NEURODEGENERATIVE DISEASES

The transgenic mouse is the most commonly used and diversified animal model in NDs.[3,4,10,15,16,36,37] Extensive information on the mouse genetic background is important when developing an

ND model. Mice with different genetic backgrounds have been shown to be a crucial factor for the future development of a cognitive–behavioral pattern in a transgenic mouse model.[25] Additionally, well-established techniques in handling gametes, embryos, and surrogates, inexpensive and relatively limitless supplies, and short generation times allow a more versatile application of the transgenic mouse model than models of other species.[19] Therefore, transgenic rodents, developed with genetic defects similar to those seen in patients, are widely used in biomedical research.

Various genetic manipulation strategies are possible only in mice but not in species such as rats or NHPs.[19] Besides the overexpression of a transgene, downregulation by RNAi or microRNA, or conditional expression of a target gene, disease-related genes could be altered in embryonic stem cells by recombination techniques followed by blactocyst injection. However, the resulting chimeric mice require an additional breeding procedure in order to establish a genetically defined transgenic line. Although mouse cloning technology has not been widely used in ND, the prospect of an identical mouse model is expected to have significant impact. Transgenic mouse models of AD, PD, and HD have also been developed with various promoters, which include tissue- and cell type-specific promoters such as the prion protein (PrP) and neuron-specific enolase (NSE) promoter, the thymus-1 minigene (thy-1), a viral and housekeeping gene promoter such as cytomegalovirus (CMV), ubiquitin, platelet-derived growth factor (PDGF) promoters, and endogenous promoters such as the htt promoter.

AD mouse models are generated primarily by the overexpression of wild-type APP or APP with mutations at positions K670N and M671L (Swedish), E639Q (Dutch), D694N (Iowa), and V717F (London) that favors Aβ processing.[3,10,51] These mutants are important factors for achieving Aβ levels sufficient to lead to amyloid deposition.[3] Additionally, presenillin 1 (PS1) and 2 (PS2) affect the activity of -secretase, which results in the alteration of the Aβ42 level.[10,13] Several transgenic mice with PS1 mutations have no significant effect on Aβ deposition. However, the coexpression of APP Swedish or London mutations and the PS1 mutant, a significant increase of Aβ42, and amyloidosis at an early age were observed compared to mice with APP mutations alone.[3] A double mutant mouse (PS1 M146L/APP K670N/M671L) has plaque formation by 3 months of age compared to 9–12 months in an APP K670N/M671L mouse.[3] Besides APP and PS1, overexpression of wild-type or mutant tau protein in mice has led to various degrees of neurofibrillary pathology, which is highly related to the number of tau repeats.[3,10] A triple transgenic mouse model with the combination of mutant APP, PS1, and tau has resulted in an early onset at 3 months of age of plaque formation, positive for phosphorylated tau and neurofibrillary tangles.[52,53] A transgenic mouse with triple APP mutations (Swe/Dut/Iowa) has also been generated with early-onset and robust amyloid accumulation.[51]

Animal model targeting modifiers of amyloid pathology have also been developed. These include overexpression and knockout models of apolipoprotein E (ApoE) and BACE1.[54–57] An increase in the level of ApoE results in enhancement of amyloid deposition,[55] whereas knockout of ApoE results in a decrease of deposition in transgenic mice.[54] A similar result was observed in BACE1. Consistently, a mouse deficient in low-density lipoprotein receptor-related protein (LRP), an ApoE receptor, has an increase in amyloid deposition.[10] However, transgenic mice overexpressing TGF-β1 have an increase in vascular deposition and a decrease in plaque deposition. These animal models suggest how complicated the neuropathology in AD is and these modifiers play an influential role in amyloid pathology in APP mice. In fact, ApoE is considered one of the risk factors for AD.

Several candidate genes including PARK 1 (α-synuclein), 2 (Parkin), 5 (UCH-L1), 6 (PINK1), 7 (DJ1), and 8 (LRRK2) have been identified and are related to PD.[1,7,9] Among these genes, α-synuclein is the first linked to PD. Several mutations of α-synuclein have been identified and are sporadically distributed at low percentages in familial PD cases. Overexpression of both wild-type and mutant α-synuclein has resulted in a decrease of dopamine and dopamine transporter with behavioral impairment.[4,27] However, no significant difference was found when different promoters were used, which includes tyrosine hydroxylase (TH), PDGF, and the Thy-1 promoter.[4] On the other hand, the parkin gene is related to familial autosomal recessive juvenile PD.[1,7,9,27] Loss of parkin function results in an abnormal accumulation of its substrate such as glycosylated α-synuclein.[15] A variation in neuropathology was also found in the deletion of exons 2, 3, and 7 of the parkin gene. Some common features include no loss of nigrastriatal DA neurons and behavioral impairments that were observed in exon 3 and 7 deletions but were undetectable in exon 2-deleted mice.[15] Mouse models with DJ-1 knockout, reduced Nurr1, and the loss of Pitx3-aphakia have also been generated recently. Variations in neuropathology and behavioral impairments suggest that Nurr1 and Pitx3-aphakia mice are well suited for studying later stages of AD because of the loss of nigrastriatal dopaminergic neurons, whereas DJ-1 mice may be best for the study of early-onset parkinsonism.

Genetically HD is less complex than AD and PD.[2,7,30] The extended glutamine tract at the 5′ region of exon 1 of htt has been identified and linked to HD.[58–60] Variations in neuropathology and behavioral decline are highly correlated with the length of the poly(Q) in patients as well as in HD mice.[58,60–62] In addition to the poly(Q) tract, promoter, which regulates the expression of mutant htt, is also important in the development of animal models. Although mice are not the perfect model for humans, HD mice present features that are highly relevant to HD and are great tools in understanding the etiology and the development of cures.[19,32] Although the function of *htt* has not been clearly determined, *htt* knockout is embryonic lethal and knockin mice do not have neuropathology identical to that seen in HD patients. Systemic overexpression of mutant *htt* is lethal with a board spectrum of HD phenotypes including motor impairment and neuropathology. However, the cause of death in R6/2 mice, one of the most popular HD mouse models,[61] is not directly linked to the deteriorating effect of HD but to complications that lead to physiological dysfunction.

Although most of the PD, AD, and HD mice present certain features of cognitive–behavioral decline and motor deficit, which lead to further insight on the molecular basis of neurodegenerative diseases, highly sensitive testing for in-depth analysis in mice is very limited. Therefore, the need for an animal model that allows longitudinal studies such as noninvasive imaging analysis as well as access to more accurate testing methodology for evaluating cognitive–behavioral and motor impairment are important in unraveling the etiology of the disease and developing diagnostic tools and cures.

TRANSGENIC RAT MODEL OF NEURODEGENERATIVE DISEASES

For over a century the rat has been the model of choice for studies of many human diseases. Several hundred rats lines including inbred strains, congenics, and mutant rats exist. Unfortunately, germline transgenic rats are less available to biomedical researchers. In the context of neurological science, the rats have served as important animals for the study of neural development and disease, neurodegeneration, addiction, and behavior. There are several reasons for the wide use of rats in biomedicine: (1) the availability of extensive baseline data that make the interpretation of the experimental results more meaningful, (2) their larger size makes many live operations feasible, and (3) certain physiological similarities of the rat to humans.

Although transgenic mice have proven to be important models for human diseases, there are many cases in which rats are superior models due to metabolic similarities and larger body size including larger brain for the development of neurosurgical interventions. In some instances, transgenic rats provided a more appropriate phenotype when compared to mice bearing the same transgene.[63] For example, rats are a superior animal model for studying autoimmune diseases such as rheumatoid arthritis.[64] Transgenic rats have also been very useful in transplantation research, in which microsurgery is an essential procedure. However, there are currently only a handful of transgenic rat lines compared to transgenic mouse lines. This is mainly due to inefficient gene transfer methods and limited understanding of gamete and embryo manipulation skills in the rat.[65] In recent years, little advancement has been made in rat germline modification techniques; further improvement in gene transfer technology will ensure the wider application of transgenic rats as human disease models.

Fortunately, genomic resources for the better utilization of rat models of human disease are growing rapidly.[66] With the completion of the Human Genome Project, there is an unprecedented need for animal models to determine gene functions and to test new therapeutic strategies aimed at curing human disease. There is no doubt that the recent completion of the rat genome sequence further improves the utility of the rat as a model organism. Therefore, genetically modified rats will play a pivotal role in those advances since they offer many unique advantages as models of human disease. Despite the availability of remarkable new genomic tools, the development of genetically modified rats is still in its early stages and complex genetic manipulation such as gene targeting is not currently available.

PRONUCLEAR MICROINJECTION METHOD FOR THE GENERATION OF TRANSGENIC RATS

The generation of transgenic rats by PI often requires a large number of embryo donor and recipient animals. The procedure is labor intensive, and requires significant technical skill. Moreover, the production of transgenic rats by PI is inefficient due, in part, to difficulties associated with observing the pronuclei and a high postinjection lysis rate (30–35%). Rat zygotes are often not synchronized as they are in mice and thus finding the appropriate timing for visualization and injection of the pronucleus is timely and labor intensive. To generate five or six transgenic founder animals, about 800–1000 embryos have to be injected if outbred strains such as Sprague–Dawley and Wistar (see Table 35–2) are used. These shortcomings are magnified when creating transgenic rats in an inbred background such as Fischer 344 and Lewis, primarily due to their suboptimal response to superovulation, higher sensitivity to microinjection, and lower gene transfer efficiency. Due to low efficiencies many investigators initially create transgenic rats using outbred stocks, i.e., Sprague–Dawley, and subsequently backcross them to the desired inbred genetic background using a congenic approach. This approach is not only expensive due to animal housing, but also time consuming, requiring at least 10 generations of backcrossing.[67,68] Since the significance of genetic background in animal disease models cannot be discounted, the availability of a simple and reliable methodology to create transgenic rats with desired genetic background is urgently needed.

GENERATION OF TRANSGENIC ANIMALS USING VIRAL VECTORS

Since the production of transgenic rats by PI is inefficient, the development of alternative gene delivery method(s) is critical for the advancement of transgenic rat models of NDs. An alternative approach to generating germline transgenic animals is the microinjection of viral vectors into the perivitelline space (PVS) of zygotes or MII oocytes. This method appears to yield a much higher transgenic rate (Table 35–2) compared to the PI method and overcomes many of the problems associated with the highly inefficient PI method in the rat. In addition, lentivirus-mediated delivery of small interfering RNA (siRNA) into cycling, noncycling mammalian cells, embryonic stem cells, zygotes, and their derivatives has been successfully demonstrated.[69,70] The combination of lentiviral gene transfer and siRNA technology has further accelerated the need for rat disease models that require the suppression or the loss of gene function.

Table 35–2
Transgenic efficiency using pronuclear microinjection of plasmid DNA or perivitelline space microinjection of lentiviral vector in the rat

Method of injection	*Number of zygotes injected*	*Postinjection survival (%)*	*Number of embryo transfers*	*Number of transgenic founder*	*Overall (number injected/ number transgenic (%))*
Pronuclear microinjection[a]	800–1000	65–70	25–27	5–6	0.6
Perivitelline space microinjection[b]	30–40	90	2–3	8–10	25–30

[a]Based on Charreau *et al.*[63]
[b]Unpublished data.

An alternative to the transgenic rat model, lentiviral gene transfer, has led to the possibility of focal transgenesis. Lentivirus is injected into a selected region of the brain and gene function could then be studied. Focal transgenesis has been widely used in ND research because it is fast and effective in determining gene function. Functional studies of α-synuclein and parkin in PD, APP, and tau in AD rat models have been reported, which accelerate the understanding of gene function and the role of genes in disease development.[11,27,33,41,71]

TRANSGENIC RAT MODEL OF NEURODEGENERATIVE DISEASES

Only limited numbers of transgenic rat models of NDs were developed in recent years because of the low efficiency. Most of these transgenic rats were generated by the traditional PI method. A transgenic rat model of NDs was first reported in 1998.[13] The PS1 gene was introduced into rats and a significant increase of apoptosis in primary cortical neurons was observed.[13] Transgenic rat models that carry various combinations of APP and PS1 mutations have also been developed. However, no senile plaque of aggregated Aβ was observed in these rats.[29] In addition to an AD model, a truncated rat htt cDNA with 52 CAG repeats under the control of the rat htt promoter was microinjected into the pronucleus of rat zygote.[31] These rats exhibit adult-onset HD with typical histopathological alterations.[31] *In vivo* imaging including MRI and PET was also performed in these rats and longitudinal studies could be accomplished. Although several rat models of HD were developed afterward, the development of ND rat model remains slow.[30,71] So far, no transgenic rat model of PD has yet been reported and the search for candidate genes remains controversial.

Only recently has lentivirus been shown to be highly efficient in generating transgenic animals.[43,47,50] Compared to PI, lentiviral gene transfer results in a much higher transgenic rate (Table 35–2). Although transgenic rat lines remain primarily generated by PI, the versatile application of lentivirus has thrived in recent years not only in focal gene transfer but also in the creation of a transgenic animal model.[33,41,47,49,50,72,73] We have generated several transgenic rat lines at a high rate as summarized in Table 35–2. A brief but precise protocol will be discussed in the following section.

GENERATION OF TRANSGENIC RAT USING LENTIVIRUS

RAT SUPEROVULATION Female rats (28–30 days old) are superovulated using SC implantation of 8 units of follicle-stimulating hormone (FSH), introduced via Alzet miniosmotic pumps, and followed by an intraperitoneal (ip) injection of 15 units of luteinizing hormone (LH) approximately 50–52 h after FSH implantation.[74] To obtain zygotes, donors will be mated with male rats right after LH injection.

RAT EMBRYO COLLECTION Superovulated female rats are euthanized by CO_2 inhalation 20–24 h post-LH injection. The oviducts are excised and placed into a culture dish containing TL-HEPES supplemented with 1 mg/ml hyaluronidase (Sigma Chemical Co., St. Louis, MO) and 4 mg/ml bovine serum albumin (BSA) (Sigma Chemical Co., St. Louis, MO). The extended, translucent oviductal ampulla is dissected to release the clutch of zygotes into the solution in a culture dish. Zygotes are then incubated with hyaluronidase for about 5 min to enable dissociation and removal of the cumulus cells. An inverted microscope is used to evaluate zygotes for the presence of polar bodies, pronuclei, and sperm tail to verify fertilization. The cumulus-free zygotes are washed by transferring them through three drops of hyaluronidase-free TL-HEPES before being placed into 40 µl culture drops of KSOM under oil in culture dishes, and placed in an incubator (humidified 5% CO_2/95% N_2) at 37°C. The zygotes are subjected to lentiviral injection via PVS 1–2 h after collection.

SURGICAL EMBRYO TRANSFER To obtain pseudopregnant embryo recipient rats, 8- to 10-week-old Sprague–Dawley female rats (HSD: Sprague Dawley® SD®) are synchronized by ip injection of 40 µg gonadotropin-releasing hormone (GnRH) analog des-Gly^{10} [D-Ala^{6}] ethylamide (Sigma L4513) and with mature, vasectomized Sprague–Dawley males 4 days after hormone injection. For verification of mating and hence pseudopregnancy, the female rats are removed the following morning and checked for the presence of a vaginal plug.

For embryo transfer (ET), the recipient rats are anesthetized by injecting the ketamine:xylazine mixture intramuscularly (im) into the biceps femoris muscle. Approximately 5 min after the injection, the dorsal and lateral skin is clipped and the surgery site prepared with three alternate scrubs of betadine and alcohol. The skin of the dorsum is sagittally incised (10–15 mm in length) on the midline at the level of the paralumbar fossa. The skin incision is then rolled laterally to superimpose the paralumbar fossa. The muscle layers and the peritoneal wall are opened via incision and spread to create a window about 8–12 mm in length that permits retraction of the ovarian fat pad. The ovary is gently grasped with a tissue forceps and retracted/extracted until the ovary, the ovarian bursa, and the oviduct are exposed and visualized using a stereomicroscope at 10–15×. A few drops (~25 µl) of epinephrine (VEDCO, St. Joeseph, MO; 1 mg/ml) are sprinkled over the bursa to reduce bleeding. The bursa is gently dissected using watchmaker forceps to gain access to the infundibulum. PVS-injected embryos are loaded into a small column consisting of a few microliters of phosphate-buffered saline (PBS) within a 150-µm-diameter transfer pipette. The transfer pipette is inserted into the infundibulum, 8–10 injected zygotes are discharged into the oviduct, and then the ovary is carefully replaced into the peritoneal cavity. After repeating the procedure on the contralateral side, the skin is closed using wound clips (Fisher Scientific, Pittsburgh, PA).

LENTIVIRAL VECTOR CONSTRUCTION The gene of interest is inserted into a lentiviral vector backbone such as "pFUW"[43] [F, flap; U, ubiquitin promoter; G, green fluorescent protein; W, woodchuck hepatitis virus posttranscriptional regulatory element (WRE)]. In brief, pFUW is a self-inactivating vector that is composed of the WRE in order to increase the transcription level and minimize the position effect. Additionally, an HIV flap element was inserted between the 5′ LTR and the internal promoter to increase the titer of the virus.

COLLECTION OF AND CONCENTRATION OF VECTOR 293FT cells are plated into a 10-cm tissue culture plate the day before the cotransfection with pΔ8.9 and pVSV-G into a 293FT packaging cell (Invitrogen, Inc.). Culture medium is collected at 48 h posttransfection for 3 consecutive days at 24-h intervals. The supernatant is centrifuged at 25,000 × *g* for 90 min. The vector pellet is resuspended and aliquoted in 50 µl of 0.1× Hanks' balanced salt solution and kept frozen at −80°C. All procedures were performed inside a Biosafety level II cabinet. All of

the plasticware and instruments that have contacted the vector are decontaminated with 10% bleach or autoclaved before disposal.[38]

LENTIVIRAL INJECTION The procedure for lentiviral injection in the PVS is performed as described for NHP oocytes in the next section.

GENOTYPING Two weeks after delivery, tailsnips are taken from all potential founder rat pups, DNA extracted, and genotyped using an appropriate primer set by polymerase chain reaction (PCR). Furthermore, Southern blot analysis is performed to determine copy numbers of the transgene of interest.

CURRENT STATUS OF THE TRANSGENIC NONHUMAN PRIMATE MODEL OF NEURODEGENERATIVE DISEASES

NDs are complex disorders in which declines in neuropathology and psychiatric alterations are highly related to aging. Although transgenic mouse and rat models of neurodegenerative diseases such as AD, PD, and HD with certain clinical features have been created, a limited neuropathological pattern such as neurodegeneration is the major drawback of these animals. Chemical induction of HD and PD in NHPs has also been reported with similar neuropathological damage and psychiatric alteration; however, the role of genetic defects cannot be identified in the course of disease development. Due to the close relationship between human and NHPs, the development of transgenic NHP models will be able to mimic human conditions not only physiologically but also in terms of the genetic defects that lead to AD, PD, or HD. Therefore, disease onset and development could then be elucidated with the aid of a transgenic NHP model. Additionally, high-resolution brain imaging technology such as MRI and PET and cognitive–behavioral testing can be carried out in the NHP simultaneously, which is not possible in other animal models. A high degree of similarity in motor repertoire between NHPs and humans allows direct comparison of the neurological phenotype between the NHP model and patients. Because of this, a transgenic NHP is expected to have a significant impact on ND research. However, due to the difficulty in creating a transgenic NHP, an alternative strategy has been developed to bypass the creation of a germline transgenic monkey and to study gene function at a selected brain region. Focal transgenesis (stereotaxic delivery of a viral vector) is one of the most popular techniques in neuroscience because of the latest development of a lentiviral vector that allows efficient gene transfer in inactive cells such as neurons.[33,41] Although focal transgenesis is fast and efficient, the role of the gene defect will be restricted to a selected brain region and a selected group of neurons, and its role beyond neurological functions may be easily overlooked. Therefore, focal transgenesis is not the solution for a germline transgenic animal that carries the genetic defect in all body cells, which best mimics patient conditions. Although both strategies are unique and are very useful in ND research, careful interpretation of results should be taken when using these animal models.

Focal transgenesis by the injection of lentivirus has been widely used to study disease-related gene function in rodents and NHPs.[33,41] However, there is only one report of the creation of a transgenic NHP.[14] Although a transgenic NHP is not commonly used in the ND model, the potential impact of the transgenic NHP model in ND research could be considerable because of the great similarity to humans including motor repertoire, brain structure and function, and genome constitution. Here we have a brief protocol for the generation of a transgenic NHP model of NDs. Preparation of a lentiviral vector was previously described when the transgenic rat model was discussed.

GENERATION OF TRANSGENIC NONHUMAN PRIMATES

FOLLICLE STIMULATION Hyperstimulation of female rhesus monkeys exhibiting regular menstrual cycles is induced with exogenous gonadotropins. In brief, subcutaneous injection of a GnRH antagonist (Antide; Serono Inc.) and twice daily injection of r-hFSH (Serono Inc.) for 6 days is followed by twice daily injections of r-hFSH and r-hLH (Serono Inc.). On day 7 of the stimulation, ultrasonography is performed and r-hCG is administered for induction of ovulation when follicles of 3–4 mm in diameter are observed.

FOLLICULAR ASPIRATION BY LAPAROSCOPY Follicular aspiration is performed at 27 h post-hCG. Oocytes are aspirated from follicles using a needle suction device lined with Teflon tubing. Multiple individual follicles are aspirated via continuous vacuum, and collection tubes are immediately transported to a dedicated primate oocyte/zygote laboratory for oocyte recovery and evaluation of the maturation stage.

COLLECTION AND EVALUATION OF RHESUS OOCYTES The contents of each collection tube are diluted in TALP-HEPES supplemented with 2 mg/ml hyaluronidase. Oocytes are rinsed and then transferred to preequilibrated CMRL medium prior to the evaluation of maturation. MII-arrested oocytes, exhibiting expanded cumulus cells, a distinct PVS, and a first polar body, are selected for PVS injection and subsequent fertilization.

***IN VITRO* MATURATION** Oocytes are matured in modified CMRL-1066 containing 20% heat-inactivated fetal bovine serum (FBS; Hyclone Laboratories Inc., Logan, UT) supplemented with 5 μg/ml ovine FSH and 10 ng/ml ovine LH for up to 36 h in 50-μl drops of medium under saline-equilibrated silicone oil at 37°C in a humidified atmosphere of 5% CO_2 in air.

INFECTION OF MATURE RHESUS OOCYTES/ZYGOTES WITH THE VSVG PSEUDOTYPE MII-arrested oocytes and fertilized oocytes are selected for PVS injection followed by *in vitro* fertilization in oocytes. VSVG pseudotype solution is loaded into the injection needle by micropipette, mounted onto a micromanipulator, and connected to a microinjector. After microinjection, the oocytes are returned to the maturation drop and fertilized by intracytoplasmic sperm injection (ICSI), whereas the zygote is returned to the culture medium.

COLLECTION, PREPARATION, AND HANDLING OF RHESUS SPERM Rhesus males of proven fertility are trained to routinely produce semen samples by penile electroejaculation. After serial washes, the sperm samples are counted and diluted to a concentration of 20×10^6 sperm/ml. Sperm suspensions are incubated at 37°C under 5% CO_2 in air for 6 h, at which point 1 mM caffeine and 1 mM dibutyryl cyclic adenosine monophosphate (dbcAMP) is added for the final hour to stimulate hyperactivation.

FERTILIZATION BY INTRACYTOPLASMIC SPERM INJECTION A single sperm is aspirated tail-first into an injection needle from the sperm-polyvinylpyrrolidone (PVP) to the oocyte-containing drop. Oocytes are immobilized with the polar body at

the 12 o'clock position and the injection needle is inserted through the zona into the cytoplasm at the 3 o'clock position. The oolemma is breached by gentle cytoplasmic aspiration and the sperm will then be released into the oocyte.

ASSESSMENT OF SUCCESSFUL FERTILIZATION AND *IN VITRO* EMBRYO CULTURE Fertilization is assessed within 3–6 h by detection of the second polar body using RC optics. Pronuclei are assessed between 12 and 16 h post-ICSI. After completion of the first cleavage division (24–28 h post-ICSI), two-cell embryos are cocultured in CMRL + 10% FBS (Hyclone Laboratories, Inc., Logan, UT) on a Buffalo rat liver cell (BRL 1442; ATCC, Rockville, MD) in 100 µl drops overlaid with oil. Embryos are selected at the 4- to 16-cell stage for transfer into selected surrogates.

SELECTION AND PREPARATION OF SURROGATE FEMALES Rhesus females with normal menstrual cycles and natural cycles similar to those of the egg donor are screened as potential surrogate mothers. Blood samples, beginning on day 8 of the menstrual cycle (day 1 is the first day of menses), are collected and analyzed daily for serum progesterone and estrogen. Surgical ET is performed on day 2 or 3 following ovulation by transferring two four- to eight-cell embryos into the oviduct of the recipient.

RHESUS EMBRYO TRANSFER BY LAPAROTOMY Surgical ET is performed by mid-ventral laparotomy. The oviduct is cannulated using a Tomcat catheter containing two four- to eight-cell stage embryos in HEPES-buffered TALP, containing 3 mg/ml BSA. Embryos are expelled from the catheter in about 0.05 ml of medium while the catheter is withdrawn. The catheter is flushed with medium after removal from the female to ensure that the embryos are successfully transferred.

CONFIRMATION OF PREGNANCY To confirm embryonic implantation, blood samples are collected daily and analyzed for serum estrogen and progesterone concentrations. If hormone levels indicate a possible pregnancy, the pregnancy is confirmed by a transabdominal ultrasound on day 35 posttransfer.

INFANT CARE The pregnant animal will be monitored daily for the 150 days of pregnancy because rhesus monkeys occasionally experience preeclampsia, and newborns can be lost due to complications at birth. Therefore, cesarean sections may be performed. Babies are weighed and measured, and their head circumference recorded; they are kept in an incubator and raised in the nursery facility if needed.

36 Animal Models of Nociception and Pain

James D. Rose and C. Jeffrey Woodbury

ABSTRACT

Research on the neurobiological bases of nociception and pain and related investigations of potential therapies require great reliance on animal models. There are unique challenges in the development of well-validated models in this field because of the distinction between nociception, the processing and response to potentially pain producing stimuli by lower levels of the nervous system, and pain, the conscious result of nociceptive stimulus processing by the cerebral cortex. The most frequently used models actually represent tests of nociception only and are appropriate for investigating diverse pathophysiological processes that cause nociceptive activity in peripheral tissues, nerves, the spinal cord, or subcortical regions. However, because human pain is a complex end result of nociception and consciousness-dependent processes, models intended to address pain must be validated for this purpose. Models assessing processes related to pain are relatively rare and more difficult to validate and use than those relevant only for nociception. A failure to recognize the pain–nociception distinction has significant practical consequences for successful extrapolation of results from laboratory to clinical practice.

Key Words: Nociception–pain dichotomy, Construct validity, Neocortex, Nocifensive behavior, Neural substrate.

THE NEED FOR ANIMAL MODELS OF NOCICEPTION AND PAIN

Pain research with human subjects is productive on many fronts, as shown by the large and diverse literature surveyed in the most recent edition of Wall and Melzack's *Textbook of Pain.*[1] A particularly prominent area of progress is in the use of brain imaging methods such as positron emission tomography and functional magnetic resonance imaging to advance our understanding of the higher brain processes that underlie pain.[2] However, there are great limitations on the use of humans in experimental studies of pain and animal subjects continue to be vital. *In vivo* models are particularly important because pain and its underlying mechanisms are emergent processes of a whole nervous system; these processes cannot be fully simulated in highly reduced cell or tissue systems. In addition to bettering our understanding of nociception and pain, these models are valuable out of welfare concerns for achieving a better understanding of pain–nociception processes in animals. In spite of great recent progress in deciphering the neurobiological basis of nociception and pain, this knowledge has yet to see large-scale translation into effective pain therapies. A limiting factor has been the often unsuccessful extrapolation from animal models to human clinical practice, as exemplified by recent attempts to develop new pharmacological treatments for migraine headache.[3–5] Beneficial applications from animal models could be fostered by rigorous examination of the validity and limits of these models.[3] This goal also hinges on a better understanding of the similarities and differences between nociception and pain in humans and in the animal models, an understanding that would make model selection and interpretation more valid for human applications.

This chapter's principal objectives are to clarify distinctions between nociception and pain to improve the interpretation and validity of animal models and to discuss and evaluate commonly used and important models. There are several recent reviews, some highly detailed, on animal models in nociception–pain research that should be consulted by readers wishing further information.[3,6–8]

DEFINING PAIN IN HUMANS: IMPLICATIONS FOR ANIMAL MODELS

A valid working definition of pain is vital for efforts to explain its underlying mechanisms or develop therapeutic interventions. To this end, the International Association for the Study of Pain[9] defines human pain as follows: (1) pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage; (2) pain is always subjective; and (3) pain is sometimes reported in the absence of tissue damage and the definition of pain should avoid tying pain to an external eliciting stimulus. One of the most critical conceptual advances in the understanding of pain is the distinction between nociception and pain. As Wall[10] emphasized, nociception that is "activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not pain, which is always a psychological state." It is also critical to understand that the pain experience requires conscious awareness.[11,12] In the usual course of events, tissue-damaging forms of stimuli excite nociceptors and this activity is conducted through peripheral nerves, the spinal cord, and subcortical brain structures to the cerebral cortex. If a person is conscious when nociception-related activity arrives in the cortex, further processing by extensive cortical regions results in pain.[11–14]

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

The separateness of pain and nociception is seen in diverse ways. First, nociceptive processes do not always lead to pain. People can sustain severe injuries in warfare, sports, or everyday life and either not report pain or report it differently than the extent of an injury would suggest.[15–17] Second, people with "functional" pain syndromes experience chronic, disturbing pain without any demonstrable tissue damage or pathology. Third, pain can be reduced by psychological manipulations such as a visual illusion[18] or hypnotic suggestion.[19] Fourth, pain has a strong social learning component and depends greatly on prior experience with it and interpersonal interactions that accompany this experience.[13]

THE NEUROLOGY OF NOCICEPTION AND PAIN There has been great progress in identifying the functional neuroanatomy underlying nociception and pain. We will present a brief account of the neural structures and systems implicated in nociception and pain as it pertains to the use and interpretation of animal models. Numerous excellent reviews provide more detailed information.[1,2,20–22]

Studies of diverse mammals have shown that nociceptive stimuli activate two types of nociceptive receptors in body tissues: those that appear to respond exclusively to noxious mechanical, thermal, or chemical stimuli and those that respond to combinations of these stimuli (polymodal nociceptors). Activity is conducted from these receptors to the spinal cord through both myelinated (Aβ and Aδ) and unmyelinated (C) axons. These axons synapse on dorsal horn spinal neurons, principally in the more superficial laminae, where extensive processing occurs. Ascending projections arise from neurons in diverse dorsal horn laminae, principally lamina I and V, and travel through the contralateral lateral and ventral spinal pathways.

The ascending pathways have synaptic terminations in diverse regions of the brainstem, mainly catecholamine neuron groups, parabrachial nuclei of the pons, midbrain periaqueductal gray, and diverse sites through the brainstem reticular formation. The thalamus receives multiple direct spinal projections to topographically organized lateral and nontopographically organized medial nuclei. There are significant differences between mammalian species at this level, particularly in the existence of a posterior ventromedial nucleus that seems to exist only in primates and is greatly enlarged in humans.[21] Functional imaging studies in humans have consistently shown a diverse array of cortical structures to be activated specifically in association with perceived pain, including the first and second somatosensory areas, anterior cingulate gyrus, insula, and prefrontal cortex. Diverse evidence indicates that the somatosensory cortical zones are critical for the sensory-discriminative dimension of pain, that pain intensity is related to activation of multiple zones, especially involving both hemispheres, and that the emotional-evaluative (suffering) component depends on the anterior cingulate gyrus, insula, and prefrontal cortex. In addition, it is now well established that in humans, pain experience is absolutely dependent on the functioning of these neocortical and limbic cortical areas.[22,23] The dependence of pain on these cortical regions makes sense also when it is considered that pain depends on the concurrent existence of another function: consciousness. Extensive evidence shows that the cortical regions known to be essential for pain greatly overlap with those vital to the existence of consciousness.[11,14]

In addition to the ascending pathways is a network of descending modulatory controls, centered in the periaqueductal gray and rostral ventromedial medulla, that exerts both antinociceptive and pronociceptive actions on ascending nociceptive signaling.[24]

THE ADAPTIVENESS OF NOCIFENSIVE BEHAVIORS Nociceptors form a common underlying thread throughout the evolutionary history of multicellular organisms. Nociceptors have been observed in all bilaterally symmetrical multicellular organisms that have been examined, with the notable exception of elasmobranch fishes.[14] Even the leech has nociceptive neurons,[25] many of which display close similarity to the polymodal nociceptor population that has been so well characterized in mammals.

Although nociceptors are common in the animal kingdom, the existence of nocifensive behaviors, the unconscious protective responses to noxious stimuli, is even more widespread and not specifically tied to possession of nociceptors.[26] The single-celled paramecium (absent any possibility of a nervous system) exhibits protective responses to adverse environmental stimuli. Likewise, sponges with no nervous system and jellyfish with simple nerve nets have simple, but functional nocifensive behaviors. In these and more advanced bilaterally symmetrical invertebrate organisms as well as vertebrates, the nociceptive system and nocifensive behaviors constitute an essential component to survival. Importantly, the suite of responses to nociceptive stimuli does not end simply with withdrawal reflexes, but in advanced multicellular organisms also includes complex arrays of endocrine and autonomic responses that help prepare the organism for a defense of disturbed homeostasis. Species with nociceptors showing properties in common with those of mammals could serve as useful models for investigating peripheral nociception.

DISTINGUISHING NOCICEPTION FROM PAIN: WHY IT MATTERS As explained above, nociception and pain are distinctly different things, with differing underlying mechanisms. Unless one is studying the processes that specifically mediate the conscious experience of pain or a behavioral response that is specific to such processes, nociception is being studied and the term pain should not be used. Unfortunately, these terms are frequently used in ambiguous or inconsistent ways, with significant practical costs in the use and interpretation of animal models and theoretical costs in understanding of mechanisms.

The Nociception–Pain Dichotomy in Clinical Neurology The behavioral separateness of nociception and nocifensive responses from pain is commonly seen in humans with severe neurological injury such as a spinal cord transection. Noxious stimulation of a limb below the level of the transection excites nociceptive sensory receptors and nociceptive pathways within the spinal cord. This spinal activity produces a nocifensive limb withdrawal response, but because nociceptive pathways are interrupted between the spinal cord and the cortex, no pain is felt. The pain–nociception distinction does not stop at this level.

Humans with massive damage or dysfunction of the cerebral cortex are unconscious, but can be awake and show grimacing, vocalization, and organized avoidance reactions in response to a nociceptive stimulus.[12] The importance of understanding the nociception–pain distinction was shown by the confusion and contentiousness surrounding the recent tragic case of Terri Shaivo, who in 1990 experienced a prolonged period of anoxia. Although examining neurologists agreed that she was unconscious, in an irreversible, persistent vegetative state, Mrs. Shaivo was awake, was quite reactive to noxious stimuli, and exhibited nocifensive and emotion-like behaviors, which led to claims by some that Ms. Schaivo's behaviors had to be consciously mediated. After a pro-

tracted legal dispute and interventions by government officials, her feeding tube was removed. Subsequent autopsy confirmed that her cerebral cortex had massively degenerated, a fact consistent with the diagnosis of unconsciousness.[28] The important points to be gleaned from this case are that a striking array of nocifensive behaviors can be unconsciously expressed in a human; that these are behaviors mediated by the brainstem and spinal systems rather than conscious, pain-related responses; and there is a widespread public unawareness of such things with associated societal consequences.

Valid Selection and Interpretation of Models As stated previously, effective therapies for pain have lagged behind advances in basic research. A practical example will serve to illustrate this point. Substance P was described in 1931 and its role in nociceptive neurotransmission has been known for decades.[29] Immense resources have been devoted to development of substance P antagonists, principally NK_1 receptor antagonists for pain relief, especially migraine headache. In spite of their effectiveness in animal models of dural inflammation, these drugs were ineffective in relieving human migraine pain. This negative result was not a matter of a receptor affinity mismatch because high level NK_1 receptor blockade has been achieved in the brains of humans.[30] This costly failure has been attributed to many things, including recognition that there is more to human migraine headache pain than events in the dura mater.[4,31] Here, the animal model response measure was at the most peripheral level of the complex hierarchy of nociception–pain process, but the human clinical response measure, the pain report, was at the end stage of all intervening processing.

WHAT WOULD THE PAIN OF ANIMALS BE LIKE? A most important question regarding animal models for pain is which species are capable of pain experience, or at least a pain experience that meaningfully resembles that of a human. The foregoing explanation should make it clear that most species in the animal kingdom can detect and respond to noxious stimuli but not all can experience conscious pain. There has been interest in using invertebrates and some nonmammals such as amphibians[32] as animal models for nociception on the assumption that they were more humane models than mammals. Examination of the collective neurological and behavioral evidence has led to the conclusion that fishes and amphibians are very unlikely to have a capacity for conscious pain experience, at least anything resembling that of humans.[14,32] However, there are differing views.[33,34] It is clear, though, that structural organization of the forebrain differs dramatically between mammals and nonmammalian vertebrates. Most notable is the unique presence of a neocortical component of the forebrain pallium in mammals,[35,36] with its suite of structures, and especially interconnections between them, essential to pain experience. Nonetheless, the forebrain complexity of reptiles and birds is considerable[36,37] and the presence of functional homologs of pain or consciousness-related cerebral structures, especially in birds, remains to be investigated.

The majority of animals used in nociception–pain research are mammals and the species used all have, to varying degrees, the cortical regions that correspond to those as essential to human pain experience.[14,36] However, large expanses of higher–order nonsensory, nonmotor cortex are part of the pain-related mosaic and in nonprimate mammals, only a small proportion of cerebral cortex, less than 10% in rats and mice,[38] fits this structural designation. As mentioned previously, the subcortical pathways that distribute nociception-related information to pain-related cortical zones also differ substantially between primates (especially humans) and nonprimate mammals. Clearly, significant functional differences may exist between species of mammals in general and humans in particular in terms of the how pain processing might occur.

WHEN IS AN ANIMAL MODEL APPROPRIATE FOR THE INVESTIGATION OF PAIN?

Much current research employs models specifically addressed at particular types of human pain conditions. Some models are also used to address fundamental mechanistic questions concerning nociceptive processing or actual pain experience. In either case, where an animal model is being used to investigate some aspect of human nociception and pain, it is vital to know that the model system is actually valid for the purpose. In particular, pain-related response measures must be distinguished from purely nociceptive–nocifensive response measures because pain is a psychological process that is not directly observable and must be measured indirectly through behavior.

As shown above, clinical neurology provides human examples of the pain–nociception distinction, but clear examples have been in the animal literature for many years. Responses to noxious stimuli have been studied in several mammalian species following decerebration where all of the forebrain above the midbrain is removed. Chronically decerebrate rats[39] react strongly to the insertion of a feeding tube, struggling, pushing at it with the forepaws, and vocalizing. When receiving an injection, these rats react indistinguishably from a normal rat: vocalizing, attempting to bite the syringe or the experimenter's hand and lick the injection site. Since a large body of evidence indicates that consciousness (and accordingly pain experience) depends on the neocortex, it must be concluded that these reactions are nocifensive and unconscious rather than expressions of conscious pain. It can be concluded that nocifensive behaviors can be far more complex than "simple reflexes" and even ostensibly purposive, a fact that makes the behavioral distinction between nociception and pain difficult. In fact, many assumptions about indications of pain have been based on behaviors that are sustained, organized, or directed to the site of nociceptive stimulation,[7,8,40] the type of responses fully within the capacity of decerebrate rats.

Identification of pain in humans usually depends on a verbal report, but verbal reports and other pain-related behaviors are not always reliably interpretable.[19] So, validated rating scales or other tools adopted from cognitive psychology provide sufficiently reliable means of measuring pain in humans. Correspondingly, there is a long history in experimental psychology of using nonverbal behavioral methods to assess the internal "psychological" state of an animal. It is quite possible to assess the aversiveness of a stimulus in terms of whether the animal will learn to avoid the stimulus, escape from it, or perform some behavior to escape that reflects the aversiveness of the nociceptive stimulus. An example of the last case is that a rat will leave a dark chamber and enter a brightly illuminated chamber (normally aversive to a rat) in order to escape a hot plate or electric shock.[8] Learned avoidance, or conditioned emotional responses to nociceptive stimuli, however, does not prove the existence of conscious pain, because associative learning of these types is believed to be unconsciously mediated.[41]

Another effort to establish the existence of pain in an animal, as opposed to measurement of pain intensity, was Bateson's[40] eight criteria for animal pain, which have been of interest to welfare biologists. However, when viewed in terms of what is currently known about pain[14] these criteria are flawed because they fail to distinguish nociception and nocifensive behaviors from conscious pain.[34]

EXAMPLES OF COMMONLY USED ANIMAL MODELS AND AN EVALUATION OF THEIR INTERPRETATION

Although overlap occurs in the use of some models, they can be broadly divided into those primarily used for investigation of acute nociception–pain and those for study of chronic nociception–pain. Because of the great clinical importance of chronic pain, more diverse and specialized models are used to represent particular human pathological processes such as neuropathic, bone cancer, or arthritis pain. In using waking animals for studies of nociception–pain, there is the ever-present issue of humane treatment.[6,8] Investigators are bound by ethics and statute to minimize the exposure of animals to presumably painful procedures, within the objectives of a study. This requirement has shaped the development of the animal models for nociception–pain research toward the use of relatively low-intensity, brief-duration stimuli. The welfare consideration has been an impetus to develop *in vitro* models or use species (such as amphibians; see Chapter 37 by Stevens in this volume) viewed as less likely to have a capacity for pain experience. Accordingly, as addressed below, these animal models must be validated for their intended application.

CONSTRUCTS AND TERMINOLOGY Nociception (and frequently pain) is a normal consequence of noxious stimulation, of course, but modifications of normal nociception–pain are more commonly of clinical importance. These include allodynia, hyperalgesia, analgesia, dyesthesia, paresthesia, causalgia, and neuropathic pain (Table 36–1). These terms represent human clinical complaints that animal models are intended to represent, but because some of these complaints, like paresthesia or causalgia, are identified by subjective reports, it is impossible to know how well the animal model represents them.

There are two main ways to categorize nociception/pain models[1]: (1) by stimulus duration, such as short duration (acute) stimuli and longer duration (chronic) stimuli, or (2) by level of the nervous system presumed to mediate the responses (Table 36–2[8]). Ideally, a model should meet the following criteria: specificity, sensitivity, construct validity, predictive validity, and reliability (Table 36–1).

Table 36–1
Constructs and terminology

Allodynia: pain caused by a normally innocuous stimulus.
Analgesia: a consequence of a manipulation, such as drug administration, that causes a previously pain-provoking stimulus to become nonpainful.
Causalgia: an abnormal spontaneous or stimulus-evoked burning sensation, generally due to neuropathic conditions.
Dyesthesia: an unpleasant abnormal sensation.
Hyperalgesia: intensification of the painfulness of a normally pain-producing stimulus.
Neuropathic pain: diverse pain experiences, including allodynia, hyperalgesia, and spontaneous pain due to a nervous system lesion or disease.
Paresthesia: an abnormal spontaneous or stimulus-evoked sensation.
Specificity: the stimuli used should be genuinely nociceptive. In practice, test stimuli may activate combinations of nociceptive and nonnociceptive sensory afferents. The behavioral response model should distinguish nonnociceptive from nociceptive stimuli.
Sensitivity: it should be possible to detect a range of responsiveness across a range of stimulus magnitudes, from below to above the nocifensive response threshold. Ideally, the model should also be sensitive to pharmacological or other manipulations that might modify responsiveness.
Construct validity: a most critical but often overlooked criterion is that the model should actually be an indication of nociception or pain. It is particularly important to know if the model is actually assessing pain as opposed to nociception alone. Put another way, the model should really be assessing the process or variable that it is thought to assess. If bone cancer pain in humans is of fundamental interest, the model must realistically replicate key pathophysiological and psychological attributes of human bone cancer pain. This issue emerges in many contexts, but is particularly salient in consideration of models that do not employ behavioral measures, such as histological or gene expression measures.
Predictive validity: effects of pharmacological or other therapies on the animal model should predict the effects of these treatments on human pain.
Reliability: The model must give the same results each time it is used, within and between laboratories, to make the results obtained adequately generalizable.

The Commonly Used Models Contemporary models vary greatly in sophistication and validity but the predominantly used behavioral models employ rats or mice and are based on spinal reflexes such as tail flick and paw withdrawal and entail, variously, measures of response threshold and/or latency. Additional measures associated with paw withdrawal are paw lifting, flinching, guarding, and licking. The most frequently used tests of nociception have been the tail flick, hot plate, paw pressure, writhing, and formalin tests.[6,8] The tail flick test entails radiant heat application to a localized tail region or immersion in preheated water. Tail flick is known to be a spinal reflex, but is likely modulated by descending influences from the brainstem.[6,8,24] A variation on the tail flick test is the Hargreave's test in which heat is applied to the plantar surface of a foot and withdrawal latency is measured. In the hot plate test the animal is placed on a heated metallic plate and latencies for paw licking and jumping responses are recorded. These behaviors are mediated through a combination of spinal and brainstem processes (Table 36–2). In the plantar pressure test, increasing force is applied on the plantar surface of a foot with a von Frey-type filament and threshold pressure for paw withdrawal is monitored. The latter two responses involve supraspinal, probably brainstem control (Table 36–2).

Electrical stimulation of the tail or paw has also been frequently used to elicit a hierarchy of responses, including twitching, escape behavior, vocalization, and biting the electrodes, which are thought to reflect progressively more complex neural mediation. Dental pulp stimulation has also been used for the purpose of simulating trigeminal nociception–pain states and also

Table 36–2
Common nociception testing paradigms,[a] observed behavioral outcomes, and their presumed neural substrates

Stimulus modality	*Testing paradigms*[b]	*Quantified behaviors*	*Minimal central substrates*[c]
Mechanical	Hargreave's (von Frey)	Withdrawal	Segmental (spinal)
Thermal	Tail immersion (hot or cold), tail flick, hot plate, cold plate, Hargreave's (radiant heat)	Withdrawal, jumping, escape, licking, guarding	Segmental and suprasegmental (brainstem)
Chemical	Formalin, acid, capsaicin, taxol	Licking, biting, guarding, altered posture, writhing, vocalizing	Segmental and suprasegmental

[a]Employing natural stimuli; nonnatural stimuli (e.g., electrical stimulation) are not included; see Le Bars *et al*.[6]

[c]Reviewed in Vierck.[8]

on the (questionable[6]) assumption that all the associated afferents are nociceptors.

The commonly used formalin and writhing tests exemplify tests eliciting long-duration nociceptive stimulation by irritant injection. Intradermal formalin injections are most common, but hypertonic saline, complete Freund's adjuvant, capsaicin, bee venoms, and other agents have been used. When injected into the dorsal surface of a rat's forepaw, a 0.5–15% formalin solution evokes a constellation of quantifiable behaviors, including reduced weight bearing on the paw, paw lifting, licking, nibbling, shaking, or biting. Irritant injection into the footpad of rats or mice, in contrast, produces a biphasic response, with an initial phase of about 3 min latency, a subsequent period during which responses dissipate, and a later (20–30 min latency) reappearance of behavioral reactions, which appears to stem from predominant activation of C fiber nociceptors.[8]

The writhing test involves intraperitoneal injection of any of several irritants, including phenylbenzoquinone, acetylcholine, dilute hydrochloric or acetic acid, and bradykinin. These substances irritate serous membranes of the peritoneal cavity and in rats and mice evoke abdominal contractions, large body movements, including the hind paws, asymmetric contraction of dorsal abdominal muscles, and reduced locomotion. Although intended to be a model for visceral pain, it is likely that somatic afferents are also activated by the algogenic substances.

Models using stimulation of hollow organs, particularly gastrointestinal or urogenital structures, have taken various forms: injection of formalin or other algogenic substances into the colon, capsaicin injection into the bladder, distention of organs like the colon and rectum with an inflatable balloon, or solid material introduction into a ureter. The behaviors produced depend to some extent on the specific type and location of the nociceptive stimulus, but include various types of abdominal reflexive contractions, stretching, and abdominal licking.

Models specifically designed to investigate chronic nociception–pain often include some of the same behavioral measures and nociceptive treatments previously described for investigations of acute nociception–pain. For example, the threshold nociceptive pressure required for paw withdrawal can be assessed in a normal rat by pressure with a filament (the von Frey test), but this method can test hyperalgesia after injection of an irritant like formalin into a paw. Likewise, this test can be used to assess allodynia associated with neuropathic pain caused by direct nerve injury or chronic nerve constriction.

Interpretations of the Commonly Used Behavioral Models The above-described tests are widely used because they appear to have face validity, that is, they appear to produce states that would be comparable to those that would be associated with pain in humans. In addition, the most widely used of these, like the hot plate and intradermal formalin tests, are relatively easy to perform and score on large numbers of animals, thereby lending themselves to dose–effect studies of potentially analgesic drugs or other antinociceptive manipulations. The seeming simplicity of such tests is illusory. Detailed critiques of the limitations in these models have been presented by Le Bars *et al.*,[6] Blackburn-Munro,[3] and Vierck,[8] and the interested reader is urged to read these informative and thoughtful reviews.

A detailed discussion of the technical and theoretical limitations of the various nociception–pain models is not possible here, but we will outline the major concerns. The first such as noxious temperature paradigms (e.g., tail flick, hot plate, Hargreave's) or paw withdrawal tests, there are many poorly controlled and variable aspects to nociceptive stimulus application. For example, a rat's tail is a thermal exchange organ, which places it in a very different functional category from other tissues regarding effects of thermal stimuli.[6] Furthermore, in the hot plate test, the animal's movements make thermal stimulus application highly variable. Although nociceptive stimuli are often administered in ways intended to avoid or minimize tissue trauma, it may result in variable degrees, thereby introducing the dimension of allodynia or hyperalgesia in a test where these effects are not intended. Effects of injected algogenic stimuli will differ depending on the specific agent used (formalin, capsaicin, mustard oil, etc.) and route of administration (intraperitoneal, in the bladder) presenting a complex stimulus, to say the least. In addition, nonnociceptive afferent activation is often a confounding variable in that those afferents may contribute to the elicitation of responses that are presumed to be purely nocifensive.

Response measures themselves also present difficulties in the foregoing test paradigms.[6,8] Investigator judgments are frequently a major source of variation in quantifying responses. Repeated testing of individual animals in some of the procedures, like the hot plate test, can be associated with learned aversion behaviors that modify stimulus application as well as the character of the responses. Sometimes tests of threshold become confounded with response latency, especially with longer duration stimuli. In addition, activation of nonnociceptive afferents in testing paradigms (above) may elicit flexion reflexes, confounding the interpretation of the nociceptive nature of the stimulus and response. Genetic variability and strain differences can also be a major source of confounding variability in a number of models.[6,8]

In most cases, the responses examined in the most frequently used tests such as tail flick, hot plate, paw withdrawal, and their variations could be entirely mediated by spinal reflexes or brainstem–spinal motor programs, thus constituting unconscious nocifensive responses (Table 36–2[8]). Nonetheless, some higher brain influence is probably operating in an intact, awake animal, but its presence and nature are hard to separate from subcortical processes and it is also likely to be unconsciously mediated. Consequently, none of these tests can be legitimately viewed as tests of pain, since they do not depend on a consciously mediated response. In some cases, investigators are aware of this constraint and strictly adhere to the term nociception rather than pain in interpreting their results. Unfortunately this is far from a universal practice and erroneous language and inference are common. Frequently "pain processing" or "pain transmission" is used to describe what is clearly nociceptive processing at the receptor, spinal, or subcortical level. Statements that can be found in the literature, such as pain in labor originates in the cervix or that there is inflammatory pain in the bladder, are mechanistically incorrect by implying that the conscious, psychological process of pain is somehow produced and experienced by peripheral tissues.

Development of well-validated models for pain, as opposed to nociception, is one of the most significant challenges to this field. To this end, some investigators have utilized diverse paradigms requiring behaviors clearly beyond the realm of reflexes or complex, but probably unconsciously mediated motor programs. Behaviors that are more complex than stimulus-bound flexion reflexes and are directed at the site of nociceptive stimulation, or sustained after stimulus termination, such as the vocalization afterdischarge, are sometimes taken to reflect pain. But recall that even decerebrate rats are capable of such behaviors. Measures involving learned behaviors, tasks where the animal can regulate nociceptive stimulus intensity, and assessments of disrupted feeding, sleep, or social behavior may have more validity as reflecting pain.[3,8] Presumably, these types of behaviors reflect more complex, higher-order processing in the brain, but in the absence of rigorous validation, their acceptance as indications of pain should be considered tentative.

Interpretation of Nonbehavioral Measures of Nociception/Pain Numerous reduced preparations, even *in vitro* models, are being used for studies of nociception–pain. Tissue response measures, such as neuronal expression of the early oncogene c-*fos*[42] and other markers of gene expression,[43,44] are potentially associated with processes of importance for nociception, but their significance must be qualified because they are quite removed from pain or even the dynamic, functional context of nociception. Expression of c-*fos* is commonly interpreted as an indication of neuronal response to sensory, including nociceptive stimuli. But unlike c-*fos* expression, neuronal responses to nociceptive stimuli are not all or none, not always excitatory, and not invariant. Rather, they may entail changes in pattern or inhibition, all of which are mechanistically important, but undetectable with markers such as c-*fos*. In addition, the proportion of neurons that expresses c-*fos* is often much smaller than the population that actually responds electrophysiologically[42,45] and neurons in some neurophysiologically responsive brain regions do not express c-*fos*.[42,45] There are additional problems with false-positive responses and dissociation between behavioral and c-*fos* responses to nociceptive stimuli.[42] Clearly, these indirect measures, like behavioral measures, require careful validation with respect to what they do or do not mean. Likewise, interpretations from response measures such as reflexes or neurophysiological recordings obtained under anesthesia are also subject to qualification. Measures of brain neuronal activity in animals or measures used in humans, such as functional magnetic resonance imaging, alone are never proof of pain. The relationship of such indicators to pain can be assessed only after pain has independently been shown to coexist with and be essential for putative pain-related properties of such neurophysiological correlates. Furthermore, nothing short of an intact, fully functioning animal, particularly a mammal, is a potentially suitable model for investigations of human-like pain. Highly reduced preparations are primarily valuable for understanding some elements of nociceptive signaling or peripheral pathophysiological processes that might initiate nociceptive signaling.

RECOMMENDATIONS FOR MODEL SELECTION AND INTERPRETATION

This chapter has stressed the importance of critically examining the validity of animal models to foster progress in understanding mechanisms of pain and the development of more effective treatments. To this end, we propose that particular consideration be given to the following questions: (1) is the problem or phenomenon of interest expressed at the level of nociceptive processing and nocifensive responses or the higher-order, end stage of pain; (2) is the response measure valid and appropriate for the question under investigation; (3) how valid are assumptions concerning the equivalence between the animal model and the human pain condition; and (4) is peripheral nociception of greatest importance, or is it essential to evaluate pain specifically?

The difficulty of knowing how well the putative pain experience of an animal such as a rat or mouse translates to a human-like experience is likely to remain a limiting factor in development of models that validly assess the psychological experience of pain. Future success in development of pain therapies may often hinge on more exacting attention to this issue. There is a good deal of disagreement between investigators of animal psychology on which species might manifest consciousness, a prerequisite to pain experience as we know it,[34,46] but there is a different approach to the question of pain. The dependence of the suffering dimension of human pain on cortical functioning, especially the cingulate gyrus, insula, and prefrontal cortex, is now well established.[2,13,14,22,23] It is also commonly and probably safely assumed that similar cortical regions, where present, work in at least roughly similar ways across mammalian species. On this basis, it would be possible to provide a preliminary validation of a putative animal model for pain by showing that behaviors allegedly reflecting it depend on the functional integrity of these pain-mediating cortical zones. There would still be potential for misinterpretation by confusing nocifensive behaviors with pain-dependent behaviors, but by placing the control of the response measure at the same cortical regions known to be essential to pain experience in humans, the potential for examining common mechanisms would be greatly facilitated. There is currently evidence that investigators of pain are using this approach.[8,47]

37 Nonmammalian Models for the Study of Pain

Craig W. Stevens

ABSTRACT

Processing nociceptive information is a consistent feature of the nervous system in all vertebrate species. This chapter reviews the nonmammalian models developed for pain and analgesia research, with a special emphasis on models that were used for detecting opioid antinociception. Nociceptive pathways in nonmammalian vertebrates are reviewed and endogenous opioid systems are described. Compared to mammalian models for pain research, there are relatively few models in each vertebrate class. Details are provided for the methods and the results of using an amphibian model for the testing of opioid analgesics. The chapter ends with a case study of the comparative approach in pain and analgesia research applied to the molecular evolution of opioid receptor proteins.

Key Words: Opioids, Pain, Analgesia, Animal models, Amphibians, Evolution.

INTRODUCTION: ALTERNATIVES TO THE USE OF MAMMALS FOR PAIN RESEARCH

Pain research is the study of neural pathways that convey noxious stimuli and the investigation of substances or manipulations that alter the neurotransmission of nociceptive information. As the goal of pain research is to generate safer and more effective treatments for patients in pain, this field of research is better described as "analgesia research," but this more accurate term is not widely used.

Unlike other types of biomedical research employing nonhuman animals, pain and analgesia research has an added ethical component due to the testing of analgesic agents (or manipulations) by first inducing a "painful" state in the animal subject by the application of a noxious stimulus. The effectiveness of the analgesic treatment is determined by the difference of treatment values from baseline values in the duration or intensity of the noxious stimulus at the time the animal exhibits a behavior (a nocifensive behavior) that signals nociception. Though most exposures to the noxious stimuli in the experimental setting are brief (like the hot plate and tail-flick algesiometric tests in rodents), a number of persistent pain models are used to more closely mimic the clinical scenario of chronic pain patients. The core of the ethical concern in pain and analgesia research, like many ethical issues, comes from a basic lack of knowledge: the capacity of nonhuman animals to experience nociceptive transmission as humans do, i.e., "pain," is not known. It is unknowable because "pain" is a conscious perception and it is not known if nonhuman animals have the capacity for consciousness that may be needed for the "pain" perception to exist. To think otherwise is not science, but science fiction.

But science can guide rational thought and based on the comparative neurology of central nervous system (CNS) pathways and brain structures shown to be important for nociceptive transmission and supraspinal appreciation of pain in mammalian studies, it was proposed that the potential for pain, if it exists in nonhuman animals, is less in earlier-evolved vertebrates than in mammals.[1] This idea arose from considerations of an amphibian pain model,[2–4] but similar conclusions were made in the discussion of pain and awareness in fish.[5] Thus, a continuum of the potential for pain likely exists among vertebrate classes, perhaps correlated with the capacity for consciousness, and the relative difference in this potential for pain between, say, a frog and a rat may justify developing an alternative or adjunct* nonmammalian model for pain and analgesia research on ethical grounds.[6]

The scientific basis for the use of adjunct models for analgesia research depends on the value of a comparative approach to address the question at hand. For example, the value of investigating mechanisms of opioid analgesia in adjunct models using nonmammalian vertebrates has enriched the understanding of opioid receptors and the selectivity of opioid drugs, as highlighted at the end of this chapter. While there are a great number of pharmacological and nonpharmacological means to modulate nociceptive transmission and therefore many avenues of investigation in pain research, this chapter will focus on nonmammalian models developed primarily to investigate the role of opioids in producing antinociception in behavioral models. An initial review of current knowledge of the nociceptive pathways and endogenous opioid systems in nonmammalian vertebrates is followed by a review of pain and analgesia studies by vertebrate class. A more detailed examination of the methodology and results using an amphibian model follows next. The chapter closes with a "case study" of a comparative approach to investigate the binding of opioid analgesics that leads to an increased understanding of the evolution of vertebrate opioid receptors.

*The use of "adjunct model" avoids any connotation present in the term "alternative model."

NOCICEPTIVE AND ENDOGENOUS OPIOID SYSTEMS IN NONMAMMALIAN VERTEBRATES

This section presents a summary of the existing scientific literature on nociceptive processing and endogenous antinociceptive systems in fish, amphibians, reptiles, and birds. It should be noted that there are relatively few data available on nociception in nonmammalian vertebrates, and as shown in the next section, even fewer data on the action of opioid analgesic agents. However, the basic plan of the nervous system is consistent in all vertebrates, with the major difference being a lack of neocortical brain development in earlier-evolved vertebrate species. Thus, nociceptive transmission at the lower levels in the nervous system (nociceptive primary afferent fibers and spinal cord pathways) is homologous in all vertebrates. In contrast, pain processing at higher, supraspinal centers arising later in vertebrate phylogeny may not be present in fish, amphibians, reptiles, and birds, which do not share homologous supraspinal structures.

NOCICEPTIVE PATHWAYS IN EARLIER-EVOLVED VERTEBRATES Noxious information in mammals is parallel processed throughout the nervous system, with separate pathways for the sensory-discriminative and motivational-affective aspects of pain perception.[7] To some extent, this duality of pain perception begins with the primary afferent fiber type: thinly myelinated Aδ fibers initiate the sensory-discriminative pathway and the unmyelinated C fibers may signal the motivational-affective component of pain. In mammals, the highest level termination of the sensory pathways is the sensory neocortex and the destination of motivational pathways is the limbic neocortex.[8,9]

Electrophysiology experiments using dissected nerves and characterizing single nociceptive primary afferent fibers with defined nociceptive receptive fields are not routinely done using nonmammalian species. However, there are a number of studies characterizing nociceptive pathways in the rainbow trout, *Oncorhynchus mykiss*. Anatomical data and electrophysiological examination of single units recorded from trigeminal ganglia cells identified nociceptors and nociceptive afferents that were not significantly different from those found in other vertebrates.[10,11] Notable differences include more Aδ fibers and less C fibers in fish trigeminal nerve than in mammals.[12] There are few studies of the central termination of nociceptive afferents in fish spinal cord, although substance P, a marker of nociceptive primary afferent fibers, was localized densely in the superficial aspect of the substantia gelatinosa and scattered throughout the nucleus proprius, intermediate zone, and the ventral horn.[13]

Investigations of amphibian primary afferent fibers, including nociceptive afferents, were among the first studies characterizing sensory fibers in vertebrates.[14–16] In contrast to numerous specialized end organs on mammalian afferent fibers, only three groups of afferent nerve endings were identified in amphibians. These include an "expanded tip" morphology ending at the superficial level of the dermis and two types of free nerve endings: one type terminating in the epidermis and the other ending in the deeper layers of the dermis.[17–19] Based on early electrophysiological work, the detection of all noxious sensory stimuli, including chemical, was attributed exclusively to the free nerve endings associated with thermal sensitivity in amphibians.[16] Amphibians possess both myelinated and unmyelinated afferent fibers running concurrently in mixed-fiber peripheral sensory nerves. Investigators delineate these fibers into three general classes based on morphology, conduction velocities, latency of response, and action potential characteristics: large heavily myelinated A fibers, thinly myelinated B fibers, and small unmyelinated C fibers. Their characteristics correlate well with those observed in corresponding classes of somatic sensory afferents in mammals: Aβ, Aδ, and C fibers, respectively. In general, the cutaneous nociceptors in frog skin (those responding to noxious thermal, mechanical, and chemical stimuli) arise from peripheral terminations of the thinly myelinated C fibers. In studies that separated fibers both by conduction velocity and fiber diameter in amphibians, small slowly conducting fibers transmitted the majority of all impulses induced by noxious heat, pinching, pin pricks, and the application of dilute acid to the skin.[16,20–22]

There is controversy over the central terminations of primary afferent fibers within the amphibian spinal gray,[23] although most studies indicate that sensory afferents from the skin terminate in areas of the dorsal spinal cord that correspond to laminae I–IV. The termination of small-caliber fibers associated with nociception was found exclusively in the superficial dorsal laminae (the substantia gelatinosa), while only larger fibers associated with transmission of nonnoxious information penetrate to the deeper laminae.[24,25] Electrophysiological evidence supports the existence of primary afferent synapses on motoneuron dendrites within the amphibian dorsal horn.

Little research has been done on the nociceptive pathways of reptiles. Reptiles also appear to possess only simple nonencapsulated corpuscular endings and free nerve endings, both of which are distributed throughout the dermis and epidermis.[26,27] The separation of receptor structures into categories of noxious and nonnoxious sensory function appears less discreet in the reptile and, thus far, no stimulus-specific receptor structures have been identified.[28,29] Likewise, there are remarkably few data available concerning peripheral fiber types in reptiles. In contrast to reports on amphibians, researchers report only a unimodal distribution of sensory fiber sizes, which extends over the sizes of the B and C classes of amphibian fibers.[28] Furthermore, all stimulus modalities elicit responses throughout both ranges of conduction velocity and fiber size. Additionally, the dorsal roots containing peripheral sensory afferents entering the spinal cord do not clearly segregate according to large and small fibers as in higher vertebrates.[30] Thus it is difficult to classify any specific subgroup of reptilian sensory afferents as primarily nociceptive. However, at least in the turtle, a separation of peripheral fiber types according to their sites of termination in the spinal cord was shown.[31] Smaller type A fibers associated with cutaneous sensation and nociception arborized primarily in the superficial laminae (I–III) as compared to muscle spindle and joint proprioceptive fibers that penetrated to the deeper laminae (IV–VII) where they formed monosynaptic reflex pathways with the dendritic endings of motor neurons.

Investigation of nociceptive pathways in birds utilized the domestic chicken, *Gallus gallus*. Electrophysiological recordings of single afferent fibers from teased-apart leg nerves identified both mechanical and thermal nociceptors.[32] The majority of responses were classified as C fibers responding to both mechanical and thermal noxious stimuli, but Aδ fibers were also noted. Nociceptive afferents innervating chicken skeletal muscle respond to noxious mechanical stimulation (muscle compression) and also to the injection of acetic acid into the muscle tissue.[33] Further studies in chickens showed that nasal trigeminal nociceptors are activated by ammonia vapor,[34] that joint nociceptors are activated

by the intraarticular injection of urate crystals,[35,36] and that beak amputation stimulates the firing of nociceptive afferents in the trigeminal nerve.[37] The spinal cord projections of ankle joint primary afferents were mapped to the upper layers of the chicken spinal cord dorsal horn[38] and substance P-containing fibers terminate in laminae I–II.[39,40]

SUPRASPINAL PATHWAYS OF NOCICEPTION There is scant literature on the supraspinal pathways that may process nociceptive information in nonmammalian vertebrates. Functional studies of evoked responses in supraspinal sites after specific noxious stimulation of peripheral nociceptive fibers are lacking; however, electrical stimulation of the sciatic nerve produced evoked potentials in posterior thalamic nuclei and primordial hippocampal structures in frogs.[41] Single unit recordings in trout and goldfish (*Carassius auratus*) obtained from electrodes placed in the spinal cord, cerebellum, tectum, and telencephalon after timed noxious stimuli revealed supraspinal nociceptive pathways, but more precise mapping by histological confirmation of electrode placement was not done.[42]

The sensory-discriminative pathway originating from spinal neurons makes direct connections with neuron groups farther toward the front of the brain as we ascend the phylogeny of vertebrates.[43] Therefore, fish and amphibians have direct spinal connections to the brainstem, reptiles and birds to the brainstem and the dorsal thalamus in the midbrain, and mammals to the brainstem, thalamus, and primary cortex. Pathways that appear to contribute to the motivational-affective dimension of pain follow a similar evolutionary pattern, except that more medial target sites are contacted in the brain: the medial thalamic nuclei in reptiles and the limbic cortex in mammals. Throughout phylogeny, all the target sites of spinal pathways in the brain increase in complexity, specialization, and number of neurons, suggesting that nociceptive messages to the thalamus in a reptile and mammal may not be comparable.[44]

ENDOGENOUS OPIOID PEPTIDES Nociceptive information is carried from the peripheral nociceptors to the spinal cord by the primary afferent nerve fibers in all vertebrates. These fibers terminate and synapse on second-order neurons in the dorsal horn, releasing neurotransmitters such as substance P, calcitonin gene-related peptide (CGRP), and glutamate. Using immunohistochemical techniques, all of these substances are readily identified in abundance in the spinal dorsal horn of fish, amphibians, reptiles, and birds.[45–48] Substance P and glutamate excite second-order neurons that have their cell bodies in the dorsal horn and send long fibers upward to form the ascending nociceptive pathways. Such second-order neurons within the dorsal horn that receive direct dorsal root input have not yet been identified in nonmammalian vertebrates.[49]

Also present in the spinal cord are intrinsic neurons that release met-enkephalin, an endogenous opioid peptide. Met-enkephalin inhibits the release of substance P from the central terminations of nociceptive primary afferents and decreases the firing of the second-order pain neurons. Met-enkephalin is present in the spinal cord of all vertebrate species examined.[2,39,48,50–57] In amphibians, immobilization stress produces antinociception that is blocked by the pretreatment of animals with the opioid antagonist naloxone.[58,59] This finding demonstrates that enkephalinergic neurons modulate nociceptive threshold in earlier-evolved vertebrates as they do in mammals. The molecular evolution of opioid peptides and their precursors is the subject of a number of recent studies.[60–64]

OPIOID RECEPTORS IN NONMAMMALIAN VERTEBRATES Opioid receptors are membrane proteins belonging to the superfamily of G-protein-coupled receptors (GPCR) and are the products of four distinct genes in mammalian genomes.[65] μ, δ, and κ opioid receptors, abbreviated MOR, DOR, and KOR, mediate the analgesic effects of opioids, while the role of the fourth type of opioid receptor, the nociceptin or orphanin FQ receptor (ORL), is less clear.[66] Before the advent of the genomic era, binding studies using tissue homogenates demonstrated the presence of opioid-binding sites in fish,[67–70] amphibian,[71–76] bird,[77–80] and reptile[81–83] CNS. More definite evidence for the expression of opioid receptor proteins in nonmammalian vertebrates comes from the cloning and sequencing of opioid receptor mRNA. To date, μ, δ, and κ opioid receptors were cloned and sequenced in three nonmammalian vertebrates: the zebrafish, the Northern grass frog, and the rough-skinned newt (see Table 37–1). These sequences represents two classes of nonmammalian vertebrates (Pisces and Amphibia) with no opioid receptor sequences yet available for species from the Reptilia and Aves classes. As shown at the end of the chapter, an analysis of opioid receptor sequences from nonmammalian and mammalian vertebrates demonstrates the utility of a comparative approach to investigate opioid analgesic action.

PAIN AND ANALGESIA RESEARCH USING NONMAMMALIAN VERTEBRATES

Key factors in the development of a nonmammalian model for pain and analgesia research are the identification of a nocifensive behavior that is unique to a noxious stimulus and the demonstration that the same noxious stimulus solely activates nociceptive primary afferents. In an amphibian model called the acetic acid test, the wiping response is the nocifensive behavior and a drop of dilute acetic acid is the noxious stimulus that activates nociceptors and nociceptive primary afferent fibers exclusively.[20,22,84] For other nonmammalian models, integration of neurophysiological

data with behavioral data in most cases are still lacking. A review of these adjunct models for analgesia research by vertebrate class is presented next, followed by a detailed examination of an amphibian model for analgesia research. The adjunct models for behavioral assessment of opioid antinociception are listed in Table 37–2.

PISCES Fish are not easily amenable to behavioral assays of antinociception. A study aimed primarily at the metabolism of morphine in goldfish (*C. auratus*) also described a behavioral assay using an electric prod applied caudal to the dorsal fin as the noxious stimulus.[85] The nocifensive behavior that was observed was called the agitated swim response. The voltage threshold for eliciting the swim response was consistent for each animal and with repeated testing. Morphine sulfate added to the tank water produced a dose-dependent increase in the electrical voltage needed to elicit the agitated swim response. It was also shown that goldfish became tolerant to the antinociceptive effects of morphine with repeated administration.[85] There was no attempt to attain a measure of morphine's potency (i.e., no ED_{50} value of morphine was reported) nor was opioid receptor involvement verified by pretreatment with an opioid antagonist such as naloxone. Further studies using the same model in goldfish showed that morphine administered via the intracranial route (into a space above the optic tectum) produced a dose-dependent increase in the voltage needed to elicit the swim response.[86] In this study, opioid receptor involvement was shown by naloxone antagonism of morphine's effect.

The antinociceptive effects of dermorphin, a potent and selective MOR opioid peptide originally isolated from the skin of *Phyllomedusa* frogs,[87] was tested using electrodes implanted in

Table 37–2
Behavioral models for testing opioid antinociception in nonmammalian vertebrate species

Class	*Animal/(genus species)*	*Model*	*Stimulus*	*Response*	*Notes*
Pisces	Goldfish (*Carasius auratus)*	Caudal electroshock	Electric current by handheld prod	Agitated swim response	Acute model; measured agitated swim response (ASR); morphine added to tank water or intracranial; blocked by naloxone [85,86]
Pisces	Codfish (*Gadus orhuamarisalbi*)	Caudal electroshock	Electric current by implanted electrode	Agitated swim response	Acute model; ASR quantified by force-transducer; dermorphin given by intranasal application; β-casomorphin given by IP and IM injection[88,90]
Pisces	Rainbow trout (*Oncorhynchus mykiss*)	Caudal electroshock	Electric current by implanted electrode	Agitated swim response	Acute model; ASR quantified by force-transducer; dermorphin given by intranasal application[89]
Pisces	Carp (*Cyprinus carpio*)	Caudal electroshock	Electric current by implanted electrode	Agitated swim response	Acute model; ASR quantified by force-transducer; tramadol given by IM injection; blocked by naloxone[91]
Pisces	Rainbow trout (*Oncorhynchus mykiss*)	Lip inflammation	Acetic acid/bee venom lip injection	Pain-related behaviors	Chronic model; pain-related behaviors quantified; morphine effects noted[92–95]
Amphibia	European frog (*Rana esculenta*)	Electrified grid	Electric current in floor grid	Jumping	Acute model; no antinociceptive effect of morphine[96]
Amphibia	European frog (*Rana esculenta*)	Hot plate test	Heated surface	Jumping	Acute model; no antinociceptive effect of morphine[97]
Amphibia	Northern grass frog (*Rana pipiens*)	Acetic acid test	Dilute acetic acid	Wiping response	Acute model; well-developed and validated adjunct model; sensitive to opioid and nonopioid analgesics, stress- and hypothermia-induced analgesia[58,59,98,99,121–131,136]
Amphibia	Japanese firebelly newt (*Cynops pyrrhogaster*)	Tail-flick test	Heat from lamp	Tail-flick	Acute model; effects of met-enkephalin and RFamide blocked by naloxone[100]

Table 37–2
(continued)

Class	*Animal/(genus species)*	*Model*	*Stimulus*	*Response*	*Notes*
Reptilia	Green anole lizard *(Anolis carolinensis)*	Tail-flick test	Heat from lamp	Tail-flick	Acute model; antinociceptive effects of morphine[101]
Reptilia	Nile crocodile (*Crocodylus niloticus*)	Hot plate test	Heated surface	Leg-lift or escape response	Acute model; antinociceptive effects of morphine and meperidine (pethidine)[103]
Reptilia	Green iguana (*Iguana iguana*)	Tail-flick test	Heat from thermal electrode	Tail-flick	Acute model; preliminary investigation of butorphanol[104]
Aves	Chicken (*Gallus gallus*)	Toe-pinch	Noxious mechanical	Limb withdrawal	Acute model; no antinociceptive effect of morphine[105]
Aves	Chicken (*Gallus gallus*)	Wing-shock	Electric current to underside of wing	Flight response	Acute model; morphine antinociception[106]
Aves	Chicken (*Gallus gallus*)	Hot plate test	Noxious thermal to feet	Jumping	Acute model; morphine, codeine hyperalgesia; developmental stage specific[106–111]
Aves	Chicken (*Gallus gallus*)	Formalin test	Noxious chemical in foot	Leg-lifting	Chronic model; morphine hyperalgesia, strain dependent[112,113]
Aves	Chicken (*Gallus gallus*)	Carrageenan inflammation	Inflammation-induced thermal hyperalgesia	Foot withdrawal from thermal stimulus	Chronic model; morphine produced dose-dependent antinociception[114]
Aves	Chicken (*Gallus gallus*)	Monoarthritis model	Urate crystals in joint capsule	Pain-related behaviors	Chronic model; no effect of morphine, fentanyl, buprenorphine[115–117]

the caudal region of Derjugin codfish, *Gadus morhuamarisalbi*, as the noxious stimulus.[88] The nocifensive response was similar to the agitated swim response mentioned above, but the fish was held in a flow-through chamber and the swim response was quantified by a force transducer. Dermorphin was administered into the intranasal passages (olfactory sacs) of the codfish and produced a dose-dependent antinociceptive effect. Further studies using rainbow trout, *O. mykiss*, with the same sophisticated behavioral apparatus, mapped the most sensitive areas of noxious stimulation on the trout and confirmed the antinociceptive effect of intranasal dermorphin in this species.[89] In codfish, intraperitoneal (IP) and intramuscular (IM) administration of the MOR selective opioid peptide, β-casomorphin, produced antinociceptive effects.[90] The opioid analgesic, tramadol, an MOR opioid agonist and norepinephrine/serotonin reuptake inhibitor, produced dose-dependent antinociception in the carp, *Cyprinus carpio*.[91] In this last study, pretreatment with the opioid antagonist naloxone blocked the antinociception produced by tramadol.

A chronic pain model was developed in fish by injecting acetic acid or bee venom into the lip region of trout.[92,93] These animals develop pain-related behaviors that can be quantified and antinociception determined by the reduction in pain-related behaviors. Morphine had inhibiting effects on nociceptive behaviors per se and in the presence of novel objects.[94,95]

AMPHIBIA Early studies employing a hot plate test and electrified floor grid in amphibians did not detect an antinociceptive effect of morphine.[96,97] It is likely that this was due to an inappropriate experimental design, as previously noted.[98] A behavioral assay using acetic acid as the noxious stimulus and the wiping response as the nocifensive behavior was developed using the Northern grass frog, *Rana pipiens*, and is discussed in greater detail in the next section. Other studies using the acetic acid test in amphibians demonstrated that regional hypothermia is antinociceptive and is mediated in part by endogenous opioid peptides.[99] A tail-flick test was also used to assess the antinociceptive effects of opioids in the Japanese firebelly newt, *Cynops pyrrhogaster*.[100] Intraperitoneal injection of met-enkephalin and the putative opioid peptide RFamide produced a mild antinociceptive effect that was blocked by the concurrent administration of the opioid antagonist naloxone.

REPTILIA To test the antinociceptive effects of opioids in reptiles, a tail-flick apparatus was used in the green anole lizard, *Anolis carolinensis*.[101] Intraperitoneal injection of morphine (5 mg/kg) produced a weak, but significant increase in the latency of the lizard to remove its tail from a noxious heat stimulus.

A number of nociceptive assays were characterized in the Nile crocodile, *Crocodylus niloticus*.[102] Crocodiles placed on a hot plate attempt to guard their foot pads by lifting them alternately as well as attempting to escape the heated surface. A dilute capsaicin solution instilled in the eye of the crocodile produces behavioral responses including blinking, rubbing, and head shaking. Injection of formalin in the crocodile forepaw results in

the development of paw guarding behaviors. Morphine or meperidine (pethidine) produced antinociception as measured by the increased latency for crocodiles to lift their leg or escape on the hot plate test, which was the most suitable of three assays.[103] However, these studies did not include dose–response analysis and did not assess the opioid nature of the antinociceptive effect by pretreatment with an opioid antagonist, such as naloxone or naltrexone. As mentioned in a clinical review of analgesia for exotic species,[104] there are preliminary data that the partial opioid agonist butorphanol produced antinociception in the green iguana, *Iguana iguana*, using a thermal tail-flick test.

AVES An early attempt to measure the antinociceptive effect of opioids in chicks using toe-pinch as the noxious stimulus and limb withdrawal as the nocifensive behavior did not find any antinociceptive effect of morphine up to a dose of 200 mg/kg.[105] Using an electroshock to the underside of the wing as the noxious stimulus and an elicited flight response as the nocifensive behavior in chickens, morphine at a single dose of 30 mg/kg produced measurable antinociception in this model.[106]

Using a heated floor grid, other studies found that morphine produced a *decrease* in the latency for chickens to jump.[107] This hyperalgesic effect was dependent on the age of the chicken; morphine administered to young cockerels less than 14 days old did not produce hyperalgesia.[108] The hyperalgesic effect of morphine was dose dependent and exhibited a U-shaped time course curve.[109] Using selective opioid antagonists, the hyperalgesic effect of morphine in chickens was shown to be predominantly mediated by μ opioid receptors.[110] Codeine produced both hypoalgesia (antinociception) and hyperalgesia in this model.[111]

A formalin algesiometric assay was developed in chickens, quantified by the pain-related behaviors observed after injection of formalin into the foot.[112] There was a strain difference in the hyperalgesic effect of morphine, perhaps due to differences in descending monoamine pathways.[113] Carrageenan, a chemical irritant like formalin, provided the noxious stimulus in a chronic inflammatory model using the Hargreaves method.[114] In this assay, chickens are measured for the latency to withdrawal of an inflamed foot from a lamp placed under the floor grid. Morphine produced a dose-dependent antinociception but had no effect on the edema produced by carrageenan. A chronic arthritis model was developed in chickens using an intraarticular injection of urate crystals, which models gouty arthritis.[115,116] However, intraarticular injection of morphine, fentanyl, or buprenorphine did not have any effect in reducing pain-related behaviors due to the experimentally induced arthritis.[117]

AN AMPHIBIAN MODEL FOR PAIN RESEARCH

THE ACETIC ACID TEST The acetic acid test (AAT) to determine the nociceptive threshold (NT) in frogs consists of 11 concentrations of acetic acid serially diluted from glacial acetic acid (two parts acid : one part water).[98] The concentrations are given a code number from 0 to 10 with the lowest code number equal to the lowest concentration of acetic acid. The actual molar concentration of acetic acid per each solution is given by the following equation:

$$\text{Log}[M] = 0.1716 \times (\text{Code \#}) - 0.5849$$

Nociceptive testing is done by placing, with a Pasteur pipette, a single drop of acid on the dorsal surface of the frog's thigh. Testing begins with the lowest concentration and proceeds with increasing concentrations until the NT is reached. The NT is defined as the code number of the lowest concentration of acid that causes the frog to vigorously wipe the treated leg with either hindlimb. To prevent tissue damage, the acetic acid is immediately wiped off with a gentle stream of distilled water once the animal responds or after 5 sec if the animal fails to respond. If the animal fails to respond, testing continues on the opposite hindlimb. An animal that fails to respond to the highest concentration (#10) is assigned the cutoff value of 11. The wiping response in frogs, like the tail-flick in rodents, remains intact after a high spinal transection, demonstrating sufficient circuitry in the spinal cord to mediate this behavior.[118] The wiping response has not been observed in the laboratory in the absence of noxious stimuli and appears specific for assessing nociception. As noted above, acetic acid was shown to activate nociceptive afferents in amphibians. The wiping response is also the basis for much research on the motor systems of the amphibian spinal cord.[119]

ADMINISTRATION OF ANALGESICS TO AMPHIBIANS The technique of systemic administration (SC) of drugs in frogs is similar to subcutaneous administration in rodent species. The frog is gently grasped and a tuberculin syringe fitted with a 25-gauge needle is slipped under the skin on the dorsal side of the animal. The initial location of the injection is the mid-back region, which overlies the dorsal lymph sac in amphibians (see Figure 37–1, top). The needle is gently inserted into the lymph sac (felt as a slight resistance as if injecting into a sponge) and the drug is delivered in a volume of 10 μl/g body weight. Each animal is used only once for injections to prevent possible confounding effects of repeated injections in the same animal. A saline-injected control group is run with each experiment.

The technique of intraspinal (IS) administration of drugs in frogs is remarkably similar to that described for mice.[120] Frogs are gently held with the nondominant hand and using a tapered 26-gauge needle fitted to a microsyringe, the needle is introduced into the spinal cord slightly lateral to the neural spine at the articulation between the seventh and eighth vertebrae. This articulation is felt by probing with the needle and is located by triangulation of the dorsal protuberances of the iliac crest of the frog (see Figure 37–1, middle). The region of intraspinal injection overlies the area of the lumbar enlargement. Penetration of the needle sometimes produces a mild hindlimb extension or trembling, which discontinues after a 2–3 sec delivery of the drug. Previous experiments employing radiolabeled morphine demonstrated that over 98% of intraspinal morphine remained within two or three segments of the site of injection throughout the time course of the experiment.[121]

Using a modification of the methods for intracerebroventricular (ICV) administration in rodents, animals are injected with 3 μl of drug or saline vehicle into the third ventricle. Briefly, animals are administered a local anesthetic (0.5 ml, 2% lidocaine) suffused just under the skin of the skull region. A midline incision is made and the top of the skull is exposed by retraction. A hand-held microsyringe, fitted with an 8 cm length of PE-10 and a 1.5-inch, 29-gauge needle cannula is used to deliver the drugs. Placement of the needle is made through the skull at a depth of 2.5 mm, midline and just anterior to the optic tectum, a site shown in pilot studies to fill the brain ventricles with dye (see Figure 37–1, bottom). Visualization of the brain structures through the thin

cartilaginous skull of amphibians also aids in the consistency of injection sites.

EFFECTS OF OPIOID ANALGESICS IN AMPHIBIANS Initial studies of the analgesic effects of opioid administration in amphibians were conducted using nonselective opioid agonists, endogenous opioid peptides, and antagonists.[121–124] These studies showed that both exogenous opioid agonists and endogenous opioid peptides could raise the nociceptive threshold in amphibians by an action at opioid receptors. Tolerance to the analgesic effects of daily morphine administration was documented[125] and stress-induced release of endogenous opioids was shown to produce analgesia, which was potentiated by enkephalinase inhibitors.[59] Other behavioral studies include an investigation of the effects of opioids on noxious and nonnoxious sensory modalities,[84,126] and an examination of agents acting on α_2-adrenergic receptors after systemic and spinal administration.[127,128]

Later results of systematic studies examining the antinociception of selective μ, δ, or κ opioid agonists administered by different routes yielded an important finding: the relative antinociceptive potency of μ, δ, or κ opioid agonists after systemic, intraspinal, or intracerebroventricular administration in amphibians was highly correlated to that observed in typical mammalian models and to the relative analgesic potency of opioid analgesics in human clinical studies.[129–131] These data established the amphibian model as a robust and predictive adjunct model for the testing of opioid analgesics.[1,6,132] Table 37–3 provides a summary of the opioid agonists used in behavioral studies of opioid

antinociception following systemic, spinal and supraspinal routes of administration.

However, emerging results from both behavioral and binding studies in *R. pipiens* suggested that the selectivity of amphibian opioid receptors was different from the selectivity of mammalian opioid receptors. The MOR, DOR, and KOR type selective opioid antagonists, β-FNA, naltrindole, and nor-BNI,[133–135] did not show type selectivity in blocking the antinociceptive effects of selective opioid agonists in amphibians.[136] In radioligand binding studies, β-FNA, naltrindole, and nor-BNI competed with [^{3}H]naloxone binding from brain and spinal cord homogenates with equal apparent affinity, but did show type-selective competition against selective opioid agonist radioligands.[74–76] Still lacking was the ultimate identification of the types of opioid receptor proteins expressed in *R. pipiens* from molecular cloning studies.

AN EXAMPLE OF THE COMPARATIVE APPROACH: THE EVOLUTION OF VERTEBRATE OPIOID RECEPTORS

The number of full-length cDNA sequences for opioid receptors in nonmammalian vertebrates deposited in GenBank is surprisingly small. At present, there are no databank sequences for any type of opioid receptor from any species of Reptilia or Aves. From class Pisces there was an initial entry of μ opioid receptor sequences expressed in the white suckerfish, *Castomus commersoni*,[137] and more recently, the triad of μ, δ, and κ opioid receptor cDNAs was cloned from the zebrafish, *Danio rerio*.[138–140] The cloning of full-length opioid receptors in *R. pipiens* was particularly needed given that there is a corresponding dataset of opioid behavioral and binding data. Other nonmammalian species do not have a corresponding dataset of opioid binding and behavioral studies to integrate molecular cloning and *in vitro* results with whole animal, behavioral data on opioid antinociception.

CLONING AND SEQUENCING OF AMPHIBIAN OPIOID RECEPTORS Three full-length clones of opioid receptors were obtained by reverse transcriptase polymerase chain reaction (RT-PCR) amplification of *R. pipiens* brain and spinal cord cDNA. On the basis of high homologies to existing vertebrate sequences, these clones were named *rpMOR* (GenBank number AF530571), *rpDOR* (AF530572), and *rpKOR* (AF530573) as novel orthologs to mammalian μ, δ, and κ opioid receptors. A fourth type of opioid receptor protein, *rpORL* (AY434690), was recently sequenced and was homologous to existing *ORL* proteins.

The percent identity of amino acids in *rpMOR* compared to the zebrafish μ opioid receptor was 79%, and ranges from 83 to 84% compared to mammalian μ opioid receptors. The frog δ opioid receptor, *rpDOR*, had 77% identity with the zebrafish ortholog and 73% identity compared to mammalian δ opioid receptors. Mammalian κ opioid receptors ranged from 70 to 71% identical to *rpKOR* and the zebrafish κ opioid receptor was 64% identical to *rpKOR*.

BIOINFORMATICS OF VERTEBRATE OPIOID-LIKE RECEPTORS The bioinformatic analysis of the amphibian opioid receptor used existing matched datasets of μ, δ, and κ opioid receptors from other vertebrate species. Somewhat surprising, there are only four vertebrate species, excluding the amphibian data, that have full-length sequences for all three types of opioid receptor cDNA deposited in GenBank. These species are the zebrafish (*Danio rerio*), mouse (M*s* μ*scularis*), rat (*Rattus norvigecus*), and human (*Homo sapiens*). Phylogenetic dendrograms (trees) were constructed using existing alignment (ClustalW) and molecular evolution software. The nearest-neighbor joining trees for each vertebrate opioid receptor type gave the accepted evolutionary relationship, with the fourth type of opioid receptors (ORL) used as an outgroup to root the three classical types of opioid receptors (see Figure 37–2). As shown, the three groups of opioid receptor types did not arise from a single, common ancestral sequence but rather the group of κ opioid receptors shared a common ancestral sequence with the branch bifurcating later to the μ and δ opioid receptor groups.

As pharmacological selectivity is correlated with similarity of amino acid sequences at the GPCR family level (e.g., opioid receptors vs. muscarinic receptors) it is reasonable to assume that the type selectivity within family members (e.g., *MOR*, *DOR*, and

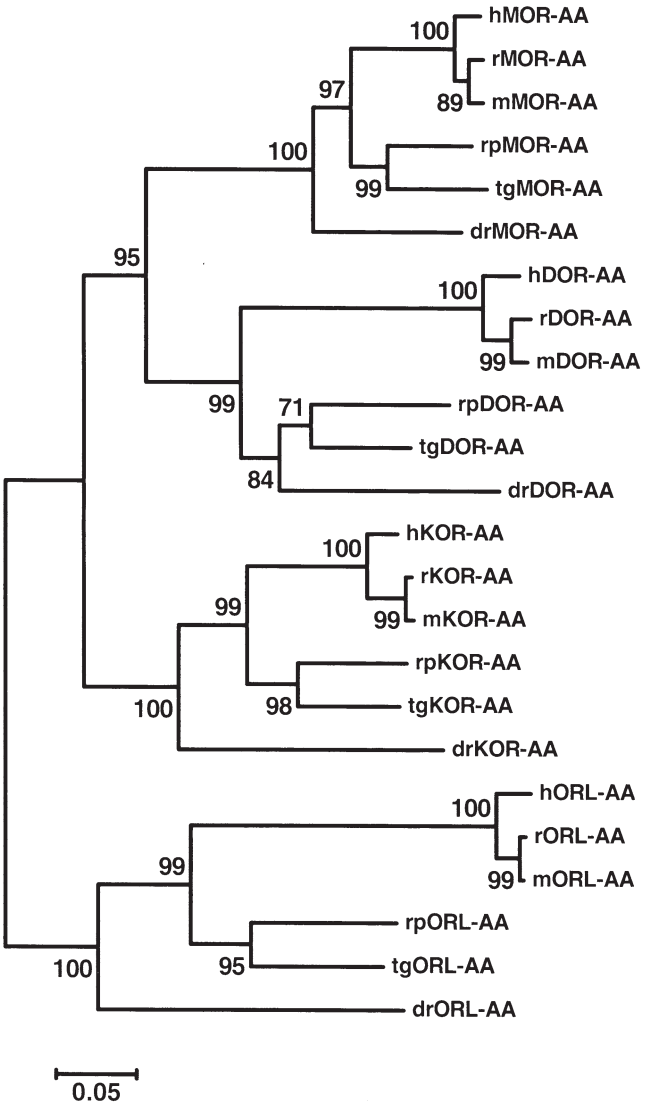

Figure 37–2. Phylogenetic analysis of the vertebrate *OpR* proteins. The neighbor-joining algorithm was used (h, human; r, rat; m, mouse; rp, frog; tg, newt; and dr, fish). The corresponding vertebrate *ORL* proteins were used as the outgroup. Numbers provide the bootstrap value (percent reliability out of 1000 replicates) and the scale bar is the proportional difference (e.g., 0.05 = 5% divergence in sequence) for a given unit of branch length.

KOR) is also correlated with percent identity or similarity. The results of pair-wise BLAST analysis[141] for the three types of opioid receptor sequences within each species yielded a rank order of divergence such that in earlier-evolved vertebrates, μ, δ, and κ opioid sequences were more closely related to each other than in humans and other mammals. For the percent similarity comparison, these values reached statistical difference such that the mean values of similarity of μ, δ, and κ opioid receptors in nonmammals were greater than the similarity of μ, δ, and κ opioid receptors in mammals (Table 37–4). Insofar as divergence of molecular sequence is related to the greater type selectivity of opioid receptors, this finding gave rise to the novel hypothesis that opioid receptors are more type selective in mammals than in nonmammalian species. The hypothesis that opioid receptors in earlier-evolved vertebrate are less selective is supported by behavioral and binding studies in amphibians[74,136] and by binding studies on zebrafish opioid receptors expressed in Chinese hamster ovary (CHO) cells.[138,142]

Further bioinformatic analysis of the vertebrate opioid receptor sequence dataset leads to identification of individual amino acids that may be crucial for determining type selectivity of opioid analgesics. Using this comparative approach, novel hypotheses were generated that lead to a greater understanding of the molecular evolution of vertebrate opioid receptors and the mechanism of the opioid analgesic selectivity.[4,149]

CONCLUSIONS

The comparative approach to investigations of pain and analgesia has great promise for contributing to a greater understanding of analgesic mechanisms in humans. Additionally, much research using adjunct nonmammalian models for the assessment of antinociception is needed to make sound clinical decisions in veterinary treatment of exotic animals (i.e., not dogs or cats, but fish, amphibians, reptiles, and birds).[143] There has been some transfer of knowledge from basic studies of antinociceptive effects in *R. pipiens* to the clinical application of analgesics for use during oocyte harvesting in *Xenopus laevis*.[144] However, for both improved clinical treatment of humans and animals,[145] additional studies of nociception in nonmammalian species and the development of adjunct models for analgesia are critically needed.

Models of Behavior V

Cardiovascular A

38 Animal Models of Vascular Development and Endothelial Cell Biology

VICTORIA L. BAUTCH

ABSTRACT

There have been great advances in the past 15 years in our understanding of how blood vessels form and function. Many of these advances result from the availability of several animal models that allow for embryological, molecular, and genetic manipulations of the developing vasculature. Here I describe four vertebrate animal models used in studies of vascular development. The frog, zebrafish, avian, and mouse embryos are compared historically and currently. Recent advances using each model are highlighted. Finally, I describe the use of animal derivatives, the chick chorioallantoic membrane and mouse embryonic stem cells, for studies of blood vessel formation.

Key Words: Vascular development, Angiogenesis, Animal models, *Xenopus* embryos, Zebrafish embryos, Avian embryos, Mouse embryos, Transgenesis, Genetic analysis.

OVERVIEW OF ANIMAL MODELS OF VESSEL DEVELOPMENT

Numerous animal models, both historically and currently, have helped us understand blood vessel formation. Important steps include the differentiation of angioblasts to endothelial cells, the initial assembly of endothelial cells to form vessels in the embryo, the expansion of the vessel network, and the remodeling of vessels to accommodate the physiological needs of the organism. These processes were first described, then perturbed using physical agents, pharmacological compounds, and genetic tools. The first known description of embryonic blood vessels was provided by Aristotle in 350 BC, when he cracked open chicken eggs and followed the stages of avian development![1]

The animal models of vascular development revolve around vertebrate organisms, since invertebrates do not have a closed circulatory system. However, it might be argued that the fruitfly *Drosophila melanogaster* has provided a model of blood vessel formation, because a tracheal system develops that opens to the environment and allows diffusion of oxygen into the organism.[2] Elegant genetic dissection of tracheal development in the fly has led to a model of tube formation that seems to hold for vertebrate vessels in its essential points. Specifically, both systems appear to develop according to a "hard-wired" genetic program that starts the process, while later physiological inputs from the organism are translated into molecular cues that modify and modulate the tube system to maximize efficient function. Moreover, it was recently shown that the formation of lumens in developing vessels proceeds via vesicle fusion within the endothelial cells, in a manner very similar to lumen formation in the fly tracheal system.[3]

This chapter will focus on four major vertebrate models of blood vessel formation: the frog (*Xenopus laevis* and *tropicalis*), the zebrafish (*Danio rerio*), the avian chick (*Gallus gallus*) and the Japanese quail (*Coturnix japonica*), and the rodent mouse (*Mus musculus*) and a stem cell model derived from mouse cells. Historically the frog and avian embryos were the tools of choice, for reasons outlined below. However, in recent years the relatively new field of zebrafish development has blossomed, and this vertebrate is particularly useful for aspects of vessel development. The mouse has also gained in popularity in recent years, with the advent of genetic tools and more sophisticated technology for analysis of mammalian embryos. Finally, we and others have utilized mouse embryonic stem cells, which can differentiate to produce endothelial cells and primitive blood vessels, as a parallel model to address questions of mammalian vascular development.

XENOPUS AS A MODEL OF VASCULAR DEVELOPMENT

The historical advantages of the frog *X. laevis* are that the embryos are large and development occurs rapidly outside the mother, allowing for manipulation and visualization. Thus fate mapping studies showed that the endothelial cells that form blood vessels arise from mesoderm in the ventral part of the embryo.[4,5] The frog was also used by Cleaver and Krieg in ground-breaking studies showing that migration of precursor cells (angioblasts) from lateral areas to the midline in response to a vascular endothelial growth factor (VEGF) signal initiates formation of the dorsal aorta, a large and important vessel for all vertebrates.[6,7] More recently, the injection of a compound that binds endothelial cells, DiI-Ac-LDL, was used to image the patent vasculature at successive stages of frog development.[8]

Despite these and other important studies, until recently the use of *Xenopus* has been limited because much of the frog vascular development is not amenable to perturbation by morpholinos, the method of choice to manipulate gene expression in *Xenopus* embryos. This is because morpholinos, which block gene expression by blocking splicing or translation, are injected early and diluted out with cell division. Thus they are ineffective for

(P. M. Conn, ed.), © 2008 Humana Press Inc., Totowa, NJ.

probing many aspects of vascular development in the frog that occur at later stages. However, in recent years a second species, *X. tropicalis*, has gained in popularity because it is possible to do forward genetics in this model. That is to say, the generation time is such that it is feasible to mutagenize a male, and derive offspring that carry mutations that can be screened and analyzed.[9] This is not possible in the original *X. laevis*. Thus we can look forward to genetic dissection of aspects of vascular development in the frog to complement forward genetics in zebrafish. This will be useful since the frog eventually develops lungs and breathes air, while the fish has gills and gets oxygen from the water. Moreover, it was recently shown that the frog develops a lymphatic vasculature that resembles that of mammals,[10] so the development of this parallel vascular system to move lymph fluid can be dissected using the frog model.

ZEBRAFISH AS A MODEL OF VASCULAR DEVELOPMENT

HISTORY OF ZEBRAFISH AS A MODEL ANIMAL As mentioned above, the zebrafish has only recently gained popularity as an animal model for development and vascular development. In the 1970s, George Streisinger discovered that zebrafish embryos could be physically manipulated to develop as homozygous diploids, thus allowing for easy genetic analysis.[11] This technology proved difficult—more developmental defects were introduced by the process than by the mutagen used to generate mutations! However, he and others realized that the zebrafish had a generation time that allowed for forward genetic screens, with many of the physical advantages of the frog embryo. The zebrafish was firmly established when several major investigators conducted genetic screens for developmental defects and began to analyze these mutations.[12,13]

ADVANTAGES OF ZEBRAFISH FOR VASCULAR DEVELOPMENT The zebrafish embryo presents several advantages for the study of vascular development. Similar to the frog embryo, it is fairly large, development occurs outside the mother, and the embryos are clear, allowing for easy visualization of developmental processes. Once blood flow commences, patent vessels can be easily seen through the movement of the blood cells. Additionally, it is possible to use microangiography, and several years ago Weinstein and colleagues used this technology to produce a complete atlas of vascular development in the zebrafish.[14] Even more recently, several groups have generated transgenic zebrafish that express green fluorescent protein (GFP) in the developing vasculature,[15,16] thus allowing for identification of subtle vascular defects.

Additionally, it is possible to perturb cardiac or vascular development in the zebrafish embryo without these perturbations inducing immediate lethality, because the embryo obtains oxygen from the water. Thus cardiovascular mutations and perturbations can be dissected *in vivo*, and the effects of cardiac function on vessel development can be assessed. For example, a mutation named *silent heart* fails to produce a beating heart, yet the vasculature continues to develop for some time, indicating that a heartbeat or blood flow is not essential for these stages of vascular development.[17] These advantages have led several groups to invest in the development of highly sophisticated imaging technologies that allow for live image analysis of vascular development in zebrafish, and lineage tracing of progenitor cells.[18,19]

The major advantage of the zebrafish model is that it is a vertebrate embryo with a developing vasculature that is amenable to forward genetic screens. Thus a series of mutations can be isolated, characterized, and cloned to further our understanding of novel pathways that may be involved in vascular development, as well as novel relationships among players and pathways already identified.[20] Investigators have combined tools for visualization of vascular development described above with forward genetic screens.[21] It is also possible to do chemical screens to identify compounds that perturb wild-type vascular development or rescue vascular mutations, since embryos will develop for a time in 96-well formats.[22] This aspect of zebrafish biology is especially attractive to pharmaceutical companies that have access to chemical libraries and would like to uncover new therapeutic targets or drugs.

RECENT ADVANCES USING ZEBRAFISH TO STUDY VASCULAR DEVELOPMENT Among the recent outpouring of studies using the zebrafish to study blood vessel formation, the studies that elucidated a genetic pathway for specification of arteries vs. veins are particularly compelling. It was known that both genetic cues[23] and blood flow[24] influenced the decision of vessels to become arteries or veins, but the mechanism was not known. Weinstein and colleagues used a combination of available mutants, morpholino or RNA injection, and chemical inhibitors to define a molecular pathway that determines artery fate in zebrafish. In genetic terms, *hedgehog* signaling is upstream of *vegf* signaling, which in turn is upstream of *Notch* signaling, to determine arteries.[25,26] A mutant screen uncovered an additional mutation that proved to be a lesion in the phospholipase C γ gene, and this gene is downstream of *vegf* signaling in arterial specification.[27]

AVIAN MODELS OF VASCULAR DEVELOPMENT

HISTORY OF AVIAN MODELS OF VASCULAR DEVELOPMENT As mentioned above, the chick embryo was used to visualize vascular development historically. The chick, along with its cousin the quail, has continued to be used in recent times, primarily because the embryos are accessible to manipulation *in ovo*, and further development is possible. The identification of an epitope on quail angioblasts and blood vessels via production of a specific monoclonal antibody called QH1[28] led to the first complete description of blood vessel formation in a model animal.[29] Moreover, the QH1 antibody has allowed for distinction of quail vessels (QH1 is not found on chick vessels) in transplants of quail tissue into chick hosts. These quail–chick chimeras were used to show that most mesoderm contains cells that can differentiate into endothelial cells and form vessels,[30] and that angioblasts from different mesoderm sources have different potentials. Specifically, mesoderm near endoderm is thought to produce angioblasts that can give rise to "hemogenic endothelium," endothelium that can differentiate into blood cells, while mesoderm near ectoderm does not have this capacity.[31,32] The avian models have been overshadowed in recent times because they are not amenable to genetic analysis, but as we shall see below, new technologies can overcome that deficit to some extent.

ADVANTAGES OF AVIANS AS A MODEL OF VASCULAR DEVELOPMENT The accessibility of the avian embryo has been combined with gene delivery techniques to successfully manipulate gene expression in some areas of the embryo. Some studies have used viral vectors that encode genes for overexpression studies.[33,34] However, recently embryo electroporation has

been used to deliver gene expression to embryonic sites. The most popular site is the neural tube, since it is possible to deliver the DNA to the central cavity prior to electroporation.[35,36] This has so far limited the use of this technology for widespread studies of vascular development in the avian, but technically any tissue can be targeted if DNA can be provided to it. The DNA usually encodes proteins that lead to overexpression of the gene of interest, or dominant negative constructs that block function. However, recently modified vectors to produce small hairpin RNAs that lead to local loss of function have been reported, and it is likely that viral delivery of interfering RNA will become a popular method to produce loss-of-function phenotypes in the avian vasculature.[37] We and others have adapted the protocol to deliver genes to quail embryos, thus allowing for subsequent analysis of vessel pattern with the QH1 antibody (J. James and V.L. Bautch, unpublished results).

RECENT ADVANCES USING AVIAN MODELS OF VASCULAR DEVELOPMENT

How Does Blood Flow Influence Vessel Identity? Eichmann and colleagues[24] used the avian yolk sac to manipulate flow parameters in an elegant study showing that blood flow is required to maintain arterial identity once it is established. They took advantage of the accessibility of the embryo and yolk sac and ligated the right vitelline artery in the yolk sac. The arterial marker neuropilin 1 was immediately downregulated, and with time venous markers such as neuropilin 2 and Tie-2 were upregulated. Moreover, reperfusion led to upregulation of the arterial markers, showing that in the avian yolk sac blood flow is a determinant of vessel identity.

Imaging Vascular Development Little and colleagues have produced an elegant analysis of vascular development in the avian embryo using dynamic imaging techniques.[38,39] They used the avian embryo because the early stages of development are relatively flat and accessible compared to the mouse. They labeled the QH1 antibody with a fluoror, and injected it into living embryos. The labeled antibody binds the developing vessels and allows for imaging of early events. Using this live imaging technology they have described migration of endothelial cells over preexisting vessels.

How Does the Neural Tube Pattern Blood Vessels? We took advantage of the avian model to develop mouse–quail chimeras that carried grafts of mouse presomitic mesoderm, a source of angioblasts. These grafts and embryonic stem (ES) cell-derived embryoid body grafts were shown to contribute mouse endothelial cells to the vascular plexus that forms around the developing avian neural tube (perineural vascular plexus, PNVP).[40,41] Further embryo manipulations placed a mouse neural tube ectopically into the avian embryo, and showed that the neural tube was the source of a signal leading to PNVP formation.[42] Studies using explanted tissues placed in collagen showed that VEGF-A is a critical component of the signal.[42] Recent work in our laboratory has utilized electroporation technology to manipulate gene expression locally in the developing neural tube, with a goal of further defining the role of VEGF-A in vessel patterning around the neural tube (J. James and V.L. Bautch, unpublished results).

AVIAN DERIVATIVES AS MODELS OF VASCULAR DEVELOPMENT It is noteworthy that alongside the avian embryo, the developing vasculature of an extraembryonic tissue called the chorioallantoic membrane (CAM) has been used extensively to study aspects of angiogenesis. The CAM was first used to show that tumor tissue could induce new blood vessel formation,[43] and many cancer researchers have tested both pro- and antiangiogenic compounds using the CAM. Briefly, a day 3 chick embryo is opened, and a paper or bead containing a compound is placed on top of the CAM. After 3–4 days of incubation the CAM is harvested and the amount of vasculature determined by quantitative measures.

RODENT MODELS OF VASCULAR DEVELOPMENT

HISTORY OF RODENT MODELS OF VASCULAR DEVELOPMENT Mouse and rat are the primary experimental models for mammalian development because of their size, ability to reproduce, and a rich history of genetics for the mouse. However, their utility for studies of vascular development was hampered by the fact that development occurs *in utero* and is difficult to visualize. Moreover, most perturbations to the developing vasculature quickly lead to embryonic death, and historically there was not a good *in situ* marker for immature mammalian vessels. However, the finding that PECAM (platelet endothelial cell adhesion molecule) is expressed on mouse angioblasts and early vessels[44–46] and the development of a high-quality monoclonal antibody to mouse PECAM[47] have provided a powerful tool for visualization of mouse embryonic vessels. This and advances in genetic manipulation discussed below have made the mouse the premier model for studies of mammalian vascular development in recent years. Of the models discussed here, the processes and mechanisms of vascular development in the mouse most closely mimic those of human vascular development, so there is great interest in using and refining this model of vascular development.

ADVANTAGES OF THE MOUSE AS A MODEL OF VASCULAR DEVELOPMENT The primary advantage of the mouse is that it is possible to manipulate the genome by introducing mutations into specific genes.[48] This results from several technologies developed in the 1980s and 1990s. First, ES cells that can produce descendants contributing to the germline of the animal have been isolated. These ES cells can be manipulated *in vitro* prior to reintroduction to a mouse embryo. Second, it is possible to target a specific gene locus in ES cells via homologous recombination. Thus it is possible to mutate or delete one of the two alleles of a gene in ES cells, select for the rare homologous recombination (“targeting”) events, and then reintroduce the cells to embryos, eventually leading to animals with the mutation in both alleles. In this way numerous genes have been deleted, and the effects on mammalian vascular development analyzed. Examples are the two high-affinity receptors for VEGF-A, flk-1 (VEGFR-2) and flt-1 (VEGFR-1), that when deleted lead to perturbed vascular development and death.[49,50] However, the phenotypes of the mutant embryos were very different; deletion of flk-1 led to reduced vessel development, while deletion of flt-1 led to vessel overgrowth. This was among the first evidence that the receptors did not function in the same way in vascular development.

In recent years it has become possible to selectively delete genes in the developing vasculature.[51,52] This is done by introducing recombination sites (loxP) into one allele of a gene in ES cells, and then generating an animal with sites in both alleles. These mice are then mated with mice that express the relevant recombinase (Cre) in only the developing blood vessels.[53–56] This modification has allowed investigators to analyze the function of genes

in vessels that may have required roles in other places of the embryo earlier in development. Even more recently, an inducible form of the recombinase has been used, and in this scenario excision of the allele occurs in vascular tissues only when the inducer is present.[57,58]

Along with these techniques to manipulate gene function, the ability to analyze vascular phenotypes in the mouse embryo has grown quite sophisticated. There are now numerous markers of endothelial cells: markers that distinguish arteries from veins and markers that distinguish blood-carrying vessels from lymphatic vessels.[59] These markers are of three types: antibodies that recognize proteins or epitopes that are vessel specific (see PECAM description above), antisense RNA *in situ* hybridization probes that recognize vessel-specific mRNAs, and reporter genes that are placed into a gene locus, then are expressed when gene expression is activated. The most popular of the reporter genes is bacterial *lacZ*. The *lacZ* gene encodes the β-galactosidase protein that turns a substrate blue only in the cells that express *lacZ*, so vessels or vessel subsets are stained blue after the chemical reaction. Recently GFP has also been used as a reporter gene because it allows for live imaging.

RECENT ADVANCES USING MOUSE MODELS OF VASCULAR DEVELOPMENT

What Regulates Blood Vessel Branching? Analysis of the pattern of blood vessels in mid-gestation mouse embryos carrying mutations has implicated several molecular signaling pathways in the regulation of blood vessel branching. Among these branching regulators are pathways that regulate axon guidance in the developing nervous system, including the semaphorin (Sema) pathway and the netrin pathway. The Sema pathway is complicated, because some Semas interact with neuropilins, and the neuropilin coreceptors can complex with either vascular-expressed flk-1 or neuronal or vascular-expressed plexins. However, recently it was shown that plexin D1 is expressed primarily in blood vessels, and a knockout mutation led to vascular defects.[60] The netrin pathway was shown to be involved in branching by analysis of a mutation in a netrin receptor, UNC5B.[61] It is not clear whether this pathway promotes or decreases branching,[62,63] but it is clearly involved in the processes.

Does Vasculogenesis Occur after Birth? Until the mid-1990s the dogma in the field was that vasculogenesis, the process whereby endothelial progenitor cells form a vessel while differentiating, occurred only during the early stages of development. Subsequent to those stages, all vessel formation and expansion were thought to occur via angiogenesis—the migration, division, and fusion of endothelial cells already in vessels. However, evidence suggested that perhaps endothelial cells could be formed *de novo* in some situations, and evidence for this model was provided through the use of the mouse. Mice were irradiated so their bone marrow was destroyed, and then bone marrow from a "marked" donor was grafted into the host. Once recovered, the chimeric mouse now had a "marked" bone marrow, and it was subjected to various situations in which new vessels form. In ischemic injury recovery and tumor angiogenesis, marked cells were seen in the perivascular area, suggesting that bone marrow-derived cells could contribute to neoangiogenesis.[64] While there is controversy about the lineage and ultimate fate of the bone marrow cells, most investigators think that an endothelial progenitor (EPC) resides in the bone marrow, and it can be mobilized to sites of new vessel formation and perhaps differentiate into an endothelial cell. Thus vasculogenesis may not be confined to embryonic stages, but may occur alongside angiogenesis in the adult as well.

MOUSE DERIVATIVES AS MODELS OF VASCULAR DEVELOPMENT The major mouse derivative used for studies of vascular development is the ES cell that was discussed above in the context of targeted mutations. ES cells can be aggregated and differentiate *in vitro* to form embryoid bodies, which can then cavitate to become cystic.[65,66] This programmed differentiation leads to the formation of endoderm and mesoderm, and subsequently derivatives of these lineages.[67,68] Amazingly, endoderm-derived factors such as VEGF-A provide appropriate signals for the differentiation of endothelial precursors, vasculogenesis leads to the formation of primitive vessels, and then angiogenesis results in the expansion of a primitive vascular plexus in this model.[69,70] We and others realized that if the embryoid bodies are reattached prior to cavitation, vascular development proceeds as described above.[67,69] Thus embryoid bodies or ES cell cultures can be manipulated both genetically and pharmacologically to address questions of vascular development. Simon and colleagues have shown a requirement for hypoxia-driven gene expression in vascular development using the ES cell model.[71] We recently developed ES cell lines that express vascular-restricted GFP, and this allowed us to image the dynamic processes of vascular development.[68] Using this tool we showed that the VEGF-A receptor flt-1 (VEGFR-1) positively modulates branching morphogenesis of developing vessels, probably via modulation of the amount and/or spatial context of signaling through the flk-1 (VEGFR-2) receptor.[72]

Keller and colleagues[73,74] used the ES cell model to elucidate lineage relationships. Specifically, evidence for a bipotential common precursor of both blood and endothelial cells, called the hemangioblast, was presented. Mouse ES cells were partially differentiated as described above, then dissociated to single cells and plated in conditions conducive to differentiation of both blood cells and endothelial cells. The finding that single cells could give rise to both endothelial and blood cells was consistent with the presence of a hemangioblast among the cells. Subsequent studies *in vivo* corroborated this finding,[75] but these studies did not distinguish between a true bipotential cell and a multipotential progenitor that could also differentiate into other mesodermal lineages. Recently an elegant study using zebrafish provided evidence that a bipotential hemangioblast does exist, although many endothelial cells do not seem to go through this intermediate.[19] The latter study points out the utility of having multiple models of vascular development available for analysis. The cells were tracked by injecting a compound that was then uncaged in a single progenitor cell using a laser. This was technically challenging in the zebrafish embryo and is not currently feasible in the other models.

CONCLUSIONS

Our understanding of blood vessel formation has benefited enormously from the availability of several animals models of vascular development, and there have been great strides in our understanding of vascular development at the cell and molecular level in the past several years. I predict that in the near future much will be added to this knowledge base through the creative use of animal models of vascular development such as those described here. More to the point, even more advances will likely

come from the integrated use of multiple animal models of vascular development. For example, it is possible to envision a forward genetic screen in zebrafish to uncover a novel gene important in vascular development, then manipulation of the gene through RNA and morpholinos in both the fish and frog, followed by vascular-specific inducible deletion in the mouse. In this way a comprehensive analysis of the role of a particular gene in vascular development should be elucidated. The sequencing of the relevant genomes and reagents for microarray analysis will no doubt augment future efforts to further understand the mechanisms regulating the development of blood vessels.

39 Models of Behavior

Cardiovascular

Lina Badimon, Laura Casaní, and Gemma Vilahur

ABSTRACT

Experimental models of thrombosis are important research resources that have helped to increase our understanding and knowledge of the pathogenesis of the atherothrombotic process as well as to develop novel therapeutic approaches. In fact, different animal models and procedures have been implemented in thrombosis research in order to provide new insights into the mechanisms that have already been outlined in isolated cells and protein studies. Moreover, animal preclinical studies have rendered a solid rationale for conducting prospective randomized trials in patients with coronary artery disease.

INTRODUCTION

This chapter reviews the more common animal models used in the study of thrombotic disease, focusing primarily on the management, particularities, and topics related to the porcine animal model because of its human resemblance, particularly in the cardiovascular system.[1–7]

THE USE OF ANIMAL MODELS TO STUDY ARTERIAL THROMBOSIS

Autopsy and angiographic studies have pointed out the importance of plaque rupture with subsequent exposure of atherosclerotic components as a key step of thrombus formation and the subsequent clinical events. However, "the paradigm of plaque rupture" presents several contradictions that must be considered. As such, autopsies have shown that a substantial minority of victims of sudden coronary death shows superficial plaque erosion without plaque rupture,[8,9] and although plaque disruption accounts for up to two-thirds of patients in whom unstable angina or acute myocardial infarction develops, in most cases plaque disruptions are asymptomatic, although they may contribute to the growth of the atherosclerotic plaque.[10,11] Despite this, there is no doubt that a defect in the surface of the atherosclerotic plaque is almost always associated with mural thrombosis, which, at least, leads to plaque progression.

The study of thrombosis and its inhibition is based on *in vitro*, *ex vivo*, and *in vivo* approaches that combined have helped to widen the knowledge of the thrombotic process itself. Indeed, the availability of transgenic and knockout animals makes it possible to pinpoint the relative functional importance of single changes in specific gene products and hence facilitates the formulation of new strategies for cardiovascular protection and the prevention and treatment of thrombosis. However, on the other hand, domestic swines have been widely used as biomedical research models for human diseases due to their similarities in cardiovascular anatomy and physiology as well their ability to develop spontaneous or diet-induced atherosclerosis. Nevertheless, the objectives of a study should mandate the type of animal model to use in order to avoid repetitive and unneeded experiments. For instance, although swine are up to 90% similar to humans, there are some molecular differences in the mechanisms involved in arterial thrombosis that must be taken into account in order to properly evaluate the data.

ANIMAL SIZE MATTERS?

Some of the reasons for the frequent use of small animal models in research include (1) low cost, (2) ready availability, (3) reduced ethical concern compared to large animals, especially primates, and (4) small size that limits the quantities of new agents required for *in vivo* screening. These characteristics have permitted rapid evaluation of new agents in sufficiently large populations to perform meaningful statistical analyses. In addition to these practical indications for their use, small animal models have the added advantage of well-defined genetic characterization, and, in the case of mice, the availability of transgenic and gene knockout animals. Furthermore, small animals have figured prominently in the study of the contributions of thrombosis to luminal narrowing following arterial injury.[12] In contrast, large animal models such as pigs have the advantage of being more comparable to humans, especially because of their susceptibility to develop atherosclerosis.[1,7,8,13] Furthermore, their large size has permitted the evaluation of their coronary arteries, rather than the aortas studied in small animals because of its relatively larger size. In addition, the ability to induce atheromatous disease, which simulates the lesions observed in humans, is a strong attribute of the pig as a large animal model. Conversely, the disadvantages of large animal models are primarily the reverse of the advantages of small animal

models. These include greatly increased cost, heightened ethical concerns, less precise genetic characterization, and a scarcity of transgenic models and antibodies.

THE PIG AS A COMMONLY ACCEPTED RESEARCH ANIMAL MODEL

Previously published articles mainly present three types of atherothrombotic-related experiments, sometimes combined, performed in pigs: (1) feeding animals with fat-rich diets, (2) intravascular interventions to induce damage (balloon, grafting, etc.), and (3) extracorporeal arteriovenous shunts into which flow chambers of varying patterns are coupled. However, before thoroughly reviewing these topics several pig-related features deserve to be acknowledged to better understand the swine model of atherothrombosis.

SWINES NUTRITIVE REQUIREMENTS The majority of swines used in research weight between 10 and 80 kg and require approximately 600–2800 g of food per day.[14] Experimental animals can be fed with the commercial chow used for feeding farm animals, although it has been specially formulated in order to obtain a rapid growth rate. However, if there is a research requirement to use animals between 9 and 18 kg (40–60 days old) they should be fed with a nutrient-enriched diet (i.e., postweaning chow). Diet transition should be performed by mixing increasing parts of growing chow with the postweaning chow in order to reduce the presence of food-related diarrheas. For long time period studies, it is desirable to feed the animal with a restricted diet (3.5% of their total weight) to avoid handling difficulties related to animal overweight. This food restriction (also used in farm animals) covers all the animal nutritive and metabolic requirements as published by the National Research Council (NRC).[15] Commercial diets for farm pigs usually contain antibiotics, promoters, and other supplements to increase weight gain. If these components can somehow interfere with the study objectives, free-additive diets can be especially formulated and obtained from local venders. Finally, oral drug administration in swines is easy to perform, especially after overnight fasting. The suggestion is to mix or dissolve the drug within a small amount of chow before offering them the calculated ration. Swine approximately require 2.5 liters of water per kg of consumed food per day. Water should be provided by an automated watering system to avoid water restriction-related neurological syndromes such as "salt poisoning" or "sodium toxicosis."[16,17]

HEART ANATOMY AND VASCULARIZATION The heart of the pig is anatomically similar to humans except for the presence of the left azygous (hemiazygous) vein, which drains the intercostal system into the coronary sinus,[18] and for the size, which tends to be a bit smaller. The heart blood supply is mostly right side dominant since it originates from the posterior septal artery[19] and both anatomy and function of the pig coronary system as well as the histological anatomy of the aorta are comparable to humans. However, on the other hand, pig blood vessels are more friable and prone to vasospasm during manipulation, and thus require careful handling during blood withdrawals. Although animal models generally have the advantage of a shorter time to lesion development, pig atherosclerosis is quite slow and occurs both spontaneously and by experimental induction (i.e., intake of a high atherogenic diet). Moreover, if allowed to develop over time, mild atherosclerotic lesions first appear in coronary arteries and both atherosclerotic plaque distribution and composition (lipid, fibrinogen, smooth muscle cells, and macrophage content)[20] follow a pattern comparable to that of humans.[21–23] Human-like pig lipoprotein metabolisms may help to explain in part the above mentioned similarities. In relation to pig hemodynamics, either physiological cardiac function or mechanically induced myocardial infarction and the subsequent arrhythmogenic activity in reperfusion are also analogous to humans as well as the wound-healing process.[24] Actually, although wound healing in the myocardium has typically used both swine and sheep models, ruminants' healing somehow differs from humans since it is mainly characterized by the formation of collagenous scars.[25] Finally, unlike other animal models, after gradual occlusion of the coronary vessels induced by both balloon injury and an atherogenic diet, swines may develop coronary restenosis syndrome.[19,21,22,24,26–28]

HUSBANDRY AND MANAGEMENT Recommendations for housing laboratory swine are regulated by the European Directive 2003/65/CE, by local governmental animal care laws, and in the United States by the National Institutse of Health, *Guide for the Care and Use of Laboratory Animals*.[29] Plastic slats (PVC, vinyl) are preferred in biomedical research facilities because they are easy to clean and better isolate animals from humidity. If possible, heating plates should be installed in all pens (Figure 39–1). Swine reared for meat received standard treatments for endoparasites and ectoparasites and vaccinations against common swine diseases at appropriate ages and intervals. However, according to our previous experience, animals that are going to be part of a long-term project should undergo preventive treatment with antibiotics and antiparasites for 3 days as soon as they arrive at the animal facilities to avoid the presence of infectious diseases that may modify physiological pig parameters.

Restraint methods should be discouraged in biomedical research because of the stress they induce.[30] Subsequently, short-term chemical restraint agents and anesthetics may be used in order to obtain blood samples.

ANESTHESIA, ANALGESIA, AND SURGERY Animal pain and suffering are clinically important conditions that adversely affect the quality of life of the animals and as a result may influence the experimental data. Drugs, techniques, or husbandry methods used to prevent and control pain must be tailored to individual animals and should be based, in part, on the species, breed, age, procedure performed, degree of tissue trauma, individual behavioral characteristics, degree of pain, and health status. Preventive analgesia before major surgery must be performed with agents that do not interfere with platelets or the coagulation system. Accordingly, the use of opioids, particularly buprenorphine and fentanyl, is highly recommended. In our group, we use different agents to induce swine anesthesia depending on the amount of sample required and on the nature of the objectives we want to accomplish. For instance, tranquilization with 2.2 mg/kg of azaperone is more than enough to obtain a small blood sample (less than 10 ml) from the auricular vein or to cannulate a superficial vein (auricular or mammary vein). Once tranquilized, animals can be induced to anesthesia with an intravenous bolus of pentobarbital (5 mg/kg) to either obtain larger

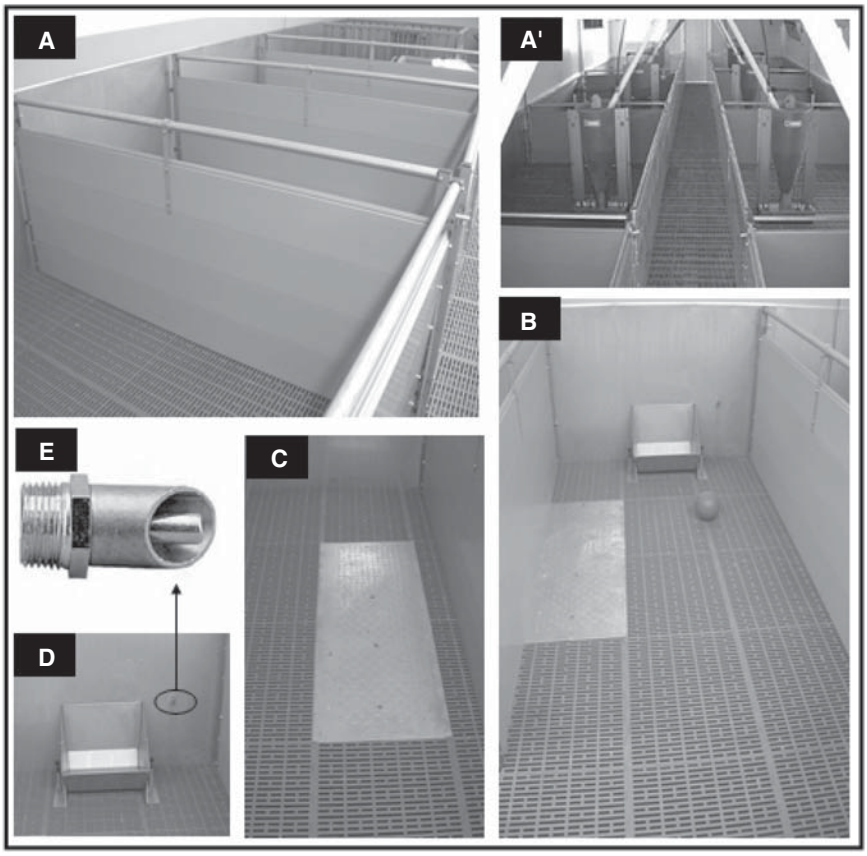

Figure 39–1. Swine PVC pens in a biomedical research facility. (A, A′) General view of pens. The walls in contact with the animals are covered with stainless steel. These are 1-m height plastic separations between pens and slip-free fiberglass slat flooring for greater hygiene. (A) The size of the pens allows a resting and a feeding area; toys can be as simple as balls. (C–E) Details of integrated aluminum heating plates, stainless-steel feeders (easily fixed to the floor with a mobile screw), and nipple drinkers placed at a standard height of 30 cm.

amounts of blood via the femoral vein/artery or to perform small surgical procedures. An intramuscular combination of tiletamine/zolazepam and medetomidine induces a fast anesthetic status sufficient to perform small surgery such as central vessel catheterization.

To achieve general deep anesthesia a continuous infusion of pentobarbital-saline (infusion rate of 2 mg/min) should be used, rather than repeated pentobarbital bolus injections. Deep anesthesia can also be induced by pentobarbital and maintained with volatile anesthesia (i.e., isofluorane). Within this context, it is important to emphasize that higher doses of pentobarbital (>30 mg/kg) have previously been described to reduce platelet reactivity[31] and an overdose can cause fatal respiratory and cardiac depression.

THE PIG AS A TOOL FOR EVALUATING ATHEROTHROMBOTIC DISEASE

DIET-INDUCED ATHEROSCLEROSIS Swine can develop hypercholesterolemia and atherosclerotic lesions by diet induction (high cholesterol content diets), reaching plasma cholesterol levels similar to those in humans. Indeed, after a 50-day period with a standard hypercholesterolemic diet, we have previously observed that almost all pigs developed early atherosclerotic lesions (fatty streaks) localized in the abdominal aorta and to a lesser extent in the coronary arteries. In such cases, lesion composition was similar to early stage human atherosclerosis.[20] As expected, increasing the diet induction period to 100 and 150 days was associated with a higher degree of lesion severity made evident when suitable fat stain was applied (Sudan IV). Notwithstanding, animals employed in these long period studies tend to be within the prepuberty period and as a consequence their lesions are not as severe as those developed in adult humans over the years. Older animals (over 6 months) can be used to obtain atherosclerotic models of greater human resemblance,[32] but management will be even more difficult because of their considerable weight (up to 200 kg). To overcome size-related problems, minipigs are becoming increasingly used. Indeed, miniature swine are preferable to commercial swine as animal models because of their small size and small growth rate, which allow them to maintain weight and size throughout adulthood. They are docile and easily handled, and there are several miniature strains available to better fit the scientific purpose. Miniature pigs have been used in several fields of biomedical

research studies such as cardiovascular disease (models of thrombosis and restenosis), diabetes, transplantation, and dermal applications.

Miniature pigs can be allocated in the same pens as larger pigs (increasing the number of animals per pen) and feeders and drinkers can be adapted to their size. However, the principal disadvantages of using miniature pigs as a substitute for common pigs are the maintenance requirements and the high cost of the animals. As a consequence, miniature pig breeders are not extensively distributed in all countries.

***EX VIVO* PORCINE MODEL OF THROMBOSIS** The *ex vivo* porcine model of thrombus formation (e.g., flow chambers coupled to extracorporeal shunts) has become essential for testing the effect of blood elements and rheology as well as atherosclerotic vessel components in thrombus formation in a controlled manner.[33–40] At the same time it is reproducible and easy to manipulate and thus allows the evaluation of the thrombogenic effect of different plaque constituents (e.g., collagen, fatty streaks, smooth muscle cells),[33–35] the different degrees of shear stress (to mimic different degrees of stenosis),[36,37] and the antiplatelet effects of new antithrombotic compounds.[20,35,37,40–43]

Shear stress measures the difference in blood velocity between the center of the vessel and along the vessel wall. Atherosclerosis preferentially occurs in areas of turbulent blood flow and low fluid shear stress, whereas laminar blood flow and high shear stress are atheroprotective. The Badimon perfusion chamber allows control of the blood flow as well as the degree of stenosis and thus evaluates moderate to high-risk thrombotic situations. A positive correlation between vessel stenosis and platelet deposition has previously been described.[44] Furthermore, platelet axial distribution analysis indicates that the apex (not the flow recirculation zone distal to the apex) is the segment with the greatest platelet accumulation, suggesting the crucial role of sudden changes in the degree of stenosis after plaque rupture, that is, shear stress changes in acute platelet response.[36] The Badimon perfusion chamber also makes it possible to analyze the thrombogenicity of different degrees of vascular injury as occurs during atherothrombogenesis. As such, in situations in which a relatively mild injury to the vessel wall may occur, the thrombogenic stimulus is relatively small, and the resultant thrombus is labile and may then be incorporated into the plaque, as may occur in the episodic asymptomatic progression of atherosclerotic plaques as well as in patients with unstable angina and transient ischemia. In contrast, deep vessel injury, particularly in the presence of severe stenosis, leads to relatively persistent thrombotic occlusion as may occur in myocardial infarction.

INSIGHTS FROM VON WILLEBRAND DISEASE ANIMAL MODELS

von Willebrand disease (vWD) is a genetic bleeding disorder that arises from the abnormalities in the vW factor (vWF). It is the most common inherited bleeding disorder in humans, and over the past years several animal species have also been described as suffering from this disease, whether through spontaneous mutation (pigs and dogs) or through a genetically engineered mutation (mice).[45] All these different animal models have been extremely useful in exploring the characteristics of vWD and in testing new treatments. Indeed, the interaction of platelets with vWF is crucial in the initiation and development of any thrombotic process since it enables platelets, via its surface glycoprotein receptors, to adhere to exposed subendothelium and to respond to blood shear stress.[46–48] In fact, Fuster and Badimon[1,49] were among the first to show a striking difference in the atherosclerotic lesions in the aorta between normal pigs and vWD pigs, both in spontaneous and in diet-induced atherosclerosis, demonstrating protection against atherosclerosis in V vWD pigs. The pig is a good model for studying vWD since vWF localization in endothelial cells and platelets mimics that of humans as do clotting and platelet characteristics. Additionally, in normal pigs the level of vWF is close to the human level whereas in cow, sheep, or goat it is 6- to 12-fold higher.[45] Canine vWD is also similar to humans. Over the years, many dog breeds have been identified as suffering from this disease, making vWD the most common inherited bleeding disorder in dogs. However, under the term "canine vWD" there seems to be a very heterogeneous group of bleeding disorders with different subtypes and mode of inheritance.[50] Actually, canine vWD can vary in genetic transmission, clinical severity, and diagnostic laboratory findings. Thus, in contrast to pigs, vWD dogs have not been used extensively for research purposes.[51] Finally, it deserves to be mentioned that vWD has also been reported in other animal species such as murine,[52,53] rabbits,[54] and cats.[55] However, extrapolation of the results obtained from these animals to humans remains to be completely elucidated.

ANIMAL MODELS OF PLAQUE RUPTURE

By its very nature, rupture of an atherosclerotic plaque is difficult to study in humans. Moreover, since rupture of an atherosclerotic plaque occurs in a stochastic fashion, it is also difficult to identify triggering factors and equally hard to investigate treatments addressed toward plaque stabilization. Thus, a good animal model not only may help to better understand the mechanisms behind its rupture but also to test treatments to prevent it from happening. Spontaneous hemorrhage and rupture are considered extremely rare events in large animal models and thus have been found only in the coronary arteries of pigs with inherited hyper-low-density lipoprotein cholesterolemia or in cholesterol-fed pigs with streptozotocin-induced diabetes.[56,57] In contrast, many interesting rodent studies related to plaque rupture have been published in recent years. Some authors have described the presence of blood-filled channels within the advanced coronary lesions as well as plaque ruptures and thrombi in the aortic origin of old apolipoprotein (apo) $E^{-/-}$ mice[58] whereas other studies have reported the presence of luminal thrombi in ruptured plaques of spontaneously dead $apoE^{-/-}$ mice.[59] On the other hand, other investigators have evaluated the harmful effect of combining several risk factors. As such, it has been reported that either in double knockout mice with homozygous null mutations in the apoE and the high-density lipoprotein (HDL) receptor, scavenger receptor class B, or a combination of hypertension and dyslipemia (hypertensive rats transgenic from human cholesteryl ester transfer protein) increases plaque vulnerability and thrombi formation. Despite all these, the most simplistic approach to induce plaque rupture and subsequent thrombus formation is by direct mechanical injury of the vessel of interest. Table 39–1 describes different approaches already established in order to induce plaque rupture and the subsequent thrombi formation in different animal models.[60–70]

Table 39–1

RABBIT MODELS OF THROMBOSIS

The use of rabbits has been widely extended because with the appropriate precaution, they are easy to handle and cost-effective. There are three breeds of rabbits commonly used in biomedical research: New Zealand White, Dutch Belted, and Flemish Giant. All of them are mainly used as animal models for the study of atherogenesis,[2,61] plaque instability and rupture,[62,65] and myocardial infarction,[71] and to evaluate the efficacy of new antithrombotic and antiatherosclerotic drugs.[72]

Rabbits do not develop spontaneous atherosclerosis as they are vegetarian. However, rabbits can rapidly induce vascular lesions after the administration of a rich atherosclerotic diet (0.5–4% cholesterol content) during 8–16 weeks.[2] Moreover, transgenic rabbits have also been developed to obtain models of hereditary hyperlipidemia (WHHL-rabbit) Yet, rabbit atherosclerotic lesions differ from human atheroma since their lipid and macrophage content is much higher[10] as is their hypercholesterolemic index. Accelerated atherosclerotic lesions can also be developed in rabbits by a combination of balloon injury and hypercholesterolemia feeding.[61]

MICE MODELS OF THROMBOSIS

Mice do not develop atherosclerosis without genetic manipulation since they have a lipid physiology that is radically different from that in humans, most of the cholesterol being transported in HDL-like particles. On the other hand, the mouse has not been as widely used as the pig as a model to test the possible therapeutic usefulness of antithrombotic agents.[8] The reasons for this may be related to the small size of the murine arteries, which limits the manipulation of isolated vessel segments, the lack of standardization of the model, and mostly the differences from the human model, which decidedly limit the extrapolation of mouse findings to clinical relevance in humans. Thus, an accurate determination of the mouse hemostatic system with regard to coagulation and fibrinolytic systems, platelet structure, and platelet receptor/enzyme system is required and differences between the two species must be acknowledged and appreciated in the interpretation of the data. As an example, platelet counts in mice on average are four times those of humans and platelets are only approximately one-half the volume of human platelets. An excellent and comprehensive review of the murine hemostatic system has been provided by Tsakiris *et al.*,[72] and important aspects of murine platelet receptor function have recently been reviewed by Ware.[73] However, despite these species-related differences, the use of murine models is particularly advantageous. On one hand, it makes it possible to easily perform several techniques of vascular injury as described in Table 39–2. On the other hand, the murine model not only offers numerous immunological approaches (e.g., monoclonal antibodies), but also provides genetically modified animal strains with defined defects in platelet function that open new ways to identify the individual roles and the interplay of platelet proteins in thrombus formation.[74–81]

Finally, the usefulness of intravital microscopy in the mice model of thrombosis deserves to be mentioned since it allows testing the *in vivo* relevance of the *in vitro* observations. Indeed, the study of the microcirculation by intravital microscopy represents a sophisticated research tool to examine complex biological interactions and disease mechanisms as well as to develop and test novel approaches aimed at the prevention or attenuation of disease-associated microvascular disorders and cellular dysfunction such as the ones that occur in atherosclerosis and thrombosis pathogenesis. In addition, using the intravital microscopic technique, circulatory and cellular disorders in surgical diseases and procedures, such as ischemia/reperfusion, trauma, sepsis, and inflammation, as well as wound healing, may be analyzed.

Table 39–2
Different models to induce vascular injury

Vessel wall injury models	*Method*
Photochemical injury	Vessel irradiation in the presence of rose Bengal or sodium fluorescein[77]
Mechanical injury	Pinching arteries with needle forceps (Folts model)[78]
	Denuding the endothelium via balloon catheters
	Infusion of a portion of a vessel with air or saline
Electrical injury	Application of an electrical current through the vessel with an electromicrocoagulator
Chemical injury	*Ex vivo* application of ferric chloride; applicable only in guinea pigs, rats, and mice[79–81]
Laser injury	Argon laser: irradiation followed by visualization of the injury with intravital microscopy[82]

ANIMAL MODELS OF VENOUS THROMBOSIS

Thrombogenesis in veins is mainly attributed to some combination of hypercoagulability, stasis, and vascular injury. All these triggering factors induce tissue thromboplastin (tissue factor) release to the flowing blood forming thrombin and fibrin that trap red blood cells. Thus, in contrast to arterial thrombotic lesions (platelet-rich thrombus, "white thrombus"), venous thrombosis is predominantly "red" and fibrin-rich. Animal models for venous thrombosis appear to be particularly useful for studying the pathophysiology of blood coagulation *in vivo* and the pathogenesis of venous thrombosis. For instance, this model has helped to define the role of activated protein C, the interplay between inflammatory and procoagulant mediators, and the regulatory role of PAI-1 in thrombolysis in addition to therapeutic approaches.[82] In fact, Dorffler-Melly[83] and Levi[82] have previously published interesting literature searches in MEDLINE and EMBASE databases offering an in-depth review of small and large animal models of venous thrombosis, pointing out their advantages, usefulness, and limitations.

CONCLUSIONS

Clinical observations provide the substrate to build up pathophysiological hypotheses, but for obvious ethical reasons our ability to test these hypotheses in humans is very limited. Cell biology-related studies have helped to answer mechanistic questions, but lack the complexity of a real disease, thus limiting the scope of testable hypotheses. On the other hand, studies using rodent or large animal models have proved to be essential for *proof of concept* since they yield *in vivo* approaches to confirm critical hypotheses previously evaluated in relevant *in vitro* models. Moreover, DNA technology made it possible to create a number of knockout and transgenic rodent models that have enhanced our understanding of cardiovascular disease and expedited the development of new gene therapies. However, while small animal models provide experimental convenience and ease in manipulation, more clinically relevant models are necessary to study the mechanisms surrounding human atherothrombogenesis. Large animal models, although associated with higher cost and handling-related difficulties, have shown an atherothrombotic pattern more comparable to that of humans. To date, considering all models, the porcine model is one of the most useful currently available atherothrombotic models. Indeed, pig animal models have been shown to address specific questions related to blood and atherosclerotic vessel mechanisms involved in thrombus formation that have been eventually translated to clinical situations. Despite all of this, efforts in developing the "ideal" animal model for atherothrombotic evaluation must continue. Furthermore, for this purpose, it may be critical to construct animal preclinical trials that resemble human trials in order to make clear what data and important conclusions can be justifiably extracted from animal models.

40 Animal Models for Atherosclerosis, Restenosis, and Endovascular Aneurysm Repair

András Kónya, Kenneth C. Wright, Matthew Gounis, and Krishna Kandarpa

ABSTRACT

Animal models have significantly advanced the understanding of mechanisms involved in atherosclerosis and restenosis and have allowed the evaluation of therapeutic options. The current focus of research is to develop strategies to prevent restenosis. These include pharmacological and biological interventions directed primarily against smooth muscle cell proliferation, endovascular devices for recanalization and/or drug delivery, and an integrated approach using both devices and pharmacobiological agents. Devices aimed at the percutaneous endoluminal exclusion of aortic aneurysms have also generated a great deal of interest. Experience over many decades with animal models for vascular research has established that a single, ideal model for atherosclerosis, restenosis, or aneurysm formation does not exist, although recent development of transgenic variants of currently available models has widened the available options. Nevertheless, an appreciation of the individual features of natural or stimulated disease in each species is of the utmost importance for the proper design and execution of relevant experiments.

Key Words: Animal models, Atherosclerosis, Arteriosclerosis, Restenosis, Angioplasty, Stenting, Drug-eluting stents, Endovascular aneurysm repair, Endovascular grafts, Transcatheter embolization.

INTRODUCTION

Almost all medical knowledge and treatment, especially in the last century, has involved work with laboratory animal models. Since the early part of the twentieth century, research using animal models has contributed to more than half of the significant medical discoveries and during some periods, accounted for more than 75% of the major advances. Two-thirds of the Nobel prizes awarded since 1901 have been for discoveries involving the use of laboratory animal models.

The selection of the laboratory species, breed, and strain to be used as a model for human disease is one of the most important decisions to be made by an investigator. The goals of the research play an important role in the selection of the laboratory animal model to be used. The validity of any information derived from the animal is dependent on the appropriateness of the model. Thus, a detailed consideration of species and model features that are favorable and applicable to the specific purpose of the research is important. Since new animal models are continually being identified and characterized, a thorough literature search should always be conducted to determine what models are available and which are the most relevant.

ATHEROSCLEROSIS

BACKGROUND Atherosclerosis is a focal disease that localizes mainly in areas of disturbed blood flow[1] and bears many features of chronic inflammation.[2] The lesion of plaque consists of endothelial cells, monocytes/macrophages, smooth muscle cells (SMC), and a matrix of collagen, proteoglycans, and calcification. Lesion formation begins with the influx of monocytes/macrophages, which become loaded with cholesteryl ester to create the so-called "fatty streak." These lesions may progress by the influx of additional monocytes and T cells, whose secretory products, along with those of endothelial cells, result in migration of SMC, where they proliferate and synthesize matrix components. Some cells in the plaque die, leaving a necrotic core and extracellular cholesterol clefts, which are hallmarks of advanced lesions. The luminal face of the lesion often has a fibrous cap, generated by SMC stabilizing the plaque.[3]

Previously, atherosclerosis has been viewed as a disease of uncontrolled plaque growth eventually leading to total occlusion.[4] New clinical findings suggest that acute coronary events are triggered by rupture and hemorrhage of vulnerable atherosclerotic plaques.[5] The plaque consists of a highly thrombogenic core and a slender and fragile fibrous cap that separates the core from blood coagulation factors, thereby precluding formation of thrombus on the surface of the intact plaque.[4] Disturbance of cap integrity leads to exposure of the plaque's thrombogenic interior and subsequent thrombosis. Such ruptures of the fibrous cap may recur over many years without causing complete occlusion of the vessel, and thereby may often remain clinically silent.

The reasons for the thinning and rupture of the fibrous cap are not known. One theory hypothesizes that the rupture is a result of

Table 40–1
Characteristics of an ideal animal model of arteriosclerosis[11]

1. Inexpensive	
2. Easy to maintain and handle	
3. Proper size	
4. Reproducible in a laboratory setting	
5. Well-defined genetic characteristics	
6. Sharing important aspects of human disease	
7. Lesion development:	Develop naturally on a normal diet
	Progress slowly over the animals' lifetime
	Cause clinical sequelae at middle to old age
8. Lesion pathogenesis:	Complete range from fatty streak to atheromatous plaques
9. Lesion complications:	Calcification
	Ulceration
	Hemorrhage
	Stenosis
	Thrombosis

loss of SMC, thought to be the main producers of cap-stabilizing collagen. This is caused by the loss of cells from apoptosis that may be mediated by the interaction between SMC and monocytes/macrophages.[6,7] According to a second hypothesis, plaque rupture is the result of an imbalance between the production of plaque-stabilizing collagen and the action of corrosive enzymes.[8] An immunohistochemical study has shown that macrophages accumulated in the plaque express high levels of matrix metalloproteinases and tissue factors[9] that are thought to make the fibrous plaque fragile by digesting the extracellular matrix. Therefore, the search for an animal model of atherosclerotic plaque rupture should be seen against this background.

Arteriosclerosis is a disease that really affects only humans and one or two other species, such as the pig and certain nonhuman primates, and because of this researchers must resort to genetically modified models to even partially reproduce the condition.[10] It has never been easy to find a good animal model of the atherosclerotic process itself. The ideal animal model of human arteriosclerosis should posses several important characteristics[11] (Table 40–1).
